American Society of Human Genetics 65th Annual Meeting
October 6–10, 2015 Baltimore, MD

POSTER ABSTRACTS

Session Topic/Title	Abstract/Poster Board Numbers	
	Start #	End #
Bioinformatics and Genomic Technology	1588	1917
Cancer Genetics	2567	2794
Cardiovascular Genetics	508	647
Clinical Genetics and Dysmorphology	2344	2489
Clinical Genetic Testing	1918	2099
Complex Traits and Polygenic Disorders	704	1021
Cytogenetics	2490	2538
Development	2539	2566
Epigenetics	391	467
Ethical, Legal, Social, and Policy Issues in Genetics	2155	2195
Evolutionary and Population Genetics	1447	1587
Genetic Counseling	2196	2215
Genetics/Genomics Education	2216	2241
Genome Structure, Variation, and Function	3026	3193
Health Services Research	2242	2262
Metabolic Disorders	2263	2343
Molecular Basis of Mendelian Disorders	2795	3025
Pharmacogenetics	648	703
Prenatal, Perinatal, and Reproductive Genetics	2100	2154
Psychiatric Genetics, Neurogenetics, and Neurodegeneration	1022	1253
Statistical Genetics and Genetic Epidemiology	1254	1446
Therapy for Genetic Disorders	468	507

Posters should remain on the board for all three days (Wednesday through Friday)

The program and abstract/poster board number next to each listing is followed by an **W** (Wednesday), **T** (Thursday), or **F** (Friday) to indicate the day on which authors must be present at their poster boards.

391T

The functional MTHFR C677T polymorphism modulates global DNA methylation and associates with non-random differentially methylated regions (DMRs) in autism spectrum disorder. *A.J.M. McNaughton[1], P. Liang[2], K. Calli[3], S. Gannon[3], Y. Qiao[3], M. Hudson[1], F. Solehdin[3], N. Nebesio[2], M. Ayub[1], E. Rajcan-Separovic[3], S. Lewis[3], X. Liu[1].* 1) Dept. Psychiatry, Queen's University, Kingston, Ontario, Canada; 2) Dept. Biological Sciences, Brock University, St. Catharines, Ontario, Canada; 3) Dept. Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada.

5,10-methylenetetrahydrofolate reductase (MTHFR; EC 1.5.1.20) is a key enzyme in DNA methylation. Two functional polymorphisms in *MTHFR*, C677T (rs1801133, p.Asp233Asn) and A1298C (rs1801131, p.Glu429Ala), were extensively studied in many disorders and C677T was implicated to be linked with autism in multiple studies with the low activity allele 677T associated with increased risk for autism especially in sporadic cases. We hypothesized that the 677T allele may be associated with reduce global DNA methylation levels in a non-random fashion which could influence condition-specific gene pathways. In this study, we investigated C677T in relation to global methylation levels in subjects with autism spectrum disorder (ASD) using methyl binding protein sequencing (MBD-Seq) approach. We found that the 677T allele carriers had lower global methylation levels than the 677CC allele group, although the significance is marginal. 154 significant differentially methylated regions (DMRs) were identified between the two allele groups. Interestingly, despite a genome-wide hypomethylation, a significant number of DMRs (93/154 or 60.4%) show a hypermethylation status in the 677T allele group. The identified DMRs demonstrate a highly heterogeneous distribution pattern, with chromosomes 3 and 9 having significantly more DMRs than expected for their chromosome size, while chromosomes 2, 5 and 13 showed an opposite pattern. Furthermore, these DMRs are highly biased towards CpG islands, especially those in non-repetitive intergenic regions. Most interestingly, about 10% (14/154) of these DMRs are found in proximity to genes known to be associated with ASD and related conditions, despite an apparent under-representation of these genes. Altogether, these results suggest that *MTHFR* 677T may modulate global DNA methylation and target autism related genes in a non-random fashion to increase the risk for autism.

392F

Alignment and Methylation Analysis of Tandem Repeat Elements in Cancer using Targeted Next-Gen Bisulfite Sequencing. *J. Alexander[1], J. Zhou[1], A. Meyer[1], A. Miller[1], M. Poulin[1], L. Yan[1], W. Timp[2].* 1) EpigenDx Inc., Hopkinton, MA., USA; 2) Johns Hopkins University, Baltimore, MD, USA.

Global DNA hypomethylation is a common epigenetic alteration in tumor cells, and is closely associated with hypomethylation of interspersed DNA repetitive elements. This hypomethylation is thought to promote the initiation and progression of tumorigenesis through the aberrant activation of repetitive elements. Tandem repeat elements such as NBL-2, Sat-2 and D4Z4 have shown more variability in DNA methylation from normal to cancer tissue. Some cancer specimens show NBL-2 and D4Z4 hypomethylation and others hypermethylation. It appears that the changes in DNA methylation levels of individual tandem repetitive elements may be unique for each type of cancer. This indicates that distinct epigenetic factors may have unique roles. The chromosomal locations of these repeats may be an important factor in whether they are hypo or hypo methylated. Bisulfite PCR primers for repetitive elements were designed to a relatively conserved region of the element to avoid using degenerated primers. The PCR region between the primers is more variable depending on their location within the genome. Multiplex PCR including assays for Sat-2 and NBL-2 was performed on tissues from 40 cancerous and adjacent normal tissue in four cancer types (breast, colon, ovarian and cervical). Following the Ion Torrent protocol, libraries were generated and sequenced on a PGM system. The resulting FASTQ files were then aligned to two references: the whole bisulfite genome, and each chromosome individually. Results from the two alignments were compared to identify any differences, which could indicate artificial alignments. Simplex PCRs of the assays for Sat-2 and NBL-2 were then performed and subjected to the same sequencing preparation and analysis. The comparison of multiplex and simplex PCRs, as well as alignment to different references, may provide insight into the most accurate approach for repetitive element analysis on Next-Gen Sequencing. By mapping the differences in the locations of Sat-2 and NBL-2 the 40 pairs of samples, valuable information about the role epigenetic regulation may play in repetitive element transposition and cancer.

393T

Integrating single-base resolution quantitative epigenomic and transcriptomic sequence data to analyze differential gene expression in normal and tumor liver tissue samples. *K.R. Booher, H. Chung, D. Tan, Y.C. Chew, D. Cubberley, E. Putnam, K. Giang, X. Sun.* Epigenetic Analysis Services, Zymo Research Corporation, Irvine, CA.

Recent technological advances driving the next-generation sequencing revolution finally allow the generation of single-base resolution datasets that fully examine the diverse molecular mechanisms influencing gene expression. Though one-dimensional studies utilizing either RNA-seq, ChIP-seq, or DNA methyl-seq are able to partially explain differential expression, it is increasingly evident that only a pursuit of multi-omics approaches can provide the in depth and detailed information necessary to fully understand gene expression changes associated with human disease. However, combining data from different labs or commercial service providers is subject to user and platform-specific batch effects that may adversely affect data quality and thus interpretation. Using an integrated epigenomics/transcriptomics approach that combines sequence data generated entirely from the same matched liver tumor and adjacent normal tissue sample set in one laboratory setting, we demonstrate a thorough relationship between the interplay of epigenetic influences and gene expression. We assessed genome-wide DNA methylation (5-mC) patterns using an expanded Reduced Representation Bisulfite Sequencing (RRBS)-style protocol that increases genome coverage compared to the classic RRBS method. We overlapped 5-mC data with genome-wide, single-base resolution DNA hydroxymethylation (5-hmC) data generated using a unique protocol known as Reduced Representation Hydroxymethylation Profiling (RRHP) that is specifically designed to pair with RRBS data and differentiate 5-hmC from 5-mC modifications. In addition, chromatin immunoprecipitation followed by sequencing (ChIP-seq), and transcription profiling (RNA-seq) facilitated coupling of the 5-mC/5-hmC data with differential histone modification and gene expression profiles. Complete QC steps to assess starting sample purity and quality (TapeStation, nano-drop, and Qubit), efficient chromatin immunoprecipitation enrichment (qPCR), library construction and quantification (TapeStation and qPCR), and Illumina sequencing read quality score filtering (Trim Galore!) ensured suitable data for downstream analysis. Surprisingly, we found that many sites with similar RRBS-determined 5-mC levels have differential 5-hmC modifications based on the RRHP data. Particularly informative gene regions identified using genome-wide approaches were validated through targeted bisulfite sequencing.

394F

Characterization of differential DNA methylation in transcription factor binding sites across human cancers. *B.N. Lasseigne[1], R.C. Ramaker[1, 2], M.K. Kirby[1], D.S. Gunther[1], S.J. Cooper[1], R.M. Myers[1].* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) University of Alabama in Birmingham, Birmingham, AL.

CpG DNA methylation (DNAm) is an established driver of cancer etiology, progression, and metastasis. However, genome-wide surveys of DNAm differences between tumor and paired normal tissues often result in thousands of differentially methylated CpGs, complicating interpretation of such results. In order to better understand which CpGs might be important cancer drivers and identify important transcription factors involved in different cancers, we developed and implemented a bioinformatics pipeline for CpG enrichment in the binding sites of 161 transcription factors (TFs) studied by ENCODE. With this pipeline, we examined many in-house and publically available cancer data sets for differential DNAm enrichment or depletion in TF binding sites. We found that most TF binding sites appear to be significantly protected from tumor-induced DNAm changes ("protected TFs"). Additionally, a subset of TFs with binding sites enriched for tumor-induced DNAm changes ("unprotected TFs") appear to be specific to each cancer, implicating particular TFs as drivers of tissue-specific tumor biology. We characterized CpGs in protected and unprotected TFs by many genomic features including local CpG density, CADD score, proximity to transcription start site, proximity to binding motif, and copy number variation. We also examined the relationship between binding site enrichment and TF expression, as well as expression of genes nearest unprotected binding sites with concentrated tumor-induced DNAm changes. As part of an ongoing project to incorporate genome-wide functional regulatory element data with large-scale functional genomic disease datasets we have developed an R package for high-throughput statistical analysis of these datasets to aid in identification of CpGs and TFs that may be important in cancer. This methodology provides a useful tool for interpreting epigenetic alterations in the context of transcription factor regulation in cancer.

395T

HiTMAP: A High-Throughput Methylation Analysis Program for Targeted Bisulfite Sequencing. *B.S. Pullman[1], Y. Yang[1], I. Feng[1], A.B. Costa[2,3], S.A. Scott[1].* 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Neurosurgery, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Scientific Computing, Icahn School of Medicine at Mount Sinai, New York, NY.

DNA methylation plays essential roles in gene expression, imprinting and X chromosome inactivation, and epigenetic deregulation has been directly implicated in Mendelian disorders and tumorigenesis. Many techniques have been developed to detect CpG methylation, the most common involving bisulfite conversion coupled with DNA sequencing. The availability of high-throughput sequencing has prompted the development of both whole-genome bisulfite sequencing as well as highly quantitative and multiplexed targeted bisulfite sequencing; however, these methods require significant computational resources and expertise to manage and analyze the data. Therefore, we developed HiTMAP: a High Throughput Methylation Analysis Program to address the need for a stand-alone program capable of analyzing high-throughput targeted bisulfite sequencing data. HiTMAP is a comprehensive web tool that takes raw, targeted bisulfite sequence data (FASTA) and demultiplexes against sample barcodes, aligns sequencing reads to *in silico* bisulfite-converted genomic reference sequences, quantitates CpG methylation levels, and exports resulting methylation data for both individual CpG sites and amplicon regions. The user-facing side of HiTMAP provides an online interface for uploading raw sequence and reference files, setting alignment, methylation quantitation, and quality metric parameters, and for retrieving and saving analysis output data and result figures. The front end was written in JavaScript with AngularJS and D3. Backend computation, including BWA alignment, is accomplished on a server cluster that runs Scala code with the Akka HTTP library for asynchronous data processing. Compute intensive steps, like sequence alignment, are dynamically queued and queried through a generic DRMAA interface to Mount Sinai's batch-processing supercomputer, Minerva. CpG methylation quantitation by HiTMAP was validated using a targeted single-molecule real-time bisulfite sequencing (SMRT-BS; Pacific Biosciences) dataset (four amplicons, 30 cell lines; 21,967 reads), which revealed a very strong correlation (r=0.98) between HiTMAP and the commonly used Bismark bisulfite sequencing analysis pipeline. Coupled with an online raw data submission system (*hitmap.stuartscottlab.org*), HiTMAP eliminates the need for manual data manipulation, local computational resources and expertise, and provides a fast and efficient mechanism to measure CpG methylation from targeted high-throughput bisulfite sequencing data.

396F

A systematic study of normalization methods for Infinium 450K methylation data using whole-genome bisulfite sequencing data. *T. Wang[1], W. Guan[2], J. Lin[5], N. Boutaoui[1], G. Canino[3], J. Luo[4], J.C. Celedón[1], W. Chen[1,5].* 1) Division of Pediatric Pulmonology, University of Pittsburgh, Children's Hospital of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, University of Minnesota, Minneapolis, MN; 3) Behavioral Sciences Research Institute, University of Puerto Rico, San Juan, PR; 4) Department of Pathology, University of Pittsburgh, Pittsburgh, PA; 5) Departments of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA.

DNA methylation, an epigenetic mechanism, plays an important role in disease etiology. The Illumina Infinium HumanMethylation450 (450K) BeadChip is a widely used platform in large-scale epidemiologic studies. This platform can efficiently and simultaneously measure methylation levels at ~480,000 CpG sites in the human genome in multiple study samples. Due to the intrinsic chip design of two types of chemistry probes, data normalization or preprocessing is a critical step to consider before data analysis. To date, numerous methods and pipelines have been developed for this purpose, and some studies have been conducted to evaluate different methods. However, validation studies have often been limited to a small number of CpG sites to reduce the variability in technical replicates.In this study, we measured methylation on a set of samples using both whole-genome bisulfite sequencing (WGBS) and 450K chips. We used WGBS data as a gold standard of true methylation states in cells to compare the performances of eight normalization methods for 450K data on a genome-wide scale. Analyses on our dataset indicate that the most effective methods are peak-based correction (PBC) and quantile normalization plus beta-mixture quantile normalization (QN.BMIQ). To our knowledge, this is the first study to systematically compare existing normalization methods for Illumina 450K data using novel WGBS data. Our results provide a benchmark reference for the analysis of DNA methylation chip data, particularly in white blood cells.

397T

Microsatellite Instability (MSI) is associated with Differential DNA Methylation in Colorectal carcinoma and may have interaction with location of the tumor. *F. Jasmine[1], M. Kamal[2], M. Rahman[2], S. Roy[1], M. Raza[2], R. Paul[2], H. Ahsan[1], Z. Haq[2], M.G. Kibriya[1].* 1) Public Health Sciences, The University of Chicago, Chicago, IL; 2) Bangabandhu Sheikh Mujib Medical University, Dhaka, Bangladesh.

Introduction: Colorectal Cancer (CRC) is one of the most common malignancies worldwide. The role of MSI and DNA methylation in tumor tissue is well known in CRC. MSI may cause error in DNA replication resulting in loss of function of tumor suppressor genes leading to carcinogenesis. In past, using paired tumor-normal tissue on Infinium 27K methylation array we demonstrated a large number of differentially methylated loci to be associated with CRC. The array mainly focused on the promoter CpG islands. In the present study using larger number of samples and 450K methylation array, that addresses promoter sites, shores, shelves, gene body and deep sea on a genome-wide scale, we explored whether differential methylation is associated with MSI status. **Methods:** We carried out a genome-wide methylation assay for a total of 172 paired samples from 86 CRC patients (m=50, f=36) at different stages (stage1:16, stageII: 25 and stageIII: 45). Of them 24 had MSI, and 15 had somatic mutation in KRAS (rs112445441).**Results:** First, we compared the methylation data between tumor and corresponding normal tissue using mixed model 2-way ANOVA and identified a total of 1700 tumor-specific DML covering 634 genes that were significant at FDR 0.05 and the magnitude of difference (delta beta) was at least 20%, which was very close to what we previously reported using the other 27K array. In the next step, we explored if (a) methylation status of these tumor-specific DML were different among the MSI and MSS tumor tissues and (b) if there was interaction between MSI status and location of the tumor (right-sided and left-sided CRC). We found that methylation status was significantly different (at FDR 0.05, with delta beta 20%) in 22 loci (representing 12 genes) between MSI and MSS tumors. All these loci were hypermethylated in MSI tumors compared to MSS. Of these 22 loci, 21 were in CpG Islands near the gene and only one was in shore (closest gene *ETS1*). We also found significant interaction ($p<0.05$) between MSI status and location of the tumor for 4 loci (*GATA2, ZNF568, LMO2* and one inter-genic loci) where difference of methylation is more pronounced only if the tumor is MSI and on the right side of the colon. **Conclusions:** In this genome-wide methylation study of CRC, we identified a number of genes that are hypermethylated in MSI compared to MSS tumors suggesting an association between DNA methylation and MSI status in CRC.

398F

DNA methylation landscape of sporadic and melanoma-prone patients. *A.C.V. Krepischi[1], E.S.S. de Araújo[2],R.F. Ramalho[2], M.I. Achatz[3], L.F. Moredo[4], J.P. Duprat[4], C. Rosenberg[1], D.M. Carraro[2].* 1) Institute of Biosciences, University of São Paulo, São Paulo, SP, Brazil; 2) International Research Center, A. C. Camargo Cancer Center, Sao Paulo, Brazil; 3) Department of Oncogenetics, A. C. Camargo Cancer Center, Sao Paulo, Brazil; 4) Department of Skin Cancer, A. C. Camargo Cancer Center, Sao Paulo, Brazil.

Melanoma is the most deadly form of skin cancer. Around 10% of melanoma cases are hereditary, and nearly half of them have unknown etiology. Abnormal DNA methylation as either predisposition factor or biomarker has been poorly explored in skin melanomas. Our goal was investigating whether melanoma-prone and sporadic melanoma patients carry distinctive DNA methylation patterns compared to healthy controls. The leukocytes' methylomes from 19 unrelated melanoma-prone and 12 sporadic melanoma patients, all of them negative for germline *CDKN2A* mutations, were obtained using the HM450K platform (Illumina). Methylation data was compared with a control group of 11 healthy controls. Bias adjustment and normalization were achieved by BMIQ, and differential methylation analysis was processed using the RnBeads package. Genes associated with the top 100 differentially methylated sites (significant p-value and higher methylation differences) were annotated by DAVID and cBioPortal tools. Melanoma-prone patients exhibited DNA methylation differences compared to controls mainly at CpG islands, whereas sporadic melanoma patients presented differential methylation at genic sequences located outside promoters and islands. Seventy-four genes were found to be differentially methylated mainly at promoters regions (58%) in melanoma-prone patients. On the other hand, sporadic melanoma group displayed 72 genes mostly hypermethylated (94%) at gene bodies. An *in silico* analysis of each set of genes using melanoma data from TCGA studies revealed that above 50% of all of the genes (53% and 66% for sporadic and melanoma-prone patients, respectively) presented at least 10% of genetic alterations in the tumors. However, only the gene set detected in the sporadic melanoma group showed statistical enrichment for cancer pathways. Our preliminary analysis revealed a distinctive epigenomic profile in leukocytes from sporadic and melanoma-prone patients compared to controls, which were divergent regarding DNA methylation profile and associated genes. Additional studies are necessary to confirm this findings, and to elucidate if such results are related to the melanoma etiology.Funding: FAPESP 2013/07480-8.

399T

Quantification and application of potential epigenetic markers in maternal plasma of pregnancies with hypertensive disorders. *H.J. Kim[1], S.Y. Kim[1], J.H. Lim[1], D.E. Lee[1], D.J. Kim[1], S.Y. Park[1], M.Y. Kim[2], J.Y. Han[2], J.S. Choi[2], H.K. Ahn[2], D.W. Kwak[2], H.M. Ryu[1,2].* 1) Laboratory of Medical Genetics, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea, South Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Dankook University College of Medicine, Seoul, Korea.

ABSTRCTSObjective: To identify novel epigenetic markers that are specifically hypermethylated in placenta and hypomethylated in maternal blood cells, we used methylation profiling array data from the our previous study, and evaluated the quantitative aberrations of candidate marker in maternal plasma of pregnancies with hypertensive disorders. **Methods:** Selected hypermethylated regions by methylation profiling analysis were validated by bisulfite direct sequencing. Using real-time PCR, we compared the concentrations of *DSCR3, RASSF1A and SRY* as cell-free fetal DNA markers and *HYP2 and GAPDH* as cell-free total DNA markers in 72 normal pregnancies, 16 early-onset preeclampsia (EO-PE), 47 late-onset preeclampsia (LO-PE) and 29 gestational hypertension (GH) at 6 - 42 gestational weeks .**Results:** Among 7 identified regions, the most differentially hypermethylated *DSCR3* was selected for potential fetal-specific epigenetic marker. The concentrations of all target sequences were significantly correlated with gestational age at sampling in the control group ($P < 0.001$ for all target sequences). A strong positive correlation was observed between *DSCR3* and *SRY* ($r = 0.369$, $P = 0.006$), *DSCR3* and *RASSF1A* ($r = 0.696$, $P < 0.001$), *DSCR3* and *HYP2* ($r = 0.842$, $P < 0.001$), *RASSF1A* and *HYP2* ($r = 0.598$, $P < 0.001$). In the EO-PE, *DSCR3* and *RASSF1A* concentrations were significantly higher at 24-32 weeks onwards ($P < 0.05$ for both). Moreover, *HYP2* concentration was significantly elevated from 15 weeks of gestation compared with control group. In the LO-PE, *DSCR3, RASSF1A* and *HYP2* concentrations were significantly higher only at 33-42 weeks compared with control group. Concentrations of all markers in GH group were not significantly different from control group. There were no statistical differences among the patients groups.**Conclusions;** Along with the well-known *RASSF1A, DSCR3* and *HYP2* quantification is a promising epigenetic markers for prediction of PE, especially for the early prediction of EO-PE.

400F

Abnormal DNA methylation in T-lymphocytes from patients with CF. *E. Kvaratskhelia[1], N. Dabrundashvili[1], E. Maisuradze[1], M. Gagua[1], T. Topuria[1], L. Margvelashvili[2], E. Abzianidze[3].* 1) Tbilisi State Medical University, Institute of Medical Biotechnology, Tbilisi, Georgia; 2) Hospital 'New Life', Department of Medical Genetics and Diagnostics, Tbilisi, Georgia; 3) Tbilisi State Medical University, Department of Molecular and Medical Genetics, Tbilisi, Georgia.

Cystic fibrosis (CF) is caused by the mutations of the CFTR gene. T-lymphocytes from patients with CF are characterized by reduced expression of anti-inflammatory cytokines and elevate level of pro-inflammatory cytokines. Although the mechanisms responsible for cytokine dysregulation are not well defined, epigenetic factors such as DNA methylation or histone modification might contribute.In the previous work we have found that T-lymphocytes from CF patients express elevated level of DNMT3a, while no significant changes was observed at levels of DNMT1 compared to healthy subjects. In presence of the high dose of 5-AzaC the level of DNMT3a was decreased which was accompanied by an increased amount of IL-10.In this study we analyzed the DNA global methylation levels in T-Lymphocytes derived from CF subjects. Peripheral blood was obtained by venepuncture from CF and healthy subjects. The CF patients were in stable clinical condition and were not receiving systemic corticosteroids. The written informed consent was obtained from the parents of all patients. PBMC were isolated by Ficoll-Paque-1077 (Sigma-Aldrich, Germany) density gradient centrifugation and washed with PBS twice. CD4+ T cells were isolated from PBMC using the CD4+ T Cell Isolation Kit (Miltenyi Biotec GmbH). Cells were activated with 20ng/ml PMA and 250 ng/ml ionomycin . At 48 h after incubation genomic DNA was isolated using QIAamp Mini kit (QIAGEN). Global DNA methylation was measured using the Methylated DNA Quantification Kit as described by the manufacturer (abcam). This kit measures the5-methylcytosine (5-mC)content. The degree of DNA methylation determined was based on the obtained OD readings.Our data showed that DNA methylation levels were significantly reduced in stimulated CF T-cells compared with controls. We also analyzed the relationship between global DNA methylation status and expression ofDNMTsin CD4+T cells obtained from CF individuals. This analysis demonstrated that DNMT3alevel positively correlated with the overall methylation levels in 5-AzaCtreated CD4+T cells, while there was no significant correlation betweenDNMT1 levels and global methylation status in CF CD4+T cells compared with healthy subjects. In summary, data presented in this report demonstrates that abnormal DNA methylation in CD4+ T cells from CF individuals likely plays the significant role in the aberrant immune response during Cystic Fibrosis.

Early prediction of hypertensive disorders of pregnancy using maternal characteristics, epigenetic markers and serum markers. *S.Y. Kim[1], H.J. Kim[1], D.E. Lee[1], J.H. Lim[1], S.Y. Park[1], M.Y. Kim[2], J.Y. Han[2], D.W. Kwak[2], S.Y. Park[2], H.M. Ryu[1,2].* 1) Laboratory of Medical Genetics, Medical Research Institute, Cheil General Hospital and Women's Healthcare Center, Seoul, Korea; 2) Department of Obstetrics and Gynecology, Cheil General Hospital and Women's Healthcare Center, Dankook University College of Medicine, Seoul, Korea.

Objective: To investigate the maternal plasma levels of cell-free fetal DNA and cell-free total DNA throughout gestation using tissue-specific epigenetic markers in pregnancies with hypertensive disorders and healthy pregnancies and to evaluate the predictive value of these epigenetic markers, maternal characteristics and serum markers for developinghypertensive disorders of pregnancy.Methods: A nested case-control study was conducted with maternal plasma throughout gestation collected from 16 early-onset preeclampsia (EO-PE), 47 late-onset preeclampsia (LO-PE), 29 gestational hypertension (GH) and 72 uncomplicated pregnancies. All women underwent routine first- and second-trimester prenatal serum screening at the Cheil General Hospital. We performed a real-time PCR to quantify levels of *RASSF1A*, *DSCR3* and *SRY* as cell-free fetal DNA markers and *HYP2* and *GADH* as cell-free total DNA markers.Results: Significantly positive correlation between level of *RASSF1A, DSCR3* or *HYP2* and gestational age at sampling was observed in all study groups ($P < 0.005$ for all). There were also significant positive correlations between *RASSF1A* and *HYP2, DSCR3* and *HYP2, SRY and RASSF1A* as well as *SRY* and *DSCR3* in PE, GH, all case and control groups ($P < 0.05$ for all). The level of *HYP2* was significantly elevated in both PE and all case groups compared with control group from 6-14 weeks of gestation. At 15-23 weeks and 24-32 weeks, *HYP2* level was a significantly different between EO-PE and controls, PE and controls as well as all cases and controls ($P < 0.05$ for all). At 33-41 weeks, the levels of *RASSF1A, DSCR3* and *HYP2* were significantly elevated in EO-PE, LO-PE, PE and all cases with controls ($P < 0.05$ for all). The final parameters for the prediction of pregnancies with hypertensive disorders included *RASSF1A*, *DSCR3*, *HYP2* at 15-23 weeks' gestation, PAPP-A, AFP, uE_3, β-hCG, InhA, maternal age, and body mass index. ROC curve analysis showed that *HYP2* appeared the most discriminative marker for EO-PE [AUC 0.98 (95% CI 0.86-1.00)], PE [AUC 0.71 (95% CI 0.56-0.83)] and all cases [AUC 0.67 (95% CI 0.57-0.76)], followed by the first trimester PAPP-A for EO-PE [AUC 0.81 (95% CI 0.69-0.90)], PE [AUC 0.69 (95% CI 0.58-0.78)] and all cases [AUC 0.66 (95% CI 0.53-0.78)]. Conclusion: The addition of *HYP2* gene as a cell-free total DNA marker to PAPP-A may be useful for the early prediction of PE, especially for EO-PE.

402F

Missing data imputation using genome-wide DNA methylation data. *W. Guan[1], C. Chong[1], B. Wu[1], Y. Li[2], J.S. Pankow[1], E.W. Demerath[1], J. Bressler[3], M. Fornage[3], M.L. Grove[3], E. Boerwinkle[3].* 1) University of Minnesota, Minneapolis, MN; 2) University of North Carolina, Chapel Hill, NC; 3) University of Texas Health Science Center at Houston, Houston, TX.

DNA methylation is a widely studied epigenetic mechanism. Alterations in methylation patterns may be involved in the development of common diseases. Unlike inherited changes in genetic sequence, variation in site-specific methylation varies by tissue, developmental stage, disease status, and may be impacted by aging and exposure to environmental factors such as diet or smoking. While these wide-range correlations pose analytical challenges in epigenome-wide association studies (EWAS), including reverse causality and confounding by non-genetic factors, it brings opportunities to impute missing values for phenotypes such as blood cell counts using rich methylation data such as that provided by the Illumina Infinium HumanMethylation450 (HM450) BeadChip. We evaluated two statistical methods for missing data imputation: 1) a projection-based method (Houseman et al., 2012); and 2) a variable selection based multiple imputation method. Through simulations, we showed that both methods can properly control false positive rate, but the projection-based method may lead to biased estimates in subsequent association testing. On the other hand, the multiple-imputation method can lose power when the missing rate is high. We illustrated the methods with data from the Atherosclerosis Risk in Communities (ARIC) study to carry out an EWAS between methylation levels and smoking status, in which missing cell type compositions and white blood cell counts were imputed.

A genome-wide study of DNA methylation and prediction of diabetic nephropathy. *G.D. Fufaa[1], R.L. Hanson[1], S. Kobes[1], R.G. Nelson[1], K. Susztak[2].* 1) NIDD/NIH, Phoenix, AZ; 2) University of Pennsylvania, Philadelphia, PA.

Cross-sectional studies suggest that DNA methylation at some CpG sites differs between those with and without diabetic nephropathy, but there are few longitudinal studies that support these observations. We examined the role of DNA methylation in prediction of diabetic nephropathy in a longitudinal study of American Indians. We designed two nested case-control samples for different stages of kidney disease: one involving cases who developed severe albuminuria (SA) (urinary albumin:creatinine ratio ≥300 mg/g) among individuals who initially did not have SA (167 cases, 195 controls), and one involving cases who developed end-stage renal disease (ESRD) among those who initially had SA or estimated glomerular filtration rate <60 ml/min (82 cases, 101 controls). Genome-wide DNA methylation was measured in peripheral blood leukocytes on the Illumina 450 Infinium array. After exclusion of probes containing SNPs and restriction to probes which were highly reproducible (false discovery rate [FDR]<0.05 for the correlation among duplicates), 77,110 CpG sites were tested for association with nephropathy. Conditional logistic regression was used to estimate the hazard ratio (HR) associated with a 1 standard deviation difference in methylation at each site, controlled for age, sex, diabetes duration and the first 4 principal components. P-values for SA and ESRD were combined for a global test of association with development of nephropathy. No site achieved a FDR <0.05, but several suggestive signals (FDR<0.50) were observed. The strongest association with SA occurred at a site near *ZC3H12D* on chromosome 6 (HR=0.51, $P=3.2\times10^{-6}$), while the strongest association with ESRD occurred near *PTPRD* on chromosome 20 (HR=0.41, $P=2.8\times10^{-6}$). The strongest combined association was near *ALHD1A3* on chromosome 15 ($P=1.9\times10^{-6}$; HR=0.60 for SA, HR=0.66 for ESRD). Analysis of the top 1% of differentially methylated sites showed that they were more often hypomethylated in those who progressed to diabetic nephropathy compared with the remaining 99% of sites ($P=7.4\times10^{-6}$ for SA, $P=1.3\times10^{-3}$ for ESRD, $P=1.1\times10^{-4}$ for combined). Pathway analyses using DAVID showed that the top 1% of probes for the combined analysis were significantly enriched for genes involved in focal adhesion and in T-cell receptor signaling. These studies identify several CpG sites and pathways at which DNA methylation (particularly hypomethylation) may predict development of diabetic nephropathy.

404F

Comparison of DNA methylation profiles in sib-pairs discordant for intrauterine exposure to maternal gestational diabetes mellitus. *S. Kwak[1], E. Kim[2], S. Choi[3], K. Park[1], J. Sung[2], H. Jang[3].* 1) Department of Internal Medicine, Seoul National University Hospital, Seoul, South Korea; 2) Department of Epidemiology, School of Public Health, Seoul National University, Seoul, South Korea; 3) Department of Internal Medicine, Seoul National University Bundang Hospital, Gyeonggi-do, South Korea.

Offspring of women with a history of gestational diabetes mellitus (GDM) is at significantly increased risk for development of obesity and diabetes. It is suggested that intrauterine hyperglycemia induce epigenetic change in fetus which might have detrimental effect on future metabolic phenotypes. In this study, we compared pair-wise DNA methylation status between siblings whose intrauterine exposure to maternal GDM are discordant to each other. A total of 19 sib-pairs born from 18 Korean women who experienced both normal pregnancy and GDM pregnancy were included. DNA was extracted from peripheral leukocytes when the offspring were at age between 4 and 15 years. An epigenome-wide association study was conducted using Illumina Infinium HumanMethylation 450 BeadChip assays. Differential methylation was compared within each sib-pairs discordant for GDM pregnancy adjusting for their age, and sex. In the unsupervised clustering based on Manhattan distance, 33 samples were closely related to intrauterine GDM status. Children of GDM pregnancy were generally younger, leaner and smaller than their counterparts, but the differences in anthropometrics disappeared when quartile growth at ages were compared. A total of six CpG sites were differential methylated within sib-pairs with false discovery rate of less than 0.1 ($P < 1.50 \times 10^{-6}$). The six sites were located in *MFHAS1*, *LOC92973*, *PACRG*, *HNF4A*, *PITPNM3*, and *RREB1*. Among these CpG sites, cg08407434 which is located at *HNF4A* was consistently hypermethylated in offspring of GDM with mean pairwise difference methylation of 1.3% ($P = 9.10 \times 10^{-7}$). Using Ingenuity pathway analysis of differentially methylated regions, we found that immune response was overrepresented by hypermethylated genes. To the best of our knowledge, this is the first study to investigate the epigenome-wide difference in methylation within sib-pairs discordant for intrauterine hyperglycemia. We found several suggestive CpG sites with differential methylation, including the one located in *HNF4A* which warrants further investigation.

405T

DNA methylation may mediate the association of cigarette smoking and prostate cancer progression. *I.M. Shui[1,2], R. Rubicz[1], M.S. Geybels[1], J.L. Wright[1], S. Kolb[1], S. Zhao[3], M. Bibikova[4], J. Fan[4], B. Klotzle[4], E.A. Ostrander[5], Z. Feng[6], J.L. Stanford[1].* 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Harvard TH Chan School of Public Health, Boston, MA; 3) National Institute of Environmental Health Sciences, Research Triangle Park, NC; 4) Illumina, San Diego, CA; 5) National Human Genome Research Institute, Bethesda, MD; 6) MD Anderson Cancer Center, Houston, TX.

Background: Smoking is associated with prostate cancer progression and DNA methylation could mediate this relationship. Aims of this study were to assess if a) smoking at the time of diagnosis is associated with disease recurrence following radical prostatectomy, b) smoking is associated with differential methylation profiles in prostate tumor tissue, and c) the smoking-related differential methylation is also associated with disease recurrence.Methods: Men with prostate cancer were identified from 2 population-based case-control studies. We included 799 men who had radical prostatectomy as primary therapy. Of these men, 523 had Illumina 450K methylation data from tumor DNA. Cox proportional hazards models evaluated the association between smoking and prostate cancer recurrence. Multivariable linear regression with empirical Bayes shrinkage (*limma*) assessed differential methylation by individual CpG positions (DMPs) and *Probe Lasso* was used to identify differentially methylated regions (DMRs). DMPs identified in Aim b were carried forward to test their association with prostate cancer recurrence.Results: For the primary analysis, men were categorized as never (43%), former (47%), or current (10%) smokers. Current smoking vs. never smoking was associated with a significantly increased risk of fatal prostate cancer (HR: 4.55, 95% CI: 2.10, 9.83, p=0.0001). There was substantial differential methylation when comparing current vs. never smokers. 33194 CpG sites had an FDR q<0.05 and ≥5% difference in beta value; 2098 had ≥10% difference. Moreover, 71% of the 33194 CpGs associated with smoking were also associated with fatal prostate cancer (q<0.05 and ≥5% difference in beta value); 28% had ≥10% difference. Top DMPs and DMRs associated with recurrence included regions known to be imprinted and those associated with bone disorders, cancer susceptibility, cholesterol metabolism, and immune function. There was no evidence of differential methylation between former and never smokers, suggesting that methylation changes may be reversible upon smoking cessation. Conclusions: Our results provide evidence that DNA methylation could be an important mediator for smoking and prostate cancer recurrence. Importantly, former smokers had a reduced risk of prostate cancer recurrence and a methylation profile similar to never smokers. Future steps will be to identify specific biologic mechanisms relevant to the smoking-methylation-prostate cancer relationship.

406F

DNA Methylation at residue cg05575921 in the aryl hydrocarbon receptor repressor is the most sensitive and specific indicator of smoking status in epigenome. *A. Andersen[1], N. Hollenbeck[1], E. Andersen[2], T. Osborn[2], M. Gerrard[3], F. Gibbons[3], K. Wang[4], R. Philibert[1,2].* 1) Psychiatry, University of Iowa, Iowa City, IA; 2) Behavioral Diagnostics, Iowa City, IA; 3) Department of Psychology, Center for Health Intervention and Prevention, University of Connecticut, Storrs, CT; 4) Department of Biostatistics, College of Public Health, University of Iowa, Iowa City, IA.

Smoking is the largest preventable cause of morbidity and mortality in the world. Despite the development of numerous preventive interventions and public policy changes in the last 50 years, one in five US adults is a smoker. The effectiveness of ehavioral and pharmacologic interventions to aid smoking cessation have been limited by lack of early identification of smoking cases, when interventions are most effective. Unfortunately, the validity of self-report measures of smoking have been shown to be limited, particularly in younger smokers. Biomarkers for smoking such as cotinine and carbon monoxide have significant limitations in this group, particularly when smoking is intermittent. Furthermore, both e-cigarettes and nicotine replacement therapies may confound cotinine measurement as a sensitive and specific indicator of smoking. Epigenetic measurement has the potential to overcome the limitations of these approaches and guide early intervention, before smoking behavior has become ingrained and health consequences have emerged. We have previously demonstrated that smoking is associated with genome-wide changes in DNA methylation. Here, we determine the sensitivity and specificity of ten of the most consistently replicated CpG loci with respect to smoking status using data from a publically available dataset. We show that methylation at many of the more commonly cited loci, such as in F2RL3, display ethnically contextual effects that render them unacceptable for general usage. We further show that methylation status at a CpG locus in the aryl hydrocarbon receptor repressor, cg05575921, is both sensitive and specific for smoking status in adults of all ethnicities, with a receiver operated curve characteristic (ROC) area under the curve of 0.99. Modeling analyses of cg05575921 consumption show that demethylation at this locus is a function of both average recent consumption and total lifetime consumption. The locus is responsive to smoking over short periods of time with notable changes evident in less than 4 weeks. Given recent demonstrations that methylation at this locus reflects both intensity of smoking and the degree of smoking cessation, we conclude that a methylation-based assay at this locus could have a prominent role in understanding the impact of new products, such as e-cigarettes on initiation of cigarette smoking among adolescents, while improving the prevention and treatment of smoking and smoking related disorders.

407T

Estimation of Cell Type Specific DNA Methylation Effects using Whole Blood Methylation Data. *R. Barfield[1], A. Bacarelli[2], X. Lin[2].* 1) Harvard University, Cambridge, MA; 2) Harvard T.H. Chan School of Public Health, Boston, MA.

Association analysis of DNA methylation data is challenged by cell type heterogeneity, as DNA methylation collected in studies is typically a mixture of different cell types. For example, studies using whole blood measure DNA methylation from a mixture of different lymphocytes. This cell type heterogeneity can potentially bias results, as DNA methylation is known to be an important mechanism of tissue differentiation, and thus may differ by cells. Current methods to adjust for this involve including observed or estimated cell type counts as additional covariates in the analysis. These methods however do not estimate the exposure effects on cell type specific DNA methylations. Direct measurements of cell type specific methylations involve intensive lab work and are costly. We develop in this paper a statistical method to estimate exposure effects on cell-specific methylations using whole blood methylation data when cell type counts are available but cell-specific methylations are unavailable. Specifically, we assume cell type specific regression models of the exposure effects on cell type specific methylations. We treat cell specific methylations as missing data, and develop an EM algorithm to estimate the exposure effects on cell type specific methylations adjusting for covariates by using whole blood methylation data and cell type counts. To the best of our knowledge, this is the first method to estimate these effects without assaying each cell type. We applied our method to the Normative Aging Study to study the smoking effect on cell type specific methylations.

Genome-Wide DNA Methylation Signatures of Salivary Gland Inflammation in Sjögren's Syndrome. *M.B. Cole[1], D. Quach[2], H. Quach[2], L.F. Barcellos[2], L.A. Criswell[3].* 1) Department of Physics, University of California, Berkeley, Berkeley, CA; 2) Division of Epidemiology, Genetic Epidemiology and Genomics Laboratory, School of Public Health, University of California, Berkeley, Berkeley, CA; 3) Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center, Department of Medicine, University of California, San Francisco, CA.

Sjögren's Syndrome (SS, OMIM #270150) is a chronic, multi-system autoimmune disease characterized by progressive destruction of the exocrine glands, with subsequent mucosal and conjunctival dryness. A growing body of evidence indicates that many epigenetic changes are associated with disease status and that epigenetic marks can provide unique insights into complex disease mechanisms. We report on results of a case-control study of DNA methylation (DNAm) differences within labial salivary gland tissue, using biopsies sampled from 13 severe SS cases and 13 controls in the Sjögren's International Collaborative Clinical Alliance (SICCA; http://sicca.ucsf.edu/; HHSN268201300057C) registry. We have methylotyped gland tissue and sorted PBMCs from these subjects using the Illumina HumanMethylation450 (450k) BeadChip platform. In addition to standard background correction and normalization techniques, we applied an adaptive normalization scheme to adjust for residual associations between DNAm and control measures. Principal component analysis (PCA), applied to the 404,353 CpG sites passing strict QC criteria, clearly distinguishes glands of primary SS cases from those of controls. We find over 10,000 significant differentially methylated positions (DMPs) that show significant overlap with the promoters of genetic risk loci as a whole, with particular enrichment seen in the promoters of *CXCR5* and *BLK*. We also observe an extended region of differential methylation surrounding *PSMB8* and *TAP1* in the MHC class II region. Despite a previous report of association between global DNAm and ICAM1expression in the context of SS, we fail to detect differential methylation in the promoter of the *ICAM1* locus. On the other hand, differential methylation patterns surrounding several non-coding RNAs suggest many indirect consequences of the observed salivary gland *hypo*-methylation in SS. Transcription factor motif enrichment analysis highlights the specific nature of these methylation differences, demonstrating co-localization of DMPs with interferon-stimulated response element (ISRE) and PU-Box motifs. DNAm signatures derived from sorted PBMCs show that disease-associated changes in DNAm are linearly correlated with cell-type specific patterns, resolving differential lymphocyte proportions. Our results emphasize the utility of CpG methylation not only as a biomarker of disease status, but also as an independent probe of underlying disease processes.

DNA methylation profiles in ADHD: comparison between boys and girls. *T.V.M.M. Costa[1], C. Milani[1], F.A. Marchi[2], G.M. Novo-Filho[1], E.A. Zanardo[1], M.M. Montenegro[1], F.A.R. Madia[1], R.L. Dutra[1], F.B. Piazzon[1], A.M. Nascimento[1], M. Rocha[1,3], M.B. Veronesi[1], C.A. Kim[4], V. Schuch[5], C.B. Mello[5], M. Muszkat[5], L.D. Kulikowski[1,3,4].* 1) Laboratório de Citogenômica, Departamento de Patologia, Faculdade de Medicina da USP, São Paulo, Brasil; 2) Laboratório NeoGene, AC Camargo Cancer Center, São Paulo, Brazil; 3) Centro de Reprodução Humana e Genética,Departamento de Saúde Coletiva, Faculdade de Medicina do ABC, Santo André, Brasil; 4) Unidade de Genética, Departamento de Pediatria, Instituto da Criança, HC/FMUSP, São Paulo, Brasil; 5) Núcleo de Atendimento Neuropsicológico Infantil Interdisciplinar (NANI), Departamento de Psicobiologia da Escola Paulista de Medicina, UNIFESP, São Paulo, Brasil.

Attention deficit hyperactivity disorder (ADHD) is one of the most common neurobehavioral disorder diagnosed in childhood. ADHD is etiologically heterogeneous. On the other hand, it has a high heritability (around 80%) and it is diagnosed twice more often in boys than in girls. Although it has a high heritability, the genetic architecture of ADHD is still largely unknown and molecular markers for diagnosis havenotbeen identified yet. DNA methylation is an important epigenetic mechanism associated with silencing of genes in CpG islands. Thus, the investigation of methylation profile in patients with ADHD is very important and could reveal different and interesting aspects of the disorder. DNA methylation profiles were performed using DNA extracted from blood lymphocytes of 13 carrying ADHD (9 boys and 4 girls, ages 08-15) by Illumina Infinium HumanMethylation450 BeadChip. Children were diagnosed according to Diagnostic and Statistical Manual of Mental Disorders (DSM-IV-TR). We pre-processed the array data using GenomeStudio software and full analysis was performed using specific packages within the environment R. The comparison between boys and girls considered delta-beta ($\Delta\beta$) <-0.20 or > +0.20. The probes were annotated according to the data provided by Illumina, using the genome hg19 reference. After the comparison between boys and girls we obtained 20 differentially hipomethylated probes and 20 differentially hipermethylated probes. Our previous results showed significantly methylated probes involved in several networks, including Glutamate pathways, pointing out the relevance of glutamate, which is closely associated to the Central Nervous System and could be modified by epigenetic factors. In this sense, tissue-specific DNA methylation profiles considering gender may provide novel insights into pathogenic mechanisms of ADHD and also help in future epigenetic therapies.Grants: FAPESP: 14/02565-8 and FINEP-CT INFRA 0160/12 SP8.

A genome-wide analysis of differential methylation regions in the nucleus accumbens of rhesus macaques after long-term alcohol use. *B. Ferguson, R. Cervera-Juanes, L. Wilhelm, S. Gonzales, K. Grant.* Div. of Neurosciences, ONPRC, Oregon Health Science Univ., Portland, OR.

The long-lasting behavioral plasticity associated with alcohol addiction may be related to changes in epigenetic mechanisms that regulate neural gene expression, contributing to the widespread gene expression changes observed after alcohol use. The nucleus accumbens (NAc), a critical component of the reward system, is associated with risk for alcohol use. Here, we investigated the long-term effects of alcohol on the NAc methylome of male rhesus macaques after 12-months of alcohol or water (controls) self-administration. We used targeted bisulfite DNA sequencing to identify significant differentially methylated regions (DMRs) between controls (C), low-moderate drinkers (LMD) and heavy drinkers (HD) using Comb-p software. Our results revealed 51 significant, gene-specific DMRs among the three groups. Interestingly, some of the DMRs were uniquely detected in either the HD or LMD groups (39), while others appeared to be correlated with alcohol dose (16). The location of the DMRs in the promoter and within the gene body, together with the preliminary gene expression data suggest a potential role of the DMRs in regulating total transcript level and the expression of alternative transcripts. The DMRs map to genes encoding proteins with functions linked to ion transport, cytoskelton binding, cell surface recptors and transcriptional regulation. The majority of the genes associated with DMRs are involved in neuronal functions, suggesting that DNA methylation may play a central role in the neural adaptation to chronic alcohol use.

411T

Intra-individual dynamics of transcriptome and genome-wide stability of DNA methylation during three months. *R. Furukawa[1], T. Hachiya[1], H. Ohmomo[1], Y. Shiwa[1], K. Ono[1], S. Suzuki[2], M. Satoh[1], J. Hitomi[1], K. Sobue[1], A. Shimizu[1].* 1) Iwate Medical University, Shiwa-gun,Iwate, Japan; 2) Keio University,Shinjuku-ku, Tokyo,Japan.

Cytosine methylation in CpG dinucleotides is one of the key epigenetic mechanisms that regulate gene expression. DNA methylation is considered to be stable, and to define "fields" for producing the transcriptomes that characterize the functional differences of cells. Although gene expression patterns are well known to change in response to various stimuli, it remains unclear to what extent DNA methylation contributes to short-term dynamics in gene expression. In the present study, we examined the short-time dynamics and stability of gene expression and DNA methylation in peripheral blood mononuclear cells (PBMCs) and monocytes. We collected blood 24 times from one healthy volunteer in three months and obtained PBMCs and $CD14^{high}CD16^{low}$ monocytes using cell sorter (SH800, Sony). After extraction DNA and RNA, we measured gene expression and DNA methylation levels by RNA sequencing and by Illumina Infinium HumanMethylation450 BeadChip microarrays, respectively. First, to extract genes showing dynamic change in expression, we calculated the coefficient of variation for each gene as an indicator of the expression change, and defined the dynamic expression genes by detecting outliers from a baseline. From these dynamic genes, we removed the genes that the expressions were associated with the change in cell-type composition by using a linear regression model and the ANOVA test to detect Cell-type composition/Expression Associations (CEA). As results, we obtained 1,637 and 5,279 dynamic non-CEA genes in PBMCs and monocytes, respectively. Next, we assessed to what extent the DNA methylation levels explain the expression of the dynamic non-CEA genes. As an index of the contribution of DNA methylation to the gene expression, R^2 values were obtained by a linear regression model. Unexpectedly, there was no significant difference between the distributions of R^2 values to the dynamic and the non-dynamic non-CEA genes, meaning that the contribution of DNA methylation to the dynamics of non-CEA genes was not significant. Additionally, the standard deviation of the methylation levels of CpG loci near the dynamic genes was less than that of CpG loci located near the non-dynamic genes. From these results, it was considered that the DNA methylation levels of the CpG that located the vicinity of the dynamic non-CEA genes were quite stable, and the extent of the contribution of the DNA methylation to the dynamics of gene expression was small at least in several months.

412F

Characterizing a genomic map of 5-hydroxymethylcytosine in human brain at single base resolution through next-generation sequencing. *J.A. Gross[1], A. Pacis[2,3], G.G. Chen[1], L.B. Barreiro[2,3], C. Ernst[1], G. Turecki[1].* 1) Douglas Mental Health Univ Inst, Montreal, Quebec, Canada; 2) CHU Sainte-Justine Research Centre, Department of Genetics, Montreal, Quebec, Canada; 3) Departments of Biochemistry and Pediatrics, University of Montreal, Montreal, Quebec, Canada.

The recent discovery that methylated cytosines are converted to 5-hydroxymethylated cytosines (5hmC) by the family of ten-eleven translocation enzymes has sparked significant interest on the genomic location, the abundance in different tissues, the putative functions, and the stability of this epigenetic mark. 5hmC plays a key role in the brain, where it is particularly abundant and dynamic during development. Using AbaSI-Seq, we comprehensively characterize 5hmC in the prefrontal cortices of 24 subjects. We show that, although there is inter-individual variability in 5hmC content among unrelated individuals, approximately 8% of all CpGs on autosomal chromosomes contain 5hmC, while sex chromosomes contain far less. Our data also provide evidence suggesting that 5hmC has transcriptional regulatory properties, as the density of 5hmC was highest in enhancer regions and within exons. Furthermore, we link increased 5hmC density to histone modification binding sites, to the gene bodies of actively transcribed genes, and to exon-intron boundaries. Finally, we provide several genomic regions of interest that contain gender-specific 5hmC. Collectively, these results present an important reference for the growing number of studies that are interested in the investigation of the role of 5hmC in brain and mental disorders. Understanding the differences in the genomic locations of hmC will shed light on the growing debate as to whether hmC represents a novel epigenetic mark or whether it is simply an intermediate product of active DNA demethylation.

413T

Strong components of epigenetic memory in cultured human fibroblasts. *N.A. Ivanov[1], R. Tao[1], J.G. Chenoweth[1], A. Brandtjen[1], M.I. Mighdoll[1], J.D. Genova[1], R.D. McKay[1], Y. Jia[1], D.R. Weinberger[1,2,3,4,5], J.E. Kleinman[1], T.M. Hyde[1,5,6], A.E. Jaffe[1,7,8,9].* 1) Lieber Institute for Brain Development, Baltimore, MD; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 4) Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD; 5) Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD; 6) Department of Biological Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 7) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore MD; 8) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore MD; 9) Center for Computational Biology, Johns Hopkins University, Baltimore MD.

Differentiation of pluripotent cells from fibroblast progenitors are potentially transformative tools in personalized medicine. We previously described culture of scalp- and dura-derived fibroblasts from postmortem tissue, and identified relatively greater success culturing the dura-derived cell lines. We hypothesized that these differences in growth in culture were related to epigenetic differences between the cultured fibroblasts by sampling location, and therefore generated genome-wide DNA methylation and transcriptome data on 11 intrinsically matched pairs of dural and scalp fibroblasts from donors across the lifespan (infant to 85 years). While these cultured fibroblasts were several generations removed from the primary tissue and morphologically indistinguishable, we found widespread epigenetic differences by sampling location at the single CpG (N=101,989), region (N=697), "block" (N=243), and global spatial scales suggesting a strong epigenetic memory of original fibroblast location. Furthermore, many of these epigenetic differences manifested as differences in gene expression levels, particularly at the region-level (69.4%). We further identified 7,265 CpGs and 10 regions showing significant epigenetic memory related to the age of the donor, as well as an overall increased epigenetic variability, preferentially in scalp-derived fibroblasts (83% of loci were more variable in scalp). This was hypothesized to result from cumulative exposure to environmental stimuli in the primary tissue. By integrating publicly available DNA methylation datasets on individual cell populations in blood and brain, we identified significantly increased inter-individual variability in our scalp- and other skin-derived fibroblasts. This increased inter-individual variability is on a similar scale as epigenetic differences between different lineages of blood cells. Lastly, these epigenetic differences did not appear to be driven by somatic mutation - while we identified 63 probable variants across the 11 subjects, there was no association between mutation burden and age of the donor (p=0.86). These results depict a strong component of epigenetic memory in cell culture from primary tissue, even after several generations of daughter cells, related to cell state and donor age.

Epigenome Characterization of Human Genomes using the PacBio® Platform. *J. Korlach.* Pacific Biosciences, Menlo Park, CA.

In addition to the genome and transcriptome, epigenetic information is essential to understand biological processes and their regulation, and their misregulation underlying disease. Traditionally, epigenetic DNA modifications are detected using upfront sample preparation steps such as bisulfite conversion, followed by sequencing. Bisulfite sequencing has provided a wealth of knowledge about human epigenetics, however it does not access the entire genome due to limitations in read length and GC-bias of the sequencing technologies used.In contrast, Single Molecule, Real-Time (SMRT®) DNA Sequencing is unique in that it can detect DNA base modifications as part of the sequencing process. It can thereby leverage the long read lengths and lack of GC bias for more comprehensive views of the human epigenome. I will highlight several examples of this capability towards the generation of new biological insights, including the resolution of methylation states in repetitive and GC-rich regions of the genome, and large-scale changes in the methylation status across a cancer genome as a function of drug sensitivity.

M-QTL analysis between asthma GWAS loci and DNA methylation interactions. *A. Kumar[1,2,3], S.K. Merid[1], C. Söderhäll[1,7], C. Xu[4,5], O. Gruzieva[1], J. Kere[6,7], G. Pershagen[1], G. Koppelman[4,5], E. Melén[1,7,8].* 1) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 2) Department of Epidemiology and Public Health, Swiss Tropical and Public Health Institute, Basel, Switzerland; 3) University of Basel, Basel, Switzerland; 4) University of Groningen, University Medical Center Groningen, Department of Pulmonology, GRIAC research Institute, Groningen, the Netherlands; 5) University of Groningen, University Medical Center Groningen, Department of Genetics, GRIAC research Institute, Groningen, the Netherlands; 6) Department of Biosciences and Nutrition and Center for Innovative Medicine (CIMED), Karolinska Institutet, Stockholm, Sweden; 7) Centre for Allergy Research, Karolinska Institutet, Stockholm, Sweden; 8) Sachs' Children's Hospital, Stockholm, Sweden.

Background: Asthma is characterized as a chronic inflammation disease and has increased in prevalence over the decades. The genome-wide association studies (GWAS) have implicated several single nucleotide polymorphisms (SNPs) with varying risk estimates for asthma, but the etiology and prevalence change is still unexplained. Thus, the interaction between genetic and epigenetic variations can help us find SNPs associated with altered DNA methylation (mQTL) to explore the cis and trans-regulatory relationships that may affect the gene regulation and disease phenotypes. **Methods**: Using the Illumina Infinium HumanMethylation450 beadchip, DNA methylation was measured from peripheral blood of 464 individuals (231 patients with asthma-ever doctor diagnosis and 233 controls) up to 8 yrs age from the BAMSE study. We currently focused on cytosine-phosphate-guanine (CpG) sites in the *ORMDL3 and IL1RL1* genes, that have been implicated in multiple asthma GWAS, with genotypes derived on same samples using SNPs from Human610-Quad beadchip imputed (minimac) on 1000 Genomes reference panels (phase 1). "SNP x mQTL" interactions were examined using logistic regression models adjusting for gender, case/control status and population stratification eigenvalues. **Results**: A total of 15 CpG sites were identified in the two loci. Preliminary analyses in cases and controls separately yielded a high overlap in significant results after Bonferroni correction (BC); we thus combined cases and controls to increase power. Consequently, in the *ORMDL3* region, six local CpGs out of nine were significant after BC, with cg10909506 showing the strongest association with rs17608925 ($p=1.05x10^{-15}$) in comparison to the top GWAS SNP, rs7216389 ($p=6.499x10^{-12}$, $R^2=0.17$). Similarly, cg25869196 with rs11676124 ($p=2.78x10^{-9}$) and cg20060108 with rs887971 ($p=1.33x10^{-11}$) were found significant in *IL1RL1* gene region, out of six CpGs, while the relevant top GWAS SNP, rs1420101 was less significant, with no correlation. **Conclusion**: Our results on two well-known asthma susceptibility genes indicate that CpG sites that are significantly associated with SNPs manifest *cis*-mQTLs effects, although some *trans*-mQTLs associations were also found. The strongest mQTL effects were seen for other SNPs than the top GWAS SNPs. Thus, studying these DNA methylation changes as part of integrative genomics pipelinecan help us disentangle the molecular mechanism of the diseases better.

416F

DNA Methylation Score as a Biomarker in Newborns for Sustained Maternal Smoking During Pregnancy. *S.J. London[1], M. Wu[2], S. Zhao[3], S. Haberg[4], P. Ueland[5], R.M. Nilsen[7], O. Midttun[6], S.E. Vollset[4,5], B. Joubert[1], S. Peddada[2], W. Nystad[4], S.E. Reese[1].* 1) Epidemiology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC; 2) Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Biostatistics and Computational Biology Branch, NIEHS, Research Triangle Park, NC; 4) Norwegian Institute of Public Health, Oslo, Norway; 5) University of Bergen, Bergen, Norway; 6) Bevital AS, Laboratory building, Bergen, Norway; 7) Department of Research and Development, Haukeland University Hospital, Bergen, Norway.

Maternal smoking during pregnancy leads to numerous adverse outcomes in offspring. We previously identified highly reproducible methylation signals using a genome wide methylation platform (Illumina 450K) that reflect sustained, but not transient, smoking during pregnancy. Questionnaire assessment of smoking in pregnant women may not detect all smokers and timing of assessments may be insufficient to assess sustained smoking. There is no biomarker of sustained smoking during pregnancy. We used data on a short-term smoking biomarker, cotinine, measured in maternal plasma during pregnancy and Illumina 450K whole newborn cord blood DNA methylation in a pregnancy cohort (N=1279) to develop a biomarker in newborns of sustained maternal smoking during pregnancy. We used logistic least absolute shrinkage and selection operator (LASSO) regression with area under the curve (AUC) cross-validation to train a model predictive of sustained maternal smoking in pregnancy. A subset of CpGs that we determined to be most predictive of smoking from the LASSO was used to estimate the probability that a newborn's mother was a smoker. The regression coefficients of these CpGs were used to develop a smoking score that reliably predicted smoking status in the train set (N=1058; AUC=0.98 Sensitivity=85%, Specificity=98%). As expected, predictive performance was lower on the much smaller test set (N=221; AUC=0.87, Sensitivity=57%, Specificity=93%). This smoking score can be applied to other studies with Illumina 450K methylation data. It represents a promising novel biomarker in newborns of sustained maternal smoking during pregnancy. This should be useful in studies with limited time course information on maternal as well as to fill in missing individual data. It also provides a means to evaluate self-reported questionnaire data. This quantitative biomarker, which incorporates duration as well as dose, might improve the ability to detect health effects of maternal smoking during pregnancy.

Whole-genome bisulfite sequencing data from multiple human tissues reveal novel CpG island loci of tissue-specific regulation. *I. Mendizabal[1,2], S.V. Yi[1].* 1) School of Biology, Georgia Institute of Technology, Atlanta, GA; 2) Department of Genetics, Physical Anthropology and Animal Physiology, University of the Basque Country UPV/EHU, Spain.

CpG islands (CGIs) are one of the most widely studied regulatory features of the human genome, with critical roles in development and disease. Despite such significance and the original epigenetic definition, currently used CGI sets are typically predicted from DNA sequence characteristics. Although CGIs are deeply implicated in practical analyses of DNA methylation, recent studies have shown that such computational annotations suffer from inaccuracies. Here we used whole genome bisulfite sequencing from ten diverse human tissues to identify a comprehensive, experimentally obtained, single-base resolution CGI catalog. In addition to the unparalleled annotation precision, our method is free from potential bias due to arbitrary sequence features or probe affinity differences. In addition to clarifying substantial false positives in the widely used UCSC annotations, our study identifies numerous novel epigenetic loci of regulation. In particular, we reveal significant impact of transposable elements on the epigenetic regulatory landscape of the human genome, and demonstrate ubiquitous presence of transcription initiation at CGIs, including alternative promoters in gene bodies and non-coding RNAs in intergenic regions. Moreover, coordinated DNA methylation and chromatin modifications mark tissue-specific enhancers at novel CGIs. Enrichment of specific transcription factor binding from ChIP-seq provides mechanistic roles of CGIs on regulation of tissue specific transcription. Consequently, the CGI catalog provides a comprehensive and integrated list of genomic hotspots of epigenetic regulation.

Epigenome-wide association study suggests that SNPs in the promoter region of *RETN* influence plasma resistin level via effects on DNA methylation at neighboring sites. *M. Nakatochi[1], S. Ichihara[2], K. Yamamoto[3], K. Ohnaka[4], Y. Kato[5], S. Yokota[6], A. Hirashiki[7], K. Naruse[8], H. Asano[6], H. Izawa[9], T. Matsubara[8], M. Yokota[10].* 1) Bioinformatics Section, Center for Advanced Medicine and Clinical Research, Nagoya University Hospital, Nagoya, Japan; 2) Graduate School of Regional Innovation Studies, Mie University, Tsu, Japan; 3) Department of Medical Chemistry, School of Medicine, Kurume University, Kurume, Japan; 4) Department of Geriatric Medicine, Graduate School of Medical Sciences, Kyushu University, Fukuoka, Japan; 5) Department of Registered Dietitians, Faculty of Health and Welfare, Tokai Gakuin University, Kakamigahara, Japan; 6) Department of Internal Medicine, Iwakura Hospital, Iwakura, Japan; 7) Department of Advanced Medicine in Cardiopulmonary Disease, Nagoya University Graduate School of Medicine, Nagoya, Japan; 8) Department of Internal Medicine, School of Dentistry, Aichi Gakuin University, Nagoya, Japan; 9) Department of Cardiology, Fujita Health University Banbuntane Hotokukai Hospital, Nagoya, Japan; 10) Department of Genome Science, School of Dentistry, Aichi Gakuin University, Nagoya, Japan.

Aims Human resistin is considered to be a biomarker or mediator of metabolic and inflammatory diseases. To investigate epigenetic regulation of the plasma concentration of resistin, we performed an epigenome-wide association study for this parameter and DNA methylation (DNAm) in an elderly Japanese cohort and then assessed the relation of single nucleotide polymorphisms (SNPs) associated with the plasma resistin concentration to DNAm level at identified sites.*Methods* The association of plasma resistin level with DNAm status was examined in 191 nondiabetic elderly Japanese men in Kita-Nagoya with the Illumina Infinium HumanMethylation450 BeadChip array. The association between DNAm status at specific sites in the flanking region of the resistin gene (*RETN*) and *RETN* mRNA abundance was then evaluated with a public data set for 1202 monocyte samples from a multiethnic cohort. Finally, the association of DNAm status and SNPs in the promoter region of *RETN* was assessed in two cohorts composed of 191 Japanese individuals in Kita-Nagoya and 287 Japanese individuals in Fukuoka.*Results* The plasma resistin level showed a negative genome-wide significant association with DNAm status at a CpG site located in the promoter region of *RETN* ($\beta = -0.270 \pm 0.041$, $p = 6.02 \times 10^{-10}$). Four DNAm sites in the *RETN* promoter region including the CpG site ($\beta = -0.298 \pm 0.016$, $p = 4.23 \times 10^{-70}$) showed a negative genome-wide significant association with *RETN* mRNA abundance in monocytes. Furthermore, DNAm level at the CpG site was negatively associated with the minor alleles of the *RETN* promoter SNPs rs34861192 and rs3219175 (Kita-Nagoya, $\beta = -0.396 \pm 0.043$, $p = 4.43 \times 10^{-17}$; Fukuoka, $\beta = -0.334 \pm 0.035$, $p = 3.50 \times 10^{-19}$). The SNPs rs34861192 and rs3219175 were in complete LD in the Kita-Nagoya samples.*Conclusions* Although the minor alleles of rs34861192 and rs3219175 have been reported to be positively associated with circulating resistin level in Japanese, the mechanism by which they regulate the circulating resistin concentration has remained unclear. Our results suggest that *RETN* promoter SNPs might influence the circulating resistin level through an effect on DNAm at the CpG site and on *RETN* mRNA abundance in monocytes.

Epigenetic Regulation of Differential *HLA-A* Allelic Expression Levels. *V. Ramsuran[1,2], S. Kulkarni[2], C. O'hUigin[1], Y. Yuki[1], D. Augusto[1,2], X. Gao[1], M. Carrington[1,2].* 1) Cancer Inflammation Program , National Cancer Institute, Frederick, MD; 2) Ragon Institute of Massachusetts General Hospital, Massachusetts Institute of Technology, and Harvard University, Cambridge, MA.

MHC class I expression levels influence the strength of immune responses and represent another variable in determining outcome to disease beyond peptide binding alone. Identification of the *HLA* loci that vary in allelic expression levels and delineating the mechanism responsible for expression variation may provide the opportunity to modify their expression therapeutically. We have examined the expression levels of allelic lineages at the *HLA-A* locus in a sample of 216 European Americans using a real time PCR assay, which amplifies all *HLA-A* lineages specifically with equal efficiency, and observe a gradient of expression that associates with *HLA-A* allelic lineage ($R=0.6$, $p=5x10^{-25}$). DNA methylation of the *HLA-A* gene appears to contribute to the variation in *HLA-A* mRNA expression levels, as a significant inverse correlation was observed between *HLA-A* mRNA expression levels in untreated cells and the degree to which expression is increased after treatment of the cells with a DNA methyltransferase inhibitor ($R=0.6$, $p=2.8x10^{-6}$). Further, deep sequencing and chromatin immunoprecipitation assays revealed allelic lineage specific methylation patterns within the *HLA-A* promoter region where increased DNA methylation levels correlated significantly with reduced *HLA-A* expression levels ($R=0.89$, $p=3.7x10^{-9}$). These data demonstrate *HLA-A* allelic lineage specific variation in expression levels, and DNA methylation as a key factor in contributing to this variation.

420F

Epigenome-wide association analyses of healthy human skin and blood DNA methylation profiles in relation to total body nevus count. *L. Roos[1], J. Sandling[2], D. Glass[1], T.D. Spector[1], P. Deloukas[3], V. Bataille[1], J.T. Bell[1].* 1) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 2) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 3) William Harvey Research Institute, Queen Mary University of London, London, United Kingdom.

The strongest risk factor for melanoma is the number of melanocytic nevi. Nevi senesce from middle age onwards, but this can be delayed in individuals at high risk of melanoma. Genes such as *MTAP, CDKN2A,* and *PLA2G6* as well as those involved in telomere function have already been associated with nevus count. We performed an epigenome-wide association study (EWAS) by analyzing DNA methylation profiles from the Illumina 450k array in relation to total body nevus count, both in skin tissue from a sun-protected area and whole blood in 327 and 404 healthy female individuals, respectively.We identified 3 CpG sites in skin tissue that were significantly associated with nevus count at a false discovery rate (FDR) of 5%. The strongest signal ($p = 2.1 \times 10^{-8}$) was a CpG site hypermethylated with increasing nevus count, located in a CpG island shore upstream of lincRNA *AC144831.1*. The second ranked CpG was hypomethylated with increasing nevus count and was located in the promoter region of *C15orf48*, which is upregulated in skin carcinoma samples. The third CpG site was hypermethylated with increasing nevus count and locates in the transcription start site (TSS) of *ARRD1*, implicated in embryogenesis and tissue maintenance. At a less stringent threshold (FDR=10%) we found a negative correlation between DNA methylation and nevus count 200bp upstream of the TSS of *RAF1.* Mutations in *RAF1* can lead to oncogenic properties in melanoma, and *RAF1* inhibitors have been developed as successful drug targets. These results did not replicate in the whole blood EWAS. There we did identify 9 CpG sites that were significantly associated with nevus count at EWAS (FDR 5%). Among the significant findings was a CpG site located within *EBF3,* involved in neural development, which is of particular relevance as melanocytes are derived from the neural crest.To conclude, this is the first EWAS for total body nevus count and is performed in a phenotype relevant tissue, skin, as well as whole blood samples. We have identified CpG sites near genes that are relevant for the formation of nevi and melanoma. Furthermore, different significant CpG sites were found across the two tissues, indicating that the signal in skin tissue might be tissue-specific and potentially have direct mechanistic involvement. Future work will aim to integrate genetic variation, DNA methylation, and gene expression to increase our understanding of the mechanisms underlying development and formation of nevi and melanoma.

421T

DNA methylation profiling of brains of Parkinson disease patients. *S.K. Sivasankaran, A. Hossein, A. Mehta, L.G. Maldonado, K. Nuytemans, W.K. Scott, E.R. Martin, J.M. Vance, J.I. Young.* John P. Hussman Institute for Human Genomics, Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA.

Parkinson's disease (PD) is a chronic multifactorial neurological disorder that mostly affects people over the age of 60. It is the second most common neurodegenerative disorder with a prevalence of 1.5 million people in U.S. alone and about 60,000 additional patients newly diagnosed each year. The core pathology of PD is defined by progressive loss of dopamine-producing neurons in the substantia nigra in brain. Approximately 15-20% of PD patients have a family history of PD, and there are rare cases with Mendelian inheritance. Genetic studies have identified several chromosomal loci associated with PD. However, the vast majority of PD cases are idiopathic, with disease likely caused by other genetic factors, epistatic effects, and gene-environment interaction effects. Recently, increasing evidence suggests that epigenetic mechanisms, such as DNA methylation and histone modification may also regulate the expression of PD-related genes, and contribute to PD etiology.Here, we investigated genome-wide DNA methylation in 24 (12 PD cases and 12 controls, matched on sex and race/ethnicity) prospectively collected autopsied brains to assess the methylation state of anterior cingulate gyrus DNA in relation to PD. We used state-of-the art data processing protocols, including normalization of probe intensity and background. For differential methylation tests, we performed logistic regression, adjusting for batch and age of death as covariates. A total of 17 cytosine-phosphate-guanine (CpG) sites were differentially methylated in our analysis (adjusted p-value < 0.05). Of particular interest is a differentially methylated CpG site located within the 5'-UTR of the tripartite motif-containing protein 2 (*TRIM2*, p-value = $1.7x\ 10^{-07}$). *TRIM2* is an excellent candidate gene as it is expressed in brain, had been linked to axonal function and previous studies found it associated to peripheral neuromuscular disorders. In mice, deficiency of *TRIM2* causes neurodegeneration.Our analyses suggest that the identified DNA methylation changes may have a role in PD and will be complemented by methylation profiling in additional brain regions.

422F

Genome-wide DNA methylation changes in the dorsal and ventral striatum of individuals with chronic cocaine dependence. *K. Vaillancourt[1,2], G.G Chen[1], A. Diallo[1], R. Poujol[1], C. Ernst[1,3], D.C. Mash[4], G. Turecki[1,2,3].* 1) McGill Group for Suicide Studies, Douglas Hospital Research Center, Verdun, QC; 2) Integrated Program in Neuroscience, McGill University, Montreal, QC; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada; 4) Department of Neurology, University of Miami Miller School of Medicine, Miami, FL.

Background: Cocaine dependence is a chronic relapsing disorder whose development and trajectory is impacted by multiple genetics and environmental factors. Transcriptional changes accompany the transition from recreational cocaine use to cocaine dependence and epigenetic mechanisms may mediate these effects. Recently, several studies have identified epigenetic marks that are associated with the acquisition of compulsive drug seeking in animal models, but little is known about the role of epigenetics in human cocaine dependence. Of particular interest is DNA methylation as it represents a mitotically stable mark that has been shown to be altered by environmental experience.**Methods**: We used Reduced Representation Bisulfite Sequencing (RRBS) on post mortem nucleus accumbens and caudate tissue from 25 dependent cocaine users and 25 drug-free and age-matched controls. This approach has allowed us to detect genome-wide cytosine methylation at base pair resolution. Differentially methylated regions (DMRs) were validated using targeted bisulfite sequencing and cell-type specificity will be investigated in neuronal and non-neuronal nuclear fractions that have been separated using Fluorescence Activated Cell Sorting (FACS).**Results**: All RRBS libraries contained more than 4 million reads at 10X coverage and are well aligned to the human genome. In addition, all libraries were bisulfite converted with over 98% efficiency. Our study has identified multiple clusters of hyper- and hypomethylation associated with chronic cocaine dependence, in both brain regions. Differentially methylated regions span gene bodies, including introns and exons, as well as promoters and intergenic regions. High throughput discovery of cocaine-associated networks and pathways allow us to investigate the epigenetic changes in brain that accompany the transition from cocaine abuse to chronic cocaine dependence.Funded by NIDA (DA033684).

Preliminary study on Genome wide methylation profile of liver biopsies in HCV infected patients with severe hepatic fibrosis. *L.R.S. Vasconcelos[1,2], R.F. Carmo[4], V.C.S. Sousa[3], S. Cabantous[5], C. Chevillard[5], L.M.M.B. Pereira[2], P. Moura[3], A. Dessein[5].* 1) Parasitology Departament, Aggeu Magalhães Research Center - FIOCRUZ-PE , Recife, Brazil; 2) Liver and transplant institute of Pernambuco - IFP-PE, Recife, Brazil; 3) Biological sciences institute - University of Pernambuco -ICB/UPE, Recife, Brazil; 4) Federal University of São Francisco Valley- UNIVASF, Petrolina, Brazil; 5) Immunology and Genetics of Parasitic Diseases, INSERM 906, Università d'Aix-Marseille, Marseille, France.

Introduction:Hepatitis C virus (HCV) infection is a major cause of chronic hepatitis, liver cirrhosis and hepatocellular carcinoma (HCC) worldwide. It is unknown why some individuals will develop severe forms of the disease.Studies have shown the importance of DNA methylation in the liver fibrosis progression. Therefore, theexploration of DNA methylation in the stages of liver fibrosis may disclose triggering mechanismsof HCV outcome.We conducted an exploratory investigation on methylation profileof liver biopsies from patients with HCV. Materials and Methods: Liver biopsies sampleswere collectedfrom HCV-RNA positive patients before treatment (n= 12),and they wereclassified byMETAVIR score.Six patients had fibrosisF0-F1 and 6 had F3-F4.Liver DNA was extracted with Zimo research kit and Illumina HumanMethylation450 BeadChip arrays was used to identify regions of hypo- or hypermethylation influencing hepatic fibrosis. Results:Regardingbiochemical analysis, serum levels of ALT, ASTand alpha-fetoproteinwere higher intheF3-F4 group (p=0.03, p=0.01 and p=0.04, respectively) characterizing active liver disease. Top methylation analysis showed 95 CpGs sites differentially methylated in F0-F1 vs. F3-F4 ($p < 5 \times 10\text{-}15$),in which12 siteswere-hypomethylated (in 10 genes) and 83 hypermethylated (in 64 genes). We performed Global methylation analysis in the 5kb distance of promoter regions from the genes that were differentially methylated ($p < 0.05$) in F0-F1 vs. F3-F4, top 10 genes hypermethylated included genes of innate immunity, extracellular matrix and mitochondrial function and top 10 hypomethylated included genes of Ras signaling and mitochondrial function ($p < 5 \times 10\text{-}5$). The pathway enrichment analysis showed that six pathways were associated to the F3-F4 methylation profile; BSID: 83105 (pathways in cancer); 102279 (endocytosis); 373901 (HTLV-I infection); 83051 (cytokine-cytokine receptor interaction); 523016 (transcriptional misregulation in cancer) and 658418 (viral carcinogenesis) PcBonf $< 3.99 \times 10\text{-}2$. Conclusion: Global methylation analysis in the promoter regions showed an important epigenetic regulation of genes involved with mitochondrial function, extracellular matrix, cell signaling and immunity, which may be related to the liver damage caused by HCV and that may emerge as a trigger for carcinogenesis, since F3-F4 profile strongly associated to cancer development.Further studies are being conducted to confirm this hypothesis.

424F

Epigenetic suppression of VEGF in retinal pigment epithelial cells by vitamin C. *G. Wang, D. Sant, J. Chen, D. Van Booven, V. Camarena.* Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst. for Human Genomics, Univ Miami, Miami, FL.

We and others recently reported that ascorbate is critical for DNA demethylation by serving as a cofactor for ten-eleven translocation (TET) dioxygenases to convert 5-methylcytosine (5mC) to 5-hydroxymethylcytosine (5hmC) in DNA. In this study, we examined the epigenetic effect of ascorbate in cultured human retinal pigment epithelial ARPE-19 cells. Treatment with ascorbate increased the global content of 5hmC in a time- and dose-dependent manner. RNA-seq was then conducted to evaluate the influence of ascorbate treatment on the transcriptome of ARPE-19 cells. We found 993 genes that were differentially expressed comparing cells cultured with (50 mM) or without ascorbate for 7 days using three different methods (EdgeR, DESeq and BaySeq). The expression of the top 10 genes (based on fold changes and *P* values) was further verified by qRT-PCR. In particular, a significant decrease in VEGFA expression (0.26 fold) was found after ascorbate treatment. The effect of ascorbate on VEGFA expression was further verified by western blot and ELISA of the conditioned media, in which ARPE-19 cells were cultured for certain periods of time. We are now examining 5mC and 5hmC in the VEGFA promoter region. Further, RPE appears to be one major source of VEGF after comparing its transcriptome with that of primary human retinal microvascular endothelial cells (1~2% of adjusted reads). Ocular anti-VEGFA therapy has been used to treat eye disorders such as neovascular age-related macular degeneration (AMD) and diabetic retinopathy. Whether it is antibody-based or VEGF-trap, the anti-VEGFA therapy is only effective for a subgroup of patients. Our results, though preliminary, suggest that ascorbate could be an epigenetic treatment for these ocular diseases.

Set-based Methods for DNA Methylation Analysis. *Q. Yan[1], R. Fan[3], D. Weeks[2], N. Boutaoui[1], G. Canino[4], J. Celedon[1], W. Chen[1,2].* 1) Division of Pulmonary Medicine, Allergy and Immunology, Department of Pediatrics, Children's Hospital of Pittsburgh of UPMC, University of Pittsburgh, Pittsburgh, PA; 2) Departments of Human Genetics and Biostatistics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA; 3) Biostatistics and Bioinformatics Branch, Division of Intramural Population Health Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 4) Behavioral Sciences Research Institute and Department of Pediatrics, University of Puerto Rico, San Juan, Puerto Rico.

With advances in microarray and next-generation sequencing technologies, genome-wide epigenetic data at a high resolution are available for hundreds and even thousands of subjects. Among these epigenetic data, the investigation of DNA methylation, (the addition of methyl groups to cytosines in the CpG dinucleotide context) can complement genetic studies. Although, in rare situations, a single methylated locus is associated with a disease, researchers are more interested in the association of a set of methylated loci, such as CpG islands, CpG shores and UTRs. In genetic studies, various methods have been developed to test for association between a group of rare genetic variants and complex diseases, and these methods can be extended to analyze set-based methylation loci for their effects on diseases. In this work, we conduct set-based statistics for examining association between set-based methylated loci and diseases. We propose two set-based approaches originally designed for genetic association analysis, Sequence Kernel Association Test and Functional Linear Model, to make them compatible with methylation data by considering the correlation between methylated loci. Results from our simulation studies show that both approaches retain the desired Type I error rate, and have comparable power in all the scenarios we considered. Finally, we illustrate the use of our proposed approaches by analyzing whole-genome DNA methylation data from studies on asthma and rheumatoid arthritis (RA). We identified potential differentially methylated genes associated with asthma-related traits, and found that the HLA gene (associated with RA in genetic studies) is differentially methylated in subjects with and without RA.

426F

Comprehensive Identification of Osteoblast-Specific DNA Methylation Signatures. *F. Yu, H. Shen, H.W. Deng.* Center for Bioinformatics and Genomics, Department of Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, Tulane University, New Orleans, LA, USA.

DNA methylation is an important epigenetic modification that contributes to the lineage commitment and specific functions of different cell types. Previous studies have suggested that DNA methylation plays important roles in regulating several genes that are critical for osteoblast differentiation and activities; however, the osteoblast-specific methylation pattern at genome-wide scale has not been fully examined. In this study, we compared the genome-wide DNA methylation profiles of human osteoblast with 21 other types of untransformed human cells in order to identify osteoblast-specific hyper- and hypo-methylation events. Genome-wide DNA methylation profiles assayed by reduced representation bisulfite sequencing (RRBS) were obtained from the ENCODE dataset. By carrying out differential methylation analysis, we identified 295 significant ($q < 0.001$, absolute mean methylation difference >20%) osteoblast-specific differentially methylated regions (DMRs), including 247 (84%) hyper- and 48 (16%) hypo-methylated regions. Interestingly, significant DMRs were not enriched in CpG islands (CGIs), but enriched in CGI shores and shelves, as well as 'open-sea' areas. Also, significant DMRs were more frequently observed in gene body and intergenic regions rather than regions proximal to transcriptional start sites. The gene ontology and phenotype ontology analyses revealed that the significant DMRs were highly enriched in biological processes related to transcriptional regulation and skeletal morphology and development. By integrating the DMR data with the extensive gene expression and chromatin epigenomics data in ENCODE and NIH Roadmap Epigenomics project, we observed complex, context-dependent relationships between DNA methylation, chromatin states, and gene expression, suggesting diverse DNA methylation-mediated regulatory mechanisms. Our results also suggested a number of novel osteoblast-relevant genes. For example, the integrated evidences from DMR analysis, histone modification and RNA-seq data strongly support a highly expression of a novel isoform of *neurexin-2* (*NRXN2*) gene in osteoblast. *NRXN2* was known to function as a cell adhesion molecule in the vertebrate nervous system, but its functional role in bone is completely unknown. In summary, we identified a number of key osteoblast-specific methylation events and revealed novel epigenetic mechanisms that may be critical for osteoblast differentiation and functions.

427T

Integration of DNA methylomic and transcriptomic changes in postmortem prefrontal cortex of subjects with alcohol use disorders. *H. Zhang[1], F. Wang[1], H. Xu[1], H. Zhao[2], J.H. Krystal[1], H.R. Kranzler[3], J. Gelernter[1].* 1) Psychiatry/VAMC, Yale University School of Medicine, West Haven, CT; 2) Department of Biostatistics, Yale University School of Public Health, New Haven, CT, USA; 3) Department of Psychiatry, University of Pennsylvania Perelman School of Medicine and VISN4 MIRECC, Philadelphia VAMC, Philadelphia, PA, USA.

DNA methylomic alterations in the prefrontal cortex (PFC) may contribute to risk for alcohol use disorders (AUDs). The DNA methylome in postmortem PFC of 16 male and seven female pairs of AUD and control subjects (46 European Australians) was examined using Illumina's HumanMethylation450 BeadChip assays. 1,812 CpGs (mapped to 1,099 genes) were differentially methylated in male AUD subjects ($9.5\times10^{-9} \leq P_{nominal} \leq 7.2\times10^{-4}$ and $q < 0.05$). In female subjects, no CpGs survived multiple testing corrections for their association with AUDs ($q > 0.05$). The above 1,812 CpGs were over-presented in two AUD-associated co-methylation modules ($M_{turquoise}$: 1,048 CpGs/683 genes; M_{blue}: 429 CpGs/304 genes) in male subjects ($P_{hyper} \leq 0.001$). Biological processes enriched for genes in these modules included neuron development and transcription regulation. Moreover, genes mapped by CpGs in these two modules were enriched in GWAS-identified genes associated with substance (alcohol, cocaine, opioid, or nicotine) dependence or psychiatric disorders (attention-deficit/hyperactivity disorder, autism spectrum disorder, bipolar disorder, major massive depression, or schizophrenia). Additionally, 106 of the 1,812 CpGs were mapped to 93 genes (e.g., AUD-associated genes *GRIK3*, *GRIN2C*, and *GABRA1*) with differential expression in postmortem PFC of male AUD subjects. Our findings suggest that DNA methylation alterations in reward-related brain regions result in an increased risk of AUDs.

428F

Epigenome-wide assoication in host genome for HIV infection. *K. Xu[1,2], X Zhang[1,2], Z Wang[6], Y Hu[4], R Sutton[5], Emu B[5], J Krystal[1,2], A Justice[3].* 1) Psychiatry, Yale School of Medicine , New Haven , CT; 2) Connecticut Veteran Health System, 950 Campbell ave, building 35, West Haven, CT; 3) Yale University School of Medicine, New Haven Veterans Affairs (VA) Connecticut Healthcare System, West Haven; 4) National Institute of Cancer, Center of Bioinformatics 9609 Medical Center Drive, Rockville, Maryland 20850; 5) Section of Infectious Diseases, Department of Internal Medicine, Yale University School of Medicine, New Haven, Connecticut, USA; 6) Department of Biostatistics, Yale School of Public Health.

Background: Epigenetic control of human immunodeficiency virus (HIV) gene expression is critical for viral transcription and latency in host T cells and macrophages. Little is known, however, regarding epigenetic changes in the host genome associated with HIV infection. Here, we report an epigenome-wide association study (EWAS) in 384 patients with and without HIV infection. We further tested the relationship of HIV-associated CpG sites with viral replication.**Methods:** Subjects were from the Veterans Aging Cohort Study (VACS) of HIV positive and negative patients in care in U.S., Department of Veterans Affairs Medical Centers. DNA was extracted from whole blood. 485,578 CpG sites were profiled using Illumina HumanMethylation 450K Beadchip. Data filtering, normalization, quality control were performed using programs in the R package. Generalized Linear Model was applied for association of each CpG site with HIV infection covariate for critical confounders. P value was corrected by Bonferroni correction. **Results:** Between HIV+ and HIV- patients, we found significant differential methylation at 211 CpG sites in genes implicated in HIV replication, immune, and inflammatory processes. Pathway analysis revealed the gene enrichments on chromosome 6p21, a region hosting Major Histocompatibility Complex (MHC) (false discovery rate q=0.0002). Specifically, two genes associated with inflammatory response were dys-regulated in HIV+ patients. First, three CpG sites in the promoter region of *NLRC5* (NOD-, LRR-, and CARD-containing 5), were hypomethylated in HIV+ patients, presumably increasing its gene expression. Increased *NLRC5* expression would inhibit the expression of *NFKB* and negatively regulate type I interferon signaling pathways. Second, *TNF*-α was hypermethylated in the gene body in HIV+ patients. Consistent with immune dysfunction, methylation of *NLRC5* and *TNF*-α correlated with HIV viral load in these patients after adjusted for CD4, CD8, and WBC counts (ps < 0.00001).**Conclusion:** Genome-wide methylation changes in PBMCs in HIV infected patients may influence immune function. Alterations in DNA methylation patterns in specific genes of HIV infected patients could affect outcome and might be targeted in novel approaches to therapy. **Acknowledgement:** The project was funded by NIH grants R21AA022870, R03DA039745, K12DA000167. We appreciate the supports from National Center of PTSD, U.S. Department of Veterans Affairs and Yale Center of Genetic Analysis.

Exploration of hydroxymethylation in Kagami-Ogata syndrome caused by hypermethylation of imprinting control regions. *K. Yamazawa[1,2], K. Matsubara[2], M. Kagami[2], K. Nakabayashi[3], K. Hata[3], M. Fukami[2], T. Ogata[2,4].* 1) Clinical Genetics Center, National Hospital Organization Tokyo Medical Center, Tokyo, Japan; 2) Department of Molecular Endocrinology, National Research Institute for Child Health and Development, Tokyo, Japan; 3) Department of Maternal-Fetal Biology, National Research Institute for Child Health and Development, Tokyo, Japan; 4) Department of Pediatrics, Hamamatsu University School of Medicine, Hamamatsu, Japan.

Background: 5-hydroxymethylcytosine (5hmC), converted from 5-methylcytosine (5mC) by Tet enzymes, has recently drawn attention as the 'sixth base' of DNA since it is considered to be an intermediate of demethylation pathway. Nonetheless, it remains to be addressed how 5hmC is linked to the development of human imprinting disorders. In this regard, conventional bisulfite (BS) treatment is unable to differentiate 5hmC from 5mC, thus it is hypothesized that BS conversion-derived 'hypermethylation' at imprinting control regions (ICRs) which may cause human imprinting disorders would be in fact attributable to excessively increased levels of 5hmC as well as 5mC.**Methods:** We applied the newly developed oxidative BS (oxBS) treatment to detect 5hmC in blood samples from Kagami-Ogata syndrome (KOS14) patients caused by perturbed expression of clustered imprinted genes on 14q32.2 resulting from the hypermethylation of ICRs at this locus, IG-DMR and *MEG3*-DMR.**Results:** oxBS with pyrosequencing and cloning-based sequencing revealed that there were few amounts of 5hmC at the hypermethylated IG-DMR in blood sample from KOS14 patients. oxBS with genome-wide methylation array analysis demonstrated that global levels of 5hmC were very low with similar distribution patterns in blood samples from KOS14 patients and normal controls. We also confirmed that there was a huge amount of 5hmC in brain sample from a normal control. **Discussion:** 5hmC is not a major component either at the abnormally hypermethylated ICRs or at a global level, at least in blood from KOS14 patients. Considering that brain contains a large amount of 5hmC, neural tissues from KOS14 patients are promising analysis candidates to elucidate the role of 5hmC in the neurodevelopmental context.

Peripheral blood DNA methylation markers associated with abstinence among chronic injection drug users in the ALIVE study. *K.M. Bakulski[1], K.S. Benke[2], A.E. Jaffe[2, 3], S.H. Sabunciyan[4], G.D. Kirk[1], S.H. Mehta[1], B.S. Maher[2].* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Mental Health, Johns Hopkins University, Baltimore, MD; 3) Lieber Institute for Brain Development, Baltimore, MD; 4) Pediatrics, Johns Hopkins University, Baltimore, MD.

Background: Liability to drug addiction has a complex etiology with substantial contributions from both genetic and environmental factors. Epigenetic status represents an intersection of these factors that has not yet been explored in drug addiction epidemiologic studies.**Objectives**: The goals of this AIDS Linked to the Intravenous Experience (ALIVE) pilot study are to identify whether chronic injection drug use (IDU+) followed by abstinence (IDU-) is associated with blood DNA methylation marks, and to test whether these marks are associated with brain tissue DNA methylation comparing opiate users to controls.**Methods:** Among an ALIVE study subsample of 23 HIV-negative African American males, DNA was isolated from peripheral blood mononuclear cells at two time points. Baseline samples were taken from individuals with at least ten years of IDU+; the second sample followed at least two years of IDU-. Genome-wide DNA methylation was assessed using the Illumina Infinium 450k HumanMethylation array. We compared methylation status at each site during chronic use to cessation using a Wilcoxon Rank Sum test. We also tested the highest-ranking sites identified in blood for their concordance in post-mortem brain tissues of opiate drug users from the Lieber Institute for Brain Development.**Results:** While no single test reaches significance after False Discovery Rate correction (minimum P-value $<10^{-6}$), many sites exhibit marked difference (after cessation – chronic use). The average effect size (Cohen's d) among the top results is roughly 3. When we examine genome-wide average methylation status in injectors before (IDU+) and after cessation (IDU-), we find a significant decrease in methylation in the IDU- versus IDU+ sample. In addition, we observed large intra-individual variation at many sites in the pre- and post- comparison.**Conclusions:** In a pilot study, we performed a genome-wide scan of longitudinal DNA methylation among continuous injection drug users. Though underpowered to reach genome-wide significance, we identified genomic locations of DNA methylation sites measured in blood associated with cessation of drug use. These sites also appear to be altered in brain tissue from injection drug users, and may provide further insight about the role of epigenetics in drug addiction. Further work is needed, including study in the larger cohort as well as replication in additional populations, to clarify drug abuse mechanisms and the potential role of DNA methylation.

Identification of housekeeping genes for DNA methylation study across different human ethnicities and tissues. *D.P. Chen, S.J. Wu, Y.C. Lin, C.S.J. Fann.* Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

DNA methylation is an important epigenetic mechanism and participates in numerous cellular processes. Methylation array data has increased rapidly; for example, the number of Illumina HumanMethylation450 datasets publicly available in Gene Expression Omnibus has increased six times since 2013. Housekeeping genes (HKGs) of DNA methylation studies are crucial, because they can be used to normalize methylation datasets across different studies and to validate the efficiency of Bisulfite conversion. Previously, few studies have reported HKGs in methylation studies. However, most of HKGs found are either fully methylated or unmethylated.In this study, we proposed a systematic method to identify HKGs that are stable and consistent in methylation level. We used Illumina HumanMethylation450 BeadChips as platform, which contains more than 485K probes. We downloaded 309 datasets from different human ethnicities, tissues and conditions. To avoid batch effects, data within a chip is normalized by median and median absolute deviation (MAD). Median and MAD are less sensitive to outliers than mean and standard deviation. After quality control, such as negative beta values, redundancy, and low call rate, etc., 183 datasets were used for the analyses.Two methods were used to find the HKGs. For the first method, 12% of total probes with smaller variances across all chips were retained. The remaining probes were examined by the "two-one-sided test" that compares the averages of one probe from two datasets. All possible pairwise comparisons were performed, and the probes with close averages in many pairs of datasets were regarded as HKGs. For the second method, all probes were ranked within each dataset according to their variances, and then the ranks of probes were combined across datasets via geometric mean. Top ranked probes were regarded as HKGs. The result showed that RBM22, ARHGEF6, ZBTB8OS and a few other genes were identified as HKGs by using both methods. To our knowledge (by using PubMed, Web of Science, etc.), no evidence has been reported that these identified HKGs are disease- or tissue-specific differentially methylated genes.

DNA Methylation Changes Observed in Rheumatoid Arthritis Joint Tissue Are Detectable in CD4+ Naive T Cells from Peripheral Blood. *C. Holingue[1], B. Rhead[1], M. Cole[1], X. Shao[1], H. Quach[1], D. Quach[1], E. Sinclair[2], J. Graf[3], T. Link[5], R. Harrison[3], V. Chernitskiy[3], W. Wang[4], G. Firestein[4], L. Barcellos[1], L. Criswell[2].* 1) Genetic Epidemiology and Genomics Laboratory, University of California, Berkeley; 2) University of California, San Francisco, Division of Laboratory Medicine; 3) University of California, San Francisco, Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center; 4) University of California at San Diego, La Jolla; 5) University of California, San Francisco, Department of Radiology and Biomedical Imaging.

Aberrant DNA methylation patterns have previously been associated with rheumatoid arthritis (RA) [MIM 180300]. Our study aimed to determine whether differentially methylated CpGs in synovium-derived fibroblast-like synoviocytes (FLS) of RA patients were also differentially methylated in peripheral blood samples. DNA methylation was measured by generating 371 genome-wide DNA methylation profiles for 63 RA cases (57 seropositive), and 31 controls using Illumina HumanMethylation450 (450k) BeadChips. Cells from peripheral blood were FACS-sorted and CD14+ monocytes, CD19+ B cells, CD4+ memory T cells, and CD4+ naive T cells were assayed for each individual. One-tailed Wilcoxon rank sum tests were used to analyze case-control differences in the FLS candidates within these four cell types. Receiver operating characteristic (ROC) curve analysis was employed to test the predictive power of a hypermethylation score based on the differentially methylated sites we observed. Of the 5,532 hypermethylated FLS candidates, 1,056 (19%) were hypermethylated in CD4+ naive T cells of our RA cases compared to controls (FDR $q<0.05$). No other CpG candidates achieved significance in the other cell types. A hypermethylation score was calculated based on these results and had an area under the curve (AUC) of 0.73 when predicting RA case status. This hypermethylation score was compared to having the HLA-DRB1 shared epitope (SE) (yes/no) and a continuous genetic risk score consisting of 43 non-HLA SNPs (Yarwood 2013 and Eyre 2012). The SE model had an AUC of 0.66 (0.56-0.77), and the genetic risk score had an AUC of 0.51 (0.38-0.63). A combined model of shared epitope, GRS and the methylation score had an AUC of 0.78, which was the best predictive model. Both methylation score and SE remained significant ($p<0.05$) when included in a multivariable logistic model of methylation score, SE and genetic risk score, with RA case-status as the outcome. Although the methylation score had a greater AUC than the SE (0.73 versus 0.66), the SE had a larger odds ratio in the multivariable logistic regression model (5.31 versus 1.06). Our results suggest that measurement of DNA methylation in CD4+ naive T cells of peripheral blood may have diagnostic or prognostic value and represents one of the first steps towards precision medicine in RA.

433T

Comparing variability in the SeqCap Epi CpGiant and the Illumina 450k methylation microarray for characterizing the human methylome. *A.C. Just[1], R.O. Wright[2], M.M. Tellez-Rojo[3], A.A. Baccarelli[1].* 1) Environmental Health, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Preventive Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 3) National Institute of Public Health, Center for Research in Nutrition and Health, Cuernavaca, Morelos, Mexico.

Background: The SeqCap Epi CpGiant is a targeted enrichment bisulfite sequencing assay designed to maximize overlap with the popular Illumina Infinium HumanMethylation450 BeadChip microarray. No prior publications have compared these two epigenome-wide methylation assays. In comparing these platforms we characterize the precision of these approaches, particularly in overlapping CpG sites and as a function of the read depth (number of sequencing reads at a given site).Methods: WBC DNA extracted from two cord blood samples collected in the PROGRESS cohort were assayed multiple times on the SeqCap Epi CpGiant (8x each) at Roche and the Illumina 450k at Illumina (15x and 2x, respectively) each according to their manufacturers specifications. Data preprocessing for the SeqCap Epi next generation sequencing data followed the Roche protocol including quality assessment, read filtering, alignment to the hg19 reference genome for bisulfite treated DNA with BSMAP, removal of PCR duplicates, and summarization of methylation at CpG contexts in aligned reads. Preprocessing for the Illumina 450k used out-of-band background correction. SeqCap Epi CpGiant and Illumina 450k results were compared at loci overlapping Illumina 450k CpG probes according to the Illumina annotation file.Results: Across all 16 runs, the CpGiant included reads on 3.7 million CpG sites on either strand of which 3.5 million were found in all 16 runs. Comparing across strands within samples, all 16 runs of the CpGiant had at least 30% of sites with a difference of more than 10% in the estimated methylation between strands (minimum of 10 reads on both strands). There were 446,886 sites covered by the CpGiant of the possible 482,421 CpG sites in the Illumina 450k. The across-replicate (technical) variance was higher for the CpGiant at 74% of these overlapping sites, and this did not vary substantially when stratifying by mean read depth of the CpGiant replicates.Discussion: The recently developed SeqCap Epi CpGiant covers a larger proportion of the methylome but an analysis of replicate samples suggests lower precision than the popular Illumina 450k microarray, even at high read depths. This may be a limitation when expecting small differences in methylation associated with environmental exposures or subtle phenotypic changes. More work is needed to understand determinants and post-processing control of technical variation in bisulfite sequencing assays.

Emerging evidence suggests that alcohol consumption alters DNA methylation (DNAm), which in turn can impact gene expression. Several studies with small sample sizes have yielded poorly replicated results for the association of alcohol consumption with DNAm. We measured DNA methylation at 475,000 CpGs using the Illumina HumanMethylation450 BeadChip on whole blood (WB) DNA from 13,346 individuals, including 9,634 of European ancestry (EA) and 2,461 of African ancestry (AA) and DNA from monocytes in 1,251 EA subjects. A linear mixed effects model tested the association of DNAm with alcohol consumption, adjusting for age, sex, BMI, batch, and differential cell count. Inverse variance weighted meta-analysis identified 881 significant (P<10-7) CpGs in EA-WB and 241 in AA-WB, and 80% of these significant CpGs displayed reduced methylation levels with increased alcohol intake.The effect estimates for the relationship between alcohol and DNAm for the 881 probes were correlated between EA-WB and AA-WB (r =0.67), and between EA-WB and EA-monocyte (r = 0.71) samples, suggesting shared effects of alcohol consumption on DNAm across different cell types and ethnic populations. About 3% of top CpGs had their effect estimates attenuated (i.e. change in beta > 20%) after additionally adjusting for smoking. Of the 881 CpGs, 341 had at least one significant methylation quantitative trait locus (mQTL, P<0.05/195562 pairs) within 100kb (n=2,500 EA). None of the significant mQTLs was a significant SNP in prior genome-wide association studies of alcohol intake. Of the 881 CpGs, 120 displayed significant correlation to transcription levels of 143 genes whose transcription start sites was within 1Mb of the CpG (P<0.05/23532 pairs, n=2,500 EA-WB). Pathway analyses for these 143 genes pointed to viral response (FDR-p=1x10-9), interferon signaling (FDR-p=5x10-8), and T-cell activation (FDR-p=7x10-7). Replication of these findings is underway.

435T

Genome-wide analysis of DNA methylation identifies a novel locus associated with bone mineral density. *J.A. Morris[1,2], P.-C. Tsai[3], F. Gao[4], V. Forgetta[2], Y. Xia[4], W. Yuan[3], C.M.T. Greenwood[1,2,5,6], E. Grundberg[1], T.D. Spector[3], J. Wang[4], J.T. Bell[3], J.B. Richards[1,2,3,6].* 1) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 2) Lady Davis Institute for Medical Research, Jewish General Hospital, McGill University, Montreal, Quebec, Canada; 3) Department of Twin Research & Genetic Epidemiology, King's College London, London, United Kingdom; 4) BGI-Shenzhen, Shenzhen, China; 5) Department of Oncology, McGill University, Montreal, Quebec, Canada; 6) Department of Epidemiology, Biostatistics, & Occupational Health, McGill University, Montreal, Quebec, Canada.

Purpose Osteoporosis is a common, complex disease characterized by increased bone fragility, often resulting in fracture. Bone mineral density (BMD) is measured to diagnose osteoporosis and estimate fracture risk. Studying the genetic determinants of BMD has led to novel disease pathophysiology insights. We sought to study epigenetic associations with BMD, as DNA methylation levels have been found to associate with disease phenotypes. **Methods** We undertook a genome-wide association study of DNA methylation levels to assess epigenetic associations with BMD. Methylation levels were estimated using methylated DNA immunoprecipitation sequencing (MeDIP-seq) to identify differentially methylated regions (DMRs) associated with BMD. BMD was measured at the forearm, femoral neck, and lumbar spine in the TwinsUK cohort, in 890, 1,518, and 1,397 twins, respectively. **Results** An intergenic DMR on chromosome 6q21 was found to be significantly associated with forearm BMD (P = 5.3×10-9). Through the usage of functional genomics data, we have linked the DMR to an enhancer putatively interacting with PRDM1, a gene regulating osteoclastogenesis. Using multiple data repositories for 3D nuclear conformations, enhancer RNAs (FANTOM5), DNase I hypersensitivity sites (ENCODE), and epigenetic marks (Epigenome Roadmap), we find evidence that the region encompassing the DMR likely contains a regulatory element of PRDM1, in that it is in close 3D proximity to the PRDM1 promoter and the DNA at these two regions is coincidentally open in relevant cell types such as monocytes, an osteoclast precursor cell. **Conclusion** Current work is underway to validate the DMR in an independent sample set by a targeted pyrosequencing-based approach for DNA methylation quantification. This study represents the most comprehensive genome-wide analysis to date of the role of methylation in BMD and forms a basis for future studies that will refine the definitive role of epigenetic-mediated effects at this osteoclast locus.

436F

Adjusting Infinium methylation profiles to suppress signals from varying cell proportion. *G.W. Nelson[1,4], L. Jia[2,4], F. Elloumi[2,4], E. Binns-Roemer[3,4], S. Limou[3,4], C.A. Winkler[3,4].* 1) BSP-CCR Genetics Core, FNLCR, Frederick, MD; 2) CCR-IFX, CCR, NCI, Bethesday, MD; 3) Basic Research Lab, FNLCR, NCI, Frederick, MD; 4) Leidos Biomedical Corp, Frederick, MD.

Methylation data ideally are generated from a single cell type, but often for practical reasons a mixture of cells is used. A well-studied case involves the use of mixed peripheral blood mononuclear cells (PBMCs). The R package minfi includes a function estimateCellCounts—implementing an algorithm developed by Housman et al.—that takes a methylation profile from mixed blood cells, typed on the Infinium HumanMethylation450 BeadChip, and returns estimates of the frequencies of common blood cell types in the sample. These estimates are then available for use as confounding covariates in analyses of methylation changes. But using cell composition as a confounding covariate may not always be a useful strategy. In the case of HIV infection, one of the strongest markers of disease progression is the loss of CD4+ T cells. This change of cell composition will strongly confound the analysis due to a loss of methylation markers characteristic of these cells. But correcting for CD4 count will tend to obscure methylation changes associated with AIDS progression. We therefore propose and construct an alternate correction strategy. The minfi package analysis is based on an Infinium data set from multiple blood cell types. Given the estimated cell composition for each sample, we subtract the methylation profile for each cell type from each sample, scaled by the proportion of that cell type in the mixed sample. This removes the cell marker variation that confounds the association analysis due to varying cell frequencies, removing the necessity of correcting for cell composition in the association analysis. Assuming that the methylation markers of disease progression are different from the cell type markers (if they are not there is no hope of observing them with mixed cell samples) we may observe the change of these markers with AIDS disease progression, and may use CD4+ T cell count as a measure of this progression. We tested this method on samples from the DC Gay AIDS cohorts, representing different stages of infection. Methylation markers that strongly distinguish CD4+ T cells will be most likely to show spurious association with AIDS progression, unless corrected for. Our correction reduced the (predominantly spurious) significance of the AIDS progression association, for most of these markers, by factors of 103 to 1010.

437T

Improvements To Existing QC Tools For Methylation 450K Arrays. *J. Romm, E. Pugh, K.F. Doheny.* CIDR/Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality Next-Gen Sequencing (NGS), Genotyping and statistical genetics consultation to investigators working to discover genes that contribute to disease. At CIDR we use automated, real-time QC reports for genotyping and sequencing projects which allows the lab group to examine and compare dozens of metrics to detect failed or problematic samples and determine what, if anything, they share in common (e.g. failed array, position on a plate, DNA source). We wanted to create a similar report for Illumina's HumanMetylation450 array to supplement the QC information available within Illumina's raw data files.To accomplish this we used the R and BioConductor package Minfito calculate metrics for each sample that are not easily available in GenomeStudio, such as mean and standard deviation of beta, intensity of the methylated and unmethylated probes, detection P value, MDS distances, the mean and standard deviation of the values for Illumina's control probes and the mean and standard deviation of a subset of methylated and unmethylated probes from the Y chromosome. We then write the metrics out as a delimited file. We combine this with information about the sample, plating and lab variables. The combined information is imported into Spotfire® and used by the lab to determine outlying samples. This information is also provided to the investigator. With the investigator, we jointly determine whether the outliers represent sample failures or a subset of samples within the study that are meant to be outliers from a larger group (e.g. different sample preparation). Sample failures are redone one time in the lab and the metrics are recalculated and released to the investigator as part of our data release.We recently used this strategy for two projects. Project 1 had ~3000 samples, which included fully methylated and fully unmethylated controls for QC. We were able to identify 3 full array failures and one sample with low overall intensity. Project 2 had ~1000 samples, which also included fully methylated and unmethylated controls for QC. 12 % of the samples less than 99% of CpG islands detected. There were also 2 distributions of study samples when looking at the beta means plotted out of Minfi, which were scattered across arrays and lab processing plates.

Lifestyle and biological age in a cohort study: methylation age vs telomere length. *A. Russo[1,2], S. Guarrera[1,2], G. Fiorito[1,2], C. Viberti[1,2], L. Iacoviello[3], M.C. Giurdanella[4], R. Tumino[4], C. Agnoli[5], V. Krogh[5], A. Mattiello[6], S. Panico[6], P. Vineis[1,7], C. Sacerdote[1,8], G. Matullo[1,2].* 1) Human Genetics Foundation-Torino, Turin, Italy; 2) Medical Sciences Department, University of Torino, Torino, Italy; 3) Fondazione di Ricerca e Cura "Giovanni Paolo II", Catholic University, Campobasso, Italy; 4) Cancer Registry and Histopathology Unit, "Civile-M.P. Arezzo" Hospital, ASP7, Ragusa, Italy; 5) Department of Preventive and Predictive Medicine, Epidemiology and Prevention Unit , Fondazione IRCSS Istituto Nazionale dei Tumori, Milano, Italy; 6) Department of Clinical and Experimental Medicine, Federico II University, Napoli, Italy; 7) Epidemiology and Public Health, Imperial College London, UK; 8) Cancer Epidemiology, CPO-Piemonte, Torino, Italy.

DNA methylation levels vary across life course and are influenced by environmental factors and lifestyle such as smoking and diet. Recently, age predictors based on DNA methylation profiles (methylation age) were developed to outline the difference between methylation-predicted age and chronological age (Dage) as a possible determinant of biological aging. To evaluate the effect of smoke and Mediterranean diet on Δage, we examined the methylation levels of more than 450K CpG sites in 292 matched case-control pairs belonging to the Italian section of the EPIC cohort. EPIC healthy volunteers were followed up for myocardial infarction and other diseases. We used the Illumina HumanMethylation450 BeadChip to assess CpG methylation levels on blood DNA provided at recruitment. Data were analyzed according to standard procedures (MethyLumi, Bioconductor). All analyses were corrected for sex, BMI, season and center of recruitment, estimated cellular subtypes and batch effect. The methylation-predicted age was created on the basis of a set of 71 methylation markers as described by Hannum *et al* (Mol. Cell. 2013). In our cohort, the correlation between methylation age and chronological age was highly significant (R=0.75; $p<$ 10-16). When analyzing the trend of Δage among current, former, and never smokers, we observed statistically significant differences between current and never smokers ($p<0.005$), as well as current and former smokers ($p<0.05$). Therefore, smoking was associated with an increased deviation of methylation age from chronological age. Conversely, in our study, smoking habits did not seem to influence leukocyte telomere length (LTL) measured on a subset of subjects (412) using RT-PCR ($p>0.05$), suggesting that methylation age could be a more reliable marker of biological age. We also evaluated the effect of adherence to a Mediterranean dietary pattern, as measured by the Italian Mediterranean Index score, according to Agnoli *et al* (Int J Cancer. 2013). Subjects who mostly followed a Mediterranean diet seemed to have a lower methylation age and longer LTL, reflecting a lower biological age. Other covariates like gender, alcohol, and BMI will be assessed, and most relevant results will be replicated within an independent population of 292 EPIC controls. In the frame of this replication analysis also the suitability of LTL as a marker of biological age will be further evaluated.

439T

Estimating and accounting for cell type composition in analysis of sequencing based methylation data. *A.A. Shabalin, M.W. Hattab, K.A. Aberg, E.J.C.G. van den Oord.* Center for Biomarker Research and Precision Medicine, Virginia Commonwealth University, Richmond, VA.

Variations in cell type composition can strongly affect measurements of DNA methylation and, if not accounted for, compromise downstream analyses or reduce its power. Estimates of sell type composition of analyzed samples can also give biological insight into case-control differences and allow to point which cell types contribute to methylation changes in bulk tissues. Next generation sequencing combined with enrichment technologies allows for measurement of DNA methylation at over 28 million common CpGs in human genome. The popular array based technologies (e.g. Illumina Infinium HumanMethylation450) interrogate up to 485 thousand methylation sites. However, unlike array based technologies, sequencing based approach produces read count type data, similar to RNA-seq data for gene expression. We have developed the proposed method with a focus on analysis of MBD-seq (methyl-CpG binding domain protein-enriched genome sequencing) data and have validated it by reproducing the analysis on whole genome bisulfite data. Existing method for estimation and accounting for cellular heterogeneity in array measured DNA methylation data are not directly applicable to sequencing based methylation measurements due to the differences in produced data and the very large number of interrogated CpGs.We present a new method for estimation and accounting cellular heterogeneity in sequencing based methylation data. The method involves normalization and weighting of methylation measurements based on the average coverage and local CpG density. The weighting is critical in reducing both variance and bias the cell type proportion estimates.We have validated the method on DNA measurements from isolated blood and brain cells. For blood we have data five frequently occurring clusters of differentiation (CD) in six subjects and samples with known cell type composition. We have further applied the method to methylation wide association studies for several large data sets, including 1,469 schizophrenia case and control blood samples, 1,200 major depression disorder (MDD) case and control blood samples and 383 MDD post mortem brain samples.

Determining the DNA methylation landscape of human pancreatic islets using whole-genome bisulphite sequencing to characterise Type 2 Diabetes GWAS regions. *M. Thurner[1,2], M. van de Bunt[1, 2], K.J. Gaulton[1], A. Barret[2], A.J. Bennett[2], C.G. Bell[3], R. Lowe[4], S. Beck[5], V.R. Rakyan[4], A.L. Gloyn[1,2,6], M.I. McCarthy[1,2,6].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, University, of Oxford, Oxford, United Kingdom; 3) Department of Twin Research & Genetic Epidemiology, Kings College London, London, United Kingdom; 4) Centre for Genomics and Child Health, Blizard Institute, Barts and The London School of Medicine and Dentistry, London, United Kingdom; 5) Department of Cancer Biology, UCL Cancer Institute, University College London, London, United Kingdom; 6) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

Type 2 diabetes (T2D) is a genetically complex disease with >80 GWAS loci identified to date.These data have demonstrated the importance of pancreatic islet dysfunction in T2D pathophysiology, but precise molecular mechanisms are mostly unknown.DNA methylation is an important tissue-specific, epigenetic mark that has a known role in common and syndromic disease. To investigate whether changes in methylation status underlie T2D association signals, we performed whole-genome bisulphite sequencing (WGBS) in 10 primary human islet samples.Samples were sequenced at 12-17X coverage to generate a full islet methylome covering 27x106 CpG sites. The high correlation between WGBS and Illumina 450k methylation data from islets (rho=0.89, 290k overlapping sites) confirmed the quality of our data. We defined low- and ultra-low methylated regions (LMRs and UMRs), which showed strong overlap with chromatin state-derived islet enhancers (82% of LMRs) and promoters (96% of UMRs), respectively. We found significant enrichment of LMRs (n=37k)in variants in high LD (r2 > 0.8) with the lead variant atT2D (fold enrichment (FE)=1.8, P=0.02) and fasting glucose level (FG) (FE=2.8, P=0.03) GWASlocicompared to matched loci.To determine whether this enrichment was due to islet-specific methylation, we took the subset of LMRs that overlapped regions with significantly different methylation (P<2.6x10-9) in islets compared to at least 4/6 publicly available methylomes (adipose, blood, buccal, liver, pancreas, lymphoblastoid cell line). These likely islet-specific LMRs (n=7.9k) showed stronger enrichment in T2D (FE=3.4, P=0.002) and FG GWAS regions (FE=7.2, P=0.007) compared to all LMRs as well as active enhancers (T2D FE=2.3, P=1x10-4; FG FE=3.8, P=5x10-4). One such islet-specific LMR, for example, overlaps the *ADCY5* GWAS variant rs11708067 that showed highly variable methylation across the WGBS islet samples and has previously been shown to be an islet methylation QTL in 450k methylation data. In addition to identifying LMRs and UMRs, we also evaluated previously known imprinted T2D loci such as *KCNQ1*. Consistent with a previously reported hemi-methylated state in adult islets, we found *CDKN1C* to be the only imprinted gene at this locus.These results highlight the utility of WGBS DNA methylation data from human islets in identifying islet specific-regulatory regions, and demonstrate that islet LMRs are enriched at T2D and FG GWAS loci.

Detection of differentially methylated regions using both mean and variance differences. *Y. Wang, S. Wang.* Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY.

DNA methylation is an epigenetics modification of DNA which plays an important role in a variety of human diseases including cancer. Studies found that DNA methylation levels between cancer and normal tissues could differ in both means and variances, and those of neighboring CpG sites are often correlated. Most existing methods on identifying differentially methylated loci (DML) or differentially methylated regions (DMRs) were developed to detect differences in mean methylation levels between two study groups. Only a few published works took variance differences into consideration to detect DML, but none for DMR detection. Here we propose 1) a generalized exponential tilt model and 2) fisher's method to detect DMRs using signals from both means and variances in methylation levels using both case-control and matched case-control designs. In both proposed methods, we smooth the site-level test statistics and consider a region as a candidate DMR when there are at least three consecutive loci whose smoothed statistics exceed a pre-defined threshold. The significance of candidate DMRs were assessed using permutation. The performances of the proposed methods that combine mean and variance signals for DMR detection were compared with parallel methods that only consider mean signals or variance signals. In simulation studies, the proposed methods are most powerful when there are weak mean and variance signals. The performances are comparable to methods that only consider mean differences or variance differences but with strong signals. We also applied the proposed methods to two DNA methylation datasets, one from an oral cancer case-control design, one from the Cancer Genome Atlas (TCGA), and identified additional DMRs that were missed by tests that only consider mean differences.

Preliminary analysis of genome-wide methylation qualitative trait loci for HIV infection. *X. Zhang[1], A. Justice[1], Y. Hu[3], Z. Wang[2], J. Krystal[1], K. Xu[1].* 1) Department of Psychiatry, Yale University, New Haven, CT; 2) Yale School of Public Health, New Haven, CT; 3) Center for Biomedical Informatics and Information Technology (CBIIT) National Cancer Institute, NIH, MD.

Background: Epigenetic changes in the host genome may play a critical role in the response to HIV infection. Genetic variation can influence the epigenetic response of that hosts to viral infection. The purpose of this study is to profile genome-wide genetic architecture of cytosine modifications in DNA derived from whole blood in an African American population with and without HIV infection.**Methods**: We detected methylation using Illumina HumanMethylation 450K Beadchip and genotyped single nucleotide polymorphisms (SNPs) using Illumina HumanExpress Exome Beadchip. We first performed epigenome-wide association study (EWAS) to identify significant CpG sites for HIV infection in 384 subjects. Generalized Linear Model (GLM) was conducted, adjusted for age, gender, race, type of drug abuse, and 10 principal components of methylation data. We identified 182 significant methylation sites after Bonferroni adjustment ($p < 0.05$). Next, we tested mQTL for 182 CpG sites and 1,347 SNPs within a window of 20,000 bp in 85 HIV positive and 36 HIV negative samples that had both methylation and genotyping data. Linear regression model was applied to examine correlations of CpG and SNP, with adjustment of age and 3 principal components of genotyping. Significant p was set at 0.05. We did not correct p value for multiple testing in this pilot study because the sample size was under power to detect significant genome-wide mQTL.**Results:** We identified 102 CpG-SNP pairs located in n 39 genes. Interestingly, these CpG-SNP pairs were enriched at promoter (22), less in gene body (20) and 3' UTR (10 probes). The rest of CpG-SNPs were in the first exon or intrageneic regions. Multiple genes carrying significant mQTLs were previously reported to involve HIV pathophysiology, such as *CD4, CCR6, NHEJ1, SDK2, REM2, ARRB1, CD207*.**Conclusion**: Our preliminary findings suggest that genetic variants control DNA methylation in HIV infection. mQTL annotation can be useful to identify novel loci for complex trait, and the genetic related methylation pattern could be applied in the classification of HIV infection, , treatment response, and HIV outcomes, . Further study in a larger sample population to replicate the findings is warranted.**Acknowledgement:** The project was funded by NIH grants R21AA022870, R03DA039745, K12DA000167. We appreciate the support from National Center of PTSD, U.S. Department of Veterans Affairs and Yale Center of Genetic Analysis.

443T

Systematic identification of downstream *trans*-effects for 1,900 known disease associated SNPs. *M.J. Bonder[1], R. Luijk[2,3] on behalf of the BBMRI-NL BIOS* Consortium.* 1) Genetics, University Medical Center Groningen, Groningen, Groningen, Netherlands; 2) Department of Molecular Epidemiology, Leiden University Medical Center, 2333 ZC Leiden; 3) Department of Medical Statistics and Bioinformatics, Leiden University Medical Center, 2333 ZC Leiden.

Genetic risk factors identified in genome-wide association studies are mostly non-coding, making it difficult to understand their functional consequences. So far, large-scale*trans*-eQTL analyses have identified such downstream functional consequences for only 233 SNPs (Westra et al, NG 2013). To increase this, we used methylation-QTL mapping in peripheral blood of 4,000 population based samples from the Dutch BBMRI-NL BIOS consortium. We observed that 1,907 different GWAS SNPs affect methylation of over 10.141 unique CpGs sites*in trans*(FDR <0.05), representing a eight-fold increase in the number of disease-associated SNPs for which downstream functional effects can be detected.

To address the question in what particular biological processes these specific CpGs are involved, we also generated RNA sequencing data for 2,000 of the samples, permitting us to empirically relate CpG methylation to gene expression effects (eQTMs) for over 12,800 CpG sites (FDR <0.05). By using different genomic annotations we could accurately predict (AUC = 0.83) whether these methylation-gene expression relationships were positive (31%) or negative (69%).

By finally integrating the*trans*-meQTLs and eQTMs and adapting pathway enrichment method DEPICT, we obtained insights in the downstream functional effects of many genetic risk factors: rs3774959 (mapping close to NFKB1 and associated with ulcerative colitis) significantly affects methylation levels of 348 different CpG sites, of which many map within genes of the NF-kappaB cascade.

These results indicate that large-scale meQTL mapping permits discovery of previously unknown downstream molecular effects for many genetic risk factors, and these effects on*trans*-methylation levels have a clear biological basis.

* BIOS stands for Biobank-based Integrative Omics Study, a BBMRI-NL Rainbow project steered by Lude Franke (UMCG), Bas Heijmans (Chair, LUMC), Peter-Bram 't Hoen (LUMC), Aaron Isaacs (EMC) Rick Jansen (VU), and Joyce van Meurs (EMC).

Race Specific Differential DNA Methylation Marks of COPD. *R. Busch[1], W. Qiu[1], G. Criner[2], D. DeMeo[1].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Section of Pulmonary And Critical Care Medicine, Temple University School of Medicine, Philadelphia, PA.

Background: African-Americans with COPD experience more severe airflow obstruction per pack-year of smoking than non-Hispanic Whites. Smoking-related DNA hypomethylation and resultant differential gene expression may contribute to the pathogenetic mechanisms of racial disparity in COPD susceptibility among African-American (AA) smokers. Prior research identified differential methylation signals related to tobacco smoke exposure, but not associations with COPD in AA. To address this knowledge gap, we investigated differential methylation of CpG sites associated with COPD among AA in the PA-SCOPE cohort.**Methods:**We assessed DNA methylation from peripheral blood samples in 357 AA smokers with (N=91) and without COPD (N=266) in the PA-SCOPE cohort using the Illumina Infinium 27K platform. After quality control, mixed linear models were used to assess associations of COPD (defined as FEV1/FVC<0.7) with differential methylation at CpG sites, controlling for age, sex, assay batch, and pack-years of smoking.**Results:**We observed 3536 CpG sites significantly associated (adjusted p-value<0.05) with the presence of COPD in the PA-SCOPE AA cohort. 1851 of these sites were hypomethylated, while 1685 were hypermethylated. Top associated hypomethylated sites included *RBFOX2* (p=3.6x10-11), *GRASP* (p=3.6x10-11), and *FXYD1* (p=3.6x10-11). Additional biologically plausible associations included hypomethylation of the *LPO* gene (p=3.3x10-10), which is involved in the production of free radicals in airway epithelial immune response, as well as hypomethylation of known COPD genetic associations such as *FAM13A* (p=5.0x10-9) and *SERPINA1* (p=6.9x10-8). Gene ontology-based analysis suggested that this gene set included a significant number of genes involved in immune processes, leukocyte activation, and wound healing, as well as responses to stimuli, signaling, and cell communication. We compared these results to the COPD-associated CpG sites in non-Hispanic whites described by Qiu et al in AJRCCM in 2012, and found that 2355 significantly differentially methylated CpG sites were unique in our AA set, including genes such as *FAM13A*.**Conclusions:**African-Americans may have a unique subset of differentially methylated gene-targets significantly associated with COPD when compared with non-Hispanic Whites. Future investigation will examine gene pathways of these targets and how this may explain racial disparities in COPD susceptibility and severity.

Masculinizing gene expression and DNA methylation in XX neural stem cells and their differentiated progeny by a single exposure of testosterone: An *in vitro* approach of understanding hormonal organization. *M. Bramble, L. Roach, A. Lipson, T. Ngun, N. Vashist, J. Gosshcalk, E. Vilain.* Dept of Human Genetics, University of California-Los Angeles, Los Angeles, CA. 90025.

The role of gonadal hormones and their influence on sexual differentiation and brain masculinization have been highly investigated in the rodent model over the past century. However, the studies that have been conducted failed to unravel at the molecular level exactly how these hormones may alter sexual behavior. Our research group recently found that neonatal androgen exposure is capable of altering DNA methylation patterns in sexually dimorphic regions of the rodent brain. The methylation differences may be an early molecular explanation as to how gonadal hormones permanently alter the developing brain, through the process known as hormonal organization. Using sex-specific embryonic day 14 C57/B6J mouse neural stem cells, we investigated the effects of exposures to testosterone propionate (TP) and its derivatives on multipotent neural stem cells prior to their maturation into neurons or astrocytes. Early results suggest significant and long lasting changes in the expression of numerous genes as a result of TP treatment at the NSC stage. We have demonstrated that testosterone exposure on XX neural stem cells can aid eliminating sex differences in gene expression, which are able to be carried over to the final stages of differentiation, again minimizing sex differences in both neurons and glia cell types. This phenomenon is likely due to epigenetic mechanisms, as we have shown that the global DNA methylation patterns in XX NSCs that are exposed to TP are not significantly different than basal XY NSCs. Prior to TP exposure however, DNA of XX NSCs are hypomethylated compared to their XY counterpart, which suggests that basal sex differences in the early developing central nervous system may be mediated through DNA methylation and other epigenetic mechanisms prior to gonadal hormone exposures during development. Using this *in vitro* approach coupled with an *in vivo* verification, we aim to elucidate the role that DNA methylation and gene expression changes have on neural stem cells, and how these alterations affect the final differentiated cell types. .

Integrative approach for functional methylation loci with next-generation sequencing. *H. Xu[1], D. Ryu[1,2], V. George[1].* 1) Dept Biostatistics & Epidemiology, Georgia Regents University, Augusta, GA; 2) Division of Statistics, North Illinois University, DeKalb, IL.

DNA methylation have been involved in cancer and many other complex diseases. Current methods for identifying disease-related DNA methylation loci are mostly based on analyzing genomic patterns of DNA methylations alone and are susceptible to high false positives. We develop an approach based on integrative analysis of RNA-seq and DNA methylation data from next-generation sequencing. Our approach combines information from the both RNA-seq and DNA methylation through Liptak's method to identifying functional methylation loci. Simulations show that it has lower false positive rate than current methods that analyze DNA methylation alone. By combining information from both types of data, our approach also has improved power compared to the methods analyzing DNA methylation alone. We applied our approach to a thyroid cancer data and identified several new functional methylation loci for thyroid cancer.

Oxidative stress pathways implicated in comprehensive epigenetic and transcriptomic assessment of adult hippocampus from fetal ethanol-exposed mice. *E.J. Diehl, B.I. Laufer, C.A. Castellani, B.A. Alberry, S.M. Singh.* Biology, University of Western Ontario, London, Ontario, Canada.

Alcohol abuse during pregnancy leads to a range of neurological abnormities termed Fetal Alcohol Spectrum Disorder (FASD). Its molecular basis is poorly understood, however epigenetic dysregulation of genetic programs in the brain are involved. We have developed a mouse model of FASD showing learning and memory impairment and persistent changes in brain gene expression into adulthood. Epigenetic phenomena likely maintain these changes; however, few studies have examined these modifications comprehensively.We examined global differences in gene expression, DNA methylation, miRNA, and histone methylation in the hippocampi of ethanol-exposed mice. We hypothesized that altered epigenetic mechanisms induce gene expression changes in the hippocampus which may underlie learning and memory impairment. Mouse pups were injected with saline or ethanol on postnatal days 4 and 7, equivalent to human trimester three. At 70 days of age, hippocampus was isolated and used for gene and miRNA expression microarray, methylated DNA immunoprecipitation microarray (MeDIP-chip), and histone H3 lysine 4 trimethylation and H3 lysine 27 trimethylation ChIP-chip.The top gene expression pathway was "Free Radical Scavenging, Gene Expression"; we confirmed four of these expression changes by droplet digital PCR (ddPCR). The top pathway for genes affected by epigenetic methylation changes was "Peroxisome biogenesis"; we confirmed two of these changes by bisulfite pyrosequencing. Alteration of pathways indicates a widespread dysregulation of the oxidative stress response. Ethanol is known to induce oxidative stress in the developing brain through a variety a mechanisms including reduction of antioxidant levels and increasing reactive oxygen species (ROS). Alteration in the epigenetic regulation of oxidative stress response genes into adulthood represents a novel point of interface between the epigenetic and oxidative stress mechanisms of FASD.

High SUMO E3 ligase PIAS1 protein expression in Breast Cancer Luminal A molecular subtype. *A. Mannermaa[1,2], R. Pirinen[3], R. Sironen[1,2], H. Peltonen[1,2], V-M. Kosma[1,2].* 1) Dept Pathology & Forensic Med, Univ of Eastern Finland, Kuopio, Finland; 2) Imaging Center, Pathology, Kuopio University Hospital, Kuopio, Finland; 3) Department of Pathology, Northern Karelia Central Hospital, Joensuu, Finland.

PIAS1 acts as a SUMO E3 ligase by specifying target proteins for SUMO conjugation by Ubc9. The sumoylation activity of PIAS1 suppresses TGFβ-induced Epithelial-Mesenchymal transition (EMT). Thus, SUMO E3 ligase PIAS1 has emerged as a critical regulator of EMT, which contributes to epithelial tumor cell invasiveness and metastasis. Interestingly, PIAS1 is also a chromatin-bound Androgen Receptor (AR) coregulator that functions in a target gene selective fashion to regulate prostate cancer cell growth. Here we report a PIAS1 immunohistochemical tumor staining study in an Eastern Finnish breast cancer sample set.PIAS1, Estrogen receptor (ER) and progesterone receptor (PR) were evaluated by immunohistochemical staining from paraffin embedded tissue samples. HER2 mutation status was obtained from clinical data of the patients.Statistical analyses were carried out using SPSS 21 for Windows. Differences between groups were analyzed by either non-parametric Kruskal-Wallis test, Mann - Whitney U-test or by Fishers's Exact Test (2-sided).PIAS protein expression was negative or weak in 22.7% of the tumors, moderate in 51.2% and high in 23.8%. We detected an association between the expression of PIAS1 and ER positivity (p=0.023) and PIAS1 positivity and HER2 amplification negativity (p=0.03) in invasive cases. After grouping tumours according to molecular subtypes Luminal A (ER+ and/or PR+, HER2-), Luminal B (ER+ and/or PR+, HER2+), Triple negative/basal-like (ER-, PR-, HER2-) and HER2 type (ER-, PR-, HER2+) a strong association between PIAS1 expression and Luminal A subtype was seen (p=0,01).Our results provide evidence for PIAS1 as a classifier of breast tumours and urges for additional studies on the role of this EMT and AR related regulator in breast cancer.

Histone Binding Strength is Quantitatively Associated with Gene Expression Across Individuals. *K. Fletez-Brant[1,3], Y. He[2], K.D. Hansen[1,3].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Dept. of Epidemiology, Johns Hopkins Bloomberg School of Public Health; 3) Dept. of Biostatistics, Johns Hopkins Bloomberg School of Public Health.

Histone modifications are known to be associated with active and inactive parts of the genome. These modifications are mainly profiled genomewide using ChIP-seq, and for technical reasons most existing experiments are performed in cell lines with unlimited input material. Little is known about differences in histone marks profiled in the same cell type but in different individuals.We study this question using publicly available data on histone modifications H3K4me1, H3K4me3 and H3K-27ac from multiple different HapMap cell lines. We show a quantitative association between the expression of a gene and H3K4me3 binding at its corresponding promoter. By analyzing input experiments on the same samples we show that the input channel measured across a promoter show some quantitative association with gene expression; this emphasises the need for using experimental controls in this analysis. By comparing with the input channel, we conclude that H3K4me3 do have a quantitative relationship with gene expression at some, but not all, promoters. This association shows H3K4me3 binding strength is a quantitative and functionally relevant measure, which is associated with biological variation. We establish a similar quantitative relationship between gene expression and strength binding by H3K4me1 and H3K27ac at corresponding enhancers, with enhancers defined by the FANTOM 5 project. Finally we establish the quantitative relationship between promoter H3K4me3 binding and gene expression in rat samples, thereby replicating our finding in a different mammal.

Inter-species comparison of endothelial cell gene regulation reveals the conserved control of vascular disease genes. *A. Medina Rivera[1,2], L. Antounians[1,3], A. Alizada[1,3], M. Liang[1,3], L. Dang[4,6], F. Gagnon[5], J. Fish[4,6,7], M. Wilson[1,3].* 1) Genetics and Genome Biology, SickKids Research Institute; 2) Laboratorio Internacional de Investigación Sobre el Genoma Humano, UNAM, Juriquilla, Queretaro, Queretaro, Mexico; 3) Department of Molecular Genetics, University of Toronto; 4) Department of Laboratory Medicine and Pathobiology, University of Toronto; 5) CIHR STAGE, Dalla Lana School of Public Health, University of Toronto; 6) Toronto General Research Institute (TGRI); 7) Heart and Stroke Richard Lewar Centre of Excellence.

Comprehensive maps of transcription factor (TF) binding and epigenetic modifications are rapidly generating new testable insights into human disease gene regulation. However, it is still not trivial to identify which gene regulatory regions have the most impact on tissue specific gene regulation. We set out to identify gene regulatory regions that are required for vascular homeostasis by making controlled cross-species epigenetic comparisons (Zoo-ChIP) in aortic endothelial cells (ECs) isolated from multiple species. We profiled the JUN transcription factor, an important member of the AP1 complex, and several histone modifications in human, rat and bovine aortic ECs cultured ex vivo. We identified shared orthologous TF binding and shared orthologous active histone modifications. We found that approximately 5% of JUN and 33% of H3K27ac are shared between human and one additional mammal (rat or cow). These shared putative regulatory DNA regions were enriched for EC pathways including angiogenesis and nitric oxide metabolism. Shared orthologous JUN binding sites also coincided with reported regulatory human disease mutations, several of which have a plausible EC component. Importantly, only a minority of these shared JUN/H3K27ac interactions could have been predicted using established measures of DNA constraint or ChIP-seq signal alone. By comparing our findings to similar studies performed in primary liver tissue, we demonstrate that comparative epigenomic profiling enriches for tissue-specific pathways and distinct human regulatory DNA mutations.

451T

Effect of natural variation in copy number on epigenetic patterning. *J. Yu, C. Li, K. Iyengar.* Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Background. Copy number variation (CNV), the most prevalent type of structural variation, has been associated with many human diseases, but its role in disease pathogenesis is far from clear. We hypothesized that CNVs alter disease risk through differences in epigenetic patterning, and performed a systematic evaluation of the *cis* relationships between CNVs and histone marks overlapping a called CNV in two embryonic cell lines, H1 and H9, and a lymphoblastoid cell line, GM12878; these lines are widely studied for epigenetics. **Data.** We obtained data from the ENCODE, Roadmap, and 1000 Genomes Project (1KG): CNV data for H1 and GM12878, and SNP chip data for H1 and H9 with CNVs called by PennCNV. When CNV calls were available from multiple sources, only overlapping calls were kept. We also obtained consolidated profiles for histone marks (27 for H1, 28 for H9, and 11 for GM12878) and DNase hypersensitivity as a covariate. **Analysis**. CNVs status were categorized as deletion (CNV=0,1), duplication (CNV=3,4), and normal (CNV=2). For each histone mark, we performed linear regression of log-signal intensity on CNV status, with and without DNase. We then performed two meta-analyses, one over H1 and H9, and the other over all three cell lines. **Results**. **1)** When adjusting for DNase, nominal significance was observed for duplications for 17 marks in H1, 16 in H9, and 8 in GM12878; among these, 9 were in both H1 and H9, and 4 in all three lines. **2)** Nominal significance for deletions was found for 3 marks in H9, 10 in GM12878, and 2 in both. **3)** After Bonferroni correction, we found significant *cis* effects of duplication on increased intensity of H3K9me3 ($p = 1e-3$ for with and without DNase) in meta-analysis of H1 and H9, and of deletion on increased intensity of the promoter marks H3K4me2 ($p = 2e-4$ and 1e-4) and H3K9ac ($p = 5e-6$ and 1e-5) in meta-analysis over all three lines. **4)** Among the CNVs driving our significant results, one duplication CNV straddled the olfactory receptor family on chromosome 14. Olfactory receptors are known to be epigenetically programmed. Another duplication CNV overlapped with defensins on chromosome 20, a known copy variable region. Several deletion CNVs overlapped with the SET domain on chromosome 12.

452F

Methylation alterations of LINE-1 and imprinting genes related to folate deficiency during embryo development. *L. Wang, T. Zhang, W. Zhen, S. Chang.* Capital Institute of Pediatrics, Beijing, China.

Periconceptional maternal folate deficiency is a risk factor for neural tube defects (NTDs), the mechanism underlied remains unclear. Intracellular folic acid is thought to be key player in providing an adequate source of methyl groups for methylation of DNA and proteins, and methylation modifications of repeat elements and imprinting genes is suggested to be sensitive to epigenetic regulation of folate acid nutrition in developmental programming. However, the mechanism of how folate deficiency altered methylations modification of repeat elements and imprinting genes in earlier development is still unclear. Our present studying analyzed methylation modification alternations of LINE-1 and imprinting genes using NTD cases, mESCs with folate deficiency, and also in mouse models with periconceptional folate-deficiency. The results implying that hypomethylation of LINE-1 was associated with an increased risk of NTDs. Folate insufficiency induced LINE-1 hypomethylation at the lowest levels in folate-free ESCs, compared with that in the folate-normal group. Moreover, LINE-1 methylation level was positively correlated with folate content, and negatively correlated with homocysteine content. Similar, kinds of imprinting genes also altered imprinting modifications in NTDs with folate deficiency, including Gnas imprinting cluster, DLK-MEG3 imprinting cluster, MEST imprinting and H19/IGF2 imprinting. Mouse embryos exhibited a significantly increased ratio of IUGR and developmental dysplasia of the brain in response to folate deficiency. Data shown here implying that periconceptional maternal folate deficiency altered the imprinting established and gene expression in fetal brains, which may be associated with the higher ratio of developmental dysplasia.

453T

Investigating Imprinting As A Mechanism For The Development Of Asthma and related phenotypes In Two Canadian Birth Cohorts. *A. Eslami[1], L. Akhabir[1], G. Ellis[1], AB. Becker[2], AL. Kozyrskyj[3], C. Laprise[4], PD. Paré[1], AJ. Sandford[1], D. Daley[1].* 1) Centre for Heart Lung Innovation, Faculty of Medicine, University of British Columbia, Vancouver, BC, Canada; 2) Department of Pediatrics and Child Health, Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada; 3) Department of Pediatrics, Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada; 4) Università du Québec á Chicoutimi, Saguenay, QC, Canada.

Background: Asthma is a complex disease caused by a combination of genetic and environmental factors. To date, 23 genome-wide association studies (GWAS) have been completed for asthma as a primary phenotype. Combined, these studies have identified 44 SNPs at a p value <1x10-6. The consensus is that main genetic effects of these common SNPs (with modest effects) do not fully explain the heritability of asthma. This has led to further studies of more complex models to identify the "missing heritability" in asthma. Genomic imprinting is an alternative mechanism, which may explain some of the missing heritability. Imprinting is an epigenetic phenomenon where the expression of genes depends on their parental origin (parent-of-origin effect). Imprinting effects have been reported in the development of many complex diseases including asthma.**Hypothesis**: Specific genomic imprinted regions are associated with asthma and related phenotypes (atopy and airway hyperresponsiveness (AHR)).**Methods**: To identify candidate genomic regions for imprinting we used GWAS data from two family-based studies (two parents and one offspring). These studies are: 1) the Canadian Asthma Primary Prevention Study (CAPPS), a high-risk asthma birth cohort and, 2) the Study of Asthma Genes and Environment (SAGE), a population-based asthma birth cohort. We used a likelihood-based variant of the Transmission Disequilibrium Test. Parent-of-origin effects were tested by including a modifier (the sex of parents) in the analysis.**Results**: In the joint analysis of CAPPS and SAGE with 148 asthmatic complete trios, 13 SNPs showed significant parent-of-origin effects with p<10-5. 3 SNPs remained significant after 100,000 permutations. Notably, we showed a parent-of-origin effect at a known imprinted gene, CTNNA3; this gene was previously associated with occupational asthma in a GWAS. Six SNPs were in or near Long non-coding (lnc)RNA genes. LncRNAs have been increasingly implicated in imprinting by modulating imprinting control regions or being imprinted themselves. The joint analyses for atopy (237 trios) and AHR (231 trios) yielded 3 and 2 significant SNPs after permutation, respectively.**Conclusion**: We identified several SNPs showing parent-of-origin effects in asthma and related phenotypes. To increase statistical power and confirm our results, we will perform a meta-analysis using 3 family studies: CAPPS, SAGE and the Saguenay-Lac-Saint-Jean and Quebec City, a French-Canadian founder population.

Somatic cell hybrids as a model system to evaluate genome editing and genomic imprinting of pig chromosomes in the development of pre-clinical large animal models. *R.D. Nicholls[1,2], M.A. Johnson[1], F. Mompart[3], S.M. Gollin[2], K.D. Wells[4,5], R.S. Prather[4,5], M. Yerle[3].* 1) Dept of Pediatrics, Div of Medical Genetics, Children's Hospital of Pittsburgh of UPMC, Pittsburgh, PA; 2) Dept of Human Genetics, School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) INRA-INPT UMR1388 Génétique Physiologie et Système d'Elevage, Castanet-Tolosan, France; 4) Div of Animal Sciences, College of Agriculture and Natural Resources, University of Missouri, Columbia, MO; 5) National Swine Research and Resource Center, University of Missouri, Columbia, MO.

Maintenance of human chromosome epigenetic states within a rodent cell has been demonstrated by using human-rodent somatic cell hybrids (SCH), including for the developmental status of globin gene expression, the active or inactive state of X chromosomes, and genomic imprinting. We have now used a pig-rodent SCH panel [Yerle M, et al. (1996) *Cytogenet Cell Genet*. 73: 194-202] to assess imprinted gene expression and DNA methylation of candidate imprinted loci. Furthermore, we are using SCH as a cellular model to explore genome editing of pig chromosomes. The SCH lines by cytogenetic analysis contain on average 5-7 pig chromosomes, for this work including *Sus scrofa* chromosome 1 (SSC1) or SSC9. Using FISH with a whole SSC1 paint probe and with a specific *SNORD116* gene locus probe, we confirmed that five SCH have a single SSC1q18 region [the location of the Prader-Willi syndrome (PWS)-orthologous imprinted locus]. Gene expression analysis showed that the PWS-orthologous genes *SNURF-SNRPN*, *SNORD116*, *SNORD107* and *MAGEL2*, as well as the syntenic *PLAGL1* gene, are differentially expressed in the SCH lines, consistent with an imprinted pattern of monoallelic expression. Using the methylation-sensitive restriction enzyme *Hha*I followed by PCR, the promoter of the bicistronic *SNURF-SNRPN* locus was unmethylated in three SCH and methylated in two SCH, correlating with gene expression and enabling assignment of paternal or maternal origin of the pig SSC1. Similarly, we are currently analyzing SSC9 candidate imprinted genes. Transfection of SCH lines with vectors encoding transcription activator-like effector nucleases (TALENs) or the CRISPR (clustered, regularly interspaced, short, palindromic repeats)/Cas9 ribonucleoprotein system designed to target sites in the PWS-orthologous domain resulted in successful induction of double-strand breaks and repair by non-homologous end joining to generate deletions ranging from 2.05 kb to ≥1.2 Mb. Levels of genome editing by both designer nucleases were greater on the transcriptionally active, paternal allele than on the silent, maternal allele, with only some CRISPR gRNA pairs functional for the latter. In conclusion, SCH are a valuable resource for imprinting assays of candidate genes in the pig. Further, SCH provide a powerful cell model to test efficacy and mechanisms of genome editing of pig chromosomes by designer nucleases. *Supported by NIH, FPWR, PWSA and the Storr Family Foundation.*.

Analysis of monoallelic expression in 1084 human individual cells revealed novel putative imprinted genes. *C. Borel[1], F. Santoni[1], M. Garieri[1], E. Falconnet[1], P. Ribaux[1], S. Antonarakis[1,2,3].* 1) Dept Genetic Medicine, Univ Geneva Medical Sch, Geneva, Switzerland; 2) Geneva University Hospitals-HUG, Service of Genetic Medicine, Geneva, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, University of Geneva, Switzerland.

Genomic imprinting results in the mutually exclusive expression of either the paternally or maternally inherited allele. Imprinted genes are implicated in the etiology of rare syndromes and have been associated with common diseases such as diabetes and cancer. More than 100 human imprinted genes have been identified so far, and the predicted number is in the range of few hundreds. We aim to identify novel imprinting genes using a single-cell (SC) RNA sequencing approach.From the proband of 2 family trio and 3 unrelated individuals, 1084 individual fibroblasts were RNA sequenced and more than 770'000 heterozygous SNVs were genotyped (WGS, 25x depth). For each gene, we analyzed the allelic specific expression through our in-house pipeline (>1 reads/site and >1SC/site). We modeled the likelihood of a gene to be monoallelically expressed with a beta-binomial distribution and evaluated the significance of the aggregate monoallelic ratio (reads sum of the most frequent allele per site / total reads) with the log-likelihood test. Genes presenting with a significant (adjusted p-value < 0.05) aggregate monoallelic ratio between 0.9-1 were retained for the identification of the allelic parent of origin. We were able to validate the imprinting status of 6 known imprinted genes and to detect 31 putative imprinted genes. We will also describe the allelic expression profile of 75 known imprinted genes in our single-cell dataset. Notably the analysis of 1084 single cells definitively improved the detection of average to low expressed genes in fibroblast with respect to bulk RNAseq allowing for a deep profiling of the allelic imbalance of each gene.In conclusion, single-cell RNA sequencing proves to be an excellent approach to overcome the intrinsic heterogeneity of the tissue and hereby it is a reliable tool to address the cell-type specificity of genomic imprinting.C.B. and F.S. contributed equally.

Tissue-specific maps of genomic imprinting across the mammalian phylogeny reveal causal evolutionary pressures. *T. Babak.* Biology, Queen's University, Kingston, Ontario, Canada.

Genomic imprinting is an epigenetic process that restricts gene expression to either the maternally or paternally inherited allele. Many theories have been proposed to explain its evolutionary origin, but understanding has been limited by a paucity of data mapping the breadth and dynamics of imprinting within any organism. We previously showed, from comparisons of tissue-specific maps of imprinting in humans and mouse, thatimprinted genes were enriched for coexpressed pairs of maternally and paternally expressed genes, showed accelerated expression divergence between human and mouse, and were more highly expressed than their non-imprinted orthologs in other species (Babak et al. Nat Gen. 2015). Here we further those efforts by developing a new method for mapping imprinting in any species, even in the absence of genotyping data that is traditionally used to infer allele-specific gene expression. We applied this method to 6 major phylogenetic branches in the mammalian lineage and will discuss the evolutionary implications of the patterns that emerged.

Genome-wide DNA methylation profiles in twins with autism spectrum disorders. *A. Anhalt[1], L.R. Simard[1], A. Hanlon-Dearman[2,3], X-Q. Liu[1,4].* 1) Department of Biochemistry and Medical Genetics, University of Manitoba, Winnipeg, Manitoba, Canada; 2) Department of Pediatrics and Child Health, University of Manitoba, Winnipeg, Manitoba, Canada; 3) Children's Hospital of Winnipeg, Winnipeg, Manitoba, Canada; 4) Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Manitoba, Winnipeg, Manitoba, Canada.

Introduction: Autism spectrum disorders (ASD) are attributed to genetic, epigenetic, and environmental risk factors. Epigenetic factors (e.g. DNA methylation) are implicated in ASD because autistic symptoms are observed in some Mendelian disorders with an epigenetic aetiology (e.g. Rett syndrome). Twins are the ideal research subjects for epigenetic studies because they share similar pre- and post-natal environments and are of the same age. Moreover, identical (monozygotic, MZ) twins share the same genetic variants but can have different epigenetic profiles. Using twins, especially MZ twins, allows researchers to separate epigenetic effects from genetic and environmental factors. Two published studies used ASD-discordant MZ twins to identify associations between DNA methylation levels and ASD. However, additional studies can build upon these findings, due to the limited sample sizes in twin studies.**Methods and Results:** We recruited same-sex twin pairs with at least one twin diagnosed with ASD. Using the Illumina HumanMethylation450 BeadChip, we generated genome-wide DNA methylation profiles from buccal and peripheral blood mononuclear (PBMC) cells for twins from six pairs (2 MZ and 4 dizygotic, DZ, pairs). We examined the correlations of global DNA methylation levels between twins. In the PBMC samples, the MZ pairs were more similar than the DZ pairs, which were more similar than the unrelated (UR) pairs (e.g. using the 10% most variable probes; MZ: r=0.98, SD=0.005; DZ: r=0.93, SD=0.006; UR: r=0.88, SD=0.02). However, the correlations were similar between the ASD-discordant and ASD-concordant pairs with the same zygosity (e.g. MZ discordant: r=0.986; MZ concordant: r=0.980). Additionally, we examined site-specific DNA methylation in an ASD-discordant MZ pair, which revealed several CpG sites with large differences in DNA methylation levels between the twins.**Conclusions and Future Directions:** Our preliminary results suggest that ASD is not related to changes in the global DNA methylation profile. However, there may be significant site-specific differences in DNA methylation levels between ASD-affected and unaffected individuals. We will further investigate the site-specific relationships between DNA methylation levels and ASD and will examine whether differentially methylated regions can be detected in both PBMCs and buccal cells. We will also use RNA-seq data to examine the correlation between differentially methylated regions and gene expression levels.

Longitudinal differences in DNA methylation profile of twins reared apart and together. *A. Ganna[1], Y. Wang[1], C. Wärnhjelm[1], X. Shen[1], T. Morris[2], C.A. Reynolds[3], N.L. Pedersen[1], S. Hägg[1].* 1) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet; 2) Medical Genomics Group, UCL Cancer Institute, University College London; 3) Department of Psychology, University of California-Riverside.

DNA methylation can be influenced by environmental and genetic factors. Twin studies can be used to evaluate the environmental contribution by controlling for the genetic effect. A study design that compares twin pairs reared together with twin pairs reared in separate families is particularly attractive because it can be used to investigate the contribution of common family environment. Several studies have suggested a modest contribution of common environment in phenotypic variation, but no previous studies have evaluated DNA methylation. In addition, no studies have examined how such differences change over time in the same individuals.We compared differences (Euclidean distances) in the overall methylation profile (Illumina HumanMethylation450 array, 428,545 probes) of 74 twin pairs (34% monozygotic - MZ) reared apart (i.e. separated before the age of 10) and 80 pairs (54% MZ) reared together from the Swedish Adoption Twin Study of Aging. Repeated measurements (max 5, mean 2.3 measurements per twin pair) were collected over a 20-years follow-up period, resulting in 710 samples with DNA methylation data. Pre-processing was done using Dasen normalization with adjustments for cell composition in blood and batch effectOverall within-pair differences in methylation profile increased over time (P-value < 0.0001, using mixed models) and were higher in DZ compared to MZ twins (p-value=0.05). Surprisingly, we found larger differences in the methylation profile of twin pairs reared together compared to those reared apart (P-value = 0.01). This effect was stronger for MZ pairs. Probe-specific analysis identified 2 probes (cg00344178, P-value=4.5x10-8 and cg10213695, P-value=2.6x10-8) that were positively associated with larger differences in MZ twins reared together after controlling for an FDR of 5%.We performed extensive sensitivity analysis by adjusting for differences in smoking, alcohol, BMI, cardiovascular disease, lipids levels, dementia, cognitive function, but the observed effect remained significant. Additional analysis assessing potential batch effects couldn't disprove our findings.Future replications needed to confirm our findings are planned in additional N=104 MZ twins.

459T

Is familial correlation in genome-wide DNA methylation level due to sharing the womb or genes? *S. Li[1], E.M. Wong[2], C. Apicella[1], J. Stone[3], G. Dite[1], J.E. Joo[2], G.G. Giles[4], M.C. Southey[2], J.L. Hopper[1].* 1) Centre for Epidemiology and Biostatistics, The University of Melbourne, Victoria 3010, Australia; 2) Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Victoria 3010, Australia; 3) Centre for Genetic Origins of Health and Disease, The University of Western Australia, Western Australia 6009, Australia; 4) Cancer Epidemiology Centre, Cancer Council Victoria, Victoria 3004, Australia.

Genome-wide DNA methylation level is studied as a risk factor for many diseases, but the genetic and environmental causes of its variation are less well studied. We measured DNA methylation from dried blood spots for 479 Australian women (mean age 56 years) comprising 66 MZ and 66 DZ twin pairs, and 215 of their sisters (130 families from Australian Mammographic Density Twins and Sisters Study), using the Illumina Infinium HumanMethylation450 BeadChip. Genome-wide DNA methylation level was defined as the average beta value across autosomal probes. We applied multivariate normal pedigree analysis using the software FISHER to adjust for age, estimate correlations, and fit variance components models where A refers to additive genetic factors, C to environmental factors shared by relatives (equally by twin pairs and to a lesser extent $s<1$ by sibling pairs), and E to individual factors. The estimated correlation in genome-wide DNA methylation level across all 468,406 probes was 0.42 (SE=0.10; $P=2\times10-5$) for MZ pairs, 0.40 (SE=0.10; $P=3\times10-5$) for DZ pairs, and 0.01(SE=0.06; $P=0.9$) for sibling pairs (including twin–sister pairs). After removing 184,424 probes with known genomic factors (SNPs, INDELs, *etc.*), the estimated correlations were 0.34 (SE=0.11; $P=2\times10-3$), 0.35 (SE=0.10; $P=4\times10-4$) and 0.04 (SE=0.05; $P=0.5$), respectively. For both measures, there was no difference between the MZ and DZ pair correlations (both $P>0.9$) and the twin pair correlations were greater than the sibling pair correlation (all $P<0.01$). Similar results were found for methylation levels in different genomic regions and chromosomes. For genome-wide methylation DNA level across all probes, we estimated A=2% (SE=11, $P=0.9$) and $s=0$; the only significant familial component was C, which explained 40% (SE=10, $P=10-4$; SE=11 when A=0) of the variance. We also found that, for non-twin sister pairs born after twins, the correlation was 0.47 (SE=0.15; $P=10-3$), which was greater than 0.01 (SE=0.19; $P=0.5$) for non-twin sister pairs born before twins ($P=0.05$). We conclude that there is no evidence from either the twin or sibling pair correlations that genetic factors explain variance in genome-wide DNA methylation level. Instead, the data are consistent with substantial variance due to non-genetic factors shared by twins alone. One explanation is that twins share the uterus at the same time. There is evidence that twin birth might influence the genome-wide methylation DNA level of subsequent sisters.

Integrative Methods to Characterize X Chromosome Inactivation Patterns in Epithelial Ovarian Cancer. *S. Winham[1], N. Larson[1], Z. Fogarty[1], M. Larson[1], S. Armasu[1], B. Fridley[2], E. Goode[1].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) University of Kansas Medical Center, KUMC, Kansas City, KS.

In females, X chromosome inactivation (XCI), randomly silences transcription of one of the two homologous copies of the X chromosome via DNA methylation in order to equalize levels of gene expression with males. This process is tissue- and cell-specific, and some genes escape XCI. While studies suggest that inactivation is skewed (one chromosome is preferentially activated) in lymphocytes from epithelial ovarian cancer (EOC) patients, the role of XCI in tumors is largely unknown. Better understanding of chromosome and gene-level XCI patterns will advance our knowledge of ovarian tumor biology.To examine the role of XCI in EOC, we integrated genotype, gene expression, and DNA methylation data from tumors of 113 ovarian cancer patients. We measured allele-specific expression (ASE) for 481 genes across the X chromosome by combining RNA-Seq, and 1000 Genomes Project imputed genotype data to identify the active alleles for each tumor. Chromosome-wide, 89 patients showed skewed XCI based on a likelihood ratio test ($P<0.01$). Using a beta-binomial mixture model, we estimated which genes escaped XCI for each patient, and 22% of genes showed variable escape patterns across tumors. We compared the tumor escape status to previously reported lymphocyte escape status, and found that on average, 14% of genes were discordant within individuals; 61% of the discordances were previously reported lymphocyte escape genes. In one tumor-normal ovarian tissue pair, 19 of 68 expressed genes showed evidence of somatic changes, with 7 genes undergoing XCI in adjacent normal tissue but escaping in the tumor, including *TSC22D3* (MIM: 300506), a transcriptional regulator previously implicated in EOC.Because XCI is governed by DNA methylation, we also assessed beta values of the Infinium 450K Array CpG probes in X chromosome gene promoter regions, and observed cis associations with ASE imbalance. To assess global XCI patterns, we performed cluster analyses on the ASE data, identifying two ASE clusters. We also identified two clusters based on the promoter methylation data, and observed strong association with the ASE clusters ($P=0.007$). We examined the relationship between the clusters and clinical factors, and found XCI patterns were associated with tumor histology, stage, and overall survival ($P<0.04$).Together, these results suggest that XCI may play an important role in EOC. Future studies to examine somatic changes with paired tumor-normal tissue are needed.

Oxytocin and Religious Brain. *J.R. Korenberg[1], L. Dai[2], J.B. King[3], M.A. Ferguson[3], J.A. Nielson[4], D. Giangrasso[3], C.S. Carter[5], H.P. Nazarloo[5], J.S. Anderson[6].* 1) Brain Institute, Department of Pediatrics, University of Utah, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Neuroscience Graduate Student, University of Utah, Salt Lake City, UT; 4) Psychiatry and Psychology, Harvard University & Massachusetts General Hospital; 5) The Kinsey Institute, Indiana University, Bloomington, Bloomington, IN; 6) Department of Radiology, University of Utah, Salt Lake City, UT.

The molecular and neural mechanisms regulating human social behaviors are fundamentally important but largelyunknown. Religious experience is one of the most powerful transformative factors in the lives of individuals andcultures, and provocative evidence showed that religion influences social behaviors in different and even controversialways. It has been suggested that religious priming serves to enhance pro-sociality for in-group members, whileincreasing aggression towards out-group. It is interesting that social peptide hormone oxytocin, has been implicatedto play a role in cooperation and competition within and between groups. In addition, recent study showed thatreligion priming and an oxytocin receptor gene polymorphism interact to affect self-control in a social context. Wetherefore hypothesized that religiouspriming will result in an increase in pro-sociality as measured by observer ratingsof social stimuli, plasma serum levels of oxytocin, and functional connectivity in social brain regions. In this study, wereport the plasma oxytocin levels before and after a thirty-minute period of religious experience in a cohort of elevenreturned Mormon missionaries. Our preliminary results showed that the plasma oxytocin and vasopressin levels arehighly associated. This is the first time to study the in vivo relationship of peptide hormones in regulating religiousbelief and will enhance our understanding of neurobiology of the effects of religious experience on social behaviors.

Val158Met polymorphism in COMT affects the brain's white matter properties during second language immersion. *P. Mamiya[1], T. Richards[2], B. Coe[3], E. Eichler[3], P. Kuhl[1].* 1) Institute for Learning & Brain Sciences, University of Washington, Seattle, WA; 2) Department of Radiology, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, wA.

Second language emersion as an adult is becoming increasingly prevalent as students prepare for college in a foreign country. There is a great variability in the level of proficiency among these late second language learners. Previous studies have demonstrated that adults learning a second language show changes in both the grey and white matter brain structures as a function of learning. It is unknown whether genetic variations influence how an individual's brain adapts while learning a second language. To address this issue, we studied Chinese students who enrolled in an English immersion program as preparation for college and investigated whether the Val158Met polymorphism in COMT can affect second language learning. Methionine (Met) substitution at codon 158 in COMT results in elevated dopamine in prefrontal cortex, and is associated with superior executive function, a high order cognitive ability known to be important for learning. We hypothesized that this polymorphism may have an effect on second language learning. Methods: We used real-time polymerase chain reaction method to identify the variant in COMT, and DTI to characterize the brain's white matter properties. We entered the COMT genotype and white matter data into a regression model to predict second language learning. Our first finding was that the Met/Val and Val/Val subjects show a significant positive correlation between the number of days they had been in the class at the time of the brain scan and enhancement of white matter properties in the voxels located in the superior longitudinal fasciculus (SLF), a fiber track important for language processing. This enhancement of white matter properties was shown as an increased fractional anisotropy (FA) and reduced radial diffusivity (RD), assessed by two DTI measures, in the SLF. This correlation was not found in the Met/Met subjects. Furthermore, the FA values in the SLF and the COMT genotype significantly predict the grades students received in the program. Comparing data from a regression model using only the FA value in the SLF to one in which we added the genetic data, we found an over 100% increase in the total variance explained. Taken together, our findings suggest that the COMT genotype may play a role in enhancing neuroplasticity in the brain's white-matter fiber tracks, enabling heightened student learning during exposure to second language learning in adulthood.

463T

Significant transcriptional changes in 15q duplication but not Angelman syndrome deletion dental pulp stem cell derived neurons. *N. Urraca[1,2], Q. Tran[5], T.G. Belgard[9], R. Memon[4], S. Goorha[2], C. Valdez[2], S. Sanchez[7], J.M. Ramirez[8], M. Donaldson[4], D. Bridges[3,6], L.T. Reiter[2,3].* 1) Le Bonheur Children's Hospital, Memphis, TN; 2) Department of Neurology, UTHSC, Memphis, TN; 3) Department of Pediatrics, UTHSC, Memphis, TN; 4) Department of Pediatric Dentistry, UTHSC, Memphis, TN; 5) Department of Preventive Medicine, UTHSC, Memphis, TN; 6) Department of Physiology, UTHSC, Memphis, TN; 7) Cytogenetics Laboratory, Instituto Nacional de Pediatria, Mexico City, Mexico; 8) Department of Biochemistry and Molecular Biology, University of Basque Country, Bilbao, Spain; 9) MRC Functional Genomic Unit, University of Oxford, UK.

The analysis of gene expression in living neurons from Angelman (AS) and Duplication 15q (Dup15q) syndrome subjects has impeded our understanding of these disorders. Here we use dental pulp stem cells (DPSC) from AS deletion, 15q Duplication and neurotypical control subjects for mRNA-seq analysis in both DPSC and DPSC-neurons. We identified 20 genes unique to AS neurons, 120 genes unique to 15q duplication and 3 shared genes that were differentially expressed versus control neurons. Copy number correlated with gene expression for most genes across the 15q11.2-q13.1 critical region. Two thirds of the genes differentially expressed in 15q duplication neurons were down-regulated compared to controls including several transcription factors, while in AS most differential expression was in the 15q region. Pathway analyses revealed steroid hormone biosynthesis genes were slightly enriched in both 15q duplication and AS neurons. We found more changes in gene expression in Dup15q than AS cell lines, perhaps because the mechanism of AS may be primarily through the degradation of UBE3A protein substrates. Comparison of gene expression changes in Dup15q DPSC neurons correlated with published postmortem idiopathic autism brain studies, indicating that this may be a valid *in vitro* model for gene expression changes in the brain. Finally, the finding of a significant increase in both *HERC2* and *UBE3A* in Dup15q neurons and significant decrease in these two genes in AS deletion neurons may explain differences between AS deletion class and *UBE3A* specific classes of AS mutation where *HERC2* is expressed at normal levels.

464F

***FXN* promoter silencing in the humanized mouse model of Friedreich ataxia.** *Y. Chutake[1], W. Costello[1], C. Lam[1], M. Pook[2], S. Bidichandani[1].* 1) Dept of Pediatrics, Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Dept of Life Sciences, College of Health & Life Sciences, Brunel University, London, UK.

Friedreich ataxia is caused by an expanded GAA triplet-repeat sequence in intron 1 of the *FXN* gene that results in epigenetic silencing of the *FXN* promoter. This silencing mechanism is seen in patient-derived lymphoblastoid cells but it remains unknown if it is a widespread phenomenon affecting multiple tissues. The humanized mouse model of Friedreich ataxia (YG8sR) carries a single transgenic insert of the human *FXN* gene containing an expanded GAA triplet-repeat in intron 1. The latter mimics the human condition, and similar to people with Friedreich ataxia tissues from the YG8sR mouse are deficient for *FXN* transcript when compared to an isogenic transgenic mouse lacking the expanded repeat (Y47R). Tissues from YG8sR mice carried similar sized expanded GAA triplet-repeats and showed evidence of increased DNA methylation at the *FXN* locus. We found that tissues from YG8sR, but not Y47R, showed deficiency of *FXN* transcript that extended both upstream and downstream of the expanded GAA triplet-repeat, suggestive of deficient transcriptional initiation. This pattern of deficiency was seen in all tissues tested, irrespective of whether they are known to be affected (dorsal root ganglia, heart, cerebellum) or spared (cerebrum, skeletal muscle, fibroblasts) in disease pathogenesis. *FXN* promoter function was directly measured by quantitative analysis of transcriptional initiation via metabolic labeling of newly synthesized transcripts in fibroblasts, which revealed significant deficiency of transcriptional initiation in the YG8sR mouse compared to the Y47R control mouse. Thus, deficient transcriptional initiation accounts for the transcriptional deficiency in the humanized mouse model of Friedreich ataxia, similar to patient-derived cells, and the mechanism underlying promoter silencing in Friedreich ataxia is widespread across multiple tissues.

465T

Chromatin accessibility in the mammalian retina: Potential impact on studies of human retinal and macular degeneration. *F. Giuste[1], R. Ratnapriya[1], Y. Hyun-Jin[1], S. Montezuma[2], T. Longo[1], A. Parker[1], A. Police Reddy[1], D. Ferrington[2], A. Swaroop[1].* 1) Neurobiology, Neurodegeneration, & Repair Laboratory, NEI, NIH, Bethesda, MD; 2) Department of Ophthalmology & Visual Neurosciences, University of Minnesota Twin Cities, Minneapolis, MN.

A majority of variants associated with common disease reside in the non-coding region of the genome. To evaluate the nature of genomic elements harboring potential susceptibility variants associated with retinal and macular degeneration, we are developing a genome-wide chromatin map of the mammalian retina. The primary cause of blindness in a vast majority of degenerative retinal diseases is the dysfunction or loss of photoreceptors. Since it is difficult to obtain photoreceptor-specific chromatin data from human retina, we have also assayed open chromatin regions in flow-sorted mouse rod photoreceptors using ATAC-seq open chromatin assay. We are beginning to integrate ATAC-seq data of mouse rod photoreceptors and of human retina with respective global transcriptome profiles. Our analyses should provide important insights into genetic and epigenetic regulation of retinal gene expression and assist in identifying the potential impact of susceptibility variants on photoreceptor function and disease pathogenesis.

466F

Locally adaptive comparison of DNase I profiles to detect fine scale differences in regulatory activity. *J. Morrison[1], R. Sandstrom[2], N. Simon[1].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Genome Sciences, University of Washington, Seattle, WA.

Variation in gene-expression and regulation leads to cell-level phenotypic variation from the scale of differences in cell identity to differences in drug sensitivity among cells of the same type. DNase I digestion experiments have been used to identify active regulatory DNA in numerous cell types. Different cell types can be characterized by sets of DNase hypersensitve sites (DHSs) - short regions with very high rates of DNase I cleavage. Analysis based on called DHSs is powerful for identifying and characterizing cell type specific and constitutive regulatory regions. However, DHS based analysis may be insufficient for characterizing more subtle phenotypic variation within a single cell type. This type of variation may be tied to a combination of dramatic and fine scale variation in DNase sensitivity. Summarizing DNase sensitivity as a series of DHSs discards information about quantitative differences and about differences in regions with lower sensitivity.In this work we explore a locally adaptive method for detecting and describing differences in chromatin accessibility by applying a recently developed method for comparing genomic profiles called Joint Adaptive Differential Estimate (JADE). JADE can be used to fit smooth DNase sensitivity profiles and identify regions where these profiles differ across phenotypic classes. In order to use JADE effectively, the smoothing strategy must be biologically informed and preserve meaningful variation while reducing the complexity of the problem. We explore adaptations of trend filtering for smoothing DNase I sensitivity data. We then apply JADE using these smoothing strategies to comparative analysis of DNase I profiles of small cell lung cancer cells classified as either sensitive or insensitive to drug therapy.

467T

ChIP-seq identifies the target genomic loci of the SMARCA6 helicase in human hematopoietic neoplasms. *J.A. Welch[1,2,3], D. Esopi[2], P. Shen[3], P. Schaughency[2,4], A. Skaist[2,4], S. Yegnasubramanian[2,4], K.H. Burns[1,3], S.J. Wheelan[1,2,4].* 1) McKusick-Nathans Institute of Genetic Medicine, The Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Oncology, The Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Pathology, The Johns Hopkins University School of Medicine, Baltimore, MD; 4) Next Generation Sequencing Center, Sidney Kimmel Comprehensive Cancer Center, Baltimore, MD.

The SMARCA6 helicase is a chromatin regulator that is thought to be important for somatic retrotransposon silencing. Like other Snf helicases, which promote transcriptional silencing in mammalian genomes, SMARCA6 has demonstrated DNA-dependent ATPase activity *in vitro*. SMARCA6 is known to interact with DNA methyltransferases DNMT1 and DNMT3B and histone deacetylases HDAC1 and HDAC2. In mice, chromatin immunoprecipitation has demonstrated an interaction between SMARCA6 and LINE, SINE, and IAP retrotransposons. Evidence from transgenic mouse models indicates that SMARCA6 function is required for retroelement silencing. Mice that are homozygous for a null mutation show decreased methylation of LINE, SINE, and IAP elements as well as derepressive H3 and H4 acetylation marks in IAPs and exhibit perinatal lethality. Defects in retroelement silencing are phenocopied in hypomorphic mice with targeted deletions of conserved helicase-encoding exons, and while viable, these animals display growth defects and age prematurely. Whether or not SMARCA6 is involved in retrotransposon silencing and localizes to retroelements in the human genome are open questions. The availability of a commercially manufactured polyclonal antibody specific to human SMARCA6 and the development of computational strategies to identify retrotransposons in high throughput sequencing data have positioned us to investigate the latter. To this end, we performed chromatin immunoprecipitation followed by sequencing (ChIP-seq) to identify the target loci of SMARCA6 in a human Burkitt lymphoma cell line. Here, we discuss our findings from these experiments.

Morpholino oligomers as a potential therapeutic option for correction of defective alternative splicing. *S. Tantzer[1], K. Sperle[1], G.M. Hobson[1,2].* 1) Nemours Biomedical Research, Alfred I. duPont Hospital for Children, Wilmington, DE; 2) Pediatrics, Thomas Jefferson University, Philadelphia, PA.

Most mutations of the proteolipid protein 1 gene (*PLP1* [MIM 300401]), including copy number changes and those affecting the coding sequence, cause the X-linked leukodystrophy Pelizaeus-Merzbacher disease (PMD [MIM 312080]). We recently showed that mutations reducing the *PLP1*/*DM20* alternative splice ratio have a distinctly different early phenotype on MRI called hypomyelination of early myelinating structures (HEMS). Although there are currently no cures for HEMS or the many other diseases that can be caused by disruption of alterative splicing, molecules that modulate aberrantly spliced products toward a more normal ratio have exciting therapeutic potential. We designed a morpholino oligomer (MO-PLP) to target the *DM20* 5' splice site, thereby increasing the *PLP1*/*DM20* ratio. Treatment of an immature oligodendrocyte cell line, Oli-neu, with MO-PLP significantly increased the endogenous *Plp1*/*Dm20* ratio as well as the *PLP1*/*DM20* ratio expressed from transfected minigene splicing constructs containing patient mutations known to reduce the *PLP1*/*DM20* ratio. Our previously published mouse model, PLP-ISEdel, carries one of these patient mutations, an intronic 19 base pair deletion of a splicing enhancer that causes a decrease in the *PLP1*/*DM20* ratio. A single intracerebroventricular injection of MO-PLP into neonatal PLP-ISEdel mice resulted in an increase in PLP/DM20 ratio of both RNA and protein in both brain and spinal cord. The effect lasted up to postnatal day 60, which is well beyond the early postnatal spike in myelination and PLP production. Our results suggest that morpholino oligomers have therapeutic potential for the treatment of HEMS and other diseases caused by misregulation of alternative splicing.

469T

Seeking drugs for Pelizaeus-Merzbacher disease using drug repositioning approach targeting a novel cellular pathology. *K. Inoue[1], H. Li[1], P.R. Mangalika[1], A. Nishizawa[1], Y. Numata[1], S. Nakamura[1], T. Morimura[1], H. Saya[2], Y. Goto[1].* 1) Dept MR & BD Res, Natl Inst Neurosci, NCNP, Kodaira, Tokyo, Japan; 2) Div Gene Regulation, Inst Advanced Medical Research, Keio Univ, Tokyo, Japan.

Pelizaeus-Merzbacher disease (PMD) is the most common, but incurable inherited hypomyelinating leukodystrophy caused by various mutations in the *PLP1* gene, which encodes a major myelin membrane lipid-protein. PLP1 amino acid substitutions often cause severe form of PMD. Although it has been thought that activation of the apoptotic pathway of unfolded protein response (UPR) triggered by accumulation of the mutant PLP1 in endoplasmic reticulum (ER) is the major cellular mechanism for oligodendrocyte cell death, attenuation of this pathway doesn't rescue the cellular phenotypes, suggesting an involvement of other underlying mechanisms. We recently identified that mutant PLP1 also interfere with intracellular transport of other normal membrane and secretary proteins, possibly affecting the normal cellular physiology. This finding has raised a hypothesis that the mutant PLP1-induced dysfunction of secretary pathway may serve as another cellular mechanism for PMD and the drugs that can enhance the transport of secretary and membrane proteins may rescue the cellular phenotype caused by mutant PLP1. To identify such drugs, we have established a screening system using HeLa cells transiently co-expressing mutant PLP1 and secretable-form luciferase reporter. We have screened a library of 1400 existing medicine, so that our findings are immediately applicable to the clinical study. We next tested if the selected compounds can also rescue the abnormal intracellular localization of KDEL receptor that is normally present in Golgi apparatus but is mislocalized in ER when co-expressed with mutant PLP1. Using these screening systems, we have identified 20 compounds that can correct the reduced intracellular transport of normal secretary and membrane proteins. These compounds may serve as potential candidates for the treatment of PMD caused by amino acid substitutions.

470W

Rapamycin as a novel treatment for vascular malformations caused by somatic mutations that activate the PI3K>AKT signaling pathway. *L. Boon[1,2], J. Hammer[1], E. Seront[3], S. Dupont[4], F. Hammer[5], Ph. Clapuyt[6], M. Vikkula[2,7].* 1) Centre Vascular Anomalies, Division of Plastic and Reconstruction Surgery, Cliniques universitaires St-Luc, Università catholique de Louvain, Brussels, Belgium; 2) Human Molecular Genetics, de Duve Institute, Università catholique de Louvain, Brussels, Belgium; 3) Department of Medical Oncology, Cliniques universitaires St-Luc, Università catholique de Louvain, Brussels, Belgium; 4) Pediatric Oncology, Cliniques universitaires St-Luc, Università catholique de Louvain, Brussels, Belgium; 5) Department of Interventional Radiology, Cliniques universitaires St-Luc, Università catholique de Louvain, Brussels, Belgium; 6) Pediatric Radiology, Cliniques universitaires St-Luc, Università catholique de Louvain, Brussels, Belgium; 7) WELBIO (Walloon Excellence in Lifesciences and Biotechnology), de Duve Institute, Università catholique de Louvain, Brussels, Belgium.

Background: Venous and lymphatic malformations (VM and LM) are congenital lesions composed of ectatic veins or lymphatic cysts, respectively. They have an incidence estimated at 1/2.000 and 1/10.000, respectively. They often cause deformity, pain, local intravascular coagulopathy or chronic infection. Inherited VMs (VMCM) are caused by germline TIE2 mutations, whereas sporadic VMs are often caused by somatic TIE2 mutations. Sporadic LMs and combined malformations are caused by somatic PIK3CA mutations.**Purpose:** The identification of the molecular bases and activation of the downstream PI3K-AKT signaling pathway opened the door for development of precision therapies. We assessed the efficacy and safety of Rapamycin, an mTor inhibitor, as a possible therapy for patients with difficult-to-treat slow-flow malformations.**Methods:** The trial is registered under VASCA-LM at clinicaltrials.gov (NCT01811667). Eighteen patients aged from 3 to 64 years with refractory-to-standard-care LM, VM and/or complex vascular anomaly were enrolled. Informed consent was obtained. Clinical symptoms included chronic daily debilitating pain, functional impairment, recurrent infections, and daily gastrointestinal bleeding. Efficacy was evaluated by anamnesis of symptoms, repeated evaluation of pain, quality of life and clinical parameters, and photographs of the lesions. Blood tests included D-dimer and fibrinogen measurements. A global self-evaluation percentage of increase/decrease in quality of life was recorded, as well as side effects, according to CTCAE version 3. Volumetric MRI was performed before initiation and at a yearly bases.**Results:** Fifteen patients reached 12 months follow-up. All patients with LMs, 6/7 patients with VMs and all patients with complex vascular anomalies experienced important relief of pain and symptoms, improved functional restraint and self-perceived quality of life. A statistically significant reduction in volume was observed with MRI with patients that reached one-year follow-up. Known side effects were not infrequent.**Conclusion:** Results from this clinical pilot study demonstrate that rapamycin can be a therapeutic option for refractory-to-standard-care slow-flow vascular malformations, which classically exhibit PI3K>AKT activation. Similar results were seen in a mouse model of VMs generated by activating TIE2 mutations. Therefore, rapamycin has great promise as the first molecular therapy for difficult-to-treat slow-flow vascular malformations.

471T

The Inflammasome: A Novel Concept in VCP Disease. *A. Nalbandian[1], A. Khan[2], R. Srivastava[2], K. Llewellyn[1], V. Kimonis[1], L. BenMohamed[2].* 1) University of California, Irvine; 2) Gavin Herbert Eye Institute.

Valosin Containing Protein (VCP) disease, discovered in 2000, is caused by mutations in the gene encoding *Valosin-Containing Protein (VCP)*. The spectrum of phenotypes associated with VCP mutations continues to expand, including disorders with overlapping pathogenesis, such as Inclusion Body Myositis (IBM) in 80%, Paget's Disease of Bone (PDB) in 50%, Frontotemporal Dementia (FTD) in 33%, and Amyotrophic Lateral Sclerosis (ALS) in 15% individuals. VCP disease patients exhibit progressive proximal limb girdle muscular weakness and eventually die from progressive muscle weakness and cardiac and respiratory failure. Histologically, patients show the presence of rimmed vacuoles and TAR DNA-binding protein 43 (TDP-43)-positive large ubiquitinated inclusion bodies in the muscles. Several studies have investigated the onset of VCP-associated myopathy, however to our knowledge, we are the first group to explore the inflammasome signaling network in this disease. We discovered induction of NLRP3-mediated inflammasome in inflammatory macrophages and neutrophils may possibly contribute to inflammation and muscle-related tissue damage observed in VCP disease. Such inflammation might be triggered by ROS, NOS or, other yet-to-be determined inflammatory mechanisms, in damaged muscle tissues; and blocking one or several of pathways of NLRP3 inflammasome checkpoints in VCPR155H/+ heterozygote mice may reduce muscle-related inflammation and tissue damage resulting in robust and sustained therapeutic effect. We also detected an increase in the IL-1b inflammatory cytokine and Caspase 1. These findings suggest that targeting the inflammasome pathway by pharmacological inhibitors may ameliorate an increasing list of disorders and can now include in VCP disease and related neurodegenerative multisystem proteinopathies.These findings suggest that targeting the mTOR pathway and restoring autophagic flux ameliorate an increasing list of disorders and can now include in VCP disease and related neurodegenerative multisystem proteinopathies. In conclusion, this pre-clinical study in VCPR155H/+ heterozygote mice may lead to a novel and powerful immunotherapy for patients suffering from VCP- and associated neurodegenerative diseases.

472W

Efficacy and Safety of Diazoxide Choline Controlled-Release Tablet in Patients with Prader-Willi syndrome. *A. Surampalli[1], M. Wencel[1], JA. Gold[1,2,3], NM. Cowen[4], V. Kimonis[1].* 1) Division of Genetics and Genomics, Department of Pediatrics, University of California Irvine, School of Medicine, Irvine, CA; 2) Loma Linda University School of Medicine, Loma Linda, CA; 3) Children's Hospital of Orange County, Orange, CA; 4) Essentialis, Inc. Carlsbad, CA.

Prader-Willi syndrome (PWS) is a complex, multi-system genetic syndrome affecting 1:10,000-1:30,000 males, females and all ethnicities. PWS is the most common syndromic form of obesity. PWS patients have a characteristic behavior disorder, mild intellectual disability, hypotonia, hypothalamic-pituitary axis dysfunction, growth hormone (GH) deficiency, hypogonadism, other hormonal deficiencies, short stature, centrally- hyperphagia, obesity, reduced lean mass and reduced energy expenditure. Diazoxide choline controlled-release tablets (DCCR) works by mimicking sensitivity to leptin and insulin in AgRP and POMC neurons, reducing de-novo fatty acid biosynthesis, stimulating β-oxidation of fat and normalizing GABA response, reducing hyperphagia, fat mass and aggressive behavior in PWS patients.Thirteen obese subjects with genetically confirmed diagnosis of PWS, between 10-22yrs were enrolled in the study PC025. Two subjects were withdrawn from the study due to a prior psychiatric illness in one and progressively compromised glycemic control at the highest dose in the other. Eleven subjects completed the open-label treatment phase, were designated as Responders (hyperphagia response rate 92%) and randomized into the double-blind phase of the study. Data was analyzed for both open-label treatment phase and double-blind phase.We found significant improvements in hyperphagia in DCCR treated subjects at the end of the open-label treatment period (-31.6%, p=0.003) and in those who continued on DCCR in the double blind phase (-29.2%, p=0.006). There was significant reduction in 'aggressive', 'threatening' , 'destructive' behavior in comparison to all other PWS associated behaviors at the end of open label treatment phase (62.5% Vs 29.8% respectively, p=0.01). The effect of DCCR on behavior seems to be independent of the effect on hyperphagia. Significant impacts were seen on fat mass (-3.8%, p=0.011), lean body mass (+5.4%, p=0.001), lean body mass/fat mass ratio (+9.8%, p=0.002) during open-label treatment. The impacts on body composition were of similar magnitude in GH treated and GH naïve subjects. DCCR treatment significantly reduced TG, Tot-C, and Non-HDL-C in both the open-label and double blind phase.The safety profile of DCCR in PWS subjects was consistent with prior studies. The most common adverse events included peripheral edema which was responsive to dose reduction and diuretics, and transient hyperglycemia.

473T

Histone Deacetylase Inhibitor Reverses Promoter Silencing in Friedreich Ataxia. *S. Bidichandani[1], Y. Chutake[1], C. Lam[1], W. Costello[1], M. Anderson[2].* 1) Dept of Pediatrics, Section of Genetics, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Dept of Biostatistics & Epidemiology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Friedreich ataxia (FRDA) is caused by an expanded GAA triplet-repeat (GAA-TR) mutation in the *FXN* gene, and patients are typically homozygous for expanded alleles containing 100–1300 triplets. Patients have a severe deficiency of *FXN* transcript, which is predominantly caused by epigenetic silencing of the *FXN* promoter. We sought to determine if a class I histone deacetylase (HDAC) inhibitor that is currently being developed as a rational therapy for FRDA is able to reverse *FXN* promoter silencing. Patient-derived lymphoblastoid cell lines bearing a range of expanded alleles (200–1122 triplets) were evaluated for *FXN* transcript levels by quantitative RT-PCR following treatment with the 2-aminobenzamide derivative drug, 109 or a related but inactive compound, 966. *FXN* transcript levels increased ~2-fold ($p<0.001$) upon treatment with 109 (but not 966), both upstream and downstream of the expanded GAA-TR mutation, suggesting that the increase is due to improved promoter function. *FXN* promoter function was directly measured by quantitative analysis of transcriptional initiation via metabolic labeling of newly synthesized transcripts in living cells, which revealed that 109 (but not 966) resulted in a ~3-fold increase in both transcriptional initiation ($p<0.01$). *FXN* promoter structure was measured via Nucleosome Occupancy and Methylome Sequencing (NOMe-Seq), a high-resolution *in vivo* footprint assay for nucleosome occupancy in individual chromatin fibers, which revealed that 109 (but not 966) resulted in a ~3-fold increase in chromatin accessibility ($p<0.0001$) at the *FXN* promoter. Epigenetic promoter silencing in FRDA is therefore reversible, and the results implicate class I HDACs in repeat-mediated promoter silencing.

Phase 3 and long-term extension study with migalastat, a pharmacological chaperone, demonstrate stable renal function, reduced left ventricular mass and gastrointestinal symptom improvement in patients with Fabry disease. *D.P. Germain[1], D.G. Bichet[2], R. Giugliani[3], D. Hughes[4], R. Schiffmann[5], W. Wilcox[6], J. Castelli[7], E.R. Benjamin[7], J. Yu[7], N. Skuban[7], J. Barth[7].* 1) Division of Medical Genetics, University of Versailles, Montigny, France; 2) Hôpital Sacré-Coeur, University of Montreal, Canada; 3) Medical Genetics Service, HCPA/UFRGS Porto Alegre, Brazil; 4) Royal Free Campus, University College London, UK; 5) Baylor Research Institute, Dallas, TX; 6) Department of Human Genetics, Emory University, Georgia; 7) Amicus Therapeutics, Cranbury, NJ, USA.

Background: Fabry disease (FD) is a progressive, devastating X-linked genetic disorder caused by the deficient activity of lysosomal alpha-galactosidase. **Objectives**: Migalastat (1-deoxygalactonojirimycin, AT1001) is an orally-administered investigational pharmacological chaperone for Fabry disease that selectively binds and stabilizes α-Gal A, leading to increased lysosomal activity. Study 011 (AT1001-011, NCT00925301) included a 6-month double-blind placebo-controlled period (Stage 1) and an 18 month open-label extension. Sixty-seven subjects were randomized; 48 subjects completed the study and continued in long term extension Study AT1001-041. **Methods**: Estimated GFR (eGFR) was assessed every 3-6 months using the CKD-EPI and MDRD equations. Left ventricular mass index (LVMi) was assessed by echocardiography every 6-12 months by a blinded central laboratory. Gastrointestinal symptoms were assessed every 6 months using the Gastrointestinal Symptom Rating Scale (GSRS). p-values are unadjusted for multiple comparisons. Efficacy results are reported for the 50 subjects with amenable *GLA* mutations. **Results**: eGFR remained stable in subjects treated up to 48 months, with mean annualized eGFR changes (±SEM) of -0.80±0.60 (CKD-EPI) and +0.70±0.80 (MDRD) mL/min/1.73m2/yr. LVMi was significantly reduced in subjects treated up to 48 months (-8.0 ±5.5 g/m2); the largest reductions were observed in subjects with abnormal LVMi at baseline (-17.2±16.5 g/m2). Improvement was observed in the diarrhea domain of GSRS during the 6-month double-blind period (-0.3 migalastat, +0.2 placebo, p=0.03), and in diarrhea, indigestion and reflux domains during the open-label extension. **Conclusions**: Treatment with migalastat for up to 48 months was associated with stable renal function, reduced LVMi and improved gastrointestinal symptoms in patients with Fabry disease who have amenable *GLA* mutations.

***Hydroxyurea induces γ-globin expression through microRNAs-mediated actions in human hematopoietic and K562 erythroleukemia cells.*.** *D.G. Pule[1], S. Mowla[2], N. Novitzky[2], A. Wonkam[1].* 1) Human Genetics, Clinical Laboratory Sciences, University of Cape Town, Cape Town, Western Cape, South Africa; 2) Hematology, Clinical Laboratory Sciences, University of Cape Town, Cape Town, Western Cape, South Africa.

Background: Hydroxyurea is the only available drug treatment for Sickle Cell Disease (SCD); but the mechanism of fetal hemoglobin (HbF) induction is poorly understood. In particular, the role of microRNAs in the post-transcriptional regulation of HbF, through potent regulators such as *MYB, BCL11A* and *KLF-1,* is understudied.**Objectives:** We have investigated the role of microRNAs in the post-transcriptional regulation of HbF in erythroid cells treated with hydroxyurea.**Methods:** As models, we used 1) hematopoietic stem cells derived from umbilical cord blood (HSCs) and 2) the K562 human erythroleukemia cell line. Both primary erythroid and K562 cells were treated with hydroxyurea and changes in *BCL11A*, *KLF-1*, *GATA-1*, *MYB,* β- and γ-globin gene expression and 7 targeted miRNAs, previously shown to be modified by hydroxyurea or associated with basal γ-globin expression were also investigated. **Results:** We differentiated CD34+ stem cells into erythroid precursors using a single-phase expansion and differentiation protocol. *BCL11A* was down-regulated and there was a marked 7-fold increase ($p < 0.003$) in γ-globin expression in both primary human erythroid and K562 cells. Down-regulation of *GATA-1* was also consistent with the above findings. Similarly, *KLF-1* was down-regulated in both cell models, corresponding to the repressed expression of *BCL11A* and β-globin gene ($p < 0.04$). In both cell models, most miRNAs was significantly up-regulated by hydroxyurea with some level of variation. Down-regulation of, another potent negative regulator of γ-globin and direct target of the up-regulated miR-15a and miR-16-1, provides a post-transcriptional tier of HbF regulation. We also demonstrated that the inhibition of miR-26b; miR-151-3p and miR-451 resulted in an apparent decrease in HbF.**Conclusions:** The data provide evidence of a microRNAs-mediated post-transcriptional mechanism for γ-globin regulation under hydroxyurea treatment. These findings will add a unique piece to our understanding of HbF regulation and incite further investigation of the post-transcriptional regulatory network for HbF expression.

476W

High-content screening for small molecule inhibitors of facioscapulohumeral dystrophy. *S.J. Palmer[1], L. Caron[2], E. Eiffe[1], A. Heaton[1], U. Schmidt[2].* 1) Novogen Laboratories Ltd, 16-20 Edgeworth David Ave, Hornsby, Sydney, NSW 2077 Australia; 2) Genea Biocells, Level 3, 321 Kent St, Sydney NSW 2000 Australia.

Facioscapulohumeral muscular dystrophy (FSHD1 [MIM 158900] and FSHD2 [MIM 158901]) is the third most common form of MD with a prevalence of 1:14,000-20,000. It initially weakens the muscles of the face and upper limb girdle, and progresses to affect most skeletal muscles. It is caused by a deletion in a subset of the D4Z4 macrosatellite repeats in the subtelomeric region of chromosome 4 (FSHD1) or a mutation in the *SMCHD1* gene (FSHD2) that regulates the epigenetic status of the D4Z4 locus. Both forms of the disease result in decreased epigenetic repression of the locus and myogenic mis-expression of the *DUX4* retrogene located in the D4Z4 repeats. Evidence indicates that the DUX4 double homeobox transcription factor initiates a cascade of inappropriate gene expression that inhibits myogenesis, increases oxidative stress, induces muscle atrophy and activates autoimmune responses. In order to develop an efficient in vitro screening system to identify novel small molecule drugs combatting the disease, embryonic stem (ES) cell lines were isolated from human embryos diagnosed with FSHD1 as part of the preimplantation genetic diagnosis service for FSHD-affected families. FSHD ES cell lines were grown in myogenic differentiation media to create myotubes that model aspects of the adult disease. In comparison with controls, the FSHD ES lines demonstrated detectable *DUX4* expression, attenuated myotube morphological parameters and an altered transcriptional profile. Correction of these criteria in vitro provides a basis for high-content screening of novel small molecule therapeutics. A large body of evidence indicates that the isoflavone molecule, genistein, can permanently modify epigenetic marks in the genome, which was elegantly demonstrated in mice carrying the epigenetic reporter allele, *Avy*. Maternal genistein supplementation increased repeat-mediated gene silencing of the locus and increased the frequency of the pseudoagouti coat colour in the offspring. Therefore, genistein and related isoflavonoid structures could increase repeat-mediated gene silencing of the D4Z4 locus in stem cells within the skeletal muscle niche, thus blocking *DUX4* expression and halting the progress of FSHD. We screened a series of novel genistein-related isoflavonoids using the FSHD ES cell assay described, which led to the identification of several lead compounds that fulfil the rescue criteria and could form the basis of the first drug treatment for this currently incurable disease.

477T

The small molecule aldehyde trap NS2 represents a pharmacological approach to enzyme replacement therapy for SSADH deficiency (SSADHD). *G.R. Ainslie[1], K.R. Vogel[1], V.C. Cullen[2], S.L. Young[2], T.C. Brady[2], K.M. Gibson[1].* 1) Experimental and Systems Pharmacology , Washington State University, Spokane, WA., USA; 2) Aldeyra Therapeutics, Inc., Lexington, MA, USA.

Succinic semialdehyde dehydrogenase (SSADH; ALDH5A1) deficiency (SSADHD; MIM 271980) is the most prevalent inherited disorder of 4-aminobutyrate (GABA) degradation. The phenotype includes developmental delay, hypotonia and expressive language impairment in childhood, and various neuropsychiatric aspects, including obsessive-compulsive disorder, in adolescence and adulthood. Epilepsy occurs in 50% of patients. Accumulation of the enzyme substrate succinic semialdehyde (SSA) associates with elevations in both GABA and the related neuromodulator, gamma hydroxybutyrate (GHB), as well as a number of other potentially toxic metabolites, including the aldehyde 4-hydroxy-2*E*-nonenal (4-HNE). Current treatment approaches target GABAergic signaling, with mixed results. Aldeyra Therapeutics has developed a small molecule aldehyde trap, NS2, which has an excellent safety profile and which is currently in a clinical trial for another genetic disease of aldehyde metabolism (Sjogren-Larsson Syndrome). We hypothesized that NS2 can trap SSA and therefore prevent its accumulation, thus indirectly lowering downstream disease markers such as GABA, GHB and 4-HNE. In this way, NS2 represents a novel therapeutic approach to SSADH deficiency by targeting the disease at its root cause. Here, we show that NS2 can react *in situ* with SSA, and additionally with 4-HNE, forming the NS2-SSA and NS2-4HNE adducts, respectively, which can be detected by LC MS/MS. This aldehyde trapping was shown to occur under physiological pH conditions, and was rapid, attaining completion in 1.5-2 hours. Initial pharmacokinetic studies in mice completely deficient for SSADH demonstrated that, after a single intraperitoneal bolus administration at 10 mg/kg, NS2 attained micromolar concentration in serum, and reached all target organs tested (brain, liver, kidney). Moreover, NS2 was able to trap SSA *in vivo* in these mice, as confirmed by the detection of the NS2-SSA adduct in target tissues 8 hours post-dose. These studies form the basis for testing NS2 in a repeated-dosing paradigm (previously shown to be non-toxic in other rodent studies) for improvement of metabolic, neurological, and lifespan outcomes. If successful, these preclinical studies may lead to trials of NS2 in SSADH-deficient patients. Aldehyde trapping may thus represent a novel, pharmacological enzyme replacement therapy for SSADH deficiency and other Mendelian disorders in which reactive aldehydes accumulate.

478W

Effects of oral eliglustat on bone parameters in treatment-naïve patients with Gaucher disease type 1: results from the phase 3, randomized, placebo-controlled ENGAGE trial after 18 months. *P. Mistry[1], D.J. Amato[2], M. Dasouki[3], S. Packman[4], G.M. Pastores[5], S. Assouline[6], M. Balwani[7], A. Ortega[8], S.S. Shankar[9], M.H. Solano[10], L.H. Ross[11], J. Angell[11], M.J. Peterschmitt[11].* 1) Yale University School of Medicine, New Haven, CT; 2) Mount Sinai Hospital, Toronto, Canada; 3) University of Kansas Hospital, Kansas City, KS; 4) UCSF School of Medicine, San Francisco, CA; 5) New York University School of Medicine, New York, NY; 6) Jewish General Hospital, Montreal, Quebec, Canada; 7) Mt. Sinai Hospital, New York, NY; 8) OCA Hospital, Monterrey, Mexico; 9) Emory University, Atlanta, GA; 10) Hospital de San Jose-Fundacion de Ciencias de la Salud, Bogota, Colombia; 11) Genzyme, a Sanofi company, Cambridge, MA.

Background: Manifestations of Gaucher disease type 1 (GD1) include splenomegaly, hepatomegaly, anemia, and thrombocytopenia. Patients are also at risk of bone complications, including decreased bone mineral density, increased risk of pathogenic fractures and joint collapse, and chronic bone pain. Eliglustat is an oral substrate reduction therapy approved for the treatment of adults with GD1. Safety and efficacy of oral eliglustat were evaluated in the placebo-controlled ENGAGE trial (NCT00891202; sponsored by Genzyme, a Sanofi company). All primary and secondary endpoints were met in the 9-month primary analysis period (Mistry et al., *JAMA* 2015;311:695-706).**Methods:**After the primary analysis, 39 of 40 patients entered a 9-month, open-label extension phase in which all patients received eliglustat. Bone evaluations during both phases of the trial included changes from baseline in bone marrow infiltration, bone marrow burden (BMB) score, and lumbar spine T- and Z-scores.**Results:**At baseline, 80% (16/20) of eliglustat patients and 75% (15/20) of placebo patients had marked to severe total BMB scores. After 9 months, significant improvements (eliglustat vs. placebo) were observed for spine and femur BMB scores; spine Z-scores also improved. Among patients receiving eliglustat for 18 months who had bone data available (n=18), improvements continued during the extension period (mean changes from baseline: total BMB: -2.15; lumbar spine T-score: +0.19, lumbar spine Z-score=+0.26). For patients switched from placebo to eliglustat (n=20), mean changes from baseline after 9 months of eliglustat were: total BMB: -0.94, lumbar spine T-score: +0.03, and lumbar spine Z-score: +0.03. No new safety concerns were identified. **Conclusions:**Patients receiving eliglustat for 18 months continued to show improvement in bone parameters beyond the initial 9-month primary analysis period.

479T

Stability is maintained in adults with Gaucher disease type 1 switched from velaglucerase to eliglustat or imiglucerase: a sub-analysis of the eliglustat ENCORE trial. *R. Pleat[1], T.M. Cox[2], T.A. Burrow[3], P. Giraldo[4], O. Goker-Alpan[5], B.E. Rosenbloom[6], J. Angell[1], L. Croal[1], L. Underhill[1], M.J. Peterschmitt[1].* 1) Genzyme, a Sanofi company, Cambridge, MA; 2) Department of Medicine, Addenbrooke's Hospital, University of Cambridge, Cambridge, UK; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Centro de Investigación Biomédica en Red de Enfermedades Raras, (CIBERER), Zaragoza, Spain; 5) Lysosomal Disorders Research and Treatment Unit, Center for Clinical Trials, O&O Alpan, LLC, Springfield, VA; 6) Cedars-Sinai/Tower Hematology Oncology, Beverly Hills, CA.

Introduction: Gaucher disease type 1 (GD1) is an autosomal recessive disorder caused by deficiency of the lysosomal enzyme acid-β-glucosidase resulting in accumulation of glucosylceramide. Clinical manifestations include anemia, thrombocytopenia, hepatosplenomegaly, and skeletal disease. The current standard of care is enzyme replacement therapy (ERT). Eliglustat, an oral substrate reduction therapy, was recently approved for the long-term, first-line treatment of adults with GD1 who are extensive, intermediate or poor CYP2D6 metabolizers. The 12-month ENCORE trial (NCT00943111; Genzyme) found oral eliglustat non-inferior to imiglucerase in maintaining disease stability in adults with GD1 who had achieved pre-specified therapeutic goals after ≥3 years of ERT (Cox, *Lancet* 2015:25Mar.pii:S0140-6736(14)61841-9).**Methods:**This post-hoc analysis examined safety and efficacy in the 30 ENCORE patients whose treatment at study entry was velaglucerase alfa: 22 of whom were randomized to eliglustat and 8 to imiglucerase. The composite primary efficacy endpoint was the percent of patients meeting all 4 pre-specified stability parameters in spleen (≤25% increase from baseline [BL]), liver (≤20% increase from BL), hemoglobin (≤1.5 g/dL decrease from BL) and platelets (≤25% decrease from BL).**Results:**Mean duration of velaglucerase treatment prior to study entry was 1.34 years at a mean dose of 49.9 U/kg/2weeks. After 12 months of eliglustat, 90% of velaglucerase-transitioned patients maintained all four stability goals; separately, 95% of patients maintained goals for hemoglobin and platelets and 100% of patients for spleen and liver. Mean ± SD changes from BL for patients transitioned to eliglustat were: spleen volume (multiples of normal [MN]), -1% ± 8.7; liver volume (MN), 1.6% ± 7.9; hemoglobin (g/dL), -0.42 ± 0.62; and platelets, 1% ± 25.9. Data were comparable in velaglucerase-transitioned patients switched to imiglucerase. Among all velaglucerase-transitioned patients, most adverse events were mild/moderate; there were no treatment-related serious adverse events, and 1 eliglustat patient discontinued treatment due to an adverse event (palpitations, moderate, possibly-related).**Conclusions:**Efficacy and safety results in velaglucerase-transitioned patients randomized to either eliglustat or imiglucerase were consistent with the full ENCORE trial population. In both groups, clinical stability was maintained and the treatments were well-tolerated.

Gene Expression Profiling of Whole Blood from TNF Receptor-Associated Periodic Syndrome (TRAPS) Patients to Understand Response to Canakinumab Treatment. *R.I. Torene[1], M. Gattorno[2], H. Lachmann[3], L. Obici[4], A. Meini[5], V. Tormey[6], R. Caorsi[2], L. Baeriswyl[7], U. Affentranger[7], S. Starck-Schwertz[7], M. Letzkus[7], N. Hartmann[7], K. Abrams[8], N. Nirmala[1].* 1) Biomarker Development, Novartis Institutes for Biomedical Research, Cambridge, MA; 2) G. Gaslini Institute, Genova, Italy; 3) Royal Free Hospital, London, United Kingdom; 4) Amyloid Centre, IRCCS Policlinico San Matteo, Pavia; 5) Pediatric Clinic, Spedali Civili, Brescia, Italy; 6) Galway University Hospitals, Galway, Ireland; 7) NIBR, Basel, Switzerland; 8) Novartis Pharmaceuticals Corporation, New Jersey, USA.

Purpose: TRAPS is an autosomal dominant condition resulting from variants in the TNF super family receptor 1A (*TNFRSF1A*) gene. Thus far, >100 different allelic variants, including SNPs, indels, and complex variants, in this gene have been identified in TRAPS patients. It is an autoinflammatory disease causing unprovoked fevers, myalgia, abdominal pain, rash, headaches, and, in severe cases, AA amyloidosis. Canakinumab is a high-affinity, human, selective, anti-IL-1b monoclonal antibody, developed for the treatment of autoinflammatory diseases. The purpose of this study was to determine whether gene expression in whole blood can support a molecular mechanism for the activity of canakinumab in TRAPS patients.**Methods:** Twenty patients with active TRAPS received open-label canakinumab 150 mg sc/month for 4 months in an efficacy and safety study. Whole blood was collected at baseline, Day 15 and Day 113 from 19 of these patients and 1 sample each from 19 untreated age-matched healthy volunteers for analysis of gene expression levels by microarrays.**Results:** All 20 patients, regardless of *TNFRSF1A* allelic variant, improved upon treatment. Gene expression profiles of these patients shifted towards that of healthy volunteers. The disease-causing gene (*TNFRSF1A*), drug target gene (*IL-1b*), and other inflammation related genes (e.g., *MAPK14 and NFKB*) were down-regulated after treatment and several inflammation related pathways were evident among the differentially expressed genes. Many of the differentially expressed genes had expression levels that correlated with neutrophil count, however, neutrophil count alone could not account for the expression differences observed.**Conclusions**: Altogether, the gene expression data support a model in which canakinumab increases neutrophil apoptosis and reduces pro-inflammatory signals through its inhibition of IL-1b. Canakinumab is able to reverse the overexpression of several genes associated with inflammatory response, including *IL-1b*. Interestingly, IL-1b blockade normalized the overexpression of the disease-causing gene, *TNFRSF1A*, at the RNA level, suggesting a direct impact on the main pathogenic mechanism of TRAPS.

Impact of NGS in rare diseases: Identification of novel biological pathways and therapeutic development in nemaline myopathy. *V.A. Gupta, A. Cankaya, A. Kondo, A. Krapf, A.H. Beggs.* Division of Genetics and Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital, Harvard Medical School, Boston, MA 02115, USA.

Next generation sequencing has opened new avenues in understanding the genetic causes of hereditary disorders. Unbiased sequencing of the human genome/exome has resulted in identification of novel genes and pathways that were previously inconceivable using traditional genetic approaches. This is particularly evident in rare genetic disorders that suffer from the limitations of small sample size and clinical heterogeneity making gene discovery very challenging. Nemaline myopathy (NM) is a rare genetic disease that is characterized by generalized skeletal muscle weakness. NMs form a highly heterogeneous group of myopathies ranging from fetal akinesia, through severe congenital forms with death from respiratory failure during the first year of life, to a mild-childhood onset myopathy with survival into adulthood. Approximately, 75% of known genes in genetically diagnosed patients encode structural proteins constituting the sarcomeric thin filaments of skeletal muscle, limiting the prospect of developing specific therapies. Using whole exome/genome sequencing in 95 NM patients, we had identified mutations in a novel kelch protein encoding gene, *KLHL41*, in five unrelated families. Unlike previously known thin filament-associated NM genes, Kelch proteins function as substrate-specific adaptors for cullin E3 ubiquitin ligase, a core component of the ubiquitin-proteasome system to regulate protein turnover. Immunofluorescence studies in patients' skeletal muscles with *NEB* and *ACTA1* mutations showed highly reduced levels of proteasomal complexes suggesting a crucial role of KLHL41 in the proteasomal pathway in nemaline myopathy. As mutations in *NEB* affect 50% of genetically diagnosed cases in NM, we evaluated the effect of proteasome regulation in restoring muscle function in nebulin deficiency in a zebrafish model. Treating *neb* -/- zebrafish with small chemicals targeting the proteasomal pathway resulted in improved skeletal muscle function. These studies provide promising novel therapeutic targets for developing treatments for nemaline and related muscle diseases for which no treatment is available yet. This signifies the impact of next generation genomic approaches in translating gene discoveries into therapeutic developments that will have tremendous impact on improving the quality of life in patients affected with rare diseases.

Systemic induced loss of NF1 in adult mouse is lethal. *A.N. Turner, K. Li, T.R. Schoeb, B.R. Korf, R.A. Kesterson.* Department of Genetics, University of Alabama at Birmingham, Birmingham, AL.

Mutations in the Neurofibromatosis type 1 (NF1) can manifest in numerous tissues as a result of loss of neurofibromin protein function(s), one of which is negative regulation of p21ras (Ras) signaling via a known GTPase activating (Ras-GAP) domain. Other potential functions of the multi-domain NF1 protein are less clear with biallelic inactivation of the NF1 gene leading to an embryonic lethal phenotype. Our lab is currently creating and characterizing mice with recurrent nonsense mutations found in NF1 patients to recapitulate the premature termination codons (PTCs) found in humans, thereby providing a model for therapeutic intervention studies (e.g. nonsense suppression therapy (NST) that enhances the insertion of an amino acid at a PTC and allows translation to proceed to produce a full-length protein). Thus, we created a novel NF1 mouse line carrying a recurrent nonsense mutation found in NF1 patients at exon 18 (c. 2041 C>T; p. Arg681Ter, Nf1st18), which when combined with a conditional knockout allele (Nf1Flox) in the proper context will develop spinal cord tumors. While our goal is to develop therapeutic interventions to inhibit or treat developing tumors associated with NF1 loss, the development of tumors in NF1 mouse models is a time consuming and costly experimental process. Therefore, we established an “acute” conditional knockout model using a tamoxifen-inducible CAGGCre-ER recombination system to gain a better understanding of the role of NF1 in the adult mouse and to develop more rapid methods of assessing neurofibromin function in response to treatment. Following inactivation of floxed NF1 allele(s), adult NF1F/F; CAGGCre-ER mice lose function of NF1 systemically and are not able to survive beyond 12 days with animals showing severe damage to mitotically active cells throughout the body, including hematopoietic cells. Similarly, mice harboring the PTC Nf1st18 allele along with a single floxed NF1 allele (NF1St18/F; CAGGCre-ER) fail to survive more than 12 days following inactivation of the floxed allele. This model allows rapid testing of nonsense suppression drugs, and the identification of NF1 sensitive cells and tissues in the adult for a more robust readout of NF1 activity to complement our current ongoing tumor studies.

Caveolae-mediated uptake of a-galactosidase A in Fabry disease *in vitro* systems. *E. Changsila, O. Goker-Alpan, T. Taber, C. Martin, C. Sejpal, M. Ivanova.* Lysosomal and Rare Disorders Research and Treatment Center, Fairfax, VA, USA.

Fabry disease (FD) is a lysosomal storage disorder due to the deficiency of the lysosomal enzyme a-galactosidase A, resulting in cardiac, renal and cerebrovascular end-organ injury. Two human recombinant a-galactosidase A (rh-aGAL-A) preparations are available as enzyme replacement therapy (ERT) for FD, however only a-galactosidase beta (Fabrazyme), has been approved in the USA. Despite of ERT, there is still a significant mortality associated with FD, suggested to be a result of lack of delivery of rh-aGAL-A to different cell types with similar efficiency. Although, mannose-6-phosphate receptor (M6PR) dependent endocytosis is believed to be the major pathway for intracellular processing of rh-aGAL-A, other mechanisms mediated by megalin, sortilin, and even passive diffusion have been implicated in different cells.We investigated the uptake and intracellular transport of rh-aGAL-A *in vitro* in cell types affected in Fabry disease including; fibroblasts derived from patients with FD and healthy controls, neuronal cells (HCN2), and embryonic kidney cells (HEK293), mainly focusing on mannose-6-phosphate receptor(M6PR)-dependent endocytosis. Enzyme uptake was measured by a-galactosidase assay, using fluorescent labeling and microscopy. Inhibitors of M6PR (mannose-6-phosphatase, or M6PR neutralized antibody), caveolae inhibitor (Filipin) and the microtubule depolymerization inhibitor (nocodazole) were used to study the endocytic process. We report that the efficiency of enzyme uptake is cell type specific. The time to maximum enzyme load was 3h for fibroblasts *vs* 6h for HCN2 cells. HEK293 cells demonstrated biphasic uptake with the first maximum occurring 1h after treatment followed by return to the basal levels and the second peak 24h after treatment. Uptake of rh-aGAL-A into lysosomes during the initial hours is achieved by caveolae-mediated endocytosis, as evidenced by the inhibition in presence of Filipin. Nocodazole blocked the uptake in all cell lines including fibroblasts from patients with FD. Unexpectedly, M6PR inhibitors did not block uptake of rh-aGAL-A, indicating that this mechanism may not operate initially or alternative M6P inhibitors will need to be investigated.

484W

Development of an Intrathecal Enzyme Replacement Therapy for Sanfilippo Syndrome Type D (Mucopolysaccharidosis IIID). *D.R. Moen[1,3], X. Zhang[3], S-H. Kan[3], J. Wood[1,4], S. Ekins[1], T-F. Chou[2,3], P.I. Dickson[2,3].* 1) Phoenix Nest, Inc., Brooklyn, NY; 2) Department of Pediatrics, Harbor-UCLA, Torrance, CA; 3) Los Angeles Biomedical Research Institute, Torrance, CA; 4) Jonah's Just Begun, Brooklyn, NY.

Sanfilippo syndrome (mucopolysaccharidosis type III; MPS III) is a devastating neurodegenerative disorder with no cure or effective treatment currently available. All subtypes of MPS III have similar clinical phenotypes with onset in infancy or early childhood: progressive and severe neurological deterioration, hearing loss, and visceral manifestations. Most patients die before reaching adulthood, but some may survive to the fourth decade with progressive dementia and retinitis pigmentosa. There are, however, many therapies in early development for MPS III, including genetic, stem cell, enzyme replacement (ERT), chaperone, and substrate reduction.MPS IIID, the rarest of the MPS III subtypes, is an autosomal recessive storage disorder caused by genetic deficiency of N-acetylglucosamine-6-sulfatase (GNS), a lysosomal enzyme vital in the pathway of glycosaminoglycan (GAG) degradation. Over time, these GAG accumulate and eventually induce cellular death, with nervous tissue most severely affected. ERT has long been a strategy to treat MPS disorders, however, due to the difficulties in delivery of therapeutic agents across the blood brain barrier, treatment of the neurodegenerative pathology of the disease has proven difficult. Therefore, our strategy is to manufacture and deliver the enzyme directly to the affected tissue via an intrathecal route. Early studies of intrathecal ERT for other forms of MPS have already shown promise, with administration early in life preventing or reversing the visible signs of neurodegeneration in animal models.Using a stably transfected Chinese hamster ovarian (CHO) cell line, we have begun producing pre-clinical levels of recombinant human GNS (rhGNS) protein. rhGNS has been purified and enzymatically characterized, and we have optimized storage conditions for both longevity and safe administration. Using MPS IIID fibroblasts, we are evaluating its cellular uptake and will further demonstrate localization in the lysosome and the ability to reduce GAG storage.

Comparison of taliglucerase alfa 30 U/Kg and 60 U/Kg in treatment-naïve pediatric patients with Gaucher disease. *M.P. Wajnrajch[1], A. Zimran[2], D.E. Gonzalez-Rodriguez[3], A. Abrahamov[2], P.A. Cooper[4], S. Varughese[4], A. Paz[5], E. Brill-Almon[5], D. Lewis[1], R. Chertkoff[5].* 1) Pfizer Inc, New York, NY; 2) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 3) Inst Privado de Hematol e Investig Clin, Asuncion, Paraguay; 4) University of the Witwatersrand & Charlotte Maxeke Johannesburg Academic Hospital, Johannesburg, South Africa; 5) Protalix BioTherapeutics, Carmiel, Israel.

Background/Objectives: Taliglucerase alfa is an enzyme replacement therapy approved for treatment of patients with Type 1 Gaucher disease (GD) and is the first approved plant cell–expressed recombinant therapeutic protein.**Patients/Methods:** Pediatric patients were randomized to receive either 30 (n=6) or 60 (n=5) U/kg of taliglucerase alfa every other week. Due to small patient numbers, there were numerical imbalances in disease parameters between the dose groups at baseline but they were clinically comparable with regard to anemia, risk of bleeding, and organ volumes. Mean percentage changes from baseline were used to compare the response between the dose groups and as a measure of control for numerical imbalances in baseline disease parameters.**Results:** Through 12 months, taliglucerase alfa 30 and 60 U/kg, respectively, increased mean hemoglobin concentration (+13.8% and +15.8%) and mean platelet count (+30.9% and +73.7%), and reduced mean spleen volume (-34.1% and -48.5%), liver volume (-14.5% and -25.0%), chitotriosidase activity (-58.5% and -66.1%), and CCL18 concentration (-50.6% and -52.6%). **Discussion/Conclusion:** Although statistical analysis was not possible due to small numbers of patients, both treatment groups demonstrated clinically meaningful improvement from baseline in these disease parameters with numerically greater improvement observed in the 60-U/kg dose group.**Disclosure:** This study was sponsored by Protalix BioTherapeutics. Pfizer and Protalix entered into an agreement in November 2009 to develop and commercialize taliglucerase alfa.

486W

Long-term safety and efficacy of taliglucerase alfa in pediatric patients with Gaucher disease who were treatment-naïve or previously treated with imiglucerase. *A. Zimran[1], D.E. Gonzalez-Rodriguez[2], A. Abrahamov[1], P.A. Cooper[3], S. Varughese[3], P. Giraldo[4], M. Petakov[5], E.S. Tan[6], A. Paz[7], E. Brill-Almon[7], R. Chertkoff[7].* 1) Gaucher Clinic, Shaare Zedek Medical Center, Jerusalem, Israel; 2) Inst Privado de Hematol e Investig Clin, Asuncion, Paraguay; 3) University of the Witwatersrand & Charlotte Maxeke Johannesburg Academic Hospital, Johannesburg, South Africa; 4) CIBERER, Hospital Universitario Miguel Servet, Zaragoza, Spain; 5) Belgrade University Medical School, Belgrade, Serbia; 6) KK Women's and Children's Hospital, Singapore; 7) Protalix BioTherapeutics, Carmiel, Israel.

Background/Objectives: Taliglucerase alfa is an enzyme replacement therapy approved for treatment of patients with Type 1 Gaucher disease (GD) and is the first approved plant cell–expressed recombinant therapeutic protein.**Patients/Methods:** This extension study of taliglucerase alfa in pediatric patients included those who were either treatment-naïve (n=10) or who were previously switched from imiglucerase (n=5). Patients received taliglucerase alfa 30 U/kg or 60 U/kg (treatment-naïve patients) or at the same dose as previously treated with imiglucerase (switch patients).**Results:** In treatment-naïve patients, taliglucerase alfa 30 and 60 U/kg, respectively, increased mean hemoglobin concentration (+19.7% and +23.3%) and mean platelet count (+23.9% and +156.6%) while also reducing mean spleen volume (-67.8% and -68.9%), liver volume (-37.0% and -34.3%), and chitotriosidase activity (-72.7% and -84.4%) from baseline through 36 total months of treatment. In patients previously treated with imiglucerase, these disease parameters remained stable through 33 total months of treatment with taliglucerase alfa. In both studies, most adverse events were mild/moderate and treatment was well tolerated.**Discussion/Conclusion:** These long-term results of taliglucerase alfa in pediatric patients with GD extend the taliglucerase alfa clinical safety and efficacy data set.**Disclosure:** This study was sponsored by Protalix BioTherapeutics. Pfizer and Protalix entered into an agreement in November 2009 to develop and commercialize taliglucerase alfa.

Eteplirsen, a Phosphorodiamidate Morpholino Oligomer (PMO) for Duchenne Muscular Dystrophy (DMD): Clinical Update. *E.M. Kaye[1], L.R. Rodino-Klapac[2], Z. Sahenk[2], L.P. Lowes[2], L.N. Alfano[2], K. Berry[2], A.M. Gomez-Ramirez[2], S. Lewis[2], K.M. Flanigan[2], L.H. Cripe[2], S. Al-Zaidy[2], P. Duda[1], P. Sazani[1], J. Saoud[1], J.R. Mendell[2].* 1) Sarepta Therapeutics, Cambridge, MA; 2) Nationwide Children's Hospital, Columbus, OH.

DMD is a rare, degenerative, X-linked recessive genetic disease affecting approximately 1:3500 male births. It is caused mainly by mutations in the *DMD* gene that result in the inability to produce functional dystrophin, an essential protein for muscle fiber function. Eteplirsen, a PMO designed to enable functional dystrophin production in boys amenable to exon 51 skipping is being evaluated in on-going clinical trials.Twelve boys aged 7-13 years with eligible genotypes were randomized 1:1:1 to weekly IV eteplirsen 30 mg/kg, 50 mg/kg, or placebo for 24-weeks. All patients then transitioned into an ongoing open-label extension trial with 30 or 50 mg/kg eteplirsen. Clinical efficacy endpoints included the 6 Minute Walk Test and Pulmonary Function Testing. Safety assessments included adverse event recording, ECG, ECHO, hematology, blood chemistry, and urinalysis.A statistically significant treatment benefit of 65.4 meters ($p \leq 0.017$) on the 6MWT over 168 weeks was observed for patients in the continuous 30 and 50 mg/kg eteplirsen cohorts who were able to perform the 6MWT (n=6) compared with the placebo/delayed-treatment cohort (n=4). PFTs including MIP (+11.1%), MEP (+13.5%), and MIP/MEP %-predicted (-2.4% & -6.3%) were stable from Week 1 through 168 in all 12 subjects.No deaths, discontinuations due to AEs, treatment-related SAEs, immune activation including infusion reactions, or clinically significant abnormal laboratory findings were reported. Treatment compliance was high with ~99% of all possible doses administered.Eteplirsen's long-term tolerability and statistically significant clinical benefit suggest it could be a viable therapy for DMD boys amenable to exon 51 skipping.

488W

CRISPR-Cas9 as a potential therapeutic tool for the Bardet-Biedl Syndrome (BBS) M390R mutation *in vitro* and *in vivo*. *M.R. Cring, J.E. Garrison, V.C. Sheffield.* University of Iowa, Iowa City, IA.

Bardet-Biedl Syndrome (BBS) is a rare, autosomal recessive disease characterized by abnormal ciliary function and biogenesis. There are several phenotypes associated with BBS, including obesity, intellectual disability, hypogonadism, male infertility, and severe retinopathy. The most common mutation contributing to BBS is M390R in the BBS1 gene, which accounts for approximately 25% of known cases. Individuals with this particular mutation suffer photoreceptor death and typically go blind within their teenage years. Gene therapy approaches to correct this phenotype in the retina are attractive due to the accessibility of the eye. Previous studies have shown that overexpression of wild type BBS1 in the retina after delivery by AAV vectors leads to overexpression toxicity and continued photoreceptor loss. Therefore, gene correction strategies that restore endogenous expression levels may be a more viable therapeutic option. The CRISPR-Cas9 endonuclease has received extensive attention in recent years due to its ease of engineering and relatively high efficacy in mammalian cells. This study tests the feasibility of using the CRISPR-Cas9 platform and a homologous donor template to correct the M390R mutation *in vitro* and *in vivo*. We show that the spCas9 can target BBS1 in IMCD-3 cells, and addition of a single stranded oligo in iPSCs can introduce the M390R mutation by homologous recombination. Recent work has shown that the *Staphylococcus aureus* Cas9 endonuclease is small enough to package into AAV vectors. Therefore, we have produced several gRNAs in plasmids containing the saCas9, including an M390R allele specific gRNA. We have also constructed a homologous donor template including synonymous changes such that endonuclease activity will cease after homologous recombination events have occurred. We are testing our saCas9 constructs in IMCD-3 cells to determine their level of endonuclease efficiency. We are delivering multiple independent CRISPR-Cas9 constructs along with gRNAs and homologous donor templates to mutant mouse brains via electroporation. Excision and sequencing of brains will determine whether homologous recombination and correction has occurred. Once this has been established, we will package the Cas9 constructs that facilitate homologous repair into an AAV2/5 vector and deliver it to the retinas of 2 week old mutant mice. These mice will be monitored and tested for photoreceptor survival by histology and ERG.

489T

Promoterless gene-targeting using adenoassociated viral (AAV)-mediated homologous recombination to treat methylmalonic acidemia. *R.J. Chandler[1], A. Barzel[2], L. Lisowski[3], M.A. Kay[2], C.P. Venditti[1].* 1) National Human Genome Research Institute, NIH, Bethesda, MD; 2) Departments of Pediatrics and Genetics, Stanford University, Stanford, CA; 3) Gene Transfer, Targeting and Therapeutics Core, Salk Institute, San Diego, CA.

Methylmalonic acidemia (MMA) is a lethal inborn error of metabolism most typically caused by mutations in methylmalonyl-CoA mutase (*MUT*). Affected patients suffer from frequent and potential lethal bouts of metabolic instability that can be treated by orthotopic liver transplantation. Adeno-associated viral (AAV) gene therapy has shown great promise as the treatment for MMA in a murine model of the disease. However, a majority of the AAV-treated mice developed hepatocellular cancer, which was determined to arise from AAV-mediated insertional mutagenesis. In an attempt to create a safer gene therapy platform for the treatment of MMA, we created a novel vector, AAV-2A-MUT, to target site-specific gene addition of human *MUT* into the mouse albumin (*Alb*) locus without the use of nuclease. A promoterless AAV backbone contained a 2A-peptide coding sequence proximal to a codon-optimized human *MUT* gene and was flanked by arms of homology immediately upstream of *the Alb* stop codon. Site-specific integration of the vector into the *Alb* locus results in the expression of *Alb* and *MUT* as a single transcript. Following transcription the 2A-peptide causes ribosomal skipping and allows Alb and MUT to be translated as separate proteins. We delivered 2.5e12 GC of AAV8-2A-MUT by intraperitoneal injection to mice with MMA at birth. At one month post-injection, we observed increased hepatic expression of the MUT by western blot, improved growth and a significant reduction of plasma methylcitrate, a disease related metabolite, in the treated MMA mice. This gene delivery approach is anticipated to provide permanent hepatic transgene expression while reducing the risk of off-target integration and vector mediated insertional mutagenesis.

490W

Choroid plexus-targeted viral gene therapy in an alpha-mannosidosis mouse model increases brain LAMAN activity globally and eliminates brain pathology. *E. Choi[1], J. Wolfe[2], S. Kaler[1].* 1) Section on Translational Neuroscience, Molecular Medicine Program, NICHD/NIH, Bethesda, MD; 2) Children's Hospital of Pennsylvania, Philadelphia, PA.

The choroid plexuses are vascularized structures that project into the cerebrospinal fluid (CSF). The specialized polarized epithelia of choroid plexuses produce CSF by transporting water and ions into the ventricles, and are post-mitotic, i.e., do not undergo turnover. We hypothesized that remodeling these epithelia to secrete missing lysosomal enzymes by one-time CSF administration of a recombinant AAV (rAAV) could be an attractive strategy for long-term treatment of lysosomal storage diseases (LSDs). Lysosomes function as digestive units of cells and specific enzymes within lysosomes break down nutrients. Patients with LSDs cannot metabolize certain nutrients, resulting in diminished lifespans and reduced quality of life. CSF-directed recombinant enzyme replacement has shown promise for several LSDs but requires repeated instillations due to short recombinant enzyme half-lives. In contrast, rAAV-mediated gene transfer to the choroid plexus could enable continuous synthesis of lysosomal enzymes and steady delivery to the brain globally. To evaluate this hypothesis, we obtained an alpha-mannosidosis mouse model generated by targeted disruption of the lysosomal acid-mannosidase (LAMAN). We cloned the human (hu) LAMAN cDNA into a rAAV shuttle plasmid and generated high titer rAAV5 expressing huLAMAN. We administered viral particles to the CSF of homozygous mutant mice by brain lateral ventricle injection on day 3 of life. We documented dose-dependent transduction and huLAMAN mRNA expression confined to the choroid plexuses of rAAV5-treated animals. Brain biochemical analyses at 1, 2 and 6 months post-treatment documented sustained increases of LAMAN enzyme activity globally across the brain. By 8 months of age, untreated mutant mice showed prominent lysosomal vacuoles in hippocampal neurons, in contrast to rAAV5-LAMAN treated mutants for which brain histopathology was comparable to wild-type. If choroid plexus-targeted viral gene therapy approach were similarly successful in larger animals and human subjects, the most significant current barriers to health for patients with LSDs could be circumvented.

Development of a Stem cell/gene therapy approach to treat Sanfilippo syndrome type B. *D. Clarke, S. Kan, S. Le, Q. Bui, V. Sanghez, P. Dickson, M. Iacovino.* Pediatrics department, Los Angeles Biomedical Institute at Harbor UCLA, Torrance, CA.

Mucopolysaccharidosis type IIIB (MPS IIIB, Sanfilippo syndrome type B) is a lysosomal storage disease characterized by profound intellectual disability, dementia, and a lifespan of about twenty years. The cause is mutation in the gene encoding α–N-acetylglucosaminidase (NAGLU), deficiency of NAGLU, and accumulation of heparan sulfate. Obstacles to treatement include the absence of mannose 6-phosphate on recombinant human NAGLU, the blood brain barrier, and degradation of the enzyme. We will address these issues using a stem cell/gene therapy approach. A fusion protein of recombinant NAGLU and a fragment of insulin-like growth factor II (IGFII) was prepared for endocytosis by the mannose 6-phosphate/IGFII receptor. The fusion protein sequence was cloned into a lentiviral vector and used to transduce NAGLU -/- induced pluripotent stem cells (iPSCs) derived from NAGLU -/- mouse embryonic fibroblasts (MEFs). The iPSCs were differentiated to Neural Stem Cells (iNSCs). NAGLU activity assays were performed to test in vitro whether the NAGLU and NAGLU-IGFII were secreted and uptaken from deficient cells in a comparable manner. Here we show that the while the secretion of NAGLU was higher compared to NAGLU-IGF2, the uptake showed opposite trend with NAGLU-IGFII more efficiently uptaken in -/- iNSCs. Our next step will be transplanting corrected iNSC expressing NAGLU or NAGLU-IGFII into the neonatal brain of NAGLU -/- mice. We will assess the distribution of transplanted cells via the expression of NAGLU and lysosomal storage markers to determine whether corrected neuronal progenitor cells will be a long lasting and effective therapy forSanfilippo syndrome type B.

492W

Rescue of Diamond-Blackfan Anemia haploinsufficiency by knock-up of the deficient protein. *I. Dianzani[1], A. Aspesi[1], E. Pavesi[1], S. Parrella[1], S. Macri[1], D. Cotella[1], U. Ramenghi[3], S. Gustincich[2], A. Follenzi[1], C. Santoro[1].* 1) Health Sciences, Università del Piemonte Orientale, Novara, Italy; 2) International School for Advanced Studies (SISSA/ISAS), Trieste, Italy; 3) Department of Public Health and Pediatric Sciences, Turin, Italy.

Diamond Blackfan Anemia (DBA) is a rare erythroid aplasia often associated with malformations. In about 70% of cases heterozygous LOF mutations are found in ribosomal protein (RP) genes and point to haploinsufficiency. DBA is considered the paradigm for ribosomopathies, a class of diseases caused by ribosome dysfunction and often characterized by bone marrow failure. Mutations in RPs either of the small or the large subunit impair rRNA maturation and ribosome biogenesis. As a consequence of the activation of ribosomal stress abnormal amounts of rRNA precursors accumulate and the P53 pathway is activated in affected cells.The aim of our project is to correct the effects of the haploinsufficiency observed in DBA by increasing the level of the deficient RP by favouring translation of the WT allele transcript. As a proof of concept precursor rRNA and the P53 pathway will be first evaluated to assess the rescue. Some of us discovered a new class of antisense non-coding RNAs (SINEUPs) that promote translation of partially overlapping sense coding mRNAs with no effects on mRNA levels. This “knock-up” activity depends on two functional domains: a 5’ overlap with the coding mRNA that confers target specificity and an embedded inverted SINEB2 element that functions as activator of translation. Synthetic transcripts with these features increase the translation of target mRNAs. We have decided to employ this technology to knock-up the synthesis of deficient RPs in cells from DBA patients, that carry a null mutation. We designed SINEUP molecules specific to RPL5 and RPS19, the two most commonly mutated DBA genes, and prepared lentiviral vectors to efficiently express them in primary cells.We show that the SINEUP technology is able to increase the level of the target RP in HeLa and erythroid cell lines without affecting the mRNA levels. Preliminary experiments on DBA patient activated lymphocytes suggest a rescue of the rRNA phenotype.

493T

CSF-directed AAV9 gene therapy plus subcutaneous copper provides superior rescue in a mouse model of Menkes disease. *M.R. Haddad[1], D. Martinelli[1], E.Y. Choi[1], P.M. Zerfas[2], P.H. Sullivan[3], D.S. Goldstein[3], L.R. Brinster[2], D. Abebe[4], J.A. Centeno[5], S.G. Kaler[1].* 1) Section on Translational Neuroscience, Molecular Medicine Branch, National Institute of Child Health and Human Development, NIH, Bethesda, MD; 2) Office of Research Services, Division of Veterinary Resources, National Institutes of Health, Bethesda, MD; 3) Clinical Neurocardiology Section, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 4) Research animal management branch, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD; 5) Joint Pathology Center, Andrews Air Force Base, MD.

Menkes disease is a lethal infantile neurodegenerative disorder caused by mutations in a copper transporter, ATP7A. Untreated patients typically die by 3 years of age. Currently, the sole available treatment involves daily subcutaneous (sc) copper injections, which however are ineffective in ≈75% of affected patients even when commenced before the symptoms occur. To develop a more complete treatment for this illness, potentially suitable even for subjects with complete loss-of-function ATP7A mutations, we tested adeno-associated virus (AAV) vectors carrying human ATP7A cDNA in the mottled-brindled (mo-br) mouse. The mo-br mouse recapitulates the symptoms and early demise of human Menkes disease. We previously demonstrated that a viral gene therapy approach using AAV serotype 5 (AAV5) in combination with copper chloride administered to the cerebrospinal fluid (CSF) was able to significantly prolong survival in mutant mice. However, growth and neuromotor defects persisted in long-term surviving mice. In the current study, we report superior outcomes (n=40 mice) using CSF-directed AAV9 in combination with sc clinical grade copper histidine. We evaluated both AAV9 and AAVrh10 vectors given their broad tropism (choroid plexus epithelia, neurons and glial cells) after CSF administration compared to AAV5 (selective choroid plexus tropism). Individual treatments with AAV alone or copper alone did not significantly enhance survival. We also compared different AAV9 and rh10 doses: 1.6x1010; 5.0x109 and 1.6x109 vg, in combination with 15 µg of sc Cu, and found that intermediate and high AAV9-ATP7A doses were most effective. In correlation with the greatest survival benefit, CSF-directed AAV9 plus sc Cu normalized growth and neurobehavioral outcomes. This synergistic treatment effect markedly improved biomarkers of brain copper metabolism in comparison to untreated mutant mice, and correlated with viral genome copy number. Brain copper measurements in combination-treated mutants were not statistically different from wild type indicating restored copper transport to the brain. Electron micrographs and H&E stain of brain regions reflected significant improvements in brain pathology in the combination-treated animals. Compared to our previous study with AAV5, the present findings strongly suggest that CSF-directed gene therapy with AAV9, in combination with sc copper, may have clinical utility for this difficult illness.

CRISPR-Cas9 Mediated Genome Editing of Myocilin in Hereditary Glaucoma. *A. Jain[1], G. Zode[2], K. Bugge[1], C. Searby[1], F. Zhang[3], A. Clark[2], V. Sheffield[1].* 1) Pediatrics, University of Iowa, Iowa City, IA; 2) North Texas Eye Research Institute, UNT Health Science Center at Fort Worth, Texas; 3) McGovern Institute for Brain Research at Massachusetts Institute of Technology, Cambridge, Maryland.

Glaucoma is a leading cause of irreversible blindness worldwide. Elevated intraocular pressure (IOP) remains the most important risk factor for glaucoma. Mutations in myocilin (*MYOC*) have been reported in >16% of Juvenile Open Angle Glaucoma and about 4% of Primary Open Angle Glaucoma patients. Mutations in *MYOC* lead to myocilin misfolding and are associated with endoplasmic reticulum (ER) stress in the trabecular meshwork (TM), the tissue that maintains aqueous humor outflow and regulates IOP. ER stress and/or death of the TM cells lead to ocular hypertension and glaucoma. Genetic depletion of *MYOC* expression does not lead to a discernable phenotype suggesting that *MYOC* glaucoma is a gain-of-function mutation. We propose to relieve ER stress in human and mouse TM cells by targeting the human *MYOC* gene using state of art CRISPR-Cas9 technology.We generated and characterized human TM cell lines overexpressing wild type and mutant human MYOC and looked for ER stress markers using quantitative PCR, Western immunoblotting and immunocytochemistry. *MYOC* was targeted by either transient transfection of px330-CRISPR plasmids or adenovirus Ad5- mediated transduction of guide RNAs targeting exon 1 of the human *MYOC* gene. Human primary TM cells were treated with Ad5-cr*MYOC* virus and evaluated for dexamethasone (DEX)-mediated MYOC accumulation and ER stress. Intravitreal injection of Ad5 viruses in transgenic (Tg)-h*MYOCY437H* ocular hypertensive mice was performed to study the effect on IOP.The results revealed that TM cell lines overexpressing mutant MYOC have increased accumulation of myocilin in the ER and increased ER stress markers compared to wild type. Both transient transfection and Ad5-mediated transduction reduced levels of MYOC and ER stress in these cells. Primary TM cells have reduced levels of DEX-mediated ER stress when pretreated with Ad5-cr*MYOC* as compared to Ad5-cas9 virus controls. Ad5-cr*MYOC* virus significantly reduced IOP as compared to Ad5-cas9 control virus in the Tg-h*MYOCY437H* mouse model. This is a proof of principle study indicating that targeting the *MYOC* gene can relieve ER stress in TM cells, rescuing their function and health, and preventing glaucoma.

Spell-Checking Nature: Versatility of CRISPR/Cas9 for the Treatment of Inherited Disorders. *D.U. Kemaladewi[1], D. Wojtal[1,2], Z. Malam[1], S. Abdullah[1], T.W.Y. Wong[1,2], E. Hyatt[1], S. Pereira[1,3], J. Stavropoulos[4], V. Mouly[5], K. Mamchaoui[5], F. Muntoni[6], T. Voit[5], H. Gonorazky[1,4], J.J. Dowling[1,2,4,7], R. Mendoza-Londono[4,7], E.A. Ivakine[1], R.D. Cohn[1,2,4,7,8].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 3) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Canada; 4) Department of Paediatrics, University of Toronto, Toronto, Canada; 5) Sorbonne Universites, UPMC Univ Paris 06, INSERM UMRS974, Paris, France; 6) Dubowitz Neuromuscular Centre, Institute of Child Health and Great Ormond Street Hospital, London, United Kingdom; 7) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 8) Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, Canada.

Recent estimates suggest that about 400 million people worldwide are affected by orphan diseases, mostly caused by primary genetic abnormalities. While orphan-drug development has made some progress over the last few years, most genetic disorders lack therapeutic options. The recent discovery and advancement of genome engineering tools, such as the CRISPR/Cas9 system, have opened up avenues for the development of novel treatment strategies. Here we explore the versatility of CRISPR/Cas9 to alter expression of disease-modifying genes as well as target disease-causing mutations in a variety of genetic disorders. First, we used the CRISPR/Cas9 system to upregulate utrophin, a compensatory protein in Duchenne muscular dystrophy (DMD). We coupled a catalytically inactive Cas9 fused to transcriptional transactivator VP16 (dCas9-VP160) with guide RNAs targeting either *UTRN A* or *UTRN B* promoters. We observed 4.1–14.6 fold upregulation of utrophin in DMD myoblasts, leading to restoredβ-dystroglycan expression.We next interrogated whether the system can be used for allele-specific targeting, such as in achondroplasia patients carrying pathogenic dominant-negative, gain-of-function mutation in fibroblast growth factor receptor 3 (*FGFR3*: c.1138G>A, p.Gly380Arg). We used *S. pyogenes* Cas9 (*Sp*Cas9) paired with a protospacer adjacent motif (PAM)-discriminating guide RNA, and detected 12 times higher indels frequency in the mutant allele compared to the wild-type by means of deep sequencing technology.Subsequently, we used the CRISPR/Cas9 system to remove large genomic rearrangements. Using *Sp*Cas9 coupled with a single RNA guide targeting the duplicated region, we removed a large 278kb tandem duplication on the X-chromosome including the *MECP2* gene. Moreover, using similar strategy, we successfully removed a 139kb region in DMD fibroblasts carrying exons 18-30 duplication in *DMD*, leading to restoration of full-length dystrophin and α-dystroglycan expression. Importantly, we found predicted off-target cutting to be minimal and not affecting any critical regions within the human genome.Taken together, our data indicate that the CRISPR/Cas9 system is a versatile approach to correct pathogenic mutations and alter expression of disease-modifying genes. Proof of concept studies utilizing patient cells as outlined here are critical in laying the foundation for further research into the application of these therapeutic strategies for numerous inherited disorders.

496W

Broad Therapeutic Window for Retinitis Pigmentosa. *S.F. Koch[1], Y.T. Tsai[1], J.K. Duong[2], L. Bonet-Ponce[3], C.W. Hsu[1], W.P. Wu[1], W.W. Wu[1], C.S. Lin[4], S.H. Tsang[1].* 1) Ophthalmology, Columbia University, New York, NY; 2) Department of Biostatistics, Mailman School of Public Health, Columbia University Medical Center, New York, NY; 3) Department of Physiology, School of Medicine and Dentistry, Catholic University of Valencia, Valencia, Spain; 4) Herbert Irving Comprehensive Cancer Center, Columbia University Medical Center, New York, NY.

Retinal gene therapy has yet to achieve sustained functional rescue after disease onset – perhaps because transduction efficiency is insufficient ("too little") and/or the disease is too advanced ("too late"). To test the latter hypothesis, we developed a novel mouse model for retinitis pigmentosa (RP) that allowed us to restore the mutant gene in *all* diseased photoreceptor cells, thereby ensuring sufficient transduction efficiency. We then treated mice at early, mid or late disease stages. At all three time points, degeneration was halted and function rescued for at least 6 months. In addition to being the first demonstration of gene therapy efficacy after onset of degeneration, our study is the first to demonstrate a broad therapeutic time window. The results suggest that RP patients are treatable, despite most being diagnosed after significant cell loss. To maximize clinical impact, our work suggests that gene therapy research must focus on improving transduction efficiency.

497T

Pre-clinical development of a genetically-modified human dermal fibroblast (FCX-007) for the treatment of recessive dystrophic epidermolysis bullosa (RDEB). *M.P. Marinkovich, MD[1], N. Ehsani-Chimeh, MD[1], N. Nguyen[1], S. Moncrief, PhD[2], V.K. Dailey[2], M. Chakiath[2], A. Elayadi, PhD[2], S. Krishnan, MS[2], J. Maslowski, MS[3].* 1) Stanford University School of Medicine, Stanford, CA; 2) Intrexon Corporation, Germantown, MD; 3) Fibrocell Science, Exton, PA.

Recessive dystrophic epidermolysis bullosa (RDEB) is an autosomal recessive, inherited skin disease caused by null mutations within the type VII collagen gene (*COL7A1*). The mutations cause an absence or reduction of functional collagen VII (COL7), which make up anchoring fibrils that maintain binding of the epidermis to the dermis. The disease is characterized by a mechanical fragility and repeated blister formation in the sub-lamina densa, at the level of the structurally defective anchoring fibrils. Currently, there is no effective therapy for this disease, and death is usually the result of aggressive squamous cell carcinoma, sepsis or malnutrition.We are developing an autologous, genetically-modified fibroblast cell therapy that is anticipated to improve skin function in RDEB patients through restoration of collagen levels. A patient's fibroblasts will be harvested, genetically modified *ex-vivo* with a functional *COL7A1* gene, and expanded in culture (FCX-007). *Ex vivo* transduction will occur through the use of a replication-defective, self-inactivating (SIN) lentiviral vector. After expansion, the fibroblasts are administered back to the patient as a local intradermal injection into target wound margins. The resulting increase in anchoring fibrils is anticipated to stabilize the connection between skin layers and reduce blistering tendency.*In vitro* product development data indicates that cGMP scale FCX-007 cells express full-length COL7 collagen exhibiting the proper trimeric form, size and binding functionality. The integrated transgene copy number and COL7 expression is dependent on viral dose. We present results from a pre-clinical animal model evaluating FCX-007 in RDEB and normal human skin xenografts implanted onto immunodeficient SCID mice. The goals of the study are to confirm persistence, distribution and localization of COL7, and to evaluate any potential for product toxicity or vector biodistribution. The data presented are intended to support an Investigational New Drug (IND) filing.We also present the study design for a proposed Phase I/II clinical trial to treat RDEB subjects with FCX-007. The primary endpoints for the study are to evaluate safety and to confirm the formation of anchoring fibrils at the basement membrane zone (BMZ) in biopsies collected from subjects after product administration.

498W

Gene therapy for a mouse model of glucose transporter-1 deficiency syndrome. *S. Nakamura[1], H. Osaka[1], S. Muramatsu[2,6], N. Takino[2], S. Aoki[1], E. F. Jimbo[1], K. Shimazaki[3], T. Onaka[4], S. Ohtsuki[5], T. Yamagata[1].* 1) Department of pediatrics, Jichi Medical University, Shimotsuke-shi, Tochigi, Japan; 2) Division of Neurology, Jichi Medical University, Shimotsuke-shi, Tochigi, Japan; 3) Department of Neurosurgery, Jichi Medical University, Shimotsuke-shi, Tochigi, Japan; 4) Division of Brain and Neurophysiology, Department of Physiology, Jichi Medical University, Tochigi, Japan; 5) Department of Pharmaceutical Microbiology, Faculty of Life Sciences, Kumamoto University, Kumamoto, Japan; 6) Center for Gene and Cell Therapy, The Institute of Medical Science, The University of Tokyo, Japan.

(Background) Glucose transporter 1 deficiency syndrome (GLUT1DS, OMIM #606777) is an autosomal dominant disorder caused by haplo-insufficiency of *SLC2A1*, the gene encoding GLUT1. The classical phenotypes of GLUT1DS are intractable seizures, intellectual disability, and cerebellar ataxia, starting in infancy. We investigated if gene delivery of GLUT1 using an adeno-associated virus (AAV) vector can correct the phenotype in a mouse model of GLUT1DS.(Materials and Methods) We generated an AAV9 vector in which *SLC2A1*-myc-DDK was expressed under the neuron-specific synapsin I promoter. Transduction was evaluated in GLUT1+/- mice after systemic administration of AAV9-SLC2A1; 1.8 x 1011 vg per mouse into the peritoneum at 7 days old. After 5 weeks, total RNA was extracted from the cerebrum, and vector-specific RT-PCR was performed. Also the brain was subjected to immunofluorescence staining using anti-myc antibody (MBL CO., Ltd, Nagoya, Japan). To evaluate motor performance, rotarod and footprint analyses were performed to the age of 20 weeks mice.(Results) In GLUT1+/- mice after injection of AAV9-SLC2A1, vector-derived RNA was detected in the brain. Exogenous GLUT1 was mainly stained neural cells in the cerebral cortex and hippocampus. Cerebellar Purkinje cells were also immune-reactive to the anti-myc antibody. In rotarod analyze, the time to falling off the rotating cylinder was longer in injected GLUT1+/- mice than untreated GLUT1+/- mice.(Discussion) We confirmed that intraperitoneally administered AAV9-SLC2A1 can cross the blood-brain barrier and express exogenous GLUT1. Although the level of exogenous GLUT1 expression was low (~1% of neurons in the total visual field), motor function was improved. In general, systemic administration has advantage in its invasiveness and disadvantage in transduction efficiency to the CNS. We are comparing intraperitoneal or intra-cerebroventricular route as a way of administration.

Engineering Recurrent, Reciprocal Genomic Disorders using CRISPR/Cas9 in Human iPS Cells. *D. Tai[1,2,3], A. Ragavendran[1,3], A. Stortchevoi[1,3], C. Seabra[1,2,3,4], P. Manavalan[1,3], S. Erdin[1,3], R. Collins[1,3], I. Blumenthal[1], C. Zhen[5], C. Lee[5], J. Gusella[1,6,7], M. Talkowski[1,2,3,6].* 1) Molecular Neurogenetics Unit, Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Department of Neurology, Harvard Medical School, Boston, MA; 3) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetic Research and Department of Psychiatry, Massachusetts General Hospital, Boston, MA; 4) Institute of Biomedical Sciences Abel Salazar, University of Porto, Portugal; 5) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 6) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT; 7) Department of Genetics, Harvard Medical School, Boston, MA.

Recurrent genomic disorders involve large copy number variations (CNVs) generated from non-allelic homologous recombination (NAHR) mediated by segmental duplications. These reciprocal microdeletions and microduplications are a major cause of human disease, often producing phenotypically distinct syndromes. However, investigation of their impact at the molecular levels have been hampered by the size of the recurrent lesion, which can encompass many genes, as well as the diverse genetic backgrounds of patients and lack of accessible tissues. The capacity to generate large reciprocal CNVs in an otherwise isogenic human induced pluripotent stem cells (iPSCs) could overcome these obstacles and provide an invaluable tool for modeling these recurrent genomic disorders. Here, we used CRISPR/Cas9 genome engineering methods to achieve this goal for the 16p11.2 microdeletion/microduplication syndrome, a common genetic cause in autism spectrum disorder, as a proof-of-principle for NAHR-mediated disorders. Using a dual-guide RNA strategy, we first ablate the 575 kb unique genic segment spanning the 16p11.2 microdeletion region. We then developed a single-guide RNA approach that uniquely targets the flanking segmental duplications. The single guide RNA strategy was able to accurately mimic the NAHR-mediated *in vivo* mechanism in the cells, generating microdeletion of the unique genic segment as well as one copy equivalent of the segmental duplications. Remarkably, the single guide method was also able to reproducibly generate microduplications, including duplication of one copy equivalent of the segmental duplication. We performed multiple replication experiments and confirmed genome and transcriptome copy number alterations using copy number analysis (qPCR), genome-wide chromosomal microarray, and RNAseq, all of which revealed that both methods were specific (no off-target CNVs were observed from array) and relatively efficient (CNV was observed in 14.8% of all clones screened). Moreover, gene-expression patterns from RNAseq recapitulated those observed in our previous human and mouse 16p11.2 microdeletion RNAseq studies. These data suggest that our genome engineering approach provides an efficient method to model recurrent, reciprocal genomic disorders in human iPSCs, which can then be differentiated to any cell type of relevance. With further optimization and development, these methods may also permit efficient correction of these defects.

500W

Chimeric U2 small nuclear RNA-DMPK trans-splicing molecule reverses pre-mRNA splicing defects in myotonic dystrophy type 1. *P.S. Lai[1,2], H.Y. Chen[3], B.X. Qian[3], S. Udayappan[3], P. Kathirvel[3,4].* 1) Dept Pediatrics, National Univ Singapore, Science Drive 2, Singapore 119228; 2) Khoo Teck Puat - National University Children's Medical Institute, National University Health System, Kent Ridge Road, Singapore 119228; 3) Dept of Clinical Research, Singapore General Hospital, Outram Road, Singapore 169608; 4) Institute of Molecular Biology, Biopolis Drive, Singapore 138673.

RNA-based therapeutic approaches have been previously explored in a number of disease models for *in situ* rescue of genes. The use of an exogenous artificial pre-mRNA splicing molecule is an attractive strategy for modifying cis-splicing processes using the endogenous spliceosome machinery and has been shown to restore loss-of-function mutations in disorders such as hemophilia, cystic fibrosis, dysferlinopathy, etc. For gain-of-function diseases, it is important that the wild type mRNA is not removed when an artificial trans-splicing molecule (ATM) is introduced to correct the mutant pre-mRNA. Myotonic dystrophy type 1 (DM1) is an autosomal dominant disorder caused by CTG repeat expansions in the 3' end of the untranslated region of the dystrophia myotonica protein kinase (*DMPK*) gene which is encoded by 15 exons spanning 13 kb of genomic DNA. In this study, we show the efficacy of correcting DM1 using an artificial trans-splicing molecule (ATM) designed to target intron 14 of the *DMPK* gene. We constructed a chimeric ATM molecule carrying pre-mRNA binding and splicing domains, coding region of *DMPK* exon 15, reporter green fluorescence protein (*GFP*) gene and specific U2 snRNA sequences. Trans-splicing efficiency of the chimeric ATM with the U2 snRNA sequences (U2-ATM250) and the ATM without U2 snRNA sequences (ATM250) was tested in myosarcoma cells (CCL-136). Compared to the ATM250, the U2-ATM250 showed increased trans-splicing efficiency of endogenous DMPK pre-mRNA from 11.85% to 30.33%. Expression of U2-ATM250 in two immortalized DM1 fibroblast clones which were differentiated by inducible *MyoD* expression showed *DMPK* pre-mRNA trans-splicing efficiencies of 36.0% and 22.61% respectively. In addition, a significant reduction ($p<0.0001$) in mutant *DMPK* mRNA aggregates (foci) was observed by *in situ* hybridization and confocal microscopy in the nuclei of the differentiated DM1 fibroblasts. These findings demonstrate that chimeric U2 snRNA–ATM can increase trans-splicing efficiency of *DMPK* transcripts and induce phenotype change in intact DM1 fibroblast cells suggesting that this strategy may have broader applications to other diseases which are amenable to 3' trans-splicing therapeutic strategy.

Silencing of Important Molecules Having Roles in Pathogenesis of Idiopathic Pulmonary Fibrosis via RNA interference and Development of New Therapeutic Modalities. *O.F. Hatipoglu[1], E. Uctepe[1], K.O. Yaykasli[2], H. Oksuz[1], S. Cigdem[1], M. Gunduz[1].* 1) Department of Medical Genetics, Turgut Özal University Faculty of Medicine, Ankara, Turkey; 2) Department of Medical Biology, Kahramanmaras University Medical Faculty, Kahramanmaras, Turkey.

Idiopathic Pulmonary Fibrosis (IPF) is a disease that is characterized by the deposition of an excessive degree of myofibroblast cells and extracellular matrix components in the lower respiratory tract and lung interstitium. Median survival is 3 years after initial diagnosis. Prevalence rate varies from 14 to 43 per 100 000 people. Today, it is thought that recurrent epithelial damage and aberrant wound healing are the basis of IPF pathogenesis, resulting in the accumulation of fibroblasts in the lung. In addition, coagulation, apoptosis, angiogenesis pathway disorders, oxidative damage, and most recently epithelial–mesenchymal transition (EMT) are implicated in the pathogenesis of this disease. Major aim of our study is to show the fundamental role of osteopontin, Twist and Wnt5a genes in IPF pathogenesis which these genes have been implicated by several studies in EMT and to show whether the suppression of these genes could be effective for IPF treatment examined. First of all, we treated A549 cell line with different dose of TGFb to create EMT. We showed that after TGFb treatment, Ecadherin expression is markedly decreased, on the contrary, Vimentin expression increased showing EMT. Then, changes in the expression of genes responsible for EMT formation and fibrosis examined at the level of mRNA and protein performing siRNA knockdown for Osteopontin, Twist and Wnt5a gene transcripts in lung alveolar cell lines.**Acknowledgements:** This study was supported by TUBITAK (The Scientific and Technical Research Council of Turkey), (Project Number: SBAG/ 113S947).

502W

Potential benefit of *CSF1R* mosaicism in a family with Hereditary Diffuse Leukoencephalopathy with Spheroids. *F.S. Eichler[1,2], P. Caruso[3], A.C. Bjonnes[2,4,5], J. Pan[1], R. Saxena[2,4,5].* 1) Dept of Neurology, Massachusetts General Hospital, Boston, MA; 2) Center for Human Genetic Research, MGH, Boston, MA; 3) Dept of Radiology, MGH, Boston, MA; 4) Dept of Anesthesia, Clinical Care and Pain Medicine, MGH and HMS, Boston, MA; 5) Medical and Population Genetics, Broad Institute, Cambridge, MA.

Mutations in the colony stimulating factor 1 receptor (*CSF1R*) have recentlybeen discovered as causal for Hereditary Diffuse Leukoencephalopathy withAxonal Spheroids (HDLS). We identified a novel, heterozygous missensemutation in the tyrosine kinase domain of CSF1R (E664K) by exomesequencing in five members of a family with HDLS. Three affected siblingshad characteristic white matter abnormalities and presented with progressiveneurologic decline. In the fourth affected sibling, early progression halted afterallogeneic hematopoetic stem cell transplantation (HSCT) from an unaffectedsibling over 15 years ago. Blood spot DNA from this subject displayed 15%chimerism in *CSF1R* acquired after HSCT. Interestingly, both parents wereunaffected but the mother's blood and saliva were ~20% mosaic for the CSF1Rmutation. Our findings suggest that increased levels of wild-type CSF1R relative to the mutant version, whetherachieved by mosaicism or chimerism, may confer benefit in HDLS and suggestthat HSCT might be considered for this disorder.

503T

Gluten-free diet is a cornerstone of Ehlers-Danlos syndrome management. *K. Angione, J.D. Milunsky, J.M. Milunsky.* Center for Human Genetics, Inc., Cambridge, MA.

Ehlers-Danlos syndrome (EDS) is a heterogeneous group of heritable connective tissue disorders divided into six major types. The most well recognized include "classical" (type I and II), "hypermobility" (type III), and "vascular" (type IV). EDS is characterized by arthralgia, joint and skin hypermobility, and vascular manifestations. Gastrointestinal (GI) issues and autonomic dysregulation are also common among individuals with EDS.EDS patients typically present with a myriad of symptoms calling for implementation of various management strategies. These may include both holistic approaches and medical interventions. We proposed that implementation of a gluten-free (GF) diet as one of several management strategies will be effective in improving the symptoms of EDS patients, particularly those suffering from multiple gastrointestinal ailments. The GF diet, while primarily used for the treatment of individuals with Celiac disease, has also been utilized as a treatment option for patients with a variety of other disorders, including irritable bowel syndrome, rheumatoid arthritis, diabetes mellitus, and chronic fatigue syndrome.Consumption of a GF diet has the potential to alleviate a wide variety of gastrointestinal symptoms, including chronic nausea/vomiting, abdominal pain, bloating, and IBS symptoms (frequent diarrhea and constipation). GF diets also yield additional benefits beyond the GI tract. Patients have reported decreased joint pain, improvement in autonomic symptoms (including fatigue, "brain fog," dizziness, and paresthesias), and an overall improvement in well-being.Out of 100 patients with a clinical diagnosis of EDS seen at our Center, 51 (51%) implemented a GF diet as part of their management plan. 38 of these patients (74.5%) reported improvement of symptoms with a "strict" GF diet. One additional patient (2.0%) reported improvement with a limited gluten diet. 12 patients (23.5%) reported that they had not observed any significant improvement of symptoms after a trial period of at least 6 weeks. In cases where multiple members of the same family were evaluated, only the proband was considered for these analyses.Adherence to a gluten-free diet significantly improves self-reported symptoms among individuals with EDS, contributing to improvement of autonomic symptoms, lowered pain scores, decreased gastrointestinal symptoms, and an overall improvement of quality of life. A GF diet should be considered an essential component of EDS management.

Transcriptome Comparison of Rat and Human Schwann Cells. *D. Sant[1], P. Monje[2], D. Van Booven[1], G. Wang[1].* 1) John P. Hussman Institute of Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) The Miami Project to Cure Paralysis and Department of Neurological Surgery, University of Miami Miller School of Medicine, Miami, FL.

Schwann cells (SCs) are the myelinating glial cells in the peripheral nervous system. Transplantation of SCs has been shown to improve functional recovery of spinal cord injury in rats, suggesting a similar cell therapy for human treatment. However, human experiments have failed to yield the same success as rat treatments. The failure to achieve the same success as in rat cells is hypothesized to be due to inherent differences between rat and human SCs rather than differences in experimental design. To investigate the differences between human and rat SCs that have led to key differences in the ability to remyelinate neurons, we performed whole transcriptome sequencing (RNAseq) on human and rat SCs grown under identical conditions. Statistical significance in the difference of levels of transcripts were determined using three separate programs: BaySeq, DESeq, and edgeR. We found that 7284 of the 16483 homologous genes (44%) were expressed differentially. Further pathway analysis using MetaCore revealed two important pathways to be deficient in human SCs, both of which are known to mediate the SC's response to axon contact and differentiation into myelinating cells: (1) in the adenylate cyclase/cAMP signaling pathway, 15 of the known 31 genes were found deficient in human SCs; (2) in the extracellular matrix (ECM)-dependent, adhesion-dependent control of cytoskeletal organization pathway, 37 of the known 111 genes were found deficient in human SCs. Knowledge of these key deficiencies can be used to predict the ability of SCs to myelinate in cell culture and after transplantion, and help in the design of human Schwann cell-specific potency assays for clinical trials of spinal cord injury.

The NIGMS Human Genetic Cell Repository at the Coriell Institute: A research participation opportunity for individuals with inherited diseases and chromosomal abnormalities. *N. Turan.* Coriell Institute for Medical Research, Camden, NJ.

The NIGMS Human Genetic Cell Repository was established at the Coriell Institute for Medical Research, an independent non-profit research institution, in 1972 by the National Institute of General Medical Sciences (NIGMS). The NIGMS Repository provides a readily accessible, centralized resource for cell lines and genetic material from individuals with genetic disorders, including heritable diseases and chromosomal abnormalities, and from individuals from various geographical locations for studies on human diversity. Samples are also collected from unaffected, first-degree relatives of individuals with genetic disease, and from apparently healthy individuals for the study of human variation.The primary goal of the NIGMS Repository is to stimulate and facilitate biomedical research, teaching, and the diagnosis and prevention of human genetic diseases by establishing and maintaining a repository of high quality, uncontaminated, well characterized, and clinically well-documented cell lines and DNA and making these resources available to investigators throughout the U.S. and abroad.The NIGMS Repository contains more than 11,300 cell lines, including human induced pluripotent stem cell (iPSC) lines, and 5,600 DNA samples, representing over 800 Online Mendelian Inheritance in Man (www.omim.org/statistics/entry, accessed 9/24/14) phenotypes.The NIGMS Repository is an invaluable resource and samples have been used for genetic testing assay development, validation and proficiency, identification of novel genes, exploration of gene function and expression, and generation iPSC lines. To date, there have been over 6,000 publications citing NIGMS Repository samples. The NIGMS Repository is also an important resource for clinicians and genetic counselors as it offers an opportunity for patients and families to contribute to the research process in addition to, or in the absence of, the availability of clinical testing or disease-specific research. Sample donation requires a blood or tissue specimen and completion of an informed consent, a submission form, and a clinical data summary.

Accelerate R&D in genetic diseases for diagnostic and therapy: initiatives from the International Rare Disease Research Consortium (IRDiRC). *S. Ayme[1], A. Mills[1], L. Lau[1], P. Lasko[2], International Rare Diseases Research Consortium.* 1) US14-Orphanet, INSERM, Paris, ile de France, France; 2) CIHR Institute of Genetics, McGill University, Montreal, QC, Canada.

Despite considerable advances in the scientific field, genetic disease patient needs are far from covered, both in terms of diagnostic measures and in terms of effective therapies. To ensure that data generated by research is optimally used for the benefit of patients, an international consortium was set up as an initiative of the European Commission and the United States' National Institutes of Health. The consortium conducted in-depth discussions with all stakeholders on the obstacles to overcome in efforts to accelerate R&D in rare diseases. This brainstorming period resulted in recommendations for funding agencies and researchers to optimize the use of shared data through database and knowledge accessibility and interoperability. Moreover, five actions were launched. The first consists in promoting the use of ontologies to describe phenomes, essential for clinical databases to become interoperable. The second is to create a data exchange platform, enabling recognition of clinically similar cases according to clinical features or genomic data in efforts to identify new clinical entities, jointly with the Global Alliance for Genomics and Health. The third is to reach an international agreement on acceptable alternatives to randomized clinical trials when they are not applicable, and increase acceptability of new methods by regulatory agencies. The fourth is to accelerate the development of criteria to measure treatment effects that are relevant to patients. The fifth is to coordinate efforts to develop the use of scientific and clinical data by using dispersed resources, including natural language, for selecting drugs as potential treatment options for rare diseases. Initiatives, both academic and commercial, have bloomed recently, targeted at identifying new therapeutic targets and to repurpose drugs. They leverage on developments in Computational Linguistics and Graph Theory, to build a representation of knowledge which is automatically analysed to discover hidden relations between any drug and any disease, representing possible Modes of Action for any given pharmacological compound. Their efficacy for selecting drugs as treatment options for genetic diseases is already documented. All these initiatives constitute IRDiRC's roadmap which will be presented. .

507T

The ketogenic diet rescues defects of hippocampal neurogenesis in a mouse model of Kabuki syndrome. *J.S. Benjamin[1,2], G.A. Carosso[1,2], G. Pilarowski[1,2], L. Zhang[1], H. Cho[1], K.D. Hansen[1,3], H.J. Vernon[1,4,5], H.T. Bjornsson[1,5].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Sch Med, Baltimore, MD; 2) Predoctoral Training Program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland; 3) Department of Biostatistics, Bloomberg School of Public Health, Baltimore, Maryland; 4) Kennedy Krieger Institute, Baltimore, Maryland; 5) Department of Pediatrics at the Johns Hopkins University School of Medicine, Baltimore, Maryland.

Kabuki syndrome (KS) is a genetically determined intellectual disability syndrome associated with distinctive facial features, immune deficiency, and growth retardation. KS is caused by mutations in either *KMT2D* or *KDM6A*, components of the histone machinery which both participate in the process of chromatin opening. If an inability of chromatin opening plays a role in the pathogenesis of KS, agents that favor chromatin opening such as the histone deacetylase inhibitors (HDACi) may provide therapeutic benefit. To test this hypothesis we previously characterized a mouse model of KS (*Kmt2d+/bGeo*), with craniofacial abnormalities, decreased H3K4me3 in the granule cell layer (GCL) of the dentate gyrus, and defects of neurogenesis and hippocampal memory. We saw rescue of all observed defects after treatment with an HDACi (AR-42) for two weeks. However, as a cancer drug, it may be difficult to transition AR-42 to the clinic, necessitating other possible treatments. Recently beta-hydroxybutyrate (BHB), a naturally produced ketone body, was shown to be an HDACi. We confirmed HDACi activity of BHB *in vitro* by a dose dependent increase in activity in an H4Ac reporter assay. To explore potential benefits of BHB *in vivo*, *Kmt2d+/bGeo* and *Kmt2d+/+* littermates were placed on a BHB promoting ketogenic diet (KD), which led to an increase of BHB in both genotypes. After two weeks on a KD we observed rescue of the neurogenesis deficiency as measured by the relative amount of doublecortin and EdU positive cells ($P<0.01$, $P<0.001$) as well as a normalization of open chromatin marks (H3Ac, H3K4me3) in the GCL ($P<0.05$, $P<0.05$) and gene expression abnormalities in the hippocampus in *Kmt2d+/bGeo*. On a KD, *Kmt2d+/bGeo* mice also demonstrated functional recovery in the number of platform crossings in a Morris water maze ($P<0.05$). In addition, exogenous administration of BHB ameliorated the neurogenesis defect supporting a mechanistic role for BHB for the observed therapeutic effect. Interestingly, while both genotypes showed increased BHB in response to a KD, *Kmt2d+/bGeo* mice demonstrate a natural predisposition towards elevating BHB compared to acetoacetate as well as an elevation of lactate compared to pyruvate ($P<0.05$), but both systems are under the control of the NADH/NAD+ ratio, an indicator of the cellular redox state. These data suggest that BHB elevation either through a ketogenic diet or exogenous administration may have therapeutic potential for KS and related disorders.

508W

Genetic Modifiers in Women with Turner Syndrome and Bicuspid Aortic Valve: Chromosomal Microarray and Whole Exome Sequencing. *P.S. Kruszka[1], S.I. Berger[1], N.K. Banks[1], A.F. Martinez[1], Y.A. Addissie[1], L.J. Olivieri[2], C.A. Bondy[3], M. Muenke[1].* 1) Medical Genetics Branch, NHGRI/NIH, Bethesda, MD; 2) Children's National Medical Center, Washington, D.C; 3) National Institute of Child Health and Human Development, National Institutes of Health, Bethesda Maryland.

INTRODUCTION: Biscupid aortic valve (BAV) occurs at a much higher frequency in individuals with Turner syndrome (>30%) than the general population (~1%). Bicuspid aortic valve is thought to result from haploinsufficiency of a putative gene or genes on the short arm of the X chromosome. This study investigates genetic modifiers of the aortic valve phenotype in women with Turner syndrome. **METHODS:** Women with monosomy X by 50 metaphase karyotype were enrolled. Aortic valves were evaluated with cardiac MRI. SNP array and whole exome sequencing completed evaluation. **RESULTS:** Twenty-five women with Turner syndrome, average age 44 years (range 27 to 68) were enrolled; 7 women had BAV (28%), 14 women had tricuspid aortic valve (TAV) (56%), and 4 women were classified as partial fusion based on cardiac MRI. Six patients had 7 copy number variations (CNVs), each of which contained genes involved in cardiac development or known to be associated with congenital cardiac malformations, including a deletion involving *CTNNA3*, a gene associated with arrhythmogenic right ventricular dysplasia. Exome sequencing yielded a total of 1,146,906 variants. Variants were then filtered for premature stop variants, splicing variants, frameshifts, and missense variants predicted to be damaging by PolyPhen-2, leaving 27,807 variants. Using these variants, a case-control evaluation was done on participants with bicuspid aortic valve versus tricuspid aortic valve using a threshold of $P < 0.01$ (uncorrected). There were 10 variants in 7 genes that were predicted to be deleterious by PolyPhen-2 with a $P < 0.01$ (uncorrected). The most significant gene was *DYNC2H1* ($P = 7.2 \times 10\text{-}4$), which was the only gene known to be associated with CHD. A candidate gene approach was conducted with 542 genes involved in cardiac development in humans and animal models. A total of 332 variants in 139 genes were found, with an equal distribution in BAV (14.7 variants/individual), TAV (12.7 variants per individual), and PF (12.8 variants per individual) ($P > 0.8$). Of the genes know to be associated with BAV (*NOTCH1, GATA6, FBN1, TGFBR2, ACTA2, HOXA1, KCNJ2*, there were two deleterious variants in *NOTCH1* found in patients, one in BAV (p.R621H) and one in TAV (p.A2044T). **CONCLUSION:** This study is the first whole exome sequencing evaluation of women with Turner syndrome. Our results suggest that the bicuspid aortic valve phenotype is a complex trait that may involve multiple modifier genes.

A comprehensive sequence analysis of 22 tRNA genes identified a critical role of mitochondrial defects in hypertension. *M. Wang[1], P.P. Jiang[1], L. Xue[2], M.X. Guan[1].* 1) Institute of Genetics, School of Medicine, Zhejiang University, Hangzhou, Zhejiang, China; 2) Attardi Institute of Mitochondrial Biomedicine, Wenzhou Medical University, Wenzhou, Zhejiang, China.

Hypertension is one of the major global public health problems, affecting approximately 1 billion worldwide, including 265 million adults in the China in hypertension.

Mitochondria can regulate multiple aspects of vascular function and be critical for pathogenesis of hypertension. However, only limited insight into the pathogenesis of hypertension has come from the genetic defects of mitochondrial genomes. In this report, we performed the first comprehensive study to investigate the spectrum and incidence of mutations in 22 mitochondrial tRNA genes in a cohort of 2070 Chinese subjects with hypertension. This analysis identified 165 nucleotide changes occurred at variable positions among 22 tRNAs. The numbers of variants varied from 3 in the tRNASer(UCN) to 24 in the tRNAThr. Then all the variants were evaluated for pathogenicity using following criteria: evolutionarily conserved nucleotides among 41 vertebrates, the absence of 512 controls, and potential structural and functional alterations. This analysis showed that 117 variants were polymorphisms and 47 variants including 4 known hypertension-associated mutations were putative pathogenic mutations. These putative mutations may destabilize the structures of tRNAs such as altering Watson-Crick (WC) base-pairings and disrupt tRNA functions included improper maturation of tRNA molecules, reduced ability to be charged by the cognate amino acid, or inability to decode corresponding codons. Consequently, a failure in tRNA metabolism may cause mitochondrial dysfunction for the development of hypertension. Our data provide the evidence that mitochondrial tRNA mutations are the important cause of hypertension, particularly accounting for 3.9% cases of 2070 Han Chinese subjects with hypertension, which may provide new insights into the pathophysiology and valuable information for management and treatment of hypertension.

510F

***PNPLA3* rs738409 is associated with APRI, a clinical predictor of hepatic fibrosis that shows association with left ventricular mass: the Strong Heart Family Study.** *S. Cole[1], K. Haack[1], J. Kent, Jr.[1], H. Göring[2], L. Best[3], E. Lee[4], R. Loomba[5], J. Umans[6], J. Weinsaft[7], R. Devereux[7].* 1) Dept Gen, Texas Biomedical Research Inst, San Antonio, TX; 2) South Texas Diabetes and Obesity Institute, University of Texas Health Sciences Center at San Antonio, Brownsville, TX; 3) Missouri Breaks Industries Research, Inc. Eagle Butte, SD; 4) Dept of Biostatistics and Epidemiology, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 5) Division of Gastroenterology and Epidemiology, University of California at San Diego, La Jolla, CA; 6) MedStar Health Research Institute, Hyattsville, MD; 7) Division of Cardiology, Weill Cornell Medical College, New York, NY.

Increased fibrosis is known to contribute to both hepatic disease and CVD. We tested these relationships in American Indians (AI), investigating whether hepatic fibrosis (HF), as assessed by the aspartate aminotransferase (AST) to platelet ratio index (APRI), is associated with left ventricular mass (LVM), a predictor of adverse cardiac outcomes. We also tested whether APRI is associated with *PNPLA3* rs738409, a known genetic risk variant for non-alcoholic fatty liver disease (NAFLD [MIM613282]). **Methods:** We studied 3,645 AI multigenerational family members from the Strong Heart Family Study (SHFS), from Arizona (AZ), North/South Dakota (DA) and Oklahoma (OK). Measures include alcohol consumption (ETOH), echocardiographically-measured LVM, alanine aminotransferase (ALT), AST (UI/L) and patatin-like phospholipase domain-containing protein 3 (*PNPLA3*) rs738409 [PNPLA3 I148M] genotypes, collected using standard methods. APRI was calculated as [((AST/AST upper limit of normal)/platelet count(109/L)) x 100]. APRI was tested for association with LVM while stratifying by ETOH (no vs. high [>3 drinks/day men, >2 drinks/day women]). Measured genotype analysis in SOLAR was used to test center-specific association between rs728409 genotype and APRI after adjustment for age, sex, BMI and ETOH, while accounting for pedigree relationships, with significance at a Bonferroni-corrected p-value=0.004. **Results:** We observed an APRI >1.5 (indicating significant HF) in 3.0%, 1.4% and 1.8% of the AZ, DA and OK participants, respectively, suggesting undiagnosed fibrotic disease in this AI population. An APRI > 1 was significantly associated with higher LVM in participants reporting either no (p=0.008) or high ETOH (p=0.01), indicating that HF may be correlated with cardiac remodeling and impaired function. Allele frequencies for rs738409 (C reverse strand; G coding missense) were 0.21, 0.55, 0.47 in AZ, DA and OK. Rs738409 was significantly associated with ALT, AST and APRI measures across all centers (p = 4x10-4 to 3.7x10-8), but unlike other populations, the G coding allele is associated with lower levels of the liver function and HF measures, suggesting additional genetic effects at this locus marked by this allele in AI. Rs738409 was not associated with LVM likely due to fibrosis being only one of many determinants of LVM. In conclusion, for the first time, and in AI, we demonstrate the association of *PNPLA3* rs738409 with APRI, a measure that links HF to CVD risk.

511W

Functional variants in a clinical setting: an example using *APOC3* R19X and extreme triglyceride levels extracted from electronic health records. *D.C. Crawford[1], K.E. Diggins[2], N.A. Restrepo[2].* 1) Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN.

In a personalized or precision medicine setting, patients with extreme triglyceride (TG) levels may be flagged for further evaluation for cardiovascular disease risk assessment (TG ≥200 mg/dl) or for the presence of hyperthyroidism, malnutrition, or malabsorption disease (TG ≤10 mg/dl). We hypothesize that the addition of functional genetic variants such as *APOC3* R19X, a variant (rs76353203) associated with low TG levels and cardioprotection, can further facilitate the triage process in assessing disease risk among flagged patients. To test this approach, we surveyed BioVU, the Vanderbilt University Medical Centers's biorepository linked to de-identified electronic health records (EHRs), for adult European American patients (>45 and >55 years of age for men and women, respectively) with the lowest percentile of TG levels. The initial search identified 262 patients with the lowest TG levels in the biorepository; among these, 184 patients with sufficient DNA and the lowest TG levels were chosen for Illumina ExomeChip genotyping. Almost half the genotyped patient sample was female (43.5%) and the average body mass index was 24.8 kg/m2. As expected based on the sampling criteria, this was an older patient population with 28% born in the 1940s and 14.7% born in the 1930s (range: 1910s to 1960s). The first mentioned TG levels for these patients ranged from 15 mg/dl to 161 mg/dl with an average first TG level of 39.3 mg/dl. More than half of the genotyped patients (60.3%) had more than one TG level in the EHR. A total of two patients were identified as heterozygotes of *APOC3* R19X for a minor allele frequency (MAF) of 0.5% in this patient population of low TG compared with a recent estimate of 0.08% in a general American population ascertained by the National Health and Nutrition Examination Surveys. Both heterozygous patients had only a single mention of TG in the EHR (31 and 35 mg/dl, respectively). In this patient population, the inclusion of *APOC3* R19X genotypes in the EHR did not assist in assessing hyperthyroidism, malnutrition, or malabsorption given no TG levels ≤10mg/dl were identified in the EHR. However, at least two patients were identified as carriers of a null variant strongly associated with cardioprotective lipid profiles and decreased risk for coronary artery disease highlighting the possible utility of inclusion of functional genetic variation in clinical risk assessment.

512T

Striatin is a novl risk gene for human dilated cardiomyopathy. *M. Dasouki[1], N. Muiya[1], M. Abouelhoda[1], E. Alsolme[2], M. Nader[1,2], N. Dzimiri[1].* 1) Genetics, King Faisal Specialist Hospital & Research Center , Riyadh, Saudi Arabia; 2) Department of Physiology,College of Medicine, Al Faisal University, Riyadh, Saudi Arabia.

Introduction: Striatin (*STRN*) is a WD-repeat calmodulin-binding protein which binds to caveolin-1 and PP2A. It is localized in the dendritic spines of the brain striatum, motor and olfactory systems as well as the intercalated disc regions of the cardiac myocytes along with the three desmosomal proteins, Plakophilin-2, Plakoglobin and Desmoplakin which are known to cause dilated cardiomyopathy (DCM). In the Boxer dogs, spontaneous mutations in *STRN,* especially an 8-bp deletion in the 3' untranslated region, have been associated with arrythmogenic right ventricular cardiomyopathy (ARVC) and DCM, manifested by ventricular systolic dysfunction, dilatation and tachyarrhythmias, syncope, and even sudden death. More recently, association studies of single nucleotide polymorphic variants in mice and humans revealed a role for striatin in QRS duration and cardiac ventricular conduction as well as modulating the interaction between salt intake and blood pressure via the nongenomic mineralocorticoid receptor pathway. However, cardiac related mutations and expression in human *STRN* are still unknown.**Hypothesis**: Genomic variants in *STRN* may have a pathogenic role in human DCM.**Methods:** The full coding region of *STRN* was Sanger sequenced in gDNA samples from 96 Saudi Arabian adult patients with idiopathic DCM, and Western blotting performed in cardiac left ventricular tissue (9 DCM versus 5 controls).**Results**: A total of 277 novel heterozygous variants were identified in the entire cohort with two hot spots (50% in exon 17 and 33% in exon 2). Within the coding sequence, 7 novel exonic missense, 1 stop-gain and 1 frameshift SNVs were found, in addition to 28 variants in the 3'UTR of the gene. The novel SNVs identified in patients with idiopathic DCM include 2 potentially damaging (*STRN*:NM_003162:exon3: c.363C>G: p.Y121X and exon18:c.2318dupA:p.D773fs) truncating variants. Western blotting results indicated that the expression of STRN is lower in DCM left ventricles compared to control myocardium.**Conclusion**: This data suggests that *STRN* is a novel risk gene for DCM. Functional characterization of the effect of these novel variants in a Zebrafish model is underway.

513F

Testing population-specific quantitative trait associations for clinical outcome relevance in a biorepository linked to electronic health records: *LPA* and myocardial infarction in African Americans. *L. Dumitrescu[1], K.E. Diggins[1], R. Goodloe[1], D.C. Crawford[2].* 1) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 2) Institute for Computational Biology, Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Previous candidate gene and genome-wide association studies have identified common genetic variants in *LPA* associated with the quantitative trait Lp(a), and emerging risk factor for cardiovascular disease. The associations are population-specific and many have not yet been tested for association with the clinical outcome of interest. To fill this gap in knowledge, we accessed BioVU, the Vanderbilt University Medical Center biorepository linked to de-identified health records (EHRs), including billing codes (ICD-9-CM) and clinical notes, to test population-specific Lp(a)-associated variants for an association with myocardial infarction (MI) among African Americans. We performed electronic phenotyping among African Americans in BioVU ≥40 years of age using five case definitions for MI (#1: 1 ICD-9 code 410.* on three consecutive days; #2: 1 ICD-9 code 410.* on two consecutive days; #3: ≥3 ICD-9 code 410.* ever; #4: ≥2 ICD-9 code 410.* ever; #5: ≥1 ICD-9 code 410.* ever) and a single control definition (exclude MI: ICD-9 code 410.* and exclude ischemic heart disease: codes 411.*, 412.*, 413.*, 414.*). After review of the EHRs using keyword searches of the clinical notes (for "myocardial infarction", "MI", "infarc", "STEMI", "NSTEMI"), a total of 311 MI cases were confirmed, resulting in a positive predictive values ranging from 87.6% (definition #5) to 99.4% (definitions #2 and #3). Among the 5,883 controls identified, 344 were frequency matched for age and sex and chosen for genotyping. A total of five known Lp(a)-associated genetic variants in African Americans were genotyped using Sequenom: rs1367211, rs41271028, rs6907156, rs10945682, and rs1652507. *LPA* rs3798220 (I4399M) previously associated with increased levels of Lp(a), MI, and coronary artery disease in European Americans was also genotyped. Tests of association using logistic regression assuming an additive genetic model revealed no significant associations ($p<0.05$) for any of the five *LPA* variants previously associated with Lp(a) levels in African Americans. Interestingly, I4399M rs3798220 was not associated with MI in African Americans (odds ratio = 0.51; 95% confidence interval: 0.16 – 1.65; $p=0.26$) despite strong, replicated associations with MI and coronary artery disease in European American genome-wide association studies. These data highlight the challenges in translating quantitative trait associations to clinical outcomes in diverse populations.

514W

***APOL1* risk allele is associated with early diagnosis of hypertension and a 2-3 mmHg increase in systolic blood pressure in young African American adults.** *G. Galarneau[1], G.N. Nadkarni[1], S.B. Ellis[1], R. Nadukuru[1], S.A. Scott[1], T.A. Manolio[2], R. Li[2], L.J. Rasmussen-Torvik[3], A.N. Kho[3], M.G. Hayes[3], J.A. Pacheco[3], R.L. Chisholm[3], D.M. Roden[4], J.C. Denny[4], E.E. Kenny[1], E.P. Bottinger[1], eMERGE network.* 1) Icahn School of Medicine at Mount Sinai, New York, New York, USA; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 3) Feinberg School of Medicine, Northwestern University, Chicago, Illinois, USA; 4) Vanderbilt University Medical Center, Nashville, Tennessee, USA.

Apolipoprotein L1 (*APOL1*) risk allele is associated with end-stage renal disease in African American (AAs). To determine whether *APOL1* was associated with blood pressure (BP) traits as predisposing factors for kidney disease, we performed a retrospective analysis of longitudinal patient health records in 3 biobanks in the Electronic Medical Records and Genomics (eMERGE) network.The discovery cohort consisted of 5,213 AAs from Mount Sinai Bio*Me* Biobank. Replication cohorts consisted of an independent set from Bio*Me* (n=1,655), Vanderbilt BioVu (n=2,889) and Northwestern NUgene (n=613) biobanks. Median follow-up was 5, 3, 6 and 8 years, respectively. We genotyped SNPs comprising the *APOL1* G1 and G2 renal risk alleles; rs73885319, rs71785313 and rs60910145 in Bio*Me*and imputed the genotypes in BioVu and NUgene with Illumina 1M data. The *APOL1* risk allele (2 copies of G1 or G2) frequencywas 14%-16%. We performed Cox proportional hazards and linear and logistic regression to test association of the *APOL1* risk allele with time to hypertension (HTN) onset, BP as a continuous outcome, and hypertensive end organ damage as dichotomous outcomes. We used METAL for meta-analyses of replication cohorts.In 457 individuals with the risk allele and diagnosed HTN, median documented onset of HTN was 2-5 years younger with age, sex and BMI as covariates in discovery (Pdis=0.04) and replication cohorts (Prep=3x10-4).To test if there were age-specific associations between the *APOL1* risk allele and systolic (SBP) or diastolic (DBP) blood pressure, we divided the cohorts in 20-year age groups (20-39, 40-59 and 60-79). In the 20-39 yo AAs without BP medication, the risk allele accounted for 2-3 mmHg SBP elevation (Ndis=946; Pdis=0.04; Prep=6x10-4 with sex and BMI as covariates; Ndis=822; Pdis=0.07; Prep=0.04 with sex, BMI and eGFR as covariates). AAs with the risk allele in Bio*Me* were more likely to manifest hypertensive organ damage including concentric left ventricular hypertrophy by echocardiogram (OR [95% CI]=1.57[1.18-2.08] P<0.01) and hemorrhagic cerebrovascular accidents (OR [95%CI]=2.66[1.31-5.38] P=0.01) with sex, age and BMI as covariates.**Conclusion:** Compared to other known BP loci, *APOL1* is a large effect size locus for SBP in young AAs that may account in part for well-documented higher BP and health disparities associated with HTN in younger AAs.

515T

MyBPH acts as a modifier of hypertrophy in patients with Hypertrophic Cardiomyopathy. *C.J. Kinnear[1], JC. Moolman-Smook[1], A. Goosen[2], M. Revera[3], PA. Brink[2], L. van der Merwe[4], JM. Mouton[1].* 1) SAMRC Centre for Tuberculosis Research, Department of Biomedical Sciences, Stellenbosch University, Cape Town, Western Cape, South Africa; 2) Department of Medicine, Faculty of Medicine and Health Sciences, Stellenbosch University, South Africa; 3) Department of Cardiology, IRCCS San Matteo Hospital, Pavia, Italy; 4) Department of Statistics, Faculty of Natural Sciences, University of the Western Cape, South Africa.

Hypertrophic cardiomyopathy (HCM) is considered a model disease to study molecular factors underlying isolated cardiac hypertrophy. HCM manifests with various phenotypes and clinical symptoms, even in families with the same genetic defects, suggesting that additional factors contribute to the disease phenotype.Recently MyBPH, a sarcomeric protein, was shown to be involved in cardiomyocyte contraction. MyBPH is structurally similar to cardiac myosin binding protein C (cMyBPC), of which the encoding gene, *MyBPC3*, is one of the most frequently implicated genes in HCM. Given the similarity between cMyBPC and MyBPH, and the critical role MyBPH plays in sarcomere contraction, we propose that MyBPH may be involved in the modulation of cardiac hypertrophy.A family-based genetic association analysis approach was used to investigate the hypertrophy modifying effects of seven single nucleotide polymorphisms (SNPs) and haplotypes in *MyBPH*, in 256 individuals from 27 families, in which three unique South African HCM-causing founder mutations (p.R403W and pA797T in β-myosin heavy chain gene (*MYH7*) and p.R92W in the cardiac troponin T gene (*TNNT2*)) segregate. Each participant underwent extensive clinical screening which included assessments of ventricle wall thickness, maximal posterior wall thickness and maximal intraventricular septum thickness by 16 2D-echocardiographic measurements taken at the mitral valve-, papillary muscle- and supra-apex levels. SNP genotyping was done using the PCR-based KASPTM genotyping assays. Genetic association between each variant and haplotype and hypertrophy traits chosen to represent the HCM hypertrophic phenotype was analyzed with a specialized mixed-effects linear model.Significant evidence for association between three SNPs and hypertrophy traits was observed when stratifying the cohort according to HCM-founder mutations. Interestingly, we observed associations between SNPs *rs2250509*, *rs3737872* and *rs762625* and hypertrophy traits only in the p.A797TMYH7 HCM founder mutation group. Furthermore, we found that several haplotypes had markedly different significant effects in two of the HCM founder mutation groups (p.A797TMYH7 and p.R92WMYH7) and in the total cohort.Our findings suggest that the hypertrophic phenotype of HCM is modulated by the compound effect of a number of variants and haplotypes in *MyBPH*. These novel results therefore provide a basis for future studies to investigate the risk profile of hypertrophy development.

516F

Functional genomic analysis of blood and cardiac tissue during ischemia reperfusion (IR). *D. McDaniel[1], D. Rigney[1], X. Zhou[2], A. Simeone[1], L. McDaniel[3].* 1) Dept Surgery, Univ Mississippi Med Ctr, Jackson, MS; 2) Dept Pathology; 3) Dept Microbiology/Immunology.

Ischemia/reperfusion (IR) during organ procurement contributes significantly to tissue injury and may cause early organ dysfunction after transplantation. Genes associated with innate immunity are prime activators of early inflammatory responses to an allograft that lead to host-induced inflammation and organ rejection. We hypothesized that Allograft inflammatory factor 1 (AIF-1)/Daintain could promote activation of innate immune response through the activation of cardiac TLRs released during organ procurement and may contribute to allograft dysfunction. We have investigated the impact of IR injury in an *in vitro* study of human heart tissue during the process of transplantation. In addition, we investigated expression levels of AIF-1 and TLRs during cardiac IR in a rat model of the left anterior descending artery (LAD) occlusion which generates ischemia in left ventricle (LV). The mRNA expression levels of AIF-1 isoform 2 and 3 were significantly increased after 30 min ischemia/60 min reperfusion ($p<0.01$ and $p<0.005$ respectively). TLR-2 expression was minimal but the TLR-4 was non-specific. In LAD study, AIF-1 and TLR mRNA transcripts were significantly increased in a time dependent- manner after IR. These markers were upregulated as early as 10 minutes after reperfusion and further they were increased several-fold after 60 minutes of reperfusion in tissue and peripheral blood cells as compared to the control group. The TLR-2 levels were greater in blood samples, whereas, the TLR-4 levels were greater in cardiac LV after 30 min LADI/60 min reperfusion. In summary, the data supports role of the AIF-1 and TLRs in early activation of innate immune response, thus the control of these genes may have therapeutic potential for strategies preventing allograft dysfunction early on after transplantation.

517W

Rare coding variants associated with blood pressure in ~13,000 individuals of African ancestry. *P. Nandakumar[1], D. Lee[1], F. Tekola-Ayele[7], B. Tayo[6], E. Ware[4], C.C. Gu[5], M. Fornage[2], S. Kardia[4], C. Rotimi[7], R. Cooper[6], D.C. Rao[5], A. Morrison[2], G. Ehret[1,3], A. Chakravarti[1].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD; 2) Institute of Molecular Medicine and Human Genetics Center, University of Texas Health Science Center, Houston, TX; 3) Department of Specialties of Medicine, Geneva University Hospitals, Geneva, Switzerland; 4) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 5) Division of Biostatistics, Department of Medicine, Washington University School of Medicine in St. Louis, St. Louis, MO; 6) Departments of Public Health Sciences and Medicine , Loyola University Stritch School of Medicine , Maywood, IL; 7) Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Hypertension is a major risk factor for cardiovascular disease. Several genome-wide association studies (GWAS) have implicated common variants at ~80 loci in systolic and diastolic blood pressure (BP) regulation across multiple populations, but the specific genes at these loci are unknown. This study focuses on identifying these and other specific BP genes associated with BP traits in individuals of African ancestry using six cohorts (GenNet, GENOA, HyperGEN, ARIC, HUFS, LUC) genotyped on the Illumina HumanExome BeadChip v1.0 (n=247,870 variants) or v1.1 (n=242,901). Data cleaning yielded a final set of 12,922 individuals and 162,702 variants for analysis. Fixed-effects meta-analyses were performed with the seqMeta R package for SBP and DBP, each adjusted for age, age-squared, sex, BMI and the first 10 principal components of ancestry from each cohort. These analyses include single variants analyzed by frequency class (common: $MAF\geq0.05$, low frequency: $0.01\leq MAF<0.05$ and rare: $MAF<0.01$), gene-based analysis with SKAT and the T1 burden test on variants with $MAF<0.01$, and those considered "damaging" (defined as intronic splice, NMD-compatible stop-gain, and conserved missense (phyloP>4)). Results were multiple test corrected by the Bonferroni method.**Results**: Associations of rare variants in *AFF1*, encoding an mRNA transcription elongation protein, (rs142319329, DBP, P=3.65x10-7) and *XPOT*, encoding an exportin, (rs140705696, DBP, P=2.58x10-7) were identified, with six and four copies across the six cohorts, respectively. Further, associations of rare variants with two to four carriers in *KIF21B*, *KRBA1* and *OR51B2* were identified for SBP. *XPOT* was also found to be significant in the SKAT test for both SBP (P=1.37x10-6) and DBP (P=3.47x10-7) and in the T1 test on damaging SNPs (P=4.33x10-6). A previous study identified an association between a locus containing *Xpot* and atrial weight index in atenolol-treated mice; the group further demonstrated expression of this gene in cardiac tissue. Additionally, for DBP, *TEC*, encoding a tyrosine kinase, was associated in the T1 test on all variants with MAF<0.01 (P=2.31x10-6), and *QSOX1*, encoding a sulfhydryl oxidase enzyme, was associated in the T1 test on damaging variants (P=3.74x10-6). Recent experiments support cardiovascular function for *QSOX1*, including its induction of vascular smooth muscle cell migration and proliferation *in vitro*. These results suggest credible candidate genes for BP regulation.

518T

The contribution of common and low-frequency/rare variants in ATP-binding cassette A1 *(ABCA1)* to lipoprotein-lipid traits. *V. Niemsiri[1], X. Wang[1], Z.H. Radwan[1], D. Pirim[1], J.E. Hokanson[2], R.F. Hamman[2], M.M. Barmada[1], F.Y. Demirci[1], M.I. Kamboh[1].* 1) Human Genetics, Graduate School of Public Health, Pittsburgh, PA; 2) Epidemiology, Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO.

Coronary heart disease (CHD) is the leading cause of deaths globally. Risk factors for CHD include abnormal lipoprotein-lipid levels (i.e., high low-density lipoprotein cholesterol [LDL-C] levels, low high-density lipoprotein cholesterol [HDL-C] levels and high triglycerides [TG]). ATP-binding cassette A1 (ABCA1), a transmembrane transporter, plays an important role in the reverse cholesterol transport, specifically in the delivery of free cholesterol and phospholipids to form nascent HDL-C particles and in the cholesterol efflux. In humans, defects in *ABCA1* cause low levels of HDL-C, including Tangier disease (TD; MIM: 2054000). In addition to HDL-C deficiency, an increased risk of CHD has been observed in TD. In this study, we aimed to identify common (minor allele frequency [MAF] ≥5%) and low-frequency/rare variants (MAF<5%) and to evaluate the genetic contribution of *ABCA1* variants to plasma lipoprotein-lipid levels. We resequenced 50 exons and exon-intron boundaries of *ABCA1* in 95 individuals with extreme HDL-C levels (≤10th and ≥90th %tile) followed up by genotyping of selected variants in the entire sample of 623 US Non-Hispanic Whites. Subsequently, we examined the association between genotyped *ABCA1* variants with four lipoprotein-lipid traits (HDL-C, LDL-C, total cholesterol [TC], and TG). We identified 404 sequence variants (including 37 novel variants), and then selected 250 variants (216 from sequencing stage and 34 from HapMap-CEU database) for genotyping. A total of 182 bi-allelic variants (MAF≥5%, n=116; MAF<5%, n=66) passed genotyping quality controls and were advanced in downstream analyses. Gene-based test showed evidence of association between 182 *ABCA1* variants and TG (P=0.0108). Single-site association analyses revealed 26 common *ABCA1* variants nominally associated (P<0.05) with at least one lipid trait, of which 17 (16 with TG; best SNP: rs2066716 [p.Thr1427Thr], P=0.0016 and 1 with TC; rs4743763, P=0.0005) remained significant after adjustment for multiple testing. Haplotype association analyses identified 60 haplotype windows and 16 regions significantly associated with at least one lipid trait (global P<0.05). Rare variant analyses demonstrated evidence of lipid-association for multiple sets of low-frequency/rare *ABCA1* variants. Our findings support the role of *ABCA1*–common and low-frequency/rare variants—contributing to plasma lipoprotein-lipid levels in the general population.

Diastolic blood pressure and intraocular pressure gene variants in relation to primary open-angle glaucoma. *L.R. Pasquale[1], H. Aschard[2], J.H. Kang[3], J.C. Bailey[4], R.R. Allingham[5], J. Haines[4], P. Kraft[2], P. Hysi[6], M. Hauser[5], J.L. Wiggs[1], NEIGHBORHOOD Consortium.* 1) Ophthalmology, Harvard Medical School, Boston, MA; 2) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 3) Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 4) Department of Epidemiology and Biostatistics, Institute of Computational Biology, Case Western Reserve University School of Medicine, Cleveland, OH; 5) Department of Ophthalmology Duke University Medical Center, Durham, NC; 6) Department of Twin Research and Genetic Epidemiology, King's College London, UK.

Purpose: Alower ocular perfusion pressure, derived as diastolic blood pressure (DBP)minus intraocular pressure(IOP),is regarded as a strong risk factor for primary open-angle glaucoma (POAG). We evaluated whether single nucleotide polymorphisms (SNPs) associated with IOP orDBP show association with POAG using data from the NEIGHBORHOOD consortium,whichincludes3,853POAGcases and 33,495 controls. Methods: We selected from two pivotol meta-analyses, 7 independent SNPs associated with IOP and 27 associated with DBP at the genome-wide significance level.We tested the association of those SNPs with POAG and also generated a genetic risk score(GRS),defined as the weighted sum of IOP-increasing and DBP-decreasing alleles. We considered weights equal to the effect estimates from the original DBP and IOP studies, and equal weights. We also considered agender-specific effect, which we evaluated through an interaction analysis.Results: Based on the original reports, the DBP SNPs and IOP SNPs collectively explain 2.2% and 1.2% of the variance in the respective traits. Overall, IOP SNPs showed strong association with POAG -fiveof seven SNPs weresignificantat the Bonferroni correction levelof 0.0015(strongest association equals OR=1.41, 95% CI: 1.28, 1.56; P=5.9x10-13). The weighted andunweightedGRS were also highly significant (OR=2.38, 95% CI: 2.02-2.81; P=3.8x10-26and OR=1.19, 95% CI: 1.15-1.23;P=2.9x10-27, respectively). In contrast, only one DBP SNP demonstrated significance at the P=0.0015 level(OR=1.17, 95% CI: 1.09-1.25; P=6.2x10-6). Neither DBP GRSwassignificantly associated with POAG (P>0.28).No gender interaction effect was identified between any GRS or any of the SNPs. Conclusion: In agreement with the existing literature, we confirmed that POAG shares genetic basis withIOP. Conversely, it appears thatthemost establishedDBP SNPshave only limited contribution to POAG. .

Sequencing of *PEAR1* to identify rare and novel genetic determinants of platelet aggregation. *M.A. Taub[1], L.R. Yanek[2], K. Iyer[3], I. Ruczinski[1], D. Vaidya[2], N. Faraday[2], D.M. Becker[2], L.C. Becker[2], R.A. Mathias[2].* 1) Biostatistics, Johns Hopkins, Baltimore, MD; 2) The GeneSTAR Program, Johns Hopkins School of Medicine, Baltimore, MD; 3) Johns Hopkins School of Medicine, Baltimore, MD.

Platelet aggregation is heritable, and GWAS have found strong replicated associations of platelet aggregation to multiple agonists with a common intronic variant (rs12041331 (SNP1)) of the platelet endothelial aggregation receptor1 gene (*PEAR1*) in African Americans (AA) and European Americans (EA). Here, we used sequencing to refine the GWAS locus and identify additional rare/novel determinants of platelet aggregation in AA and EA subjects.Whole genome sequence (WGS) data on 214 unrelated GeneSTAR subjects (44% AA) was subset to chr1:156853490-156896226 to include *PEAR1*. These genomes were phased, and imputation was done in additional GeneSTAR subjects (N=1203 AAs and N=1990 EAs) using ~1M framework GWAS SNPs and the 214 GeneSTAR genomes as reference haplotypes. Tests for association for 28 platelet aggregation phenotypes were done in (1) the set of 214 subjects with WGS; and (2) the set of 2193 subjects with imputation, stratified by race. Phenotypes included platelet aggregation at baseline and post aspirin intervention (81mg/day for 14 days) across a range of doses of three agonists (collagen, epinephrine and ADP).The WGS data showed a strong association of a novel rare variant (MAF=1%) at chr1:156872148 in AAs ($p = 1.15 \times 10\text{-}9$) with aggregation to collagen. Interestingly, it is located ~2kb away from SNP1 also in intron 1, but is not in linkage disequilibrium with it. In the larger imputed dataset, SNP1 gave the strongest signal for AAs in 27 phenotypes ($p< 5.58 \times 10\text{-}7$ for all, MAF=0.36). SNP1 was also significant in EAs across multiple agonists ($p < 7.92 \times 10\text{-}6$, MAF=0.09). While in AAs, no imputed common exonic variants showed strong signals, in EAs we observed three common exonic variants (MAF=0.13-0.17) with strong association (rs822442, rs41273221 and rs56260937, $p < 8.63 \times 10\text{-}6$, D' with SNP1 = 0.4) for aggregation to epinephrine and ADP. rs822442 is missense; rs41273221 is missense and labeled "possibly damaging" by PolyPhen.This study confirms prior work by our group which demonstrated on an independent sample (N=104) that in reference to *common* variants (1) rs12041331 is a robust determinant of platelet aggregation across all agonists in AAs and EAs, and in AAs is the single strongest determinant; and (2) in EAs, there may be additional exonic variants that determine platelet aggregation. We show for the first time a rare novel variant plays a role specific to aggregation to collagen in AAs, also found in intron 1 of *PEAR1*.

521T

Exome sequencing identifies a possible new candidate gene associated with thoracic aortic aneurysms and dissections. *Y. Wan[1], J.A. Aragon-Martin[1], M. Simpson[2], N. Morsy[1], L.J. Collins[1], D. Osborn[3], J. Bharj[3], A. Saggar[4], D. Milewicz[5], M. Jahangiri[6], E.R. Behr[1], A. Child[1].* 1) Cardiovascular and Cell Sciences Research Institute, St. George's Hospital, University of London, United Kingdom; 2) Genomic Medicine Group, Division of Genetics and Molecular Medicine, Kings College London, United Kingdom; 3) Human Genetics Research Centre, St. George's Hospital, University of London, United Kingdom; 4) Clinical Genetics Unit, St George's University of London, United Kingdom; 5) Department of Internal Medicine, University of Texas, USA; 6) Department of Cardiothoracic Surgery, St. George's Healthcare NHS Trust, London, United Kingdom.

In the absence of syndromic thoracic aortic aneurysms and dissections (TAAD) such as Marfan, Loeys-Dietz and Ehlers-Danlos syndromes, ~20% is inherited with variability in penetrance and severity as well as male gender. Currently, 18 genes have been reported which account for ~25% of all cases and include; *ACTA2*, *COL3A1*, *EFEMP2*, *FBN1*, *FLNA*, *FOXE3*, *MAT2A*, *MYH11*, *MYLK*, *NOTCH1*, *PRKG1*, *SKI*, *SLC2A10*, *SMAD3*, *TGFB2*, *TGFBR1*, *TGFBR2* and *TGFBR3*. Therefore, a large proportion of cases do not have a disease-associated gene.The SGUL database has collected 100 TAAD probands over a 25 year period, which do not have an associated disease-causing gene. One of the probands had a strong TAAD family history and was analyzed by Sanger sequencing for the most common TAAD associated mutations in *ACTA2*, *FBN1*, *SMAD3*, *TGFBR1* and *TGFBR2* genes. A synonymous rare variant was detected in the *ACTA2* gene (c.246C>T) but did not segregate with affected members in this family. The three most distantly related affected individuals in this family were processed for exome sequencing. All reported TAAD genes were analyzed and no causative mutation in all affected individuals was found. The complete variant list was further filtered by removal of all intronic and intergenic polymorphisms (except splice site-disrupting variants), homozygous variants, heterozygous variants that did not segregate with the disease and MAF of >0.1% in 900 in-house controls, 1000 Genomes and EVS databases. This filtered the candidates to six genes. Confirmation via Sanger sequencing and segregation analysis provided one non-synonymous candidate variant that was found in all affected individuals. This gene is highly expressed in smooth muscle cells, suggesting a role in cardiovascular function. Sanger sequencing of this gene in the remaining 99 TAAD probands found four further variants, one for each of four probands. *In-silico* analyses (SIFT, Polyphen-2, Mutation Taster, UMD-Predictor and Align GVGD) indicated two of the four variations are disease-causing and further testing is being performed. An *in-vivo* knockdown model for this gene using the Zebrafish (*Danio rerio*) was developed by co-injecting two non-overlapping splice-directed morpholino oligonucleotides. Comparison of five days post fertilization injected fish with uninjected controls showed a large pericardial edema, moderate to severe tail curvature and reduced eye and body size, consistent with the recently published paper on a new TAAD gene *MAT2A*.

522F

Discovery of a deleterious variant in *TMEM87B* in a patient with a hemizygous 2q13 microdeletion, uncovers a recessive condition characterized by severe congenital heart defects. *H. Yu[1], C.R. Coughlin II[1], E.A. Geiger[1], E.R. Elias[1], J.L. Cavanaugh[2], S.D. Miyamoto[2], T.H. Shaikh[1,3].* 1) Department of Pediatrics, Section of Genetics, University of Colorado School of Medicine, Aurora, Colorado; 2) Department of Pediatrics, Division of Cardiology, University of Colorado School of Medicine, Aurora, Colorado; 3) Colorado Intellectual and Developmental Disabilities Research Center (IDDRC), University of Colorado School of Medicine, Aurora, Colorado.

Congenital heart defects (CHD) have an estimated incidence ranging from 4/1,000 to 50/1,000 and remain one of the leading causes of infant mortality and childhood morbidity worldwide. Despite significant advances made in medical research, the etiology of CHD is still not completely understood. Here, we describe a patient with CHD including atrial septal defect and restrictive cardiomyopathy along with craniofacial anomalies and developmental delay. Initial screening using chromosomal microarray analysis (CMA) identified a maternally inherited 2q13 microdeletion (chr2:111,406,838-113,102,594; hg19). The subject in this study had many of the features reported in previous cases with recurrent 2q13 deletion. However, the inheritance of the microdeletion from an unaffected mother combined with the low incidence (10%) and milder forms of cardiac defects in previously reported 2q13 microdeletion cases made the clinical significance of the CMA results unclear. We next used whole exome sequencing (WES) in a trio-based analysis of the patient and his unaffected parents. WES identified a paternally inherited *TMEM87B* mutation (c.1366A>G, p.Asn456Asp) in the patient. TMEM87B, a highly conserved, transmembrane protein of currently unknown function, lies within the critical region of the 2q13 microdeletion syndrome. Furthermore, a recent study had demonstrated that depletion of TMEM87B in a vertebrate model organism affected cardiac development and led to cardiac hypoplasia. Thus, by combining molecular testing results from CMA and WES, we were able to uncover an autosomal recessive disorder characterized by a severe cardiac phenotype and caused by compound heterozygous mutations in *TMEM87B*. This study not only expands the spectrum of phenotype associated with 2q13 microdeletion, but it also further confirms the role of *TMEM87B* in the etiology of 2q13 microdeletion syndrome, especially the cardiac pathology. Our results further suggest that patients with 2q13 deletion who also have signs of cardiac defects should be subject to TMEM87B mutation screening.

523W

Rare variants in primary cilium genes may contribute to the risk of AVSD in children with Down syndrome. *H. Corbitt[1], S. Sherman[2], E. Feingold[3], R. Reeves[4], M. Zwick[2], C. Maslen[1].* 1) Knight Cardiovascular Institute, and Department of Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR; 2) Department of Human Genetics, Emory University, Atlanta, GA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 4) Department of Physiology and McKusick Nathans Institute for Genetic Medicine, School of Medicine, Johns Hopkins University, Baltimore, MD.

Down syndrome (DS) is the most common aneuploidy in humans, 1 of every 700 live births, yet the etiology of the comorbidities associated with DS is poorly understood. Congenital heart defects are the most frequently occurring birth defect seen in children with DS. In particular, the risk of atrioventricular septal defect (AVSD) is 2000-fold higher in children with DS compared to the general population. Atrioventricular septation is the mechanism that forms the heart's valves and septum in fetal development. About half of those with DS have abnormal septation events during development leading to AVSD, whereas the other half have healthy hearts. The partial prevalence of AVSD exhibits that trisomy 21 acts as a significant risk factor, but other modifiers must contribute to reach the disease state.A whole exome sequencing study of a cohort composed of cases, DS with an AVSD, and controls, DS without a heart defect, was performed to identify the genetic variants that influence this risk. We used PLINK to identify the single rare variants that are associated with AVSD. We also implemented a kernel-based method, SKAT-O, to take a gene-based approach to test the cumulative effects of rare variants. Computational tools, Mutpred and CADD, were used to predict deleteriousness of each variant.Our study coincides with a recent paradigm shift that postulates the second heart field (SHF) is responsible for the septation process, instead of remodeling of endocardial cushions. Multipotent progenitor cells from the SHF migrate and differentiate into cells that populate specific regions of the heart, such as the AV canal. The differentiation of the SHF is mediated by Sonic hedgehog (Shh) signaling through the primary cilium. We discovered four case-specific rare variants in genes that are crucial components of the ciliome (*CROCC, GLI3, CEP290*, and *ZDHHC20*). These variants are recurrent and found in 28% of the cases in this study. All four variants result in a missense change and are predicted deleterious by multiple computational algorithms. Notably, GLI3 is a transcriptional activator and a repressor of the Shh pathway and its target genes control the specification of the SHF cell fate**.** CEP290 is a major component of the primary cilium and is required for ciliogenesis as well as ciliary membrane composition. These preliminary findings imply that genes within the ciliome are a promising candidate group that may play a significant role in the pathogenesis of AVSD.

524T

Prediction of causal regulatory DNA variants regulating the QT interval phenotype. *D. Lee[1], A. Kapoor[1], A. Chakravarti[1,2].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Center for Complex Disease Genomics, Johns Hopkins University School of Medicine, Baltimore, MD.

The QT interval (MIM 610141), a measure of cardiac repolarization, is a heritable quantitative trait that has major implications for cardiovascular diseases, such as sudden cardiac death (MIM 115080) and arrhythmias (MIM 115000). Genome-wide association studies (GWASs) have identified 68 common variants at 35 loci significantly associated with QT interval variation in individuals of European ancestry. However, identification and characterization of the causal variants remains a key challenge because most of these variants are in noncoding DNA. To directly address this problem, we adopted a new computational method, deltaSVM, which can accurately predict the effect of regulatory variation from DNA sequence (Lee D†, Gorkin DU†, Baker M, Strober BJ, Asoni AL, McCallion AS*, Beer MA*. A method to predict the impact of regulatory variants from DNA sequence. *Nat Genet* (*in press*)). After removing less common variants (MAF < 0.1), we performed an in-depth analysis of the 59 QT interval associated GWAS SNPs at 32 loci. Starting with all common variants (MAF > 0.1) within LD blocks containing the GWAS SNPs, we focused on SNPs in high LD (|D'| > 0.8 and r2> 0.2) with the sentinel SNPs, resulting in 4,968 potential candidates. We demonstrated that these SNPs have three significant features: 1) They are significantly enriched in DNaseI hypersensitive sites (DHSs) in cardiac tissue, identified by DNaseI-seq on adult heart from the NIH Roadmap Epigenomics project (Pbin(X>=662 | N=4,968, p=0.05) < 2.2×10-16). 2) Significant number of the 662 candidate SNPs in heart DHSs have larger deltaSVM scores than expected by chance (Pbin(X>=103 | N=662, p=0.1) < 5.25×10-6). Notably, when each locus was individually evaluated, *SCN5A* (MIM 600163), *KCNH2* (MIM 152427), *ATP1B1* (MIM 182330) with 10% FDR and *NOS1AP* (MIM 605551), *TTN* (MIM 188840), *FADS2* (MIM 606149) with 15% FDR are predicted to have multiple significant SNPs suggesting that the combinatorial effect of multiple regulatory variants often drives the GWAS signals. 3) Many of these predicted regulatory SNPs are predicted to disrupt transcription factor binding sites (TFBSs) important for cardiac tissue, such as MEF2 and GATA, as well as generic TFBSs (AP1, ETS, CTCF, and ZEB1), demonstrating the biological relevance of our prediction. For validation, we are currently focusing on ~100 SNPs at the *SCN5A* locus using reporter assays to assess them for regulatory activity in cardiac cell lines.

Familial Combined Hyperlipidemia Is a Genetically Heterogeneous Disorder. *J.T. Rämö[1], P. Ripatti[1,2,4], S. Söderlund[3], I. Surakka[1], N. Matikainen[3,8], M. Pirinen[1], A-P. Sarin.[1,5], S.K. Service[6], R.K. Wilson[7], A. Palotie[1,2,4], N.B. Freimer[6], M-R. Taskinen[3], S. Ripatti[1].* 1) Institute for Molecular Medicine Finland FIMM, University of Helsinki, Helsinki, Finland; 2) Program in Medical and Population Genetics and Genetic Analysis Platform, The Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Heart and Lung Centre, Helsinki University Hospital and Research Program's Unit, Diabetes & Obesity, University of Helsinki, Helsinki, Finland; 4) Psychiatric and Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, Massachusetts, USA; 5) National Institute for Health and Welfare, Helsinki, Finland; 6) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, California, USA; 7) The Genome Institute, Washington University School of Medicine, St. Louis, Missouri, USA; 8) Abdominal Center, Helsinki University Hospital, Helsinki, Finland.

Familial combined hyperlipidemia (FCHL), a complex and common familial dyslipidemia defined by premature coronary heart disease (CHD) in the proband and elevated total cholesterol and/or triglyceride levels in at least twofamily members, substantially increases cardiovascular disease risk (OR 5.1). The underlying genetic architecture for this disorder remains unclear, and no clearly causal variants have yet been identified. We collected and carefully phenotyped 53 Finnish FCHL families with 1161 individuals. We genotyped and imputed 9 million genetic variants in a subset of 715 family members, selected to be most informative for genetic analyses. We first tested the enrichment and effect size of common, low-frequency and rare variants in the families. Next, we constructed weighted gene scores for LDL-C and TG based on 212 previously reported SNPs across the whole variant frequency spectrum, for which previous studies have reported association to these phenotypes. We used linear regression with the continuous scores to assess the fraction of polygenic elevated LDL-C and TG in the families.In a case-control setting, 12 mostly low-frequency variants were over1.5-fold enriched in probands. For 9 of these variants, this is the first reported association to FCHL. Affected subjects had elevated gene scores compared to non-affected family members. The scores explained up to 70 % of family-specific LDL-C or TG variation. In total, the known common lipid SNPs explained 27 % and 19 % and low-frequency SNPs 3.3 % and 4.1 % of LDL-C and TG variation, respectively.Our study shows that FCHL is highly polygenic, supporting the hypothesis that variants across the whole allele frequency spectrum contribute to this complex familial trait. Our results support the clinical tenet that FCHL is a cluster of overlapping genetic defects and metabolic dysfunctions instead of an etiologically homogenous disease entity.

526W

Pathogenetic study at the intersection of Marfan syndrome and autosomal dominant polycystic kidney disease. *D. Schepers[1], C. Golzio[2], E. Davis[2], C. Claes[1], E. Reyniers[1], A. Raes[3], N. Katsanis[2], L. Van Laer[1], B. Loeys[1].* 1) Center for Medical Genetics, University of Antwerp and Antwerp University Hospital, Antwerp, Edegem, Belgium; 2) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC, USA; 3) Department of Pediatrics, Ghent University, Ghent, Belgium.

Thoracic aortic dissections are among the most life threatening forms of cardiovascular disease. Thoracic aortic aneurysm, preceding dissection, is a prominent clinical feature of several heritable connective tissue disorders, including Marfan syndrome (MFS). MFS is caused by mutations in *FBN1*, which encodes fibrillin-1, an important extracellular matrix protein. Mutations in *PKD1* or *PKD2*, two polycystin encoding genes, are responsible for autosomal dominant polycystic kidney disease (ADPKD). Aortic and arterial aneurysms also occur in ADPKD. *Vice versa*, kidney cysts have also been observed in MFS. This clinical overlap suggests a mechanistic link between ADPKD and MFS.Here we describe a four generation family with nine affected individuals presenting with both thoracic aortic aneurysm and mild cystic kidneys. *FBN1*, *PKD1* and *PKD2* were excluded as disease causing genes by linkage analysis and/or sequencing. Subsequently, whole genome linkage analysis resulted in the delineation of a unique linked region on chromosome 16q21-q24.1. Exome sequencing was performed but no putative causal variants were found in the linked region. Copy number variation analysis identified two duplicated regions in the linkage interval, one (chr16: 86862531-870228808) gene-less and the other (chr16: 86357163-86725305) containing seven genes, including three genes encoding transcription factors of the FOX gene family (*FOXC2*, *FOXF1*, *FOXL1*), one gene encoding a methenyl tetrahydrofolate synthetase containing domain protein (*MTHFSD)* and three long non coding RNAs (*LOC732275*, *FENDRR, FLJ30679)*. The presence of the first duplication and its segregation in the family was confirmed using Multiplex Amplicon Quantification analysis. By overexpressing these genes separately and in combination with each other in zebrafish, we will explore the pathogenic mechanisms underlying not only MFS and ADPKD, but aneurysm and cyst formation in general. Preliminary results of these experiments, revealing a potential role for *FOXF1* in cyst formation, will be presented.

527T

***STEM9*, a novel non-coding RNA on chromosome 9p21, is downregulated in coronary artery calcification.** *S.K Sen[1], C. Oguz[1], J.D. Vargas[1], JJ. Barb[2], S.Y. Gebreab[1], S.K. Davis[1], J.J. Johnston[2], L.G. Biesecker[2], G.H. Gibbons[1], A.R. Davis[1].* 1) Cardiovascular Disease Section, National Human Genome Research Institute, Bethesda, MD; 2) National Institutes of Health, Bethesda, MD.

BackgroundFor almost a decade, multiple GWAS have validated a region of chromosome 9p21.3 as being very likely to have an etiological connection with cardiovascular disease (CVD). However, the GWAS lead SNPs are located in a gene desert and the mechanistic link connecting risk alleles to CVD remains a mystery. Here, we report a new transcript in this region with possible links to coronary artery calcification (CAC), a definitive and heritable CVD morphological marker.ResultsTo explore unannotated transcripts in 9p21.3, we used RNA-Seq to compare peripheral blood transcriptomes of eight advanced CAC subjects and eight matched controls, focusing on a 100Kb region surrounding the rs1333049 CAC GWAS lead SNP. A single ~350 bp transcript was discovered to be expressed above background noise levels, which was not included in any current gene or lncRNA annotation databases. ENCODE strand-specific RNA-Seq data showed this transcript to be located on the plus strand. Within the discovery set of CAC cases and controls, the transcript was significantly downregulated in cases (p=0.002). Analysis of RNA-Seq data from individual leukocyte populations in the GEO database revealed that the transcript is highly expressed in monocytes. By integrating Illumina 2.5M SNP chip data with RNA-Seq expression levels, we located an eQTL genomic variant located 18Kb from the transcript (p=0.03). Computational analysis of the transcript sequence revealed a high-confidence binding site for the *MZF1* transcription factor. Currently, we have applied for the name *STEM9* (Sense Transcript Expressed on Monocytes in 9p21) for this transcript.ConclusionsWe report the finding of a new transcript in a locus of extreme interest for CVD, along with preliminary evidence for its downregulation in CAC. Although our results reflect early stages of a work in progress, they merit deeper investigation, given the missing causality that persists despite repeated GWAS validation of the 9p21 locus.

Novel MYLK gene mutation in a Large Family with Fatal Aortic Aneurysm and Dissection: Delineation of the Clinical phenotype. *A. Shalata[1,2], Z. Borochowitz[1], M. Mahroom[1], V. Adir[1], N. Assy[3], R. Fell[4], H. Cohen[5], M. Nashashibi[6], Y. Sova[6], A. Libov[5], M. Azab[1], D. Gieger[7], G. Habib[8], W. Nsier[9].* 1) The Simon Winter Institute for Human Genetics, Bnai-Zion Medical Center, P.O.Box 4940, Haifa,; 2) Genetic Unit Ziv Medical Center, Safed, Israel; 3) Liver Disease Unit, Ziv Medical Center, Safed Israel; 4) Research Unit, Galilee Medical Center, Naharia, Israel; 5) Pathology Dep. Galilee Medical Center, Naharia, Israel; 6) Pathology Dep. Carmel Medical Center, Haifa, Israel; 7) Science Dep. Technion Inst. of Technology, Haifa Israel; 8) Internal Medicine Dep. Carmel Medical Center Computer; 9) The Internal Medicine Dep. The Nazareth English Hospital.

Herein we describe the complexity of the MYLK gene mutation effect on the clinical presentation of thoracic aortic aneurysm and dissection (TAA, TAAD) in a large multi-generational consanguineous Arab family. The patients developed splanchnic, iliac and renal arteries dissection and subclavian and innominate arteries aneurysm.The disease presents in two distinguished clinical groups (G-A and G-B). G-A: apparently healthy young family members and at the 4th decade they suffered of severe overwhelming chest pain and dyspnea that rapidly deteriorated to semi-comatose state. Most of them died within hours to few days after onset. The mode of inheritance of this devastating phenotype fits very well with the autosomal recessive pattern. G-B: Sixth to seventh decade of age asymptomatic individuals, who presented with chronic and compatible with life chest pain and effort induced breathlessness and weakness. They developed aourtic aneurysm and dissection. The mode of inheritance fit very well with the autosomal dominant pattern with incomplete penetrance.Genotyping and gene sequencing study was performed in the available patients and family members. We identified a missense mutation, (c.4471G>T, p.Ala1491Ser) located in exon 27 of the Myosin Light Chain Kinase encoding gene (MYLK gene). This change converts a codon for alanine (GCA) to a codon for serine (TCA) within the protein-kinase domain. Comparison of amino acid sequence we found that the Ala1491 is conserved in 35 out of 35 tested species. For phenotype/genotype correlataion we examined the entire available family members (no. 45) including the known patients, their parents and apparently healthy siblings. The mutation segregation fit very well with the clinical phenotype. Hence, the group A patients were homozygous while, the group B patients where heterozygous for the c.4471G>T (p. Ala1491Ser) mutation.We used the immunohistochemistry staining to study the mutation effect on the MLCK protein expression. We used aortic dissected tissue samples from 2 patients from the family and 2 other unrelated controls. Compared to the controls, the MLCK protein in our family was not detected in one patient and very weak in the other. Both patients were homozygous for the MYLK gene mutation. This finding showed that the mutation we found lead to the MLCK protein instability and to its degradation. We conclude that the c.4471G>T mutation demonstrates very well the loss of function effect in the protein level.

529W

Genetic variants near *IRS1*, body fat percentage and metabolic traits in Hispanics/Latinos from the Hispanic Community Health Study/ Study of Latinos (HCHS/SOL). *Q. Qi[1], S. Gogarten[2], C. Laurie[2], C. Isasi[1], R. Loos[3], R. Kaplan[1].* 1) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, NY; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) Department of Preventive Medicine, Icahn School of Medicine at Mount Sinai, New York City, NY.

A previous genome-wide association study (GWAS) identified rs2943650, a single nucleotide polymorphism (SNP) near *IRS1* (insulin receptor substrate 1), for which the major allele (frequency = 0.64) was associated with lower body fat percentage (BF%) (b= -0.16 ± 0.11% per allele), but with less favorable metabolic profile. The major alleles of SNPs in high LD with rs2943650 (r2>0.8 in Europeans) have also been associated with insulin resistance and dyslipidemia. So far, SNPs near *IRS1* have been predominantly studied in populations of European ancestry, whereas few studies have investigated whether SNPs near *IRS1* affect BF% and metabolic traits in a similar way in US Hispanics. We examined associations of four previously reported SNPs (rs2943650, rs2972146, rs2943641, and rs2943634) with BF% and multiple metabolic traits among up to 12,730 US Hispanics from the HCHS/SOL. Participants were aged 18-74 years from a four-city population sample. In this Hispanic population, the four SNPs were in moderate-to-high LD (r2 = 0.51~0.84), with minor allele frequencies of 20~30%. The major alleles of all four SNPs were associated with lower body fat percent, with the SNP rs2943634 (r2 = 0.65 with rs2943650) showing the strongest result (b= -0.37 ± 0.11% per major allele; P =0.001). The effect size on BF% is greater than twice stronger than that reported among Europeans (b= -0.37% vs -0.16%; P for heterogeneity =0.06). The major allele of rs2943634 was also significantly associated with lower BMI and waist circumference ($P \leq 0.003$), but with higher levels of fasting insulin HOMA-IR, LDL cholesterol and triglycerides ($P \leq 0.05$), and lower HDL-cholesterol (P=0.002). In conclusion, our study suggests a stronger association between genetic variants near *IRS1* and BF% in US Hispanics compared with Europeans. Consistent with previous results, the body-fat-decreasing allele near *IRS1* was associated with unfavorable levels of metabolic traits.

530T

Inter-individual variation in DNA methylation levels in *PLAT* and *STX2* genomic regions contribute to variation in Tissue Plasminogen Activator plasma levels. *N. Zwingerman[1], I. Kassam[1], V. Truong[1], D. Aïssi[2], J. Dennis[1], M. Wilson[3], P. Wells[4], PE. Morange[5], DA. Trégouët[2], F. Gagnon[2].* 1) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 2) UMR_S 1166, Team Genomics & Pathophysiology of Cardiovascular Diseases, INSERM, Paris, France; 3) Genetics and Genome Biology Program, SickKids Research Institute, Toronto, Ontario, Canada; 4) Department of Medicine, Faculty of Medicine, University of Ottawa, Ottawa, Canada; 5) UMR_S 1062, Nutrition Obesity and Risk of Thrombosis, INSERM, Marseille, France.

Tissue Plasminogen Activator (tPA) is a serine protease that mediates the conversion of plasminogen to plasmin, the major enzyme responsible for endogenous fibrinolysis. In some populations, elevated tPA levels are associated with thrombotic outcomes. tPA plasma levels are highly heritable, with estimates as high as 67%. A meta-GWAS identified variants in three genes involved in tPA regulation: *PLAT*, *STXBP5*, and *STX2*. Collectively, these genetic variants explain less than 1% of tPA variance. DNA methylation in these regions can regulate gene transcription and may account for variation in tPA levels. In the genomic regions identified by the meta-GWAS, we aim to identify DNA methylation levels associated with tPA plasma levels. In discovery sample of 140 individuals from 5 pedigrees ascertained on a single proband with venous thromboembolism, a linear mixed effects regression model adjusted for relatedness matrix and covariates was used, to test for association between DNA methylation levels and tPA plasma levels. DNA methylation sites located within 150kb of *PLAT*, *STXBP5*, and *STX2* gene regions were tested. Sites with FDR<0.1 were tested for replication in a study sample of 186 venous thromboembolism cases. A total of 304 DNA methylation sites were tested for association. In the discovery sample, 13 significant associations were identified (5 within *PLAT*, 1 within *STXBP5*, and 7 within *STX2*). Two associations, 1 in *PLAT* and 1 in *STX2* regions, were replicated in an independent study sample (p<0.03). *PLAT* encodes tPA, the replicated DNA methylation site in the *PLAT* region is located upstream of the gene and in an active genomic regulatory region. The second replicated methylation site is located in the intergenic region of the *STX2* gene, which has been previously shown to be associated with tPA release, and was heritable in our study sample (p<0.001). DNA methylation associations with tPA were robust to adjustment for the identified genetic variants in *PLAT, STXBP5*, and *STX2* from the meta-GWAS. Collectively, the two DNA methylation sites explain 5.7% and 1% of tPA level variation in the discovery and replication samples, respectively. Inter-individual variation in DNA methylation levels in *PLAT* and *STX2* genomic regions contribute to the variation in tPA plasma levels, providing new mechanistic insights on tPA regulation. DNA methylation may have larger effect sizes on intermediate traits than genetic variants because of their more direct relationship.

531F

Novel homozygous BMP9 nonsense mutation causes pulmonary arterial hypertension. *G. Wang, R. Fan, R. Ji, W. Zou, D. Penny, N. Varghese, Y. Fan.* Department of Pediatrics, Baylor College of Medicine, Houston, TX.

Pulmonary arterial hypertension (PAH) is a rare progressive fatal vascular disorder. Genetic predisposition plays vital roles in the development of both familial and idiopathtic PAH with most mutations identified in genes involved in the transforming growth factor beta (TGF-b) signaling pathways including BMPR2 (bone morphogenetic protein receptor type 2), ACVRL1 (activin receptor-like kinase type 1), ENG (endoglin), SMAD8 and SMAD4 genes. As a member of the bone morphogenetic proteins (BMPs), BMP9 (also known as GDF2) plays crucial role in angiogenesis and maintenance of endothelial function. Defects in the BMP9 gene have been documented in hereditary hemorrhagic telangiectasia (HHT), the most common inherited vascular disorder that is often associated with PAH.We report the case of a 5 year-old Hispanic boy who was diagnosed with severe PAH and right heart failure at 3years of age. During the admission in the pediatric intensive care unit, treatment was started with inhaled nitric oxide and intravenous epoprostenol; he was subsequently transitioned to treprostinil, sildenafil, and prophylactic enoxaparin. Now, two years later, the child is asymptomatic on sildenafil, bosentan, treprostinil subcutaneously and warfarin. Genetic screening for all the known PAH related genes revealed a novel homozygous nonsense mutation in the BMP9 gene (c.76C>T; p.Q26X). The child did not have any telangiectasias or arteriovenous malformations; family history also negative. Subsequent parental testing showed that both parents were heterozygous for the same mutation, indicating that the child inherited the BMP9 mutant allele from each parent.To our knowledge, this is the first report about BMP9 mutation in patients with PAH. The homozygous nonsense mutation may account for the early onset and severity of PAH in this patient. The absence of clinical symptoms for PAH in the parents may be due to incomplete penetrance or various expressivity of the BMP9 mutations. Our study expanded the spectrum of phenotypes related to BMP9 mutations.

532W

Association of Glutathione S- transferase M1 and T1 gene polymorphisms in South Indian stroke patients. *Usha. P[1], S. Sultana[1], K. Venkata Kolla[1], P. Vidyullatha[1], P.P. Reddy[2].* 1) Institute of Genetics and Hospital for Genetic Diseases, Osmania University, Begumpet, Hyderabad, Telangana State; 2) Genetics, Bhagwan Mahavir Medical Research Centre, Hyderabad, Telangana State, India.

ABSTRACT Stroke is a multifactorial disease caused by the interaction of several genetic and environmental factorsand a variety of risk factors such as blood pressure, diabetes, advanced age and smoking. Activecigarette smoking has been established as a major risk factor for coronary heart disease and for bothischemic and hemorrhagic stroke and the risk is particularly elevated in younger people. Glutathione S-transferases (GSTs) are the phase II enzymes that catalyze the conjugation of glutathione to a widerange of electrophiles and represent a protective mechanism against oxidative stress. So far noinformation has been provided regarding the role of GSTM1 and GSTT1 gene polymorphisms andischemic stroke in Indian populations. So the present study is carried out to investigate the associationbetween the GST M1 and T1 gene polymorphisms and the risk of stroke in a South Indian population.We genotyped 198 ischemic stroke patients and 162 age matched controls using multiplex polymerasechain reaction. Statistical analysis showed that the frequency of both wild and null genotypes of GSTM1(OR = 0.91, p = 0.68) and GSTT1 (OR = 0.60, P = 0.077) did not differ significantly between control andstroke patients. Further analysis of GSTM1 and GSTT1 genotypes among male smokers and nonsmokers category of stroke patients and control subjects showed a protective role of GSTM1 wild type(OR = 0.44, p = 0.007) and GSTT1 wild type (OR = 0.36, p = 0.01) in smokers.

Sequencing and Functional Validation Identifies Low Frequency Noncoding Variants at Chromosome 4q25 Underlying Atrial Fibrillation. *S. Lubitz[1,2], L. Weng[1,2], N. Tucker[1,2], H. Lin[3,4], C. Roselli[2], I. Christophersen[1], E. Benjamin[3,4], K. Lunetta[3,4], P. Ellinor[1,2].* 1) Massachusetts General Hospital, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Boston University, Boston, MA; 4) Framingham Heart Study, Framingham, MA.

Background: Atrial fibrillation (AF) is a heritable and prevalent cardiac arrhythmia associated with substantial morbidity. The top AF susceptibility locus is a noncoding region on chromosome 4q25 near *PITX2* that contains 4 distinct susceptibility signals tagged by common variants. We sought to identify causal alleles at the locus.**Methods**: We sequenced a 750kb region on chromosome 4q25 (median read-depth 230X) in 462 individuals of European ancestry from the Massachusetts General Hospital with early onset AF and 464 referent individuals from the Framingham Heart Study. We tested associations between overlapping rolling windows (ranging in size from 2.5kb–15kb) and AF using SKAT. We examined the contribution of variants in different allele frequency groups in stratified analyses. We tested individual variants within regions for association with AF. We tested the allele-specific enhancer activity of the variant regions with a modified luciferase reporter assay performed in a myoblast cell line.**Results**: Of the 7378 variants observed, 5988 (81%) occurred with a frequency of <1%, and 1390 (19%) with frequency ≥ 1%. Using overlapping rolling windows, we identified a specific region associated with AF that contains a known common variant association signal for AF. We refined the peak association to an ~1.5kb region and found that the association was driven by low frequency variants (minor allele frequency 1-5%), of which 3 were nominally associated with AF after adjustment for one another and associated variants at the locus (rs115779909, P=0.05; rs62339085, P=0.006; rs188425751, P=0.007). None of the 3 variants were in linkage disequilibrium with one another (all pairwise r2≤0.002). Conditioning on these variants nullified the association between the primary common variant signal in the region and AF (rs6838973, P=0.006 before adjustment, P=0.13 after adjustment). Expression of constructs containing these low frequency variants demonstrated allele-specific differences in enhancer activity as measured by luciferase activity. Of the identified low-frequency variants, rs188425751 is predicted to disrupt a *PITX2* binding site.**Conclusions**: Low frequency noncoding variants exhibiting enhancer activity explain 1 of 4 known susceptibility signals underlying AF on chromosome 4q25. Sequencing is critical for the identification of causal variation, and rolling window approaches may facilitate the discovery of causal variants in noncoding regions.

534F

Identification of wide-spread allele-specific expression at lipid GWAS loci. *M. Alvarez[1], A. Ko[1,2], E. Nikkola[1], T. Nguyen[1], R. Raulerson[3], Z. Miao[1], M. Civelek[4], F.S. Collins[5], A.J. Lusis[1,4], J. Kuusisto[6], M. Boehnke[7], R.M. Cantor[1], K.L. Mohlke[3], M. Laakso[6], P. Pajukanta[1,2].* 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Molecular Biology Institute at UCLA, Los Angeles, USA; 3) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 4) Department of Medicine, David Geffen School of Medicine at UCLA, Los Angeles, USA; 5) National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland, USA; 6) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 7) Department of Biostatistics and Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, Michigan, USA.

Recent GWAS have identified 157 loci for serum lipids. However, the actual causal variants and genes remain unknown in most of these regions. We hypothesized that some of the GWAS loci influence lipids via allele-specific transcriptional changes in adipose, a key metabolic tissue in humans. To test our hypothesis, we collected genotype, adipose RNA sequence, and phenotype data from 582 Finnish males participating in the METSIM study, and tested the lipid GWAS loci for allele-specific expression (ASE). For ASE, we counted reads (>30 reads, with >6 at the lower expressed allele) at heterozygous transcribed sites that did not show a mapping bias. Using a paired t test between reference and alternate allele counts and correcting for multiple testing, we identified 33,340 ASEs. We analyzed lipid GWAS SNPs that were either within the reported GWAS gene or in linkage disequilibrium (LD) (r2>0.8) with the reported GWAS SNP. We found an enrichment of genes demonstrating ASE genes in the lipid GWAS regions with 198 (35%) ASE SNPs in 62 (53%) adipose expressed genes in the GWAS regions, compared to 5,842 (18%) SNPs in 3,158 (40%) genes in the non-GWAS regions (P=0.004), respectively. ASE SNPs in the lipid GWAS regions showed an enrichment of H3K4m3 (P=0.0028), and a higher RNA polymerase 2 binding (P=0.017), compared to the non-GWAS ASE regions, suggesting increased transcriptional activation. To find the likely functional SNP(s) at each GWAS locus, we searched for ASE SNPs associated with lipids (P<5.3x10-8). We found 10 such GWAS genes with 54 lipid-associated ASE SNPs (*JMJD1C*, *FADS2*, *FADS1*, *ZNF664*, *APOE*, *HLA-DRB1*, *HLA-DQB1*, *MLXIPL*, *LPL*, and *PLEC*). To identify additional, separate lipid-associated ASE SNPs in the GWAS regions, we explored the ASE SNPs not in tight LD (r2<0.2) with the reported GWAS SNP for lipid associations. We discovered 18 additional ASE SNPs (within 500 kb from the reported SNP) in 15 genes that showed a genome-wide significant lipid association. We also investigated whether the expression of the ASE genes correlated with lipids, and found *APOE*, *CPNE1*, and *KANK2* to be correlated with the reported lipid trait (P<0.05). Taken together, our study in adipose transcriptomes furthers the functional characterization of 19 of lipid GWAS loci with 72 lipid-associated ASE variants in 25 genes. Accordingly, we discovered widespread ASE at the lipid GWAS loci, suggesting ASE as a first clue towards their functional consequences.

535W

Identification of a homozygous mutation in *PLXND1* in patients with a complex phenotype featuring truncus arteriosus and abnormal pulmonary venous return with predisposition to Hirschsprung disease and neuroblastoma. *C. Gordon[1], A. Guimier[1], C. Muller[1], M. Oufadem[1], D. Lehalle[2], C. Bole-Feysot[1], P. Nitschké[1], M. Singh[3], J. Epstein[3], F. Bajolle[4], D. Bonnet[4], P. Bouvagnet[5], S. Lyonnet[1,2], L. de Pontual[1], J. Amiel[1,2].* 1) Institut Imagine, INSERM U-1163, Paris, France; 2) Service de Génétique, Hôpital Necker-Enfants Malades, AP-HP, Paris, France; 3) Department of Cell and Developmental Biology, Cardiovascular Institute, University of Pennsylvania, Philadelphia, PA, USA; 4) Unité Médico-Chirurgicale de Cardiologie Congénitale et Pédiatrique, Centre de référence Malformations Cardiaques Congénitales Complexes - M3C, Hôpital Necker-Enfants Malades, APHP, Paris, France; 5) Laboratoire cardioGénétique - Hospices Civils de Lyon, Bron, France.

Truncus arteriosus (TA) is a rare congenital heart defect caused by defective septation of the outflow tract, associated with significant morbidity and mortality. We performed exome sequencing in three families in which the probands presented with either isolated TA or TA in association with other anomalies. Firstly, we identified a homozygous missense mutation in the GAP domain of *PLXND1* in three consanguineous sibs presenting TA and abnormal pulmonary venous return, associated with Hirschsprung disease (HSCR) in two out of three cases and with neuroblastoma (NB) in one. Investigation in the only surviving member of the sibship revealed generalised vascular anomalies. In the second family, we identified a frameshift mutation in *SMAD6* in siblings with isolated TA, inherited from their normal father, while in the third family, a splice site mutation in *TBX1* was identified in a patient with TA and athymia but without typical craniofacial features of DiGeorge syndrome. The cardiac phenotypes in these patients are consistent with the known roles of *Plxnd1*, *Smad6* and *Tbx1* in development of the conotruncus in mouse models, although heterozygous loss of *SMAD6* in humans appears incompletely penetrant. Our results confirm *PLXND1* mutations as a cause of cardiovascular defects in humans, and HSCR and NB may be associated phenotypes due to disrupted plexin-semaphorin signalling during neural crest development.

536T

Mutations in *TAX1BP3* cause Dilated Cardiomyopathy with Septo-Optic Dysplasia. *E. Reinstein.* Rabin Medical Center, Tel-Aviv, Israel.

We describe a Bedouin family with a novel autosomal recessive syndrome characterized by dilated cardiomyopathy and septo-optic dysplasia. Genetic analysis revealed a homozygous missense mutation in *TAX1BP3,* which encodes a small PDZ-containing protein implicated in regulation of the Wnt/β-catenin signaling pathway, as the causative mutation. The mutation affects a conserved residue located at the core of TAX1BP3 binding pocket and is predicted to impair the nature of a crucial hydrophobic patch, thereby interrupting the structure and stability of the protein, and its ability to interact with other proteins. *TAX1BP3* is highly expressed in heart and brain and consistent with the clinical findings observed in our patients, a knockdown of *TAX1BP3* causes elongation defects, enlarged pericard and enlarged head structures in zebrafish embryos. Thus, we describe a new genetic disorder that expands the monogenic cardiomyopathy disease spectrum and suggests that *TAX1BP3* is essential for heart and brain development.

537F

Impaired *PIEZO1* function in patients with a novel autosomal recessive congential lymphatic dysplasia. *B. Krock[1, 2], V. Lukacs[4], J. Mathur[6], R. Mao[1,2], P. Bayrak-Toydemir[1,2], M. Procter[2], S. Calahan[4], H. Kim[5], M. Bandell[6], N. Longo[8], R. Day[7], D. Stevenson[3], A. Patapoutian[4].* 1) Pathology, University of Utah, Salt Lake City, UT; 2) ARUP Institute for Clinical and Experimental Pathology, ARUP Laboratories, Salt Lake City, UT; 3) Department of Pediatrics, Division of Medical Genetics, Stanford University, Stanford, CA; 4) Howard Hughes Medical Institute, Molecular and Cellular Neuroscience, The Scripps Research Institute, La Jolla, CA; 5) Integrative Structural and Computational Biology, The Scripps Research Institute, La Jolla, CA; 6) Genomics Institute of the Novartis Research Foundation, San Diego, CA; 7) Department of Pediatrics, Division of Pediatric Cardiology, University of Utah, Salt Lake City, UT; 8) Department of Pediatrics, Division of Medical Genetics, University of Utah, Salt Lake City, UT.

Defective development and function of lymphatic vessels can result in primary lymphedema, a debilitating accumulation of lymphatic fluid that typically affects the extremities. The known genetic etiologies of primary lymphedema delineate the developmental processes involved in lymphatic development, such as the VEGFR3 signaling pathway. However, the genetic causes of congenital lymphedema are incompletely understood, in particular for sporadic and autosomal recessively inherited forms. This observation suggests that unrecognized developmental pathways may underlie the genetic cause of undiagnosed congenital lymphedemas. Development of the lymphatic system is regulated by interstitial pressure and shear forces induced by fluid flow; however, the molecular mechanism of mechanosensation in these cells is largely unknown. Whole exome sequencing of a pair of siblings affected with an apparent autosomal recessive hereditary lymphedema identified *PIEZO1* as a candidate gene. Both siblings were compound heterozygotes for a splicing and missense variant in *PIEZO1*, a mechanically gated non-selective cation channel that is among the few ion channels reliably demonstrated to convey mechanical cues of the environment to mammalian cells. Functional analysis of the affected individual's cells revealed severely diminished PIEZO1 responses to both mechanical stimuli and a pharmacological PIEZO1-activator. Patch-clamp analysis of the missense PIEZO1 channel in a heterologous system demonstrated strongly diminished current amplitudes as compared to wild type, likely due to reduced cell surface expression. These findings suggest a role for PIEZO1 in human lymphatic development and implicate it as a novel genetic cause of an autosomal recessive congenital lymphatic dysplasia.

538W

Contribution of CRELD1 novel mutations and Polymorphisms in occurrence of AVSD among DS patients seen In North Indian population. *A. Asim[1], I. Panigrahi[2], A. Kapoor[3], S. Agarwal[1].* 1) Genetics, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India, Lucknow, Uttar Pradesh, India; 2) Advanced Pediatrics Centre,Post Graduate Institute of Medical Science and Education Research ,Chandigarh,India; 3) Cardiology, Sanjay Gandhi Post Graduate Institute of Medical Sciences, Lucknow, India, Lucknow, Uttar Pradesh, India.

Down syndrome (DS) is caused by trisomy of chromosome 21, is the commonest genetic disorder characterized by multiple congenital abnormalities of variable severity. Almost, 50% of DS individual have congenital heart defect (CHD) out of which 40-60% has atrioventricular defects (AVSD). CRELD1 (Cysteine-rich with EGF-like domains, OMIM 607170) is the gene identified as candidate gene for AVSD in DS. The aim of the study is to reveal the status ofCRELD1variants in DS with AVSD and without AVSD.A total of 60 patients of DS with AVSD (N = 24) and without AVSD (N=36), along with 10 samples having AVSD alone were recruited. Genomic DNA was extracted from Qiagen Mini kit and Sequencing of exon 9 and 10 were performed in all PCR amplified samples.Novel substitution mutation has been identified in exon 9 at R329H and E325K in DS with AVSD group**.** While, several other polymorphism have also been identified in exon 10 namely rs9878047 (c.1049-129T > C), rs3774207 (c.1119C > T), and rs73118372 (c.1136T > C) among DS with AVSD with the frequency of 4.1%, 50% and 29.1% respectively which has been reported earlier but for the first time in our north Indian population. However, Mutation taster analysis indicates the lethality of these mutations and polymorphisms.The results emphasized the need of screening of exon 9 and 10 of CRELD1 gene among DS with AVSD as the candidate gene marker in Indian patients.

539T

Cost analysis and strategy in molecular diagnosis of Familial Hypertrophic Cardiomyopathy: from Sanger to Next Generation Sequencing. *D.A. Coviello[1], M.I. Parodi[1], S. Davi[1], E. Canepa[1], M. Castagnetta[1], P. Spirito[2], C. Rapezzi[3], C. Autore[4], B. Musumeci[4], F. Formisano[2], S. Forleo[5], S. Favale[5], D. Degiorgio[1], M. Cecconi[1].* 1) Laboratory of Human Genetics, E.O. Ospedali Galliera, Genoa, Italy; 2) Department of Cardiology, E.O. Ospedali Galliera, Genoa Italy; 3) Department of Cardiology, Alma Mater Studiorum-University of Bologna, Italy; 4) Department of Cardiology, St. Andrea Hospital, Sapienza University, Rome, Italy; 5) Cardiology Unit, Department of Emergency and Organ Transplantation, University of Bari, Italy.

Routine clinical use of NGS technologies is helping to perform accurate diagnosis with a faster T.A.T. and with lower costs. In the last seven years we have routinely performed molecular diagnosis of Familial Hypertrophic Cardiomyopathy (FHC) using Sanger sequencing on 11 major genes, 8 sarcomeric and 3 metabolic genes. To move from Sanger to NGS we developed a custom panel of 19 selected pathogenic genes for FHC (*MYBPC3, MYH7, TNNT2, ACTC1, TPM1, TNNI3, MYL2, MYL3, MYH6, TNNC1, MYOM1, MYOZ2, VCL, ANKRD1, CALR3, CAV3, GLA, LAMP2, PRKAG2*) and we used Ion Torrent technology on PGM (Life Technologies).To validate the NGS methodology we analyzed 63 selected FHC patients; in these patients, previously tested by means Sanger, were been already identified 79 mutations in 11 genes out of 19. Among 79 mutations, 3 are located in uncovered regions of the panel and the NGS analysis has identified 75 out of remaining 76. We perform a cost analysis of NGS in comparison with Sanger sequence. We use NGS in the molecular diagnostic of FHC patients and, to date, this technology has allowed us to analyze additional 23 patients; 17 different mutations have been identified in 16 patients. We have identified some critical points: a) new version of the informed consent of the patient to perform the test; c) choice of an appropriate software for analysis of the data generated; d) relevance of collaboration with the clinicians for management of results, especially in large families; e) inevitable increasing identification of new variants with uncertain pathogenic value will affect the expectance of patients, especially in predictive or pre symptomatic testing f) incomplete representation and coverage of target regions lead to missing clinically relevant mutations regions g) necessity of Sanger sequencing to confirm mutant genotypes and to achieve a desirable coverage in GC-reach regions. The validation step of NGS technology permitted us to identify 75/76 (98,5%) mutations on covered target regions. This result has confirmed the validity of this technology and permitted us to introduce the NGS techniques within the diagnostic workflow for molecular analysis of HCM at lower costs. Sanger sequencing is still used to analyze well uncoveded genomic regions and to validate the presence of a causative genotype.

540F

Implementation of diagnostic Whole Exome Sequencing to improve diagnostic yield of genetic testing for patients with thoracic or abdominal aortic aneurysm. *H.T. Bruggenwirth[1], A.S. IJpma[1,2], J.M.A. Verhagen[1], G.M. Bolman[1], J.N.R. Kromosoeto[1], D. Heijsman[1], C.E.M. Kockx[3], F.J.G.T. Sleutels[3], H.J.F.M. Eussen[1], J.E.M.M. De Klein[1], M.A. Van Slegtenhorst[1], W.G. De Valk[3], R.W.W. Brouwer[3], W.F.J. Van IJcken[3], I.M.B.H. De Graaf-Van de Laar[1], M.W. Wessels[1], D.F. Majoor-Krakauer[1].* 1) Dept Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 2) Dept of Bioinformatics, Erasmus MC, Rotterdam, The Netherlands; 3) Center for Biomics, Erasmus MC, Rotterdam, The Netherlands.

Thoracic Aortic Aneurysm (TAA) and Abdominal Aortic Aneurysm (AAA) are genetically heterogeneous. A proportion of autosomal dominant inherited TAA syndromes is associated with mutations in genes interfering with the TGFB pathway. Non-syndromic TAA was associated with mutations in genes affecting smooth muscle cell functioning. Much less is known about genes involved in AAA. In our laboratory DNA analysis of several genes (8 genes were offered), involved in TAA and AAA (evidence-based) was previously performed by Sanger sequencing of the coding parts and exon-flanking intronic regions. In general, the diagnostic yield obtained was low. To improve the diagnostic yield we have implemented Whole Exome Sequencing (WES) using HaloPlex exome target enrichment (Agilent Technologies) with Illumina sequencing on a HiSeq platform. For TAA and AAA samples at least 6 gigabases of sequence is generated (75x average coverage). A set of core-genes (*ACTA2* [MIM 611788], *COL3A1* [MIM 130050], *FBN1* [MIM 154700], *SMAD3* [MIM 613795], *TGFB2* [MIM 614816], *TGFBR1* [MIM 609192], *TGFBR2* [MIM 610168]) was selected for which the coding regions should be covered by at least 20 reads, regions with lower coverage are supplemented by Sanger sequencing. For the primary diagnostic analysis a virtual gene panel, consisting of 23 genes known to be involved in aneurysms and a SNP in *MTHFR* known to be a risk factor, is analysed. Using Cartagenia software (Agilent) we select variants, present in those 24 genes. We filter for the presence of potentially damaging heterozygous variants in case of autosomal dominant inheritance and for the presence of compound heterozygous or homozygous variants in case of autosomal recessive disease. If during this first analysis no satisfactory explanation for the phenotype is found, as a second step the exome can be opened (on basis of research), provided that informed consent has been obtained. In this poster, we present our newly developed analysis pipeline and results of the primary diagnostic analysis.

The genetics of inherited cardiac conditions. *B. Chong[1], S. Pantaleo[1], M. Chow[1], J.P. Plazzer[1,4], C. Love[2], P. James[3], D. du Sart[1].* 1) Victorian Clinical Genetics Services, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 2) Translational Genomics Unit, Victorian Clinical Genetics Services, Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; 3) Clinical Genetics, Royal Melbourne Hospital, Melbourne, Victoria, Australia; 4) InSIGHT Database Curator, Royal Melbourne Hospital, Melbourne, Victoria, Australia.

Inherited cardiac conditions, such as the cardiomyopathies or arrhythmias, have a complex genetic pathology. They are often heterogeneous, with overlapping clinical symptoms that may not always be penetrant. This adds to the complexity of determining whether gene variants are pathogenic, influence clinical severity or normal variation within the genes. Next generation sequencing (NGS) technology has enabled assessment of the large number and large size of these implicated genes. We use a custom capture NGS panel to screen for the arrhythmias, cardiomyopathies, aortopathies, congenital heart disease and unexplained sudden death conditions, with complete coverage of the entire coding region of all the genes analyzed. In 650 patients tested we identified, 54% pathogenic mutations and 19% variant of unknown significance in the arrhythmia panel; 59% pathogenic mutations and 31% variant of unknown significance in the cardiomyopathy panel; 34% pathogenic mutations and 22% variant of unknown significance in the aortopathy panel; 45% pathogenic mutations and 42% variant of unknown significance in the sudden death panel and the remaining patients in each panel were negative. The data provides detailed information about the relative contribution of the major genes to each phenotype and the distribution of variants within each gene. For some genes we compared the regions covered in our capture NGS panel with the whole exome NGS panel. By analyzing the entire gene panel in all samples, we have been able to gain an insight into the level of normal variation within these genes which in some cases questions the variant pathogenicity classification. We have also defined the key quality parameters to indicate whether a variant is in the patient's genome or an artefact or contaminant generated through the NGS process. With new population data from whole exome analyses in non-disease cohorts and our experience to date, we are now revising our NGS analysis process and improving our variant classification criteria to reflect a more evidence based classification.

Clinical and molecular lessons from targeted next generation sequencing of 51 genes involved in primary electrical disease. *B. Loeys[1, 2], D. Proost[1], J. Saenen[3], G. Vandeweyer[1], A. Rotthier[4], M. Alaerts[1], E. Van Craenenbroeck[3], J. Van Crombruggen[1], G. Mortier[1], W. Wuyts[1], C. Vrints[3], J. Del-Favero[4], L. Van Laer[1].* 1) Center for Medical Genetics, Antwerp University Hospital/University of Antwerp, Antwerp, Belgium; 2) Radboud University Medical Center, Nijmegen, The Netherlands; 3) Department of Cardiology, Antwerp University Hospital/University of Antwerp, Antwerp, Belgium; 4) Multiplicom, Niel, Belgium.

Primary electrical disease (PED) is characterized by cardiac arrhythmias, which can lead to sudden cardiac death in the absence of detectable structural heart disease. PED encompasses a diversity of inherited syndromes, predominantly Brugada syndrome, early repolarization syndrome, long QT syndrome, short QT syndrome, arrhythmogenic right ventricular cardiomyopathy/dysplasia and catecholaminergic polymorphic ventricular tachycardia. To overcome the diagnostic challenges imposed by the clinical and genetic heterogeneity, we developed a targeted gene panel for next generation sequencing of 51 genes involved in PED. Twenty CEPH samples and 20 positive control samples were used to validate the panel. A technical sensitivity and specificity of 100% respectively 99.9% was obtained. After validation, we applied the assay to 114 PED patients. We identified 107 variants in 36 different genes, 18 of which were classified as pathogenic or likely pathogenic, 54 variants were of unknown significance and 35 were classified as likely benign. In the patient groups of BrS, ARVC/D and LQTS we reached causal mutation detection rates of 23% (18/80), 37.5% (3/8) and 36.4% (4/11) respectively. In total, 46.5% of patients (53/114) had a variant, either (likely) pathogenic or VUS, that required additional molecular and clinical follow-up. We hypothesize that several VUS will also be causal because we identified more variants per gene in our PED patients compared to what could be expected by chance, based on the number of variants present in the ExAC database for these genes (eg. 3.7 times more *SCN5A* variants (MAF $\leq$ 0.001) in our PED patients compared to the ExAC database). Our data also support a putative oligogenic nature as in 17 probands we identified more than one (possible) pathogenic variant or VUS. Even more intriguing is the observation that within one family, two different pathogenic mutations cause the identical phenotype in different individuals. The latter advocates for the application of the panel testing in different affected individuals to identify to full underlying genetic architecture. Finally, we identified the first *SCN5A* founder mutation in 17 Belgian families.In conclusion, the PED MASTR Plus assay is a proficient, highly reliable and reproducible technique to routinely screen patients suffering from primary arrhythmias.

543F

Target NGS extended panel for inherited cardiomyopathies: evaluating the increased diagnostic yield in hypertrophic cardiomyopathy. *J.D.C. Marsiglia[1], T.G.M. Oliveira[1], M.M. Neto[2], L.C. Teixeira[3], J.E. Krieger[1], E. Artega-Fernandez[4], A.C. Pereira[1].* 1) Laboratory of Genetics and Molecular Cardiology, Heart Institute, University of São Paulo, São Paulo, Brazil; 2) Fleury Group - Research and Cevelopment Department (R&D), São Paulo, Brazil; 3) CEFAP - Biomedical Science Institute (ICB/USP), São Paulo, Brazil; 4) Clinical Unit of Cardiomyopathies - Heart Institute, University of São Paulo, São Paulo, Brazil.

Introduction: Hypertrophic cardiomyopathy (HCM) is a primary cardiac disease, mainly characterized by unexplained left ventricle hypertrophy, in the absence of dilatation, usually asymmetric and predominantly septal. Up to now, more than 1400 mutations have been associated with HCM in over 20 genes related to sarcomeric myofibrils, Z-disc and calcium homeostasis. The main aim of this work was to compare the diagnostic yield of an expanded gene panel for the identification of mutations related with HCM that includes non-sarcomeric genes. Materials and Methods: 111 samples from a cohort of clinically diagnosed patients with HCM were processed using an Ion Torrent PGM platform for the assessment of the diagnostic yield of a genetic panel composed of 74 genes associated with inherited cardiomyopathies. The sample NA12878, a HapMap reference sample, was used in the assessment of intra- and inter-assay reproducibility in the validation process of a proposed pipeline for the detection of genetic alterations. Variants were considered potentially pathogenic if previously described as associated with HCM or if presenting a deleterious score in at least two of three impact prediction algorithms tested (PROVEAN, SIFT and PolyPhen-2) and MAF<0.01, if available. Results: Of all 111 samples, 44 had negative or inconclusive results, 42 had one or more mutations in sarcomeric genes, 20 had one or more mutations in non-sarcomeric genes, and 5 had two mutations, one in a sarcomeric and the other in a non-sarcomeric gene. The main non-sarcomeric genes harboring causal mutations were *FLNC* and *TRIM63*, both already associated with HCM. Conclusions: We observed an increase in diagnostic yield of 20% over a panel containing only sarcomeric genes. These results suggest that current molecular genetics diagnostic testing for hypertrophic cardiomyopathy should incorporate non-sarcomeric genes.

544W

WES as a first and second-tier test for arrhythmia and cardiomyopathy. *A.A. Singleton, B.E. Friedman, K. Retterer, G. Richard, D. Macaya.* GeneDx, Gaithersburg, MD.

NextGeneration sequencing panels for inherited arrhythmias and cardiomyopathies offer a sensitivity of 30-70% depending on the phenotype targeted. Our aim was to evaluate the positive rate of whole exome sequencing (WES) for these test indications, using WES either as first-tier test or after a negative or inconclusive targeted cardiology panel. We report results of 30 consecutive cases submitted for WES to GeneDx with a clinical indication of non-syndromic arrhythmia, cardiomyopathy, and/or sudden cardiac arrest/death. Record review indicated 13 individuals (43%) had prior testing including at least one targeted panel with negative or uninformative results. Of these 13, WES revealed 6 probands (46%) with pathogenic (P) or likely pathogenic (LP) variants in 6 distinct genes. One gene was newly described and therefore had not been available as part of a cardiology panel. The other genes were not included in the specific multi-gene panel initially chosen by the provider, likely due to phenotypic overlap. In the remaining 7 individuals, WES identified only variants of uncertain significance (VUS). These VUS were identified in genes known to be associated with a cardiogenetic presentation as well as in candidate genes. In contrast, 17 probands submitted for WES did not have prior targeted testing. Of these, 6 (35%) had a positive result (P or LP variants) in 8 distinct genes. Two probands were double mutation carriers. Since 3 out of the 8 genes were newly described, the molecular diagnosis in two of the probands (including one double mutation carrier) would have been missed by traditional panel testing. Three out of 17 probands (18%) had a negative results, and 8/17 (47%) had VUS in known or candidate genes. In summary, WES testing for 30 probands with arrhythmia, cardiomyopathy, sudden cardiac arrest/death, regardless of prior testing, yielded a positive rate of 40% (12/30).The molecular diagnosis would have been missed by traditional panel testing in 3/30 probands (10%). WES proves to be a good second-tier test especially for probands in whom the clinical diagnosis is not clear. A larger systematic comparison between WES and panel testing including diagnostic yield, cost, turn-around time would be necessary to determine the utility of WES as first-line test for these cardiogenetic disorders.

545T

Lack of specificity of ACMG classification rules decreases inter-curator concordance. ClinGen's adaptation of ACMG's framework to standardize interpretation of MYH7 related cardiomyopathy variants. *C. Caleshu[1,2,3], M. Kelly[1,4], A. Morales[1,5,6], E. Ashley[1,2,8], R. Hershberger[1,5,6,7], B. Funke[1,5,9].* 1) On behalf of the ClinGen Cardiovascular Domain Working Group; 2) Stanford Center for Inherited Cardiovascular Disease, Stanford, CA, USA; 3) Division of Medical Genetics, Stanford Medical Center, Stanford, CA, USA; 4) Laboratory for Molecular Medicine, Partners HealthCare Personalized Medicine, Boston, Massachusetts, USA; 5) Division of Human Genetics, The Ohio State University Wexner Medical Center, Columbus, OH, USA; 6) Davis Heart and Lung Research Institute, The Ohio State University Wexner Medical Center, Columbus, OH, USA; 7) Cardiovascular Division, The Ohio State University Wexner Medical Center, Columbus, OH, USA; 8) Division of Cardiovascular Medicine, Stanford Medical Center, Stanford, CA, USA; 9) Department of Pathology, MGH and Harvard Medical School, Boston, Massachusetts, USA.

Background: Recognition that variants in Mendelian disease genes are often classified differently in different labs has signaled the need for advances in variant classification systems. Recently, ACMG published updated guidelines, intended to serve as a framework for classifying Mendelian variants across all areas of genetics. We investigated the application of these new guidelines to *MYH7* and cardiomyopathy.**Methods:** Ten *MYH7* variants were independently reviewed by three members of the ClinGen Cardiovascular Working Group. Reviewers classified the variants using both the new ACMG criteria and criteria previously developed by each reviewer's cardiomyopathy genetics team. This analysis provided the foundation for an in-depth review of the ACMG criteria and the development of adapted rules with optimized specificity for *MYH7*. **Results:** Classification concordance was 8/10 for institutional criteria and 3/10 for ACMG guidelines. Disagreement between institutional classifications arose mainly from privately held data, while disagreement between ACMG classifications was largely due to ACMG criteria being applied differently by reviewers. Six of seven established pathogenic and likely pathogenic variants were classified as variants of uncertain significance with the ACMG criteria by at least one of the three reviewers. Subsequent in-depth review of the ACMG criteria resulted in 18 rule adaptations that are critical to provide optimal specificity for *MYH7*. Nine rules were modified, including changes informed by cardiomyopathy specific characteristics such as incomplete penetrance, prevalence of disease-causing alleles in the general population, and the existence of 1-5% of patients with >1 pathogenic variant. Eight rules were deemed inapplicable to *MYH7*, including loss of function as a known mechanism of disease and mutational hotspots. One rule was added to enable using the number of unrelated cases as a criterion supporting pathogenicity. Fifteen rule revisions were broadly applicable across cardiovascular genetics, reflecting a general lack of specificity.**Conclusions:** The use of ACMG guidelines in their current form can decrease the concordance of variant classifications. Expert review is therefore critical to adapt this new framework to disease domains and to reflect disease and gene specific characteristics and to enable consistent application. Our work serves as a stepping stone for additional genes and diseases.

Whole Genome Sequencing is a clinically effective strategy for Inherited Cardiac Disorders. *P.A. James[1, 2], T. Thompson[1], D. Du Sart[3], R. Leach[4], D. Floerke[4], R. Tearle[4], D. Zentner[5], A. Trainer[5], J. Vohra[5], I. Winship[1,6].* 1) Genetic Medicine, Royal Melbourne Hospital, Melbourne, Victoria, Australia; 2) Department of Pathology, University of Melbourne, Melbourne, Victoria, Australia; 3) VCGS Pathology, Victorian Clinical Genetic Service, Murdoch Children's Research Institute, Melbourne, Victoria, Australia; 4) Complete Genomics Inc., Mountain View, California; 5) Cardiology Department, Royal Melbourne Hospital, Melbourne, Victoria, Australia; 6) Dept of Medicine RMH, Faculty of Medicine Dentistry and Health Sciences, University of Melbourne, Melbourne, Victoria, Australia.

Background: Identifying the underlying mutation(s) in families affected by inherited cardiac disorders allows optimal screening and risk management and is a recommended component of standard clinical care. In practice this remains unachievable in many families reflecting the genetic complexity of these disorders. We examined the potential of a whole genome sequencing (WGS) approach to genetic diagnosis and compared this to standard practice in the setting of a multidisciplinary cardiac-genetics clinic (CGC).**Methods**: Living index cases assessed in the CGC for inherited arrhythmia, cardiomyopathy or aortopathy (n=100) were consented for WGS alongside usual care. The whole genome was sequenced and annotated (Complete Genomics). Variants were filtered against public databases and whole genome data from a control cohort of healthy elderly. Clinical interpretation was applied to high quality calls for SNPs, InDels, structural variants and CNVs involving all genes associated with a cardiac phenotype (HPO database). Clinically significant results were validated by Sanger sequencing.**Results**: Analysis of 40 genomes has been completed (18 Cardiomyopathy, 19 LQTS/Brugada, 3 Aortopathy) revealing an average of 124 protein altering variants per genome in genes with a reported cardiac phenotype. For 11 individuals (27%) a potentially causative mutation was detected through targeted sequencing in standard care. This increased to 27 individuals (63%) following analysis of WGS. In 17% of cases more than one likely pathogenic change was detected. The addition of data on structural variation was an important contributor to the improved detection rate of WGS.**Conclusion**: Whole genome sequencing achieved a significant improvement in genetic diagnosis over standard investigation and gene testing. The results confirm the broad heterogeneity of inherited cardiac disorders and suggest a greater role of multiple mutations as determinants of severity across the range of inherited cardiac conditions.

547W

Molecular diagnosis of generalized arterial calcification of infancy (GACI). *K. Iravathy Goud[1], M. Kavitha[1], M. Adi Maha Lakshmi[1], R. Vempati[1], D. Sagarika[1], A. Panda[1], Y. Nitschke[2], F. Rutsch[2].* 1) Molecular Biology & Cytogenetics Laboratory, Apollo Hospitals, Hyderabad, India, India; 2) Department of generel pediatrics, Muenister University childrens Hospital, Munster, Germany.

Generalized arterial calcification of infancy (GACI) is a life-threatening disorder in young infants. Cardiovascular symptoms are usually apparent within the first month of life. The symptoms are caused by calcification of large and medium-sized arteries, including the aorta, coronary arteries, and renal arteries. Most of the patients die by 6 months of age because of heart failure. Recently, homozygous or compound heterozygous mutations for the ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) gene were reported as causative for the disorder. ENPP1 regulates extracellular inorganic pyrophosphate (PP(i)), a major inhibitor of extracellular matrix calcification. A newborn was diagnosed with GACI. The infant died at the age of 7 weeks of cardiac failure and the parents were referred to Molecular Biology and Cytogenetic lab for further workup. Cytogenetics analysis was performed on the parents, which showed normal karyotypes and mutational analysis for the ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) gene was also performed. The mutational analysis showed that both father and mother of the deceased infant were heterozygous carriers of the mutation c.749C>T (p.P250L) in exon 7 of ENPP1 and it was likely, that the deceased child carried the same mutation homozygous on both alleles and died of GACI resulting from this ENPP1 mutation. The couple was counseled and monitored for the second pregnancy. Amniocentesis was performed at 15 weeks of gestation for mutational analysis of the same gene in the second pregnancy. The analysis was negative for the parental mutations. One month after the birth of a healthy infant, peripheral blood was collected from the baby and sent for reconfirmation. The results again were negative for the mutation and the baby was on 6 months follow up and no major symptoms were seen. The parents of the child benefited enormously by learning about the disease much in advance and also its risk of recurrence. The main aim of this study is to emphasize on two aspects: (i) the importance of modern molecular techniques in diagnosis such a syndrome and (2) the difficulties faced by the physician to provide appropriate diagnosis and the adequate genetic counseling to the family without molecular facilities. This study emphasis on importance of having molecular tools in tertiary care hospitals for diagnosis of rare genetic diseases.

548T

APOE genotype influences acute phase lipid changes in response to intracerebral hemorrhage. *C.D. Anderson[1-4], C.L. Phuah[1,4], M. Raffeld[1], A.M. Ayres[2,3], A. Biffi[1,3,4], A. Viswanathan[2,3], S.M. Greenberg[2,3], J. Rosand[1-4].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) The J. Philip Kistler Stroke Research Center, Massachusetts General Hospital, Boston, MA; 3) Hemorrhagic Stroke Research Group, Massachusetts General Hospital, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA.

Background: In addition to their roles in modulating circulating lipid levels, APOE e2 and e4 alleles are genome-wide significant risk factors for intracerebral hemorrhage (ICH). ICH is accompanied by a decline in total cholesterol (TC) and low-density lipoprotein (LDL). Given the pleiotropic relationship between APOE epsilon alleles, ICH, and lipid levels, we investigated the influence of APOE status on changes in circulating lipids in the setting of ICH.*Methods:* ICH cases were drawn from an ongoing longitudinal cohort study. APOE epsilon variants were previously genotyped. Controls were drawn from a hospital clinical registry of non-cerebral acute illness. Measurements of serum lipids were standardized to four 6-month intervals before and after hospitalization for TC, LDL, triglycerides (TG) and high-density lipoprotein (HDL). Piecewise linear mixed-effects models were used to compare the impact of ICH on lipid trends before and after hospitalization. Linear regression analyses were utilised for comparing APOE allele-specific effects on temporal variation in serum lipid levels.*Results:* 212 ICH cases and 301 controls were analysed. Rates of decline in serum TC and LDL were greater at time of ICH compared to patients with non-cerebral acute illness (TC: -0.75 mg/dL/month for ICH, -0.13mg/dL/month for non-ICH subjects, p=0.0015; LDL: -0.31mg/dL/month for ICH, -0.13mg/dL/month for non-ICH subjects, p=0.31). This ICH-related decline in TC and LDL levels was associated with APOE e4 carrier status and not e2 or e3. APOE e4 carriers experienced a mean decrease of serum TC and LDL levels acutely in ICH of -20.8±33.0 mg/dL and -15.4±26.5 mg/dL, respectively compared with pre-ICH levels. In contrast, the difference in mean serum TC and LDL levels during the same time period were -3.3±36.2 mg/dL and -0.6±28.2 mg/dL, respectively in APOE e2 carriers. This decrease in TC and LDL at ICH in APOE e4 carriers remained significant ($p<0.05$ for TC, $p< 0.01$ for LDL) following adjustment for potential confounders including diabetes and statin use.*Conclusion:* ICH acutely impacts serum TC and LDL levels in ways that other non-cerebral acute illnesses do not, and APOE epsilon allele status is a strong predictor of these acute changes. APOE influence on temporal lipid trends in ICH may reflect APOE-specific differences in innate inflammatory or lipid-homeostatic mechanisms in reponse to acute cerebral injury.

549F

Knockout mice for the cardiac repolarization regulator *Nos1ap* display partial lethality and increased heart mass. *D.R. Auer, A. Kapoor, A. Chakravarti.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

We have previously identified the *NOS1AP* gene (MIM 605551) as a major gene for cardiac repolarization (QT interval: MIM 610141), a genetic risk factor for sudden cardiac death (MIM 115080), and a genetic modifier for Mendelian long QT syndrome (MIM 192500). Although *in vitro* gene targeting-based cellular and biochemical studies have shed light on *NOS1AP* function in the heart and other tissues, to enhance our understanding of its role in mammalian physiology and disease, we report the generation of *Nos1ap* knockout mice using traditional embryonic stem cell (ESC) targeting. ESCs carrying the knockout-first allele (with conditional potential; *tm1a*) were obtained from the Knockout Mouse Project. After germline transmission, *tm1a*/+ mice were bred with ubiquitously-expressing *cre* and *FLPe* recombinase lines to generate the *lacZ*-tagged, *neo*R- and exon4-deleted (*tm1b*) allele; the *lacZ*- and *neo*R-deleted, exon4-floxed (*fl*) allele; and the *lacZ*-, *neo*R-, and exon4-deleted (*exon4Δ*) allele. Among the mice obtained from heterozygous intercrosses (n=274), mice homozygous for the *tm1a*, *tm1b,* and *exon4Δ*alleles displayed reduced survival with two-thirds dying before reaching weaning age, whereas the expected numbers of homozygotes were obtained for the *fl* allele. At embryonic day 13.5 (E13.5), the expected numbers of *exon4Δ*homozygotes were observed out of 100 embryos screened, indicating that homozygous lethality occurs between E13.5 and weaning. Mice homozygous for the *tm1a*, *tm1b*, and *exon4Δ*alleles had (a) no detectable Nos1ap protein by western blotting, (b) a significant reduction in mRNA expression (0.4-fold of control for *tm1a*; P=1.1×10-5, 0.04-fold of control for *tm1b*, P=2.5×10-6; n=5 in each group), and (c) significantly increased heart weight as compared to controls (P=0.001; n=11 homozygous mutants, n=16 wildtype). Targeted RNA expression analyses in E13.5 hearts for genes that encode proteins known to interact with *Nos1ap* did not exhibit significant differences between homozygous mutants and wildtype controls. *Nos1ap* knockout mice are currently being characterized by cardiac histology, electrocardiography, echocardiography, and RNA-Seq to identify the physiological and global molecular consequences of disrupting *Nos1ap* dosage and to determine how the null phenotype is rescued in some animals.

550W

Response-eQTLs of human left ventricular tissue after ischemia. *T. Chang[1,2], V. Carey[2], S. Aranki[3], S. Body[1], C. Seidman[4], J. Seidman[5], B. Stranger[6], B. Raby[2], J. Muehlschlegel[1].* 1) Brigham and Women's Hospital, Department of Anesthesiology, Perioperative and Pain Medicine, Harvard Medical School, Boston, MA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 3) Brigham and Women's Hospital, Division of Cardiac Surgery, Harvard Medical School, Boston, MA; 4) Division of Cardiovascular Medicine, Brigham and Women's Hospital, Boston, MA; 5) Department of Genetics, Harvard Medical School, Boston, MA; 6) Department of Medicine, University of Chicago, Chicago, IL.

BBackground: Inter-individual variations in gene transcript levels are important in mediating disease susceptibility. To identify and functionally characterize genetic variation contributing to myocardial injury in humans, we performed an expression quantitative trait loci (eQTL) analysis in normal and ischemic human left ventricular myocardium to identify variants that alter expression in response to a stimulus.**Methods:** Apical punch biopsies from the left ventricle were taken from 135 patients undergoing cardiac surgery at two time points; immediately after aortic cross clamping (baseline), and immediately before aortic cross clamp removal (ischemia). We quantified genome-wide mRNA expression using an Illumina HiSeq and performed genotyping with the Illumina Omni2.5 array.The response-eQTL was defined as the delta between the ischemic and baseline sample. We examined the associations in *cis* between variants and gene expression levels with a distance of ±100kb, adjusting for demographics and clinical variables. A False Discovery Rate < 0.01 was applied to account for the large number of testing between variants and expressed genes, and only those SNPs with a MAF>5% were included. **Results:** In all, 1.5 million variants and 16000 genes were analyzed with a total of 4.3 million variant-gene pairs tested. Of those, 239 genes were shared between the baseline and ischemic state, 247 genes were unique to baseline, 84 were unique to ischemia. In addition, we identified 8 response-eQTLs.**Discussion:** We demonstrated the presence of genetic variants contributing to inter-individual variation for gene expression change in left ventricular myocardium, hereby providing evidence of a novel genetic basis for variable transcription in response to an ischemic insult in human tissue. Response-eQTL genes of particular interest were laminin alpha (*LAMA3, FDR=0, Chisq=16.8*), succinate dehydrogenase complex (SDHA, FDR=0.06, Chisq=16.3), and dihydrofolate reductase (DHFR, FDR=0, Chisq=19.9), linked to cell migration, mitochondrial respiratory function, or amino acid synthesis.

Loss of Function Mutations in *NNT* Are Associated with Left Ventricular Noncompaction. *E.E. Davis[1], M.N. Bainbridge[2,3], W.Y. Choi[4], A. Dickson[4], H.R. Martinez[5], M. Wang[2], H. Dinh[2], D. Muzny[2], R. Pignatelli[5], N. Katsanis[1], E. Boerwinkle[2], R. Gibbs[2], J.L. Jefferies[6].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Codified Genomics, LLC, Houston, TX; 4) Department of Cell Biology, Duke University, Durham, NC; 5) Department Pediatrics-Cardiology, Baylor College of Medicine, Houston, TX; 6) The Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Left ventricular noncompaction (LVNC) is an autosomal dominant, genetically heterogeneous cardiomyopathy with variable severity, which may co-occur with cardiac hypertrophy. Despite recent advances towards understanding the molecular basis of the disorder, many of the causative LVNC genes remain to be identified. Here, we generated whole exome sequence (WES) data from multiple members from five families with LVNC. In four out of five families, the candidate causative mutation segregates with disease in known LVNC genes *MYH7* and *TPM1*, encoding myosin heavy chain beta and tropomyosin 1, respectively. Subsequent sequencing of *MYH7* in a larger LVNC cohort identified seven novel likely disease-causing variants. In the fifth family, we identified a frameshift mutation in *NNT*, a nuclear encoded mitochondrial protein, not implicated previously in human cardiomyopathies. Resequencing of *NNT* in additional LVNC families identified a second likely pathogenic missense allele. Suppression of *nnt* in zebrafish caused early ventricular malformation and contractility defects, likely driven by altered cardiomyocyte proliferation. *In vivo* complementation studies showed that mutant human *NNT* failed to rescue *nnt* morpholino-induced heart dysfunction, indicating a probable haploinsufficiency mechanism. Together, our data expand the genetic spectrum of LVNC and demonstrate how the intersection of WES with *in vivo* functional studies can accelerate the identification of genes that drive human genetic disorders.

Genomic Subsets and Cell Types Contribute to the Polygenicity and Heritability of Coronary Artery Disease. *R. Do[1,6], H.-H. Won[2,3,4,5], P. Natarajan[2,3,4,5], A. Dobbyn[1,6], K. Lage[4,5,7,8], S. Raychaudhuri[5,9,10], E. Stahl[1,5,6,11].* 1) Genetics and Genomic Sciences, Icahn School of Medicine, New York, NY; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts, USA; 3) Cardiovascular Research Center, Massachusetts General Hospital, Boston, Massachusetts, USA; 4) Department of Medicine, Harvard Medical School, Boston, Massachusetts, USA; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 6) Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 7) Department of Surgery, Massachusetts General Hospital, Boston, Massachusetts, USA; 8) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Boston, Massachusetts, USA; 9) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA; 10) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK; 11) Division of Psychiatric Genomics, Icahn School of Medicine at Mount Sinai, New York, New York, USA.

Coronary artery disease (CAD) and myocardial infarction (MI) is one of the leading causes of death and disability worldwide. Genome-wide association studies (GWAS) have identified up to 45 loci associated with CAD/MI. However, the molecular consequences of these loci remains largely unknown. Efforts by the National Institutes of Health (NIH) Roadmap Project, have allowed for systematic assessment of the molecular functions of the genome. By leveraging data from the NIH RoadMap Project, we investigated links between single nucleotide polymorphisms (SNPs) associated with MI/CAD and their biological impacts on gene function. First, we stratified MI/CAD according to genomic compartments and observed that SNPs that were proximal to the protein-coding region of genes exhibited significant polygenicity and >59% of the heritability for MI/CAD. Next, we showed that the polygenicity and heritability of MI/CAD are enriched in histone modification regions in specific cell types. By focusing on 45 MI/CAD-associated SNPs identified from GWAS, we showed that a higher number of these loci are enriched within specific regulatory elements, including active enhancer and promoter regions. Finally, we observed significant heterogeneity of this enrichment across cell types, with particularly strong signal observed in adipose nuclei, brain substantia nigra, brain angular gyrus, spleen cell types and smooth muscle tissues. These results suggest that the genetic etiology of MI/CAD is largely explained by tissue-specific regulatory perturbation within the human genome.

Gene silencing and haploinsufficiency of *Jag1* in GWAS locus 20p12.2 increase blood pressure. *J. Kang[1], M. Kim[1], S. Ji[1], S. Kim[1,2], J. Lim[1], S. Hwang[3], B. Oh[1].* 1) Department of Biochemistry and Molecular Biology, School of Medicine, Kyung Hee University, Seoul, South Korea; 2) Department of Animal Biotechnology, The Graduate School of Future Convergence Technology, HanKyong National University, 327 Jungang-Ro, Ansung-Si, Gyeonggi-Do, South Korea; 3) Department of Chemical Engineering, College of Engineering, HanKyong National University, 327 Jungang-Ro, Ansung-Si, Gyeonggi-Do, South Korea.

Hypertension is a highly heritable trait, and around 40–60% of the inter-individual variation in hypertension is attributable to genetic factors. Genome-wide association studies (GWASs) have identified multiple genetic loci associated with blood pressure. The 20p12.2 locus was associated with hypertension, left ventricular wall thickness, stroke, and coronary artery disease in Europeans, East Asians, South Asians, and African ancestry individuals.We aimed to identify a causative gene in the 20p12.2 locus using mice models. Among genes on the locus, *JAG1* was selected as a candidate gene, based on the proximity to the lead SNPs (rs1327235, rs1887320), the hypertensive phenotype specified in Alagille syndrome individuals, and the role of Jagged-Notch signals in cardiovascular development. *In vivo* injection of *Jag1* siRNA in mice significantly increased blood pressure compared to control siRNA injection. Consistently, vascular endothelial specific, haploinsufficient *Jag1* mice (*Jag1*flox/+; Tie2-Cre) showed increase in blood pressure compared to wild-type mice (*Jag1*+/+; Tie2-Cre). We also found that the heart rate was increased in *Jag1*flox/+; Tie2-Cre mice compared to the wild-type. As presumed, injection of propranolol, a β-receptor blocker, reduced both elevated blood pressure and heart rate in mice, suggesting that the sympathetic surge increases the heart rate, resulting in elevation of blood pressure in *Jag1*flox/+; Tie2-Cre mice.Our study demonstrates that *JAG1* is a causative gene in the 20p12.2 locus and regulates blood pressure through sympathetic activation, and these findings may provide a novel hypertensive mechanism.

554T

The role of the anti-oxidant enzymes SOD2 and catalase in the pathogenesis of pulmonary arterial hypertension. *R.D. Machado[1], J. DeGeer[2], N. Lamarche-Vane[2].* 1) School of Life Sciences, University of Lincoln, Lincoln, United Kingdom; 2) Centre for Translational Biology, Glen site of the MUHC, 1001 Boul. Décarie, Montreal, QC.

Pulmonary arterial hypertension (PAH) is characterized by the progressive obstruction of pulmonary arterioles, amid metabolic abnormalities, leading to right-heart hypertrophy and failure. Patients with PAH display conspicuous metabolic imbalances in the pulmonary vasculature, in particular between vasoconstrictors and vasodilators associated with abnormally elevated levels of reactive oxygen species (ROS). Mutation of *BMPR2*, a receptor member of the TGF-beta signaling superfamily, is the primary genetic factor underlying disease. While this discovery broadly identifies the BMP pathway as being critical in maintaining the vascular bed, little is known of pathways downstream of BMPR-II relevant to vascular integrity.To interrogate the extent and nature of cellular dysfunction in PAH we conducted a yeast two-hybrid screen using the kinase domain of BMPR-II as bait in a lung cDNA library. This approach facilitates the elucidation of the wider BMP signaling network by the identification of novel interacting partners. Superoxide dismutase 2 (SOD2) and catalase (CAT) were independently isolated. Both enzymes are considered to be the front-line cellular defense against pathologically elevated levels of ROS and thereby of biological relevance to PAH pathogenesis. We demonstrate an association between BMPR-II and these molecules in yeast by GST pulldown and co-immunoprecipitation, in addition to identifying limited but consistent cellular co-localization in a proportion of co-transfected cells. Of considerable interest, by semi-quantitative Western blotting and immunofluorescence against endogenous protein we demonstrate that *BMPR2* haploinsufficient PAH patient cells display significant down-regulation and mis-localization of both enzymes, suggestive of a downstream effect of BMPR-II deficiency, a feature not observed in cancer cell lines used here as controls.Taken together, these data suggest that mis-handling of these enzymes by mutant BMPR-II receptors represents a significant and early defect in disease etiology. Current work now aims to determine whether restoration of SOD2/CAT expression by use of chemical mimetics has potential to reverse the cellular disease phenotype.

555F

Mechanical Stability of the Aorta in a *Col3a1* Mouse Model. *J. Meienberg[1], J. Muenger[1], J. Crabb[2], A. Mauri[2], C. Kaiser[3], G. Barmettler[3], C. Giunta[4], U. Ziegler[3], S. Zeisberger[5], E. Mazza[2], G. Matyas[1,6].* 1) Center for Cardiovascular Genetics and Gene Diagnostics, Foundation for People with Rare Diseases, Schlieren-Zurich, Switzerland; 2) Institute of Mechanical Systems, Swiss Federal Institute of Technology Zurich, Zurich, Switzerland; 3) Center for Microscopy and Image Analysis, University of Zurich, Zurich, Switzerland; 4) Division of Metabolism, University Children's Hospital, Zurich, Switzerland; 5) Swiss Centre for Regenerative Medicine, University of Zurich, Zurich, Switzerland; 6) Zurich Center for Integrative Human Physiology, University of Zurich, Zurich, Switzerland.

Ehlers-Danlos syndrome vascular type (EDS IV) is a rare autosomal dominant connective tissue disorder characterized by translucent skin, easy bruising, and arterial, intestinal and/or uterine fragility. The most severe complication is the increased risk for rupture of the aorta, leading to life-threatening internal bleeding. EDS IV is caused by mutations in the *COL3A1* gene, which encodes the alpha 1 chain of type III collagen, a fibrillar collagen expressed in walls of hollow organs. So far, only disease management and treatment of symptoms are available but no targeted therapy. Recently, a novel mouse model which has true haploinsufficiency of *Col3a1* due to a spontaneous deletion has been described. In heterozygous mice, this *Col3a1* deletion leads to reduced mechanical stability of the aorta and, in ~28% of cases, to spontaneous rupture of the aorta and thus to increased mortality similar to the phenotype of human patients. Our goal was to assess the mechanical stability of the aorta in this mouse model compared to wild-type mice.The thoracic aorta from wild-type and heterozygous *Col3a1* mice was dissected and cleaned of adherent connective tissue. 1.5-mm-long sections of aortic arch as well as ascending and descending aorta (Figure 1) were mounted on two 200-µm diameter stainless steel wires on a tissue puller (Danish Myo Technology). The mounted vessels were stretched radially until tissue damage, thereby recording the stretching force (in mM).Maximum force at tissue damage was significantly lower in heterozygous *Col3a1* mice compared to age- and gender-matched wild-type animals in both the ascending and descending parts of the aorta. For both genotypes, the mechanical stability of the aorta was decreasing with increasing distance from the heart.We developed a protocol for the assessment of the mechanical stability of mice aorta, which is suitable to detect significant differences between heterozygous and wild-type *Col3a1* mice. Our results open the way to test pharmacological substances for their potential to increase the mechanical stability of the aorta with the goal to find a therapy for patients with EDS IV and related aortic disorders.

Malicdan[1, 8].* 1) Medical Genetics Branch, NHGRI, National Institutes of Health, Bethesda, MD; 2) Therapeutics for Rare and Neglected Diseases, National Center for Advancing Translational Sciences, NIH, MD, USA; 3) Department of Neuromuscular Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan; 4) National Institutes of Health, National Institute of Neurological Disorders and Stroke, NIH, USA; 5) Office of Research Services, Division of Veterinary Resources, Office of Research Services, NIH, MD, USA; 6) Cytogenetics and Microscopy Core, National Human Genome Research Institute, National Institutes of Health (NIH), MD, USA; 7) Cardiovascular and Pulmonary Branch, National Heart Lung and Blood Institute, National Institutes of Health (NIH), MD, USA; 8) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, 20892 Maryland, USA.

Statement of Purpose: GNE myopathy (GM) is an adult-onset distal myopathy caused by mutations in the *GNE* gene which encodes a bifunctional, rate-limiting enzyme in sialic acid biosynthesis. GM is characterized by a progressive muscle weakness and atrophy, preferentially involving distal extremities. Muscle histology shows inclusion bodies and rimmed vacuoles in affected muscle fibers. Although GM is known to solely affect skeletal muscles, there are few reports of subjects with cardiac abnormalities. Through our Natural History Study (NCT01417533), we recognized that cardiac involvement may have a higher than expected occurrence in subjects with GM thus in this study we aimed to systematically characterize the cardiac phenotype in our GM mouse model. **Methods:** Patients and mouse models (Gne-/-hGNED176VTg) with GNE myopathy were subjected to cardiac physiology assessment, including electrocardiogram (ECG), Holter, and echocardiogram. In addition, GM mouse models and control littermates underwent cardiac MRI. Heart samples from these mice were collected at various ages for routine histology, immunohistochemistry, lectin histochemistry, electron microscopy, and protein analysis.**Results:** A number of patients in our cohort exhibited ECG, echocardiogram and Holter abnormalities. In mice, we found that a significant number of mice developed cardiac abnormalities progressively with age. GM mice had increased QRS interval, QT interval, and P amplitude in ECG. Echocardiogram findings show that GM mutant mice showed increased diastolic left ventricle volumes, suggesting of possible decreased cardiac functions, as compared with control. MRI findings reveal that GM mutant mice have decreased ejection fraction, decreased stroke volume, and decreased cardiac output. Histopathological analysis in GM mice revealed rimmed vacuoles in cardiomyocytes, fibrosis, decreased number of intercalated discs, and lower amount of cadherin as compared to control. **Conclusions:** Our findings provide evidence that cardiac muscles are involved in GM. It is important for clinicians to be aware of the occurrence of cardiac disease in GM for careful examination of the cardiac function and proper management. We propose that the cardiac abnormalities that we have seen are, at least in mice, compatible with restrictive cardiomyopathy. Future work will be needed to understand how aberrant sialylation in cardiomyocyes will lead to cardiomyopathy. .

Blood-Pressure Associated Variants in Natriuretic Peptide Receptor C Affect Human Vascular Smooth Muscle Cells Proliferation and Angiotensin II-Stimulated Calcium Response. *M. Ren[1], F. Ng[1], K. Witkowska[1], M. Baron[2], A. Townsend-Nicholson[2], Q. Xiao[1], A. Hobbs[1], S. Ye[1], M. Caufield[1].* 1) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 2) Structural & Molecular Biology, University College London, London, UK.

*Background***:** Advances in genetic studies of blood pressure (BP) and hypertension have identified a number of trait-associated variants so far, and a recent genome-wide association study revealed a significant association between variation at natriuretic peptide receptor C (*NPR3)* gene locus and blood pressure (BP).*Objective*: To functionally investigate the role of BP-associated variants at NPR3 gene locus in the context of BP regulatory pathways.*Methods and Results:* Primary human umbilical smooth muscle (HUASMCs) and endothelial (HUVECs) cells were collected and genotyped for NPR3 gene variants rs1173743, rs1173747, rs1173756 and rs1173771. Endogenous mRNA and protein expression levels were assessed by qRT-PCR and western blotting. Open chromatin regions were examined using formaldehyde-assisted isolation of regulatory elements (FAIRE). We found the NPR3 risk allele (major allele) of intronic SNP rs1173747 was associated with diminished endogenous mRNA and protein levels in HUASMCs, which was consistent with its minor allele being located within an open chromatin state. Cell proliferation and migration were detected by cell counting and scratch assays. Intracellular calcium response induced by Angiotensin II (AngII) was detected using a fluorescent probe (Calcium 6). It is demonstrated cells carrying the major-allele of rs1173747 had increased proliferation and intracellular calcium level in response to AngII in HUASMCs. No difference in migration rates were detected. No such genotype-dependent characteristics were observed in HUVECs.*Conclusion:* This study has provided a mechanistic explanation for susceptibility variants at NPR3 gene locus to impact BP predominantly through modulating vascular smooth muscle cell behaviours.

558F

Apolipoprotein L1 genetic variants are associated with incident chronic kidney disease but not incident cardiovascular events in a population referred for cardiac catheterization. *H. Wang[1], L. Kwee[1], D. Craig[1], C. Haynes[1], M. Chryst-Ladd[1], L. Svetkey[1], U. Patel[1], P. Pun[1], E. Hauser[1], W. Kraus[1], M. Pollak[2], S. Shah[1].* 1) Duke University, Durham, NC; 2) Beth Israel Deaconess Medical Center, Boston, MA.

Genetic variants in the apoliprotein L1 (*APOL1*) gene have been implicated in the development of chronic kidney disease (CKD) in African Americans. However, the association between *APOL1* variants and cardiovascular disease is unclear. We assessed the association of *APOL1* variants with incident CKD, coronary artery disease (CAD) and incident cardiovascular events (CVD) in a large population referred for cardiac catheterization. Two single nucleotide polymorphisms in *APOL1* (G1 allele, rs60919145 and rs73885319) and a 6 base-pair insertion-deletion (G2 allele, rs71785313) were genotyped in African Americans (n = 1760) enrolled in the CATHGEN biorepository consisting of patients referred for cardiac catheterization at Duke University Medical Center (2001-2010). Incident CKD was defined as eGFR > 60 mL/min/1.73 m2 at index catheterization with at least two subsequent eGFR < 60 separated by at least 3 months; incident CVD included myocardial infarction and need for coronary interventions. Individuals were categorized as non-carriers (Ref/Ref), heterozygote (G1/Ref or G2/Ref) or homozygote carriers (G1/G1, G1/G2 or G2/G2) of *APOL1* risk alleles. The minor allele frequency was 0.22 (rs60919145), 0.14 (rs71785313) and 0.22 (rs73885319). Homozygote carriers had a lower median eGFR than heterozygotes and non-carriers (74.8 vs. 78.7 mL/min/1.73 m2, p = 0.004) and higher prevalence of baseline dialysis (12.1% vs. 3.4%, p < 0.001). Previously identified association between *APOL1* variants and incident CKD was confirmed (OR 2.0, 95% CI 1.0 – 4.1, p = 0.05). With regards to CAD, there was a trend towards less prevalent CAD and significantly lower burden of CAD in carriers vs. non-carriers (45.8% vs. 50.3%, p = 0.08; median CAD index 19 vs. 23, p = 0.02). However, no statistically significant associations were detected between *APOL*1 genetic variants and CAD in multivariable regression using additive, dominant and recessive models, adjusted for age, sex, BMI, diabetes status, hypertension, smoking status, hyperlipidemia and baseline eGFR. There were no significant differences between *APOL1* genetic variants and time-to-event for CVD events, even when stratifying by baseline kidney function and diabetes. Our results suggest that while *APOL1* variants are significantly associated with prevalent and incident kidney disease in African Americans, they are not associated with CAD or incident CVD events in a cohort of individuals with a high burden of cardiometabolic risk factors.

559W

Regulation of postprandial lipid homeostasis by *TM6SF2* . *N. Zaghloul, R. Yang, E. OHare, K. Ryan, S. Taylor, A. Shuldiner, L. Yerges-Armstrong, C. Sztalryd-Woodle.* Genetics & Genomic Med, Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

Postprandial hypertriglyceridemia is an important risk factor for cardiovascular diseases (CVD), but the mechanisms by which genetic factors modulate it remain unclear. It is primarily driven by very low density lipoprotein (VLDL) secretion from liver or chylomicron (CM) production from small intestine in response to dietary fat. We assessed the effect of a loss-of-function missense variant, E167K in the *TM6SF2* gene which was recently found to be associated with a favorable fasting blood lipid profile as well as other lipid traits such as hepatic steatosis. *TM6SF2* is predominately expressed in liver and small intestine consistent with a potential role in both tissues in regulation of postprandial lipemia. We genotyped the variant in 2059 subjects from the Old Order Amish (OOA) and performed association analyses to determine the effects of TM6SF2-deficiency on postprandial hypertriglyceridemia. Relative to the 7% minor allele frequency (MAF) in European-American populations, the E167K is enriched to 12% in the OOA. Analysis of carriers recapitulated associations with significantly lower fasting triglycerides (TG), total cholesterol (b=-10.4, p=1.2x10-5), and LDL-C (b=-10.8, p=6.2x10-7) and higher HDL-C (b=2.2, p=3.6x10-3). Importantly, following a high fat challenge, heterozygous and homozygous individuals exhibited significantly lower TG levels at all post-high-fat challenge time points ($p<0.05$ all), and lower total area (p=5x10-3) and incremental area under the curve (p=0.02). To gain further insight into the role of *TM6SF2* in small intestine lipid homeostasis, we developed a model of *tm6sf2*-deficiency in zebrafish. Consistent with the human clinical observations, we observed a significant decrease in fasting LDL-C and increased steatosis in liver. In addition, accumulation of lipid in enterocytes was also detected. Introduction of a 3-hour high fat diet (HFD) followed by clearance of dietary lipid for 24 hours produced significant differences in the intracellular lipid content of enterocytes consistent with a possible disruption of lipid clearance from enterocytes in response to dietary lipid. Finally, in human Caco-2 enterocytes treated with shRNA against *TM6SF2* exhibited significantly more lipid accumulation relative to control cells in response to an exogenous lipid load. Taken together, these data strongly support a role for *TM6SF2* in the regulation of post prandial lipemia and likely implicate its function in enterocyte lipid homeostasis.

Role of Genetic Variants in *Cholesteryl Ester Transfer Protein* in Risk of Myocardial Infarction and Response to Therapy. *K. Hartmann[1], M. Seweryn[2], W. Sadee[1].* 1) Department of Pharmacology, The Ohio State University, Columbus, OH; 2) Faculty of Mathematics and Computer Science, University Lodz, Lodz, Poland.

Purpose Several pharmaceutical companies have designed inhibitors of cholesteryl ester transfer protein (CETP) as an adjunct or alternative to statins, which fail to prevent myocardial infarction (MI) in ~50% of cases despite lowering lipids. Initial results from clinical trials are conflicting, which may reflect the effect of genetic variants. SNPs in *CETP* have been consistently associated with HDL but less so with MI and treatment response. CETP is part of a gene family (PLTP, LBP, and BPI), which functions not only in cholesterol transport but also in immunity. A complex haplotype structure, containing frequent long haplotypes indicative of positive selection, may in part reflect activity in immunity. We propose that the lack of consistent association of CETP with MI may be due to failure to consider all relevant variants in combination, both in liver and immune related tissues.**Approach** We suggest two complementary hypotheses:1) relevant variants in *CETP* can be frequent, and potentially alter CETP expression in opposing directions; 2) the main contribution of *CETP* to MI is through lipid-immunity interactions. Our first aim was to identify SNPs associated with altered CETP mRNA expression using data from the Genotype and Tissue Expression Project (GTEx) and Framingham Heart Study (FHS), and analyze linkage patterns using 1000 genomes. We test predicted SNPs in FHS and Atherosclerosis Risk in Communities (ARIC). Our second aim was to assess the physiological role of CETP, by identifying co-expressed genes and functional networks.**Results** Our group has previously identified variants associated with decreased expression (rs247616) and increased splicing (rs5883). Analysis of expression data identified an additional SNP associated with increased expression on the haplotype opposite of rs247616, associated with decreased expression. This robust negative linkage pattern and a long, well-preserved haplotype including rs5883 suggest strong evolutionary pressure attributable to the lipid and/or potential immune functions. High expression of CETP in spleen and lymphocytes relative to liver supports a role in immunity. Co-expression analysis identified multiple genes, most with immune functions. Our initial analysis of candidate SNPs in GWAS yielded associations with both lipids and MI. Further work will test candidate SNPs in *CETP* and tightly co-expressed genes in combination to account for lipid levels and MI risk.Supported by U01GM092655 and TL1TR001069.

Increased DNA damage and mutagen sensitivity: a new genetic modifier in Pulmonary Arterial Hypertension? *K.M. Drake, S.L. Meade, M.A. Aldred.* Genomic Medicine Institute, Lerner Research Institute, Cleveland Clinic, Cleveland, OH.

Pulmonary arterial hypertension (PAH) is a life-threatening condition characterized by obliterative lung vascular remodeling. It may be heritable (HPAH), idiopathic or associated with another underlying condition. HPAH shows autosomal dominant inheritance, but the penetrance averages only 27%, suggesting that other genetic and/or environmental modifiers are important in triggering disease. Our research focuses on the role of somatic mutations. We have shown that endothelial cells from PAH lungs frequently harbor chromosomal abnormalities. We therefore tested whether PAH patients are intrinsically more susceptible to DNA damage. Lung and blood cells showed significantly higher levels of micronuclei at baseline and in response to bleomycin or etoposide. Results were consistent across all three types of PAH. Surprisingly, we found similar results in unaffected first-degree relatives, demonstrating that this is not related to PAH treatments and suggesting a possible genetic basis. The goals of the present study are to identify the gene(s) underlying this increase in DNA damage, define the spectrum of mutagen sensitivity and determine if DNA repair is normal. We are initially focusing on PAH families, combining QTL extreme phenotype mapping with parametric linkage analysis and exome sequencing to identify candidate genes. The number of micronuclei, a marker of chromosomal breakage and loss, is analyzed in blood cells at baseline and in response to mutagens. Preliminary results in two families suggest dominant segregation independent of the underlying PAH mutation. Two unaffected relatives have baseline levels of micronuclei in the control range but an exaggerated response to mutagens in the “PH range”. The timecourse of repair of bleomycin-induced damage is largely normal, but not all patients return to baseline, suggesting a subtle difference in DNA repair that may lead to accumulation of damage over time. Early results with other potential mutagens show a highly significant increase in micronuclei in response to HDAC inhibitors. HDAC inhibitors have been proposed as a potential therapy for PAH, so delineating the differences in histone acetylation patterns is now an important priority. In conclusion, our results suggest that increased levels of DNA damage may be an independent genetic modifier of PAH and increased sensitivity to mutagenic agents has important implications for clinical management.

562W

SLC39A8 polymorphism influences cellular cadmium uptake and toxicity via signalling pathway activation in relation to hypertension. *R. Zhang[1], K. Witkowska[1], J. Guerra-Assuncao[2], F. Ng[1], M. Caulfield[1], S. Ye[1].* 1) Clinical Pharmacology , William Harvey Research Institute , London, United Kingdom; 2) Barts Cancer Institute, John Vane Science Centre, London, United Kingdom.

Objective. *hSLC39A8* (human solute carrier family 39 member 8) encodes a transmembrane protein that co-transpors divalent heavy metal cations, such as Cd2+,with elusive physiological role. Recent genome-wide association studies have identified a non-synonymous single nucleotide polymorphism rs13107325 to be associated with hypertension. The aim of this study is to investigate the functional impact of rs13107325 resulting in an amino acid substitution from Ala to Thr (A391T) in SLC39A8 on Cd2+ transport and the downstream signaling pathways.Methods. Intracellular Cd2+ uptake was measured in HEK293 cells overexpressing SLC39A8 (Measure-iTTM Pb and Cd assay kit), and in human umbilical vascular endothelial cells (HUVECs) of different genotypes. Cd2+- and genotype-dependence of ERK1/2 and NF-kB pathway activation were investigated by immunoblotting and dual-luciferase reporter assay. Cytotoxicity was measured by lactate dehydrogenase assay and MTS assay. Molecular dynamics simulations were performed to predict *in silico* the effect of A391T on the structure and dynamics of SLC39A8 by using Robetta, TMHMM and etc.Results. Overexpression of Ala variant in HEK293 resulted in higher Cd2+ uptake and higher cell death as compared with the Thr variant. This is associated with increased phosphorylation of ERK1 and NF-kB activation. Similar trends were observed in HUVECs with endogenous SLC39A8. Bioinformatics tools also suggested a conformational change of the a-helical structural transition (residual 390-392) in the Thr391 mutant, which potentially attenuates the protein function.Conclusion. Increased Cd2+ uptake by SLC39A8 Ala variant (blood pressure raising allele) is associated with higher cell death in human kidney and endothelial cells. Therefore its altered function due to rs13107325 may indicate a potentail therapeutic target in hypertension.

563T

Genetics of gene expression regulation in a case-control study for Acute Myocardial Infarction in a Pakistani population. *N.I Panousis[1,2,3], S. Tuna[4], L. Lataniotis[4], A. Rasheed[5], N. Shah[5], J. Danesh[6], E.T Dermitzakis[1,2,3], D. Saleheen[5,7], P. Deloukas[4].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Institute of Genetics and Genomics in Geneva (iG3), University of Geneva Medical School, Geneva, Switzerland; 3) Swiss Institute of Bioinformatics, Geneva, Switzerland; 4) William Harvey Research Institute, Queen Mary University of London, London, UK; 5) Center for Non-Communicable Diseases, Karachi Pakistan; 6) Department of Public Health and Primary Care, University of Cambridge, UK; 7) Department of Biostatistics and Epidemiology, University of Pennsylvania, USA.

The prevalence of coronary heart disease (CHD) is higher in populations of South Asia compared to Europeans; the risk of Myocardial infarction (MI) is 2-3 fold higher. By studying patterns of gene expression and genetic variation in monocytes, which is a relevant cell type we can discover biomarkers and develop a functional understanding of how genetic variation can alter risk of CHD. We report an RNA-seq analysis of monocytes from 71 cases of confirmed acute MI and 77 healthy individuals from the Pakistan Risk Of Myocardial infarction study (PROMIS). Principal component analysis (PCA) of expression differentiated MI from healthy individuals, demonstrating whole genome differences in expression. More specifically, we identified 5244 differentially expressed genes (5% FDR), including many that had previously been associated with cardiovascular disease (*IL1R2, PDGFD, LRP1*). PCA using only few differentially expressed genes cleanly differentiated MI and healthy individuals, suggesting a method for us to detect and/or validate novel biomarkers. We also explored genetic regulation of monocyte expression, in the context of GWAS variants associated with disease. As monocytes play a central role in CHD pathogenesis, we hypothesized that variants affecting gene expression are likely to be enriched in risk alleles for cardiovascular related diseases. We tested for genetic variants associated with gene expression levels within 1Mb of the transcription start site of a gene and discovered 4799 eQTLs as well as 179 variants associated with splicing changes (asQTLs) (FDR 5%). Analyzing cases and controls separately, we identified hundreds of MI specific eQTLs, which were not associated with expression in controls. Enrichment analysis of MI-specific eQTLs and GWAS loci, using the Regulatory Trait Concordance (RTC) method revealed several loci where the eQTL and GWAS signal were tagging the same functional variant. This included eQTL variants, which mediate GWAS hits for obesity (rs11247915), lipid levels (cholesterol: rs2277862, triglycerides: rs3198697) and type2 diabetes (rs3786897). We are currently combining the above findings with phenotypic risk factors (lipid profile, lifestyle, BMI) available in PROMIS to further investigate the molecular basis of CHD. In summary, we have shown that monocyte expression is an informative biomarker for MI and genetic variants active in the cell can be informative on genetic causes of CHD.

564F

A novel functional *VKORC1* promoter polymorphism (*rs397509427*) and Warfarin resistivity in Indian patients. *T. Shukla[1], K.P. Rao[1], S.K. Munpally[2], R. Tripathi[2].* 1) Genetics Dept, Osmania University, Hyderabad, India; 2) RAS Lifesciences, Hyderabad, India.

Warfarin is used as an oral anticoagulant for the prevention of thromboembolic diseases for subjects with deep vein thrombosis, atrial fibrillation, rheumatic heart disease or open heart surgeries. The dose requirement for warfarin therapy is highly variable, both inter-individually and inter-ethnically. Apart from the involvement of Genetic polymorphisms for the interindividual variability of humans to drugs, in the case of Warfarin, two important genes, viz., *VKORC1* and *CYP2C9* are known to produce interindividual variation in warfarin therapy. The present study was undertaken for their involvement in altered drug metabolism and action.*VKORC1* is the target enzyme for warfarin, which plays an essential role in carboxylation of vitamin K-dependent coagulation factors, by recycling Vitamin K. Mutations in the *VKORC1* gene and its haplotypes were known for variable dosages during warfarin therapy. Functional studies revealed that the dominant *VKORC1* -1639 G>A promoter SNP (*rs9923231*) correlates with lower protein expression levels. In the present study, A novel mutation *rs397509427* SNP (an insertion of G, which was present at -1586 position with respect to start codon) was observed in the promoter region of the *VKORC1* gene along with the *rs9923231* SNP in 8 patients, all of whom were on a higher dosage of warfarin (>7mg/day). The in-silico studies for Transcription factor binding site prediction, Secondary structure analysis and prediction of conserved short sequences/enhancers showed that the mutation could possibly act as an enhancer binding site or affecting the binding of transcription inhibitors.Further, studies were conducted for the functional study in HepG2 cell line to assess the role of mutant promoters. The relative quantitation of luciferase mRNA expression levels in control of *VKORC1* mutant promoter, showed approximately 6 fold higher expression levels in the cells, while the luciferase assays showed a 3 fold increase in protein expression. The results correlated well with the proposed hypothesis of increased transcription and translation due to *rs397509427* mutation. It may be concluded that the mutation might enhance the efficiency of the regeneration of the reduced vitamin K which ultimately would produce more gamma-carboxylation of the vitamin K dependent clotting factors.. It is an important finding and should play a significant role in the treatment regime as a diagnostic marker, when studied on a wider range of ethnic groups.

565W

The Gly364Ser variant in the Catestatin domain of Chromogranin A enhances the risk for hypertension in Indian populations. *M. Kiranmayi[1], V.R. Chirasani[1], P.K.R. Allu[1], S. Lakshmi[1], B.S. Sahu[1], D. Vishnuprabu[2], S. Sharma[3], R. Kumaragurubaran[1], D. Bodhini[4], M. Dixit[1], A.K. Munirajan[2], M. Khullar[3], V. Radha[4], V. Mohan[4], A.S. Mullasari[5], S. Senapati[1], N.R. Mahapatra[1].* 1) Department of Biotechnology, Indian Institute of Technology Madras, Chennai, India; 2) Department of Genetics, University of Madras, Chennai, India; 3) Department of Experimental Medicine and Biotechnology, Postgraduate Institute of Medical Education and Research, Chandigarh, India; 4) Department of Molecular Genetics, Madras Diabetic Research Foundation, Chennai, India; 5) Institute of Cardiovascular Diseases, Madras Medical Mission, Chennai, India.

Chromogranin A (CHGA) is a 48-kDa protein involved in the sorting/packaging of catecholamines and neuropeptides into the secretory granules of endocrine and neuro-endocrine tissues. CHGA is also a pro-hormone that gives rise to several bioactive peptides including catestatin (CST: human CHGA352-372), a catecholamine-release inhibitor. To identify and score naturally occurring polymorphisms in the CST region of CHGA in Indian populations, we re-sequenced and genotyped the region in a South Indian (Chennai) population (n≈2680). We discovered one novel (Gly367Val) and one previously reported polymorphism (Gly364Ser). We further replicated the genotyping of Gly364Ser in a geographically-distinct North Indian (Chandigarh) population (n≈760) using Taqman assay. Of note, there was a drastic difference in the frequency of 364Ser allele between the Chennai (6.28%) and Chandigarh (3.48%) populations. In both the populations, 364Ser was found to occur in a higher frequency in hypertensive cases than controls (unadjusted odds ratio =1.440 (p=0.015) for Chennai and =2.662 (p=0.002) for Chandigarh). In the Chennai population, the 364Ser carrying individuals displayed higher blood pressure levels: SBP by ~3 mm Hg (p=0.047), DBP by ~2 mm Hg (p=0.045) and MAP by ~2.5 mm Hg (p=0.030) and higher plasma glucose levels (by ~8 mg/dl; p=0.018). In the Chandigarh population as well, 364Ser variant was found to be associated with elevated blood pressure levels: SBP by ~8 mm Hg (p=0.004), DBP by ~6 mm Hg (p=0.001) and MAP by ~7 mm Hg (p=0.001). The CST-Ser peptide generated lower Nitric Oxide (NO) levels in HUVECs (assayed by DAF-2DA) as compared to CST-WT peptide, providing a plausible explanation to these observations. Molecular modelling and molecular dynamics simulation studies of the peptides showed that the presence of 364Ser caused dramatic changes in the CST peptide secondary structure, thus, revealing a structural basis for their differential biological activities. In light of the recent reports showing direct links between NO generation and beta2-adrenergic receptor (ADRB2), molecular dockings of CST peptides to ADRB2 were carried out. While CST-WT could effectively block the binding of the antagonist cyanopindolol to the ADRB2 active site CST-Ser bound at an entirely different location, keeping the active site free for interactions. In conclusion, the Gly364Ser variant increases the risk for hypertension via modulation of NO pathway in vascular endothelial cells.

Functional Interrogation of an Intronic SNP in *SMAD3* Linked to CAD (Coronary Artery Disease). *A. Turner, A. Martinuk, M. Nikpay, P. Lau, S. Soubeyrand, R. McPherson.* University of Ottawa Heart Institute, Ottawa, Ontario, Canada.

As part of recent large meta analyses of genome-wide association studies (GWAS), we have identified several new loci associated with CAD, including *SMAD3*. SMAD3 is an important mediator of TGFb signaling, but its specific role in CAD pathogenesis is not currently clear. The novel CAD-associated SNP in *SMAD3*, rs56062135, has an effect allele frequency of 0.79 (odds ratio 1.07). Many SNPs identified via GWAS are not causal in disease pathogenesis themselves, and may instead act as proxies for the actual functional SNP(s). Our goal was to identify candidate functional CAD-associated SNP(s) at the *SMAD3* locus and characterize the roles these SNPs play in CAD pathogenesis. Bioinformatics revealed rs56062135 is perfectly linked with several other SNPs, with rs17293632 representing the best candidate to be a causal variant. rs17293632 is located in an intron in *SMAD3* with chromatin marks indicative of an enhancer and is predicted to disrupt a conserved, consensus AP-1 binding site. Luciferase assays in primary human aortic smooth muscle cells, HeLa cells, and HepG2 cells reveal rs17293632 is located in a very strong enhancer sequence. The minor allele disrupts the AP-1 site and drastically lowers enhancer activity ($p<0.001$). To determine if rs17293632 is associated with SMAD3 mRNA levels in humans *in vivo*, we selected age and gender matched patients across the three different genotypes (approximately 50 patients per genotype). RNA from whole blood was extracted from PAXgene Blood RNA tubes (PreAnalytiX/QIAGEN) and SMAD3 mRNA levels were quantified by qRT-PCR. Subsequent expression quantitative trait locus analysis revealed rs17293632 genotype is significantly associated with SMAD3 mRNA levels in whole blood ($p<0.05$). rs17293632 was also significantly associated with SMAD3 mRNA levels in 96 genotyped carotid plaque samples ($p<0.05$). Chromatin immunoprecipitation experiments in genotyped human aortic smooth muscle cells where the *SMAD3* AP-1 site is intact reveal binding of several AP-1 components to the region encompassing rs17293632. Allele-specific chromatin immunoprecipitation in aortic smooth muscle cells heterozygous at rs17293632 show AP-1 components bind less preferably to the minor allele. Our *SMAD3* data highlights that non-coding DNA variants are important in the pathogenesis of common diseases such as CAD. Ongoing functional analysis of the *SMAD3* locus is expected to identify novel mechanisms and pathways leading to atherosclerosis.

567F

Integrity of induced pluripotent stem cell (iPSC) derived megakaryocytes as assessed by genetic and transcriptomic analysis. *K. Kammers[1], J.T. Leek[1], I. Ruczinski[1], J. Martin[2], M.A. Taub[1], L.R. Yanek[2], A. Frazee[1], D. Hoyle[3], N. Faraday[2], D. Becker[2], L. Cheng[3], Z.Z. Wang[3], L. Becker[2], R.A. Mathias[2].* 1) Department of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 2) The GeneSTAR Program, Johns Hopkins School of Medicine, Baltimore, MD; 3) Johns Hopkins School of Medicine, Baltimore, MD.

Aggregation of platelets in the blood on ruptured or eroded atherosclerotic plaques may initiate arterial occlusions causing heart attacks, strokes, and limb ischemia. Understanding the biology of platelet aggregation is important to prevent inappropriate vascular thrombosis. GWAS studies have identified common variants associated with platelet aggregation, but because they are intronic or intergenic, it is not clear how they are linked biologically to platelet function. To examine this, we are funded to produce pluripotent stem cells (iPSCs) from people with informative genotypes, and then derive megakaryocytes (MKs), the precursor cells for anucleate platelets, from the iPSCs to determine patterns of gene transcript expression in the MKs related to specific genetic variants.To this end it is essential that the iPSC-derived MKs retain their genomic integrity during production or expansion. This was examined using three alternative measures of integrity of the MK cell lines: (1) mutation rates comparing parent cell DNA to iPSC cell DNA and onward to the differentiated MK DNA; (2) structural integrity using copy number variation (CNV) on the same; and (3) transcriptomic signatures of the derived MK cells. For the genotype and CNV data, we used the HumanOmniExpressExome-8v1 array on 14 paired donor DNA – iPSC and paired iPSC - MK lines, and for the RNASeq data we extracted non-ribosomal RNA from 14 paired iPS and MK cell lines.A comparison of genotypes between matched pairs of cell lines indicated a very low rate of discordance; estimates ranged from 0.0001%-0.01%, well below the genotyping error rate (0.37% estimated from controls). No CNVs were generated in the iPSCs that got passed on to the MKs. Finally, looking specifically for genes 'turned on' in MKs following differentiation from the iPSCs, we observed the following highly biologically relevant gene sets in the list of top 12 identified: platelet activation, immune response, inflammatory response, platelet formation, and regulation of cell proliferation. The most highly expressed genes in iPSCs were ribosomal proteins, while in MKs they were platelet related proteins, such as GP9 and PF4.In conclusion, the genetic and transcriptomic data strongly support high integrity of the iPSC-derived MKs. We are currently performing extensive eQTL analysis to categorize 'functional' relevance of the GWAS-identified determinants of platelet aggregation leveraging the genotype and RNASeq data.

568W

Elevated levels of oxidative DNA damage and Folate gene polymorphisms in children with congenital septal defects and their mothers. *s.B. Sunayana[1], k. Srujana[1], K. Nageswara rao[2], G. Sandhya[1], D. Sujatha[3], M. HemaPrasad[1].* 1) Human Genetics, Osmania University, Hyderabad, India; 2) Care Hospital, Banjara Hills, Hyderabad-500034; 3) National Institute of Nutrition, Hyderabad.

Congenital septal defects (CSD) are the most common type of birth defect and may result in death in uterus, in infancy, or in childhood. Maternal oxidative stress and folic acid levels are the major factors that adversely affect the fetal heart development. The present study is aimed to understand the possible etiological factors that contribute to an increase in the severity of disease. Cytogenetic analysis using fluorescence in situ hybridization (FISH) and comet assay were performed to identify the microdeletions in chromosome 22 and to measure the oxidative DNA damage in the lymphocytes, respectively. Single nucleotide polymorphisms (SNPs) of Methylenetetrahydrofolate reductase (MTHFR) (677C >T), reduced folate carrier (RFC) (A80G) and methionine synthase reductase (MTRR) were analyzed to identify the role of folic acid.Methods: One hundred and sixty two children with non-syndromic CSD and their mothers were studied with age-matched controls. Blood samples were collected from the Department of Pediatric Cardiology, Care Hospital, Hyderabad, with prior clearance from the Institutional Ethics Committee and written consent from the parents. The lymphocytes were isolated from fresh blood for comet assay as well as for the identification of 22 q11.2 microdeletions. The plasma and red blood cells (RBCs) were used for the estimation of folic acid and vitamin B12. The C-reactive protein (CRP) was analyzed using the enzyme-linked immunosorbent assay. Genomic DNA was isolated for PCR and restriction fragment length polymorphism analysis of SNPs 677C> T, 1298A>G, A80G and 66A>G genes.Results:The mean values of RBC folate in mothers with affected prepositus having 3 months infants to 15 years children with CSD showed one and a half fold reduction in RBC folate (349.6 ± 162.9ng/ml) when compared to controls (527.6±227.4ng/ml). Further, vitamin B12 levels in mothers (73.7 ± 46.2ng/mL) with CSD offspring were significantly low when compared to the controls (264.2 ± 159.1ng/mL). The mean comet tail length and CRP levels were significantly increased ($p<0.05$) in CSD children and mothers compared to the controls. The SNPs of MTHFR 677C> T, 1298A>G, RFC 80A> G and MTRR 66A>G was observed in 79.65% of CSD children and in 85.8% mothers, respectively. Conclusions: Low folate levels and genetic polymorphism have shown increased oxidative DNA damage in children with congenital septal defects and in their mothers are the important risk factors for CSD .

A Gene-by-Environment Interaction Informs Aortic Segment-Specific Vulnerability for Aneurysm Formation in Mendelian Aortopathies. *N. Wilson, J. Doyle, C. Antonescu, S. Wheelan, D. Bedja, H. Dietz, MIB-AVA Leducq consortium.* Institute of Genetic Medicine, Johns Hopkins Medical Institutions, Baltimore, MD.

Most heritable aortopathies including Marfan (MFS) and Loeys-Dietz (LDS) syndrome show aortic root aneurysm (AoRA). Bicuspid aortic valve with more distal ascending aortic aneurysm (BAV/AscAA) is the most common inherited aneurysm condition, occurring in up to 1% of people, yet its etiology remains mysterious with heterozygous loss-of-function mutations in *NOTCH1* accounting for less than 1% of cases. It remains unclear whether anatomic differences between these conditions foreshadow intrinsic differences in mechanistic underpinnings and hence therapeutic vulnerabilities. We showed that TGFb-linked ERK activation drives aortic disease in a MFS mouse model (*FBN1*C1039G/+) and that inhibition of ERK phosphorylation with either angiotensin receptor blockers (ARBs) or the ERK kinase inhibitor RDEA119 rescues AoRA in MFS mice. In contrast, calcium channel blockers (CCBs) specifically induce more distal ascending aortic enlargement and tear in MFS mice that closely mimics the pathology typically seen in BAV/AscAA. Concomitant administration of either ARBs or RDEA119 prevents both AoRA and AscAA in CCB-treated MFS mice. In an unbiased approach to mechanistically characterize this gene-by-environment interaction, we applied strict a priori filters to RNA sequencing data from aortic specimens, imposing a change in CCB-treated animals that was abrogated upon use of RDEA-119. Given that expression-profiling analysis of end-stage tissues makes it difficult to distinguish between pathogenic, compensatory and irrelevant events, we focused on alterations that occurred in tight temporal sequence with conditional provocation. Enrichment algorithms identified Notch signaling as the lead candidate pathway. Informatively CCB-treated MFS mice exposed to dibenzazepine (DBZ), a potent Notch inhibitor, showed marked acceleration of AscAA progression and rupture; DBZ had no effect on wild-type animals but also accentuated AoRA in MFS mice without CCB treatment. We conclude that: 1) there is intersection between the pathogenesis of MFS and BAV/AscAA; 2) in the face of an underlying disease predisposition, Notch signaling is protective; and 3) multiple therapeutic strategies including Notch agonism have shared potential in phenotypically discordant aneurysm conditions. Studies are underway to interrogate the relevance of the 2nd-most enriched pathway in CCB-treated MFS mice, regulation of androgen receptor activity, to the overt male preponderance among patients with BAV/AscAA.

570F

***Notch1* haploinsufficiency under the influence of maternal hyperglycemic environment increases risk of congenital heart defects by an epigenetic mechanism.** *M. Basu[1], K. Bosse[1], V. Garg[1,2].* 1) Center for Cardiovascular and Pulmonary Research and The Heart Center, Nationwide Children's Hospital , 700 Children's Drive, Columbus, OH 43205; 2) Departments of Molecular Genetics & Pediatrics, The Ohio State University.

Rationale: Congenital heart disease (CHD) is the most common birth defect with high incidence of infant morbidity and mortality. Majorities of CHDs are proposed to have a multifactorial etiology and are due to a combination of genetic and environmental factors. Pre-gestational maternal diabetes is a well-recognized non-genetic risk factor which disturbs embryonic development and increases susceptibility towards congenital malformations. Hyperglycemia results in increased production of reactive oxygen (ROS) and nitrogen species leading to endothelial-cell dysfunction and we recently demonstrated a genetic interaction between endothelial nitric oxide (NO) synthase and *Notch1* important for cardiac development. Therefore, we hypothesized that maternal diabetes in combination with *Notch1* heterozygosity in developing embryo will predispose to the development of CHD.**Methods:** We tested our hypothesis using streptozotocin-induced mouse model of type-I diabetes in mice heterozygous for a null allele for *Notch1* and performed morphological analyses on E13.5 embryos. Protein and mRNA expression were measured using immunohistochemical staining and qRT-PCR. *In vivo* results were also validated using an atrioventricular mesenchymal (AVM) cell line and chick embryo model system in presence of high glucose to dissect the underlying mechanism of gene-environment interaction.**Results:** Histologic analyses indicated that wildtype (WT) embryos [2/9(22%)] exposed to maternal diabetes have increased incidence of ventricular septal defect (VSD) compared to [0/9 (0%)] non-diabetic embryos. The incidence of VSD was further increased for diabetic *Notch1*+/- mice [12/14(85.7%)]. Analysis of non-diabetic and diabetic WT embryonic hearts revealed that hyperglycemia is associated with a gradual decrease in *Notch1* mRNA and its downstream target genes (*Hey1, Hey2, Nrg1*) with concomitant upregulation in *Jarid2* mRNA expression, an epigenetic histone mark known to regulate *Notch1*. We also detected increased production of ROS and decreased NO bioavailability in AVM cells treated with 25mM of glucose compared to normoglycemia (5.5mM). *Jarid2* expression also increased with hyperglycemia both at RNA and protein levels. *In vitro* chromatin immunoprecipitation data suggested relative enrichment of Jarid2 on *Notch1* locus with hyperglycemia. Together our data demonstrate that maternal hyperglycemia disrupts cardiac development by affecting the Notch1 signaling pathway through Jarid2-mediated repression.

Common Genotype and Environmental Risk Factors of Myocardial Infarction and High Blood Cholesterol in a Retrospective Population Study. *Y. Liang[1], A. Kelemen[2].* 1) 1Department of Family and Community Health, University of Maryland, Baltimore, Baltimore, MD; 2) 2Department of Organizational Systems and Adult Health, University of Maryland, Baltimore.

This article assesses whether risk alleles related to MI may also relate to high cholesterol; and to evaluate prediction power of the joint genetic and environmental factors influencing the risk of MI and cholesterol. The retrospective study consists of 1837 subjects, 818 having history of MI and 1019 with no history of MI aged 35 to 69 years. The data includes 29 variables such as smoking status, alcohol use, etc. 81 SNPs linked to a metabolic pathway were genotyped and preselected from the SeattleSNPs variation discovery panel. SNPs *car_CEPT_3* [OR=1.431, (1.047, 1.956)] and *car_NOS_2* [OR=1.413, (1.063, 1.877)] were found to be significantly associated with risk of MI. High cholesterol has strongest effect on MI [OR=5.397, (4.069, 7.160)] compared with other factors. HBP [OR=2.420, (1.819, 3.219)], male gender [OR= 4.252, (3.087, 5.857)], smoking status [OR=3.399, (2.376, 4.862) for current smoker; [OR=.447, (.321, .622)] for former smoker], drinking status in past 1-2 yrs [OR=.672, (.502, .901)], awere found significantly associated with MI. The interaction between drinking and smoking status was significant [OR=.459, (.220, .956)] for current smokers who drank in the past 1-2 yrs. The prediction power was increased from 72% to 80% when including both genetic and environmental factors and their interactions compared with environmental factors only. The presence of the two SNPs, *il1_2_12* and *alox_2_22* increased the odds of the likelihood of high cholesterol by 27% [OR=1.272, (1.045, 1.549)] and 42% [OR=1.424, (1.027, 1.974)] respectively. Adjusting for the demographic and clinical factors, the odds of the likelihood of high cholesterol were 33% lower [OR=0.671, (0.511, 0.881)] for people who had the *cept_2_12* allele than for people who did not have it; the odds of the likelihood of high cholesterol were 99% lower [OR=0.011,(.000, .249)] for people having no history of MI than for people having it. Gene-gene and gene-environmental interaction effects were found significantly associated with high cholesterol (gender and *cept_2_12*, family history of heart diseases and *car_esr1_2*, no MI history and age, *Alox_2_22* and *cept_2_12*). Having history of either MI or high cholesterol conditions has significant effect on each other in both ways. The common alleles gene variants (*il1* and car_*cept*.) associated with both MI and high cholesterol has been discovered, which may be potential therapeutic target for personalized treatment and precision medicine.

572T

Utilizing gene expression to uncover genotype-dependent effects of BMI in multiple tissues. *C.A. Glastonbury[1], A. Viñuela[1,2,3,4], A. Buil[2,3,4], G. Thorleifsson[5], U. Thorsteinsdottir[5,6], E. Dermitzakis[2,3,4], T. Spector[1], K. Small[1].* 1) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 2) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 3) Institute for Genetics and Genomics in Geneva (iGE3), University of Geneva, Geneva, Switzerland; 4) Swiss Institute of Bioinformatics, Geneva, Switzerland; 5) deCODE Genetics, Sturlugata 8, IS-101 Reykjavik, Iceland; 6) Faculty of Medicine, University of Iceland, 101 Reykjavik, Iceland.

On the population level obesity is robustly associated to a range of co-morbidities. However, despite a demonstrated causal role of obesity in co-morbidities such as Type 2 Diabetes, co-morbidity incidence amongst obese individuals is heterogeneous. This heterogeneity may reflect genotype-dependent responses to obesity, here termed gene x environmentBMI (GxEBMI) interactions. We leveraged the power of transcriptomics to identify GxEBMI regulatory effects in RNA-seq data from three primary tissues and one cell line (Adipose, Skin, Whole Blood & LCLs) from 856 healthy female twins from the TwinsUK cohort. A genome-wide *cis* GxEBMI scan (±1MB from TSS, MAF >5%) identified four genome-wide significant (GWS) GxEBMI effects in Adipose (*ALG9, HACL1, GAA, SMG6*) and one in Skin (*RHPN2*). Two of three GWS effects testable in the DeCODE adipose expression dataset (N = 673) replicated ($p < 0.05$, consistent direction of effect) demonstrating our findings are robust. We tested the GWS GxEBMI variants for *trans* effects (±5MB from TSS) and found rs3851570 (*cis* GxEBMI of *ALG9)*, is a *trans*- GxEBMI regulator of 151 genes in adipose (Top hit: *ZNF423* p=8.2x10-13, bonferroni corrected cutoff = 4.3x10-7**)**. The 151 *trans*- GxEBMI genes are enriched for oxidative phosphorylation (B-H, p = 1.4x10-3) and respiratory chain processes (B-H, p=8.3 x 10-3) indicating rs3851570 interacts with BMI to regulate cellular metabolism. We characterized properties of adipose GxEBMI using 423 effects identified at a relaxed threshold of p < 1x10-5 These GxEBMI are highly tissue-specific (ϖ1=0), not directly associated to BMI ($p > 0.05$; GIANT dataset, N = 250K) nor enriched for main effect *cis*-eQTLs (ϖ1=0.03). GxEBMI genes are enriched for GO metabolic process ($p = 0.01$) and GxEBMI SNPs are enriched for low p-values in large GWAS's of Insulin ($p = 0.001$) and HOMA-IR ($p = 0.006$). These findings suggest utilizing gene expression to detect GxE is a powerful approach to understand the development of obesity and adipose-relevant complex traits. As adipose tissue is a heterogeneous mix of cells, we computationally deconvolved each sample to estimate the relative proportion of 19 cell-types. The most abundant cell type estimated are adipocytes (median=0.72) followed by Macrophages (median=0.07). Overall, the immune cell fraction is strongly correlated to adiposity (% trunk fat, $r2 = 0.39$, $p < 2.2x10-16$). Ongoing work aims to identify cell-specific *cis*-eQTLs and their relationship with complex traits.

573F

What next after GxE GWAS: A bioinformatic functional characterization of the *EBF1* gene and stress interaction signal. *A. Singh, M.A. Babyak, B.H. Brummett, R. Jiang, I.C. Siegler, W.E. Kraus, S.H. Shah, R.B. Williams, E.R. Hauser.* Duke University Medical Center, Durham, NC.

Identifying the functional relationship between risk genotypes and phenotypes and understanding the influence of the environment are important steps in characterizing the genetic architecture of GxE interactions. In our previous study (Singh et al. 2014) a GxE GWAS showed that in the presence of chronic psychological stress in two population-based cohorts (MESA and Framingham), common variants in the *EBF1* gene (SNPs rs4704963, rs17056278, R2=1) contribute to inter-individual differences in human obesity, diabetes, and cardiovascular disease risk factors. The gene-by-stress interaction was replicated in three additional studies (Family Heart Study, Duke Caregiver Study, and CATHGEN Cohort) (Singh et al. 2015). In this work, we performed functional characterization using bioinformatic approaches, an existing curated knowledgebase (i.e., Ingenuity® Pathway Analysis (IPA)), and gene expression data from the CATHGEN cardiovascular cohort study (Burns et al., 62nd ASHG, 2012). In the IPA knowledgebase the T2D pathway showed the role of *GLUT4* gene in the development of insulin resistance and the *EBF1* gene interaction network showed an interacting-link between *EBF1* and a known diabetes gene *SLC2A4* (i.e., *GLUT4*). We compared the genomic sequence of the GWAS signal in multiple vertebrate species (Human, Rhesus, Mouse, Dog, Elephant, Opossum, etc.); a SNP from the GWAS signal (rs17056278) is located on a highly conserved site that includes a candidate for conserved transcription factor binding site *CCAT* (tfbscons) suggesting a potential functional role for the associated SNP. Using linear regression under the default additive genetic model adjusting for age and sex, we tested the *EBF1* SNP in an eQTL analysis with and without a stress interaction in CATHGEN Whites where chronic psychosocial stress was a computed variable (Singh et al 2015). There was a statistically significant differential expression of *EBF1* (P=0.034), expression levels being lower for the minor allele group. We did not detect a significant SNP x chronic psychosocial stress interaction on expression of *EBF1;* however, the effects were consistent with the original GWAS association in terms of the direction and trend, i.e. *EBF1* gene expression increased with increasing chronic psychosocial stress for the carriers of the minor allele but not for major allele homozygotes. To examine the relationship between chronic psychosocial stress, *EBF1* variants, and gene expression, a larger study is required.

Background: We assessed whether 234 established dyslipidemia-associated loci modify the effects of metformin treatment and lifestyle intervention (vs. placebo control) on lipid and lipid sub-fraction levels in the Diabetes Prevention Program (DPP) randomized controlled trial.*Methods*: We tested gene-treatment interactions on 1-year changes in blood lipid concentrations (high and low density lipoprotein cholesterol [HDL-C, LDL-C], total cholesterol, triglycerides) and lipoprotein sub-fraction particle concentrations and size in 2,993 non-diabetic DPP participants. *Results*: Of the previously reported SNP associations, 32.5% replicated at $P<0.05$ at baseline. Trait-specific genetic risk scores (GRS), defined as sums of the risk alleles of all trait-associated variants, were robustly associated with their respective baseline traits ($3\times10\text{-}4>P>1.1\times10\text{-}16$) for all but two traits (medium HDL and intermediate density lipoprotein, $P>0.05$). Metformin and lifestyle modified the effect of the GRS for large HDL particle numbers, such that from baseline to 1-year, each risk allele of the GRSHDL-large associated with lower large HDL levels in the metformin (b=-2.7% per GRS allele; 95%CI -4.5, -1.0; $P=2\times10\text{-}3$; *Pinteraction*=0.02 for metformin vs. placebo) and the lifestyle arm (b=-2.8% per GRS allele; 95%CI -4.6, -1.1; $P=2\times10\text{-}3$; *Pinteraction*=$5\times10\text{-}3$ for lifestyle vs. placebo), but not in the placebo arm ($P>0.05$). Moreover, lifestyle modified the effect of GRSHDL-size, such that a higher GRS associated with lower HDL particle size from baseline to 1-year in the lifestyle arm (b=-0.02nm per GRS allele; SE=0.007; $P=1\times10\text{-}3$; *Pinteraction*=$8\times10\text{-}3$ for lifestyle vs. placebo), but not in the metformin or placebo arms ($P>0.05$).*Conclusions*: Improvements in HDL particle size conferred by metformin and lifestyle may be diminished by high genetic loading for smaller particle size.

Understanding the Biological Basis of G×E Interactions in Cardio-metabolic Disease: Methylation Profiles, Genetic Variation and Caregiver Stress. *R. Jiang[1], L. Kwee[2], A. Singh[1], S.H. Shah[2], B.H. Brummett[1], M.A. Babyak[1], I.C. Siegler[1], R.B. Williams[1], E.R. Hauser[2].* 1) Department of Psychiatry and Behavioral Sciences,Duke University Medical Center, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC.

Previous studies have demonstrated and replicated an interaction between genetic variants and psychosocial stress. Minor alleles of two SNP variants (rs439401, rs157580) were associated with an adverse metabolic profile (*e.g.*, higher triglyceride levels) in stressed caregivers, but a favorable or neutral metabolic profile in non-stressed controls. We hypothesized that this interaction between psychosocial stress and genetic variation may be due to differential DNA methylation at three levels: average methylation in the candidate region (AMCR), average global methylation (AGM) and genome-wide, probe-specific methylation. We selected age- and gender-matched caregiver/control pairs and assayed the Cpg methylation level using the Infinium HumanMethylation450 BeadChip. Sample and methylation probe quality control was performed using the RnBeads package in R, resulting in 112 samples with 462,936 CpG sites for association analysis of methylation levels and SNP genotypes. The CpGAssoc package was used for statistical analysis of AMCR, AGM and individual CpG sites. We did not observe genome-wide significant p-values ($p<10\text{-}7$) with any of the individual CpG sites or a significant p-value for AGM ($p>0.05$) for association with caregiver stress or genotype. AMCR was calculated for 73 CpG sites in the 104 kb PVRL2-TOMM40-APOE-APOC region, controlling for age, gender and six PCs. Our results showed that rs439401 C/C carriers had lower AMCR than C/T and T/T carriers (p=0.045). Further analysis of rs439401 by caregiver/control status showed that this pattern was seen only in caregivers, but not in the controls. C/C caregivers had lower AMCR compared with C/T caregivers (P=0.014), and T/T caregivers (P=0.076). A similar pattern was observed for rs157580 in that G/G caregivers had higher AMCR compared to A/A (P=0.004) and A/G in caregivers (P=0.008), but not in controls. The effect of SNP variants on methylation level was seen only in caregivers, and the direction of the pattern was consistent with the relationship between SNP variants and metabolic profile in our previous studies. These findings indicate that the stressed-caregiver/non-stressed control status may moderate the association of SNP variants through methylation levels in the candidate gene region, and thus, have an impact on the metabolic phenotypes. Further replication in a larger sample is required as well as additional studies of the role of stress, SNP variants, and DNA methylation.

Genome-wide association study identifies variants that predict survivorship in individuals with coronary artery disease. *J.R. Dungan[1], X. Qin[2], M. Hurdle[2], C. Haynes[2], E. Grass[2], D. Craig[2], S.G. Gregory[2], E.R. Hauser[1,2], S.H. Shah[2], W.E. Kraus[1,2].* 1) School of Nursing, Duke University, Durham, NC; 2) Department of Medicine, Duke University, Durham, NC.

Background: We have previously reported a novel phenotype, 'survivorship in coronary artery disease (CAD)'; using a candidate gene (*LSAMP,* identified from linkage mapping in early-onset CAD) we demonstrated proof-of-principle for genetic effects unique to CAD cases for both mortality risk and improved survival. To evaluate such effects at a genome-wide level we now conduct a genome-wide association (GWA) analysis of this phenotype and hypothesize that novel candidate genes could predict survival in clinically-appreciable CAD.**Methods:** A GWA analysis was conducted for survivorship in individuals with CAD using discovery (*N*=1,099) and replication cohorts (*N*=414) of Caucasians selected from a cardiovascular biorepository (CATHGEN) of sequential patients referred for cardiac catheterization. CAD cases were defined as having a CAD index >32 (at least one-vessel CAD) and indication for catheterization was concern for ischemic heart disease. Illumina Omni Quad v1.0 GWAS chip was used with stringent QC metrics. Cox proportional hazards regression models for each SNP (additive) adjusted for age, sex, four Eigenstrat-defined principal components and seven major cardiovascular risk covariates were constructed using the R statistical package. Models were censored on time from cardiac catheterization to death (all-cause) or last follow-up time (*med* 5.2 years). Genome-wide significance was defined as $p<10\text{-}5$ for discovery and $p<0.05$ for replication. Meta-analyses of discovery and validation cohorts were conducted with a combined Z-score approach using METAL.**Results:** Of the 93 SNPs meeting genome-wide significance in the discovery analysis three SNPs replicated with nominal significance, having the same direction of effect in both cohorts: rs13007553 (*MYT1L/TSSC1*; *HR* 1.31, *95% CI* 1.01-1.7, *p*discovery=5.93x10-5, *p*replication=0.04 , *p*meta=1.05x10-5; rs587936 (*DAB2IP; HR* 0.80, *95%CI* 0.61-1.05, *p*d=3.75x10-5 *p*r=0.02, *p*m=2.13x10-5); and rs1993024, (*FSTL5/NAF1*; *HR* 0.75, *95%CI* 0.55-1.03, *p*d=4.04x10-5*, p*r=0.02, *p*m=0.03). Of the discovery SNPs, 30 were significant in meta-analysis ($p<0.001$) and had the same direction of effect in both cohorts.**Discussion:** We have identified genome-wide variants that appear to predict survivorship in CAD cases and which were not identified from prior GWAS of CAD. Similar to previously reported candidate gene results for *LSAMP*, both *TSSC1* and *DAB2IP* are related to tumor suppression suggesting a novel shared mechanism mediating survivorship in CAD.

As part of the CHARGE-Sudden Cardiac Death (SCD) working group, we have conducted the largest GWAS (4,496 cases, >25,000 controls) to date for sudden cardiac death, a phenotype defined operationally as a sudden unexpected pulseless condition due to a ventricular arrhythmia. Although the primary cause of SCD is considered to be electrical instability, the majority of SCD occurs in the setting of coronary artery disease (CAD).While no loci reached genome-wide significance following replication in our GWAS, we used this dataset to interrogate the effects of the group of SNPs associated with SCD risk factors, on sudden death risk. We employed a multi-SNP genetic risk score (GRS) approach that uses weighted linear regression to establish the relationship between SNP effect estimates for SCD and a risk factor of interest. We chose to focus on SNPs associated with two major etiological classes of SCD risk factors—ECG traits (QT, QRS, and PR intervals), and CAD associated traits (CAD, type2 diabetes [T2D], BMI, HDL, LDL, total cholesterol and triglyceride levels) at five different alpha cutoffs (α) (5e-8, 1e-5, 1e-3, 0.05 and 0.99).Of the ECG parameters, we see a statistically significant enrichment of SNPs associated with QT interval at all alpha cutoffs (at α=5e-8, p=0.007; when α=0.99, p=7.41e-7). In contrast, we find no evidence of association between the set of SNPs associated with QRS duration or PR interval and SCD at any alpha cutoff. When we focus on CAD associated traits, GRS models constructed with T2D or CAD SNPs showed statistically significant enrichment in SCD at all alpha cutoffs examined (at α=5e-8, p for CAD=2.48e-6; p for T2D=0.012). Furthermore, while the risk scores constructed from SNPs associated with lipid levels, did not predict SCD risk, GRS with BMI SNPs at 5e-8 cutoff was strongly predictive of SCD risk (p=1.29e-4).Taken together, this analysis is the first to establish the link between common variants associated with risk factors related to SCD pathophysiology and SCD risk. Furthermore, this study not only offers further support for existing epidemiological observations establishing prolonged QT interval, CAD, and T2D as SCD risk factors but also presents a compelling case to investigate the biological role for loci associated with BMI in sudden death.

DNA methylation profiling identifies a locus near a HMG-CoA synthase gene associated with triglyceride levels and modified by BMI. *F. Gagnon[1], V. Truong[1], N. Zwingerman[1], I. Kassam[1], D. Aïssi[2], J. Dennis[1], M. Wilson[3], P. Wells[4], P.-E. Morange[5], D.-A. Trégouët[2].* 1) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 2) INSERM, UMR_S 1166, Team Genomics & Pathophysiology of Cardiovascular Diseases, Paris, France; 3) Genetics and Genome Biology Program, SickKids Research Institute, Toronto, Canada; 4) Department of Medicine, Faculty of Medicine, University of Ottawa, Ottawa, Canada; 5) INSERM, UMR_S 1062, Nutrition Obesity and Risk of Thrombosis, Marseille, France.

In a candidate gene study using biobanked whole blood DNA, we reported an association of DNA methylation marks in the *CTP1A* gene with triglyceride (TG) levels in families and cases of venous thromboembolism (VTE). The *CTP1A* gene encodes for a protein expressed in liver that is essential for fatty acid oxidation, which supports the role of DNA methylation in TG regulation.To further explore the role of epigenetic marks in inter-individual variation of fasting TG levels, we conducted a genome-wide association study between TG and DNA methylation levels measured in whole blood from 214 individuals from the *French-Canadian Family study on F5L Thrombophilia* (F5L). The F5L study is composed of 5 large families ascertained on single probands with VTE. Replication was tested in 350 unrelated VTE cases from the *MARseilleTHrombosis Association Study* (MARTHA). We used linear mixed regression models adjusted for age, sex, cell type proportions, and familial correlation when analyzing the *F5L study*. Sensitivity analyses assessing potential confounders and effect modifiers were conducted.We replicated the recently reported association between TG and a DNA methylation mark in *ABCG1*, a lipid-related gene, and discovered a novel genome-wide significant association in the *PHGDH* gene. The effect size at the *PHGDH* locus was stronger in the F5L study (b=-0.21, p=2.3×10-7) than in MARTHA (b=-0.08, p=0.048). The prevalence of overweight and obese individuals (BMI≥25) was 56% and 36%, respectively, in the F5L and MARTHA studies. A stratified analysis in MARTHA revealed BMI as an effect modifier, with an effect only detected in overweight and obese individuals (b=-0.17, p=9.8×10-3) compared to individuals with normal BMI (b=-0.001, p=0.99).Follow-up analyses showed that no SNPs within 1Mb of the identified *PHGDH* locus confounded the association between the methylation marker and TG levels; but a SNP located in *HMGCS2*, a gene with similar functions as *CTP1A* and only 34 kb from *PHGDH, was* associated with the TG-methylation marker. *HMGCS2* belongs to the HMG-CoA synthase family known for its pivotal role in cholesterol synthesis and ketogenesis. A preliminary Mendelian Randomization analysis suggests an important but indirect role of the *PHGDH* methylation mark on TG level variation.These causal inference results shed light on the molecular mechanisms underlying TG level variation, and provide putative insights on the VTE-obesity association.

Coronary Collateralization Shows Sex and Ethnic Differences in the Presence of Obstructive Artery Disease. *Z. Liu[1], L. Wang[1,2], N. Vasudeva[2], P.J. Goldschmidt-Clermont[3], M.A. Pericak-Vance[1,2], D.M. Seo[3], G.W. Beecham[1,2].* 1) Human Genetics, John T. Macdonald Foundation, University of Miami, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 3) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL.

BACKGROUND: Coronary collateralization is a natural process of revascularization in the cardiovascular system. Collateral circulation protects cardiac tissues from myocardial infarction (MI) by allowing oxygenated blood to bypass the blockage in main coronary arteries. As such, collateral circulation may partly affect MI outcomes such as sudden cardiac death.**METHOD:** To better understand the genetic mechanisms of coronary collateralization, we assessed 879 patients with obstructive coronary artery disease (over 50% stenosis presented in any of the four major coronary branches: left main, LAD, LCX, RCA) from our cardiac catheterization patient cohort. Patients were assessed for presence/absence of collaterals, as well as age, sex, diabetes, anti-cholesterol medicine usage, etc. DNA samples were genotyped using the Affymetrix 6.0 genotyping platform. Due to diverse genetic backgrounds of our samples, we calculated local and global ancestry, and subsequently performed admixture mapping using logistic regression, with the presence of collaterals as an endpoint.**RESULTS:** We found sex differences in collateralization: men had statistically significantly higher rates of collaterals than women (p-value = 1.38E-04). Different race/ethnicity groups showed different rates of collateralization: white Hispanics/Latino showed higher rates of collaterals (59%) than African Americans (50%) and non-Hispanic Whites (48%) (chi-square p-value = 1.7E-02). The admixture mapping analysis showed Native American ancestry was associated with the presence of collaterals at a region on chromosome 17 (chr17:36120051–40782083, beta = 0.55, min p-value = 1.27E-04). African ancestry also showed association with collaterals at a different region on chromosome 17 (chr17:32796666–33440166, beta = 0.38, min p-value = 7.2E-04).**CONCLUSIONS:** In our study, men have higher rate of collateralization than women, which may in part explain why women have poor outcomes after MI than men. Different race ethnicity groups have different rates of collateralization, which may partially explain racial disparities in MI outcomes. Finally, we identified two regions on chromosome 17 that are likely to harbor genetic variations that influence collateralization. A following up in-depth study of these two regions is ongoing.

Exome chip meta-analysis identifies novel loci contributing to lipid levels in Asian population. *X. Lu[1], H. Zhang[1], W. Zheng[2], S. Ganesh[1], P. Sham[3], K. Mohlke[4], W. Sheu[5], J. Rotter[6], Z. Mo[7], R. Dorajoo[8], E. Tai[8], X. Lin[9], T. Wu[10], D. Gu[11], C. Willer[1], the Asian exome chip lipids Consortium.* 1) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, Michigan, USA; 2) Division of Epidemiology, Department of Medicine, Vanderbilt Epidemiology Center, Vanderbilt-Ingram Cancer Center, Vanderbilt University School of Medicine, Nashville, TN, USA; 3) Department of Psychiatry, the University of Hong Kong, Pokfulam, Hong Kong; 4) Department of Genetics, University of North Carolina, Chapel Hill, NC, USA; 5) Department of medicine, Taichung veterans general hospital, Taichung, Taiwan; 6) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute at Harbor-UCLA Medical Center, Torrance, California, USA; 7) Center for Genomic and Personalized Medicine, Guangxi Medical University, Nanning, Guangxi, China; 8) Saw Swee Hock School of Public Health, National University of Singapore and National University Health System, Singapore, Singapore; 9) Key Laboratory of Nutrition and Metabolism, Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences and Graduate School of the Chinese Academy of Sciences, Shanghai, China; 10) MOE Key Lab of Environment and Health, School of Public Health, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, Hubei, China; 11) Fuwai Hospital, National Center for Cardiovascular Diseases, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China.

Genome-wide association studies (GWAS) have identified ~160 loci contributing to lipid levels, which are heritable risk factors for cardiovascular diseases. However, most of the published variants are non-coding and explain less than half of the heritability of lipid levels. Thus, we attempted to evaluate the effect of the coding variants on lipid levels, particularly in the Asian population who have not been studied as extensively as Europeans. To identify coding and low-frequency variants associated with plasma lipids levels, we collected Exome chip genotyping data from more than 39,000 Asian samples from 20 cohorts. Lipid levels were transformed using the inverse normal distribution after adjusting for age, age2, sex, principal components. Single variant analyses in each cohort were carried out either using rvtests or RareMetalWorker. The meta-analysis of single variant and gene-level association tests were performed using RAREMETALS for HDL, LDL, triglyceride and total cholesterol levels. We identified a novel non-synonymous variant in *CD163* (HDL, $P = 3.98 \times 10\text{-}9$). Furthermore, we identified a common non-coding variant in *ACVR1C* with TC ($P = 4.83 \times 10\text{-}8$) that were not previously reported in large-scale GWAS. We also replicated 28 loci reported in prior GWAS, involving 38 coding variants. In gene-based tests, a burden of rare/lower frequency variation in *PCSK9*, *HMGCR*, *CETP*, *APOA1*, and *CD36* were associated with lipids levels. Results of the gene-level burden tests were driven primarily by single variant associations. Our study identifies novel coding variant associations and extends the allelic spectrum of variation underlying lipid levels.

581T

Molecular basis of regulatory variation at coronary heart disease associated loci. *C.L. Miller[1], M. Pjanic[1], T. Wang[1], T. Nguyen[1], J. Lee[2], B. Liu[2,3], T. Assimes[1], S. Montgomery[2,3], T. Quertermous[1].* 1) Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 3) Department of Pathology, Stanford University School of Medicine, Stanford, CA.

Genome-wide association studies have identified 46 replicated genetic loci for coronary heart disease (CHD), and 104 loci associated at a 5% false discovery rate. However, the regulatory mechanisms of these associations largely remain undefined. Given that the majority of these CHD-associated loci reside in non-coding regions, they are predicted to function via context-specific gene regulation. Recent high-throughput assays of regulatory function include the assay for transposase-accessible chromatin using sequencing (ATAC-seq) and chromatin immunoprecipitation-sequencing (ChIP-seq). ATAC-seq utilizes a Tn5 transposase to fragment and tag accessible DNA sequences, which are often coupled to transcription factor occupancy identified by ChIP-seq. Importantly, this assay may reveal the spatio-temporal regulatory profiles in limited numbers of primary cells. Using ATAC-seq in primary human coronary artery smooth muscle cells (HCASMC) we identified 147,173 accessible chromatin peaks in control versus 198,976 peaks in TGF-beta-stimulated cells (136,446 shared peaks). Using *de novo* motif enrichment analysis we identified significant enrichment of specific AP-1 family members (29.2% vs. 5.1% background), chromatin remodeling, and SMC differentiation transcription factors. Using functional enrichment analysis of overlapping regions in open chromatin, ChIP-seq and CHD loci we observed enrichment of the hypoxia inducible factor 1 (HIF-1) and TGF-beta signaling pathways (1.5x10-22 and 5.6x10-18, respectively) and relevant phenotypes, including cell migration and blood vessel morphology. Finally, we utilized these regulatory maps to explore the causal mechanisms underlying CHD-associated variants at four loci using haplotype-specific chromatin immunoprecipitation (haploChIP), luciferase reporter assays, and allelic expression imbalance in HCASMC. Taken together, these results suggest that genome-wide approaches such as ATAC-seq can be leveraged to map context-specific regulatory mechanisms of non-coding variants associated with complex diseases such as CHD, and reveal new biological and molecular insights into targeting heritable disease risk.

582F

A genome-wide association study of ischemic stroke and its subtypes identifies a novel locus near *TSPAN2*. *S.L. Pulit, National Institute of Neurological Disorders and Stroke - Stroke Genetics Network (SiGN).* University Medical Center Utrecht, Utrecht, Netherlands.

Stroke is the 2nd leading cause of death worldwide and the annual number of stroke deaths is rising. Hypertension, atrial fibrillation, and smoking are known risk factors, but a large proportion of ischemic stroke (IS) risk remains unexplained. Given the established heritability of IS, genetic variation likely accounts for some of the residual risk. IS is highly heterogeneous; the 3 most common subtypes are cardioembolic, large artery atherosclerosis (LAA), and small artery occlusion (SAO). Genome-wide association studies (GWAS) have identified only 4 confirmed risk loci; 3 are subtype specific. With the aim of elucidating disease etiology, the Stroke Genetics Network sought to perform a comprehensive GWAS by assembling the largest sample to date and employing Causative Classification of Stroke (CCS), a system that considers neuroimaging results and ancillary examinations to obtain a comprehensive evaluation of subtype. As it is centrally-adjudicated and web-based, CCS also reduces inter- and intra-observer variability.After extensive quality control to merge cases collected worldwide and publicly-available controls, we ran discovery analyses in 16,851 cases and 32,473 controls. We ran GWAS for all IS and for each subtype in CCS and TOAST, the most commonly employed subtyping system used in all previous GWAS. Since only TOAST cases were available for replication, we calculated pairwise correlations of SNP effects between CCS and TOAST GWAS. Genetic correlation between CCS and TOAST primary subtypes was moderate to strong (r = 0.61–0.75), indicating that TOAST cases were suitable for replication. SNPs with p<10-6 were selected for *in silico* lookup in an independent set of 21,842 TOAST-subtyped IS cases and 367,842 controls.Joint analysis of all data revealed a novel association at rs12122341, a common SNP near *TSPAN2* conferring risk to LAA (OR[G] = 1.2, p = 1.3 x 10-9). The 12q24 locus, previously implicated in all IS, was associated predominantly with SAO (rs10744777, OR[T] = 1.17, p = 2.9 x 10-9).*TSPAN2* knockout mice exhibit neuroinflammation and TSPAN is highly expressed in arterial endothelial, smooth muscle cells, and white blood cells. Further studies will determine if the rich repository of phenotypic data created by CCS will allow for genetic analysis of novel phenotypes, or if leveraging the genetic overlap of CCS and TOAST through broader inclusion of cases reveals more risk loci, a vital first step in improving IS diagnosis and treatment.

Chromosome 22q11 microdeletion syndrome: association of congenital heart disease with copy number variants. *G. Repetto, L. Leon, C. Vial, K. Espinoza, F. Benavides, M.L. Guzman.* Center for Genetics and Genomics, Clin Alemana-Univ Desarrollo, Santiago, Chile.

Chromosome 22q11.2 microdeletion syndrome (22q11DS) is one of the most common pathogenic genomic rearrangements in humans. Although the majority of patients share a deletion of similar size and location, 22q11DS is notorious for its highly variable clinical presentation. One of the relevant features is congenital heart disease (CHD), present in 50-60% of patients. It usually affects the cardiac outflow tract and includes defects such as tetralogy of Fallot, ventricular septal defects and truncus arteriosus, among others. The reason for the incomplete penetrance of CHD remains unknown. We hypothesize that structural genetic variation outside of the deletion region may have a modifier effect. We evaluated the association of copy number variants (CNVs) and the presence of CHD in a large cohort of Chilean patients with 22q11DS. The study included 133 patients with CHD (cases) and 120 with normal cardiac anatomy (controls). Frequency, size and location of constitutional CNVs were characterized using Affymetrix SNP 6.0 arrays. CNV calls were made with the GC model wave adjustment procedure using PennCNV software. Genome-wide CNV association was evaluated using ParseCNV. Association was assessed by Fisher´s exact testand odds ratio. The large 3Mb LCR A-D deletion was found in 92% of patients; the remainder had 2 or 1.5 Mb deletions (LCR A-C or A-B, respectively) . Statistically significant difference in frequencies were found for a duplication on chromosome region 1p36.13. The duplication was present in 8.5% of cases and 1.7% of controls (p value 0.02, OR 5.35, 95% confidence interval 3.83-6.88). The region contains noncoding RNAs, and we propose that they may exert a modifying role over the primary effect of the deletion. Funded by Fondecyt-Chile grant # 1130392.

Causal effect of blood plasminogen activator inhibitor type 1 level on increased risk of coronary heart disease. *C. Song[1,2], A.D. Johnson[1,2], C.J. O'Donnell[1,2].* 1) National Heart, Lung and Blood Institute/ Framingham Heart Study, Framingham, MA; 2) NHLBI Division of Intramural Research.

IntroductionPlasminogen activator inhibitor type 1 (PAI-1) plays an essential role in the fibrinolysis system and thrombosis. Previous studies have reported elevated blood PAI-1 levels associated with increased risk of coronary heart disease (CHD). However, it is unclear whether the association reflects a causal influence of PAI-1 on CHD risk versus an effect of shared regulators. **Methods**To evaluate for a causal role in the association between PAI-1 and CHD, we performed a systematic review and meta-analysis. We conducted an electronic literature search in PubMed of PAI-1 and CHD/Coronary artery disease/Myocardial infarction published in English between 1992 and 2015. To investigate the causal association between PAI-1 and CHD, we used genetic risk scores (GRSs) composed of PAI-1-related SNP variants, reported by the largest available genome-wide association study (GWAS) of PAI-1, as instrumental variables (IVs). We then tested whether elevated PAI-1 levels were associated with a higher CHD risk by the Mendelian Randomization (MR) approach using summarized statistics from GWASs for PAI-1 and for CHD. We integrated results by using PAI-1-related GRS composed of SNPs with different P-value thresholds in GWAS for PAI-1 (SNP association thresholds P<5e-8, 0.001, 0.01, and 0.05) as IVs to address potential bias.**Result**In the systematic meta-analysis, the highest quantile of blood PAI-1 level was associated with higher CHD risk comparing with the lowest quantile [Odds ratio (OR) =1.68; 95% confidence interval (CI): 1.41, 2.01] in an age-and sex-adjusted model. The effect size was reduced but remained significant in studies using a multivariable-adjusted model. The MR analyses consistently showed a similar causal effect size of increased PAI-1 level on risk of CHD using IVs at different P-value thresholds, and the significance level increased when using a GRS with more SNPs (OR=1.02 per unit increased of PAI-1; 95% CI: 1.02, 1.03 when using PAI-1-SNPs with P<0.05).**Conclusion**Our study indicated a small to moderate causal effect of elevated PAI-1 level on CHD risk. Further study is warranted to understand the specific molecular determinants of circulating PAI-1 on CHD risk.

585F

Genetic determinants associated with BP phenotypes. *N. Vasudeva[1], L. Wang[1,2], Z. Liu[2], P. Goldschmidt[3], M. Pericak-Vance[1,2], D. Seo[3], G. Beecham[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Foundation, Department of Human Genetics, University of Miami, Miami, FL; 3) Division of Cardiology, Miller School of Medicine, University of Miami, Miami, FL.

Hypertension is a leading cause of mortility and morbidity in the developed countries. These traits are well established as a heritable traits. Genetic variants may lead to changes in BP. However the underlying environmental factors as well as their complex interactions makes discovering the genetic determinants affecting these trait a challenging task. Multiple variants are believed to cumulatively contribute to this polygenic trait. Genome-wide genotyping was performed on 1975 subjects using Omni 2.5 Million SNPs chip. Our dataset consists of multi-ethnic populations with ~12% Blacks, ~45% Hispanics and ~37% Whites. Sample and SNP quality control were followed by Eigenstrat. To account of the effect of blood pressure lowering medications, we added 7% and 6% to systolic blood pressure (SBP) and diastolic blood pressure (DBP), mean arterial pressure (MAP), pulse pressure (PulseP) measures, respectively, for each antihypertensive medication taken. Linear regression was used to analyze single variant association adjusting for covariates such as sex, age, age^2, principal component one, anti-cholesterol medicines and diabetes. Various SNPs approached the genome-wide significant level. SNPs at chr19:2,242,829 in gene SF3A2 (p-val: 9.31E-08) and chr3:88,668,147 (p-val: 2.68E-07) for SBP, chr11: 112,260,754 (p-val: 1.27E-08), chr19: 2,242,829 (1.78E-08) for MAP approached genome-wide significant association with BP phenotypes. We will further perform a gene-based association test using the SKAT R package. A web based tool WebGestalt will be used in order to find pathways connected to these large numbers of genes. To further analyze these genotypes and pathways, we will use alternate gene based methods such as VEGAS to better understand the genetic etiology of hypertension in our population.

586W

Genome-wide association study of CVD-related loci with lipid traits in the Heart Strategies Concentrating on Risk Evaluation (Heart SCORE) study. *X.B. Wang[1], S. REIS[2], I. Halder[2], M. Barmada[1], F.Y. Demirci[1], M.I. Kamboh[1].* 1) HUMAN GENETICS, University of Pittsburgh, PITTSBURGH, PA; 2) Medicine, University of PITTSBURGH, PA.

Cardiovascular disease (CVD) is the leading cause of death worldwide. Plasma levels of total cholesterol (TC), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C) and triglycerides (TG) are significant risk factors for CVD and about 50% of the variation in these four quantitative traits is under genetic control. Two meta-analyses of published lipid genome-wide association studies have identified 157 loci that explain approximately 25-30% of the genetic variance for each of the four traits, indicating that additional genetic factors remain to be identified. In this study, we used a Illumina CVD BeadChip that contains approximately 49,000 SNPs in approximately 2,100 candidate genes selected based on their potential role in CVD to test for association with four lipid traits in 464 African American (AA) and 770 European American (EA) subjects as part of the Heart SCORE study. Seventy of the reported 157 genome-wide significant lipid loci/genes were represented on this chip. We observed significant associations (P<0.05) with SNPs in 55 of the 70 loci with strongest associations between HDL-C and *CETP*/ rs7499892 (P=3.92E-09), LDL-C and *APOE*/rs7412 (P=1.80E-06), and TG and *APOB*/rs2678379 (P=2.53E-06). In addition to the replication of known loci, we also observed multiple novel suggestive associations at P<1E-04 with the four major lipid traits. One of these novel loci, *SGK* (P=8.18E-05), was replicated in an independent study. In conclusion, we have replicated many of the known lipid loci and identified potentially novel loci for the four lipid traits using a novel CVD chip.

587T

CETP genotype is associated with phenotypic variability of HDL among other loci identified in a lipid vQTL study. *Y. Ma[1], Y. Cao[1], P. Wei[1], C.M. Ballantyne[2], J.M. Cheverud[3], C.S. Guild[4], C.E. Ndumele[5], E. Boerwinkle[1], T.J. Maxwell[6].* 1) Human Genetics Center, University of Texas Health Science Center, Houston, TX; 2) Section of Atherosclerosis and Vascular Medicine, Baylor College of Medicine, and Center for Cardiovascular Disease Prevention, Methodist DeBakey Heart and Vascular Center, Houston, TX; 3) Department of Biology, Loyola University, Chicago, IL; 4) Department of Medicine, University of Mississippi Medical Center,Jackson, MS; 5) Division of Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Computational Biology Institute, The George Washington University, Ashburn, VA.

A variance-heterogeneity quantitative trait locus (vQTL) is a genetic locus associated with phenotypic variability. vQTL can be the result of linkage disequilibrium (LD) with a functional QTL. It can also be induced by gene-by-gene (GxG) or gene-by-environment (GxE) interactions. We performed vQTL screening for triglycerides, cholesterol, high-density lipoprotein (HDL), and low-density lipoprotein (LDL) in European Americans (EA) and African Americans (AA) separately using the whole-exome SNP genotype data of the Atherosclerosis Risk in Communities (ARIC) study. A parametric bootstrap-based mean and variance joint test followed by a variance only test was performed for vQTL screening. We identified eight significant vQTLs in or near CETP and one vQTL in LIPG for HDL, one vQTL for triglycerides, and one vQTL for cholesterol in EA. We also identified five HDL vQTLs in or near CETP in AA, four of which correspond to the HDL vQTLs identified in EA. Given that vQTL can be the result of GxG interactions, subsequent GxG screening involving identified vQTLs was performed. Significant GxG interactions were identified between the cholesterol vQTL and twelve single nucleotide polymorphisms (SNPs) from eleven unique locations in EA. In addition, we also identified significant interactions between two of the HDL vQTLs and four SNPs from three different regions in EA, and four pairs of interactions involving HDL vQTLs in AA. We then used the Framingham Heart Study (FHS) data to replicate the vQTLs and significant GxG interactions identified in EA using ARIC data. Mixed effect models incorporating familial correlation were used to analyze the FHS data. Three HDL vQTLs in CETP, rs1800775, rs7499892, and rs1532624, were confirmed using FHS data. One interaction between HDL vQTL rs9989419 and rs11721627 was replicated. Our analyses have shown that CETP genotype is associated with phenotypic variability of HDL, in addition to its well-known association with mean heterogeneity of HDL. We have also demonstrated the candidate role of vQTLs in GxG study.

Objectives: We aimed to identify novel genomic mechanisms underlying blood pressure (BP) regulation by conducting genome-wide single marker and gene-based meta-analyses of the novel long term average (LTA) BP phenotype.**Methods and Results:** A total of 18,422 East Asian participants were included in the discovery stage meta-analyses (stage-1). Promising findings were tested for replication among 46,629 participants of European ancestry (stage-2). Significant SNPs and genes were determined by a P<5.0×10-8 and 5.0×10-6, respectively, in joint analysis of stage-1 and stage-2 data. For 4 loci reported by the previous LTA BP GWAS meta-analysis in participants of European ancestry, evidence of trans-ethnic replication was determined by consistency in effect direction and a Bonferroni-corrected P<1.67×10-2 (0.05/4). The current study identified one novel *ARL3* variant, rs4919669 at 10q24.32, influencing LTA systolic BP (stage-1 P=5.03×10-8, stage-2 P=8.64×10-3, joint P=2.63×10-8) and mean arterial pressure (stage-1 P=3.59×10-9, stage-2 P=2.35×10-2, joint P=2.64×10-8). Nine associations for 3 previously reported BP loci at *WBP1L*, *NT5C2*, and *ATP2B1* were also identified. Gene-based analysis revealed one novel gene, *KCNJ11,* that was associated with LTA systolic BP (stage-1 P=8.55×10-6, stage-2 P=1.62×10-5, joint P=3.28×10-9) and mean arterial pressure (stage-1 P=9.19×10-7, stage-2 P=9.69×10-5, joint P=2.15×10-9). Fourteen genes (*TMEM180*, *ACTR1A*, *SUFU*, *ARL3*, *SFXN2*, *WBP1L*, *CYP17A1*, *C10orf32*, *C10orf32-ASMT*, *AS3MT*, *CNNM2*, and *NT5C2* at 10q24.32; *ATP2B1* at 12q21.33; and *NCR3LG1* at 11p15.1) implicated by previous GWAS meta-analyses were also identified. Among the loci identified by the previous GWAS meta-analysis of LTA BP, we trans-ethnically replicated associations of the *KCNK3* marker rs1275988 at 2p23.3 with LTA systolic BP and mean arterial pressure (P=1.27×10-4 and 3.30×10-4, respectively).**Conclusion:** The current study identified 1 novel variant and 1 novel gene for LTA BP. Furthermore, we present the first evidence of relevance of the *KCNK3* locus for LTA BP in an East Asian sample.

589W

***PIK3CG* rQTL for blood pressure (SBP & DBP) modifies CHD/LDL and CHD/DBP relationships among other rQTL and GxG found in a blood pressure rQTL screen.** *T.J. Maxwell[1], Y. Ma[2], Y. Cao[2], C.M. Ballantyne[3], J.M. Cheverud[4], C.S. Guild[5], C.E. Ndumele[6], E. Boerwinkle[2], P. Wei[2].* 1) Computational Biology Institute, The George Washington University, Ashburn, VA; 2) Human Genetics Center, University of Texas Health Science Center, Houston, TX; 3) Section of Atherosclerosis and Vascular Medicine, Baylor College of Medicine, and Center for Cardiovascular Disease Prevention, Methodist DeBakey Heart and Vascular Center, Houston, TX; 4) Department of Biology, Loyola University, Chicago, IL; 5) Department of Medicine, University of Mississippi Medical Center,Jackson, MS; 6) Division of Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD.

A screen for relationship loci (rQTL) was performed between systolic (SBP) and diastolic blood pressure (DBP) separately for European (EA) and African Americans (AA) with genome-wide genotype data in the Atherosclerosis Risk in Communities (ARIC) study. An rQTL exists when the correlation between multiple traits varies by genotype. Differential gene-by-gene (GxG) and/or gene-by-environment (GxE) interactions are often responsible for rQTL. Screening for this single-locus pattern is a powerful approach to identifying loci with context-dependent effects. Parametric bootstrapping was used to identify 37 genome-wide significant rQTLs from 10 unique locations in EA. Subsequent screens for GxG using whole-exome SNP genotype data identified significant loci for DBP from 15 unique locations interacting with 5 of the rQTL in EA. We used the Framingham Heart Study (FHS) for replication. Twenty EA rQTL from 4 locations replicated in FHS using an analogous mixed effect model incorporating familial relationships. One EA GxG interaction replicated in FHS while another replicated in ARIC AA. One EA rQTL is from a cluster of correlated SNPs intronic to and 3' of *PIK3CG*. It was identified because it affects the relationship between SBP and DBP but it also is nominally significant as an rQTL for coronary heart disease (CHD) risk and DBP, and for CHD risk with both LDL and total cholesterol. *PIK3CG* has been extensively studied and is related to cardiac contractility, modified LDL uptake by macrophages, foam cell formation and blood pressure related measures. Our *PIK3CG* SNPs are separate from other loci 5' of *PIK3CG* reported in other GWAS studies. One EA rQTL (rs10520840) was involved in eleven significant GxG interactions from nine unique locations, one of which (rs7188697) was previously reported as a large hit for QT interval. We found 17 significant rQTLs from 14 locations in AA with 8 of the rQTLs interacting with SNPs from 13 locations with all but one for SBP. Currently we do not have an appropriate replication sample for the AA results. However, we did have 3 AA rQTL and one GxG replicated in FHS and one rQTL replicated in ARIC EA. One of these rQTL is a nominal rQTL for CHD and SBP and another is directly associated with CHD. Overall, there are numerous loci that affect the relationship between SBP and DBP, some due to interactions with other loci and some subsequently modifying the risk relationship between blood pressure and CHD.

590T

A smoking and diabetes status stratified analysis of peripheral arterial disease (PAD) identifies new loci and variants that my interact with these risk factors to modify the risk of PAD. *N.R. van Zuydam[1,2], M. de Andrade[3], E. Vlachopoulou[4], E. Ahlqvist[5], E. Dahlström[6], V. Salomaa[7], C.N.A. Palmer[2], J.C. Hopewell[8], H.M. Colhoun[2], I.J. Kullo[3], GoLEAD and SUMMIT.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Medical Research Institute, University of Dundee, UK; 3) College of Medicine, Mayo Clinic, Rochester MN, USA; 4) University of Helsinki, Finland; 5) Lund University, Malmö, Sweden; 6) Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, Helsinki University Central Hospital, Helsinki, Finland; 7) National Institute for Health and Welfare, Helsinki, Finland; 8) CTSU, Nuffield Department of Population Health, University of Oxford, Oxford, UK.

Peripheral arterial disease (PAD) affects approximately 200 million people worldwide. Smoking and diabetes are the largest risk factors for PAD. There are three established loci for PAD: genome wide significant (p<5x10-8) signals near *CHRNA3* and *LPA,* and another highly significant signal (p<5x10-7) in the 9p21.3 region. This study sought to expand the number of PAD associated regardless of risk factor profile and to identify variants that are specifically associated with PAD dependent on smoking and diabetes status.PAD was defined as an ankle brachial pressure index <0.9, mid-thigh to mid-foot amputations, corrective procedures related to PAD, dispensed medication to treat claudication or claudication with evidence of vascular disease. We were able to analyse a total of 6,685 PAD cases and 39,324 PAD free controls. We stratified these subjects by diabetes status (2,621 cases/14,579 controls with diabetes and 2,827 cases /21,988 controls without diabetes) and by smoking status (3,964 cases/22,597 controls from ever smokers and 1,083 cases /11,922 controls from never smokers). We performed a fixed-effects variance weighted meta-analysis and variants were tested for heterogeneity between strata. We detected genome-wide significant associations (p<5x10-8) with PAD in all individuals for known variants: rs10757272 (OR[95%CI]=1.17[1.12-1.22], p=5x10-9), in the 9p21.3 region, and rs1051730 (OR[95%CI]=1.13[1.09-1.18], p=1x10-9), near *CHRNA3.* Rs2036527 (OR[95%CI]=1.28[1.21-1.35], p=1x10-11), R2=0.9 with rs1051730), near *CHRNA3,* was associated with PAD in non-diabetic subjects and showed evidence of interaction with diabetes status (P het=5x10-7, in subjects with diabetes: OR[95%CI]=1.00[0.94-1.08], p=NS). We identified a novel association for rs10894808 (OR[95%CI]=1.55[1.41-1.69], p=9x10-9), near *B3GAT1*, in never smokers (P het=5x10-8, in ever smokers: OR[95%CI]=0.95[0.87-1.04], p=NS).In this study, presenting the largest GWAS of PAD so far, we describe one novel locus for PAD based on stratification for known risk factors. Two loci, detected at genome wide significance, showed strong evidence of interaction with either diabetes or smoking status. These results suggest that there may be different pathways contributing to risk of PAD dependent on smoking and diabetes status. .

591F

GDF-15 gene variants influence GDF-15 levels, an independent prognostic marker for cardiovascular events. *N. Eriksson[1], D. Ardissino[3], A. Budaj[4], E. Hagström[1,2], C. Held[1,2], W. Koenig[5,6,7], A. Siegbahn[1,8], P.G. Steg[9,10,11,12], R.A.H. Stewart[13], D. Waterworth[14], H.D. White[13], L. Wallentin[1, 2] on behalf of the STABILITY Investigators.* 1) Uppsala Clinical Research Center, UUppsala Clinical Research Center, Uppsala University, Uppsala, Sweden. ppsala, Uppsala, Sweden; 2) Department of Medical Sciences, Cardiology, Uppsala University, Uppsala, Sweden; 3) Azienda Ospedaliero-Universitaria di Parma, Parma, Italy; 4) Postgraduate Medical School, Grochowski Hospital, Warsaw, Poland; 5) Department of Internal Medicine II-Cardiology, University of Ulm Medical Center, Ulm, Germany; 6) Deutsches Herzzentrum München, Technische Universitàt München, Munich, Germany; 7) DZHK (German Centre for Cardiovascular Research), partner site Munich Heart Alliance, Munich, Germany; 8) Department of Medical Sciences, Clinical Chemistry, Uppsala University, Uppsala, Sweden; 9) INSERM-Unité 1148, Paris, France; 10) Assistance Publique-Hôpitaux de Paris, Département Hospitalo-Universitaire FIRE, Hôpital Bichat, Paris, France; 11) Università Paris-Diderot, Sorbonne-Paris Cité, Paris, France; 12) NHLI Imperial College, ICMS, Royal Brompton Hospital, London, UK; 13) Green Lane Cardiovascular Service, Auckland City Hospital and University of Auckland, Auckland, New Zealand; 14) Genetics, GlaxoSmithKline, King of Prussia, PA, USA.

Background: Growth differentiation factor 15 (GDF-15) is an emerging biomarker in the field of cardiovascular diseases. It is an independent prognostic biomarker for cardiovascular events and major bleeding during antithrombotic treatment. Whether there is a causal association between GDF-15 and outcomes is still unknown. Genetic markers located in the *GDF15* gene are associated with altered circulating GDF-15 concentrations. In this genome-wide association study (GWAS) we assess the genetic effects on GDF-15 in a large, global, clinical trial on patients with stable coronary heart disease (CHD).**Methods:** We performed a GWAS on 10,788 stable CHD patients enrolled in the Stabilization of Atherosclerotic Plaque by Initiation of Darapladib Therapy trial (STABILITY, ClinicalTrials.govnumber, NCT00799903). Genotype data was generated on the Illumina OmniExpressExome array. In total 10,786 patients and 733,565 SNPs passed genotype quality control of which 10,462 patients had GDF-15 measurements at baseline. GWAS analyses of GDF-15 were performed using PLINK, adjusted for established cardiovascular risk factors and genetic principal components. Analyses were performed sequentially adjusting for each genome-wide significant variant until no signals were left.**Results:** Overall the median (interquartile range) level of GDF-15 was 1248 (909 – 1814) ng/L. We identified three independent genome-wide significant SNPs associated with the GDF-15 level: rs17725099, rs1227731 and rs12459782 (lowest P-value = 3.06E-158) with minor allele frequencies of 0.25, 0.14 and 0.33, respectively. The SNPs were located close to or within the *GDF15* gene on chromosome 19 and were in predicted regulatory regions. The top hit SNP, rs17725099, explained 4.7% of the variance in GDF-15 level with an increase in median GDF-15 level between major and minor genotype of 44% (from 1128 (G/G) to 1626 (A/A) ng/L), SNPs combined explained 6.9% of the variance. Further, rs17725099 showed similar effect (beta estimate) across all self-reported ethnicity groups except black (n=118) and the effect remained when stratifying by country (n=28).**Conclusion:** We identified three independent SNPs affecting GDF-15 concentrations. The SNPs explained 6.6% of the variance in GDF-15 and the top hit SNP had similar effect on GDF-15 across all countries. The results indicate that these SNPs may be suitable for Mendelian randomization analyses in the search for a possible causal effect of GDF-15 on clinical outcomes.

592W

Population-specific genomics identifies predictor of venous thromboembolism in African Americans. *W. Hernandez[1], E.R. Gamazon[2], E. Smithberger[1], T.J. O'Brien[3], A.F. Harralson[3], M. Tuck[4], A. Barbour[3], R.A. Kittles[5], L.H. Cavallari[6], M.A. Perera[1].* 1) Dept Med, Section of Genetic Medicine, The University of Chicago, Chicago, IL; 2) Division of Genetic Medicine, Department of Medicine, Vanderbilt University, Nashville, TN; 3) The George Washington University, Department of Pharmacology and Physiology Washington, DC; 4) Uniformed Services University of the Health Sciences, Department of Veterans Affairs, Washington, DC; 5) Division of Urology, Department of Surgery, University of Arizona College of Medicine, Tucson, AZ; 6) University of Florida, Department of Pharmacotherapy and Translational Research, Gainesville, FL.

Background: Venous thromboembolism (VTE) is the third most common life-threatening cardiovascular condition in the U.S. with African Americans (AAs) having a 30 - 60% higher incidence compared to other ethnicities. The mechanisms underlying population differences in the risk VTE are poorly understood. Genome-wide association studies (GWAS) in Caucasians have confirmed the well-established risk variants, Factor V Leiden (rs6025) and prothrombin G20210A (rs1799963). However, these variants are nearly absent in AAs.Methods: To more comprehensively account for genetic variation observed in VTE risk among AAs, we conducted the firstGWAS on AAs comprised of 578 subjects (cases=146, controls=432) followed by replication of highly significant findings in an independent cohort of 159 AA subjects (cases=94, controls=65).GWAS genotypes were imputed to approximately 10 million SNPs using reference files from the 1,000 genomes haplotypes - Phase I integrated variant set. Logistic regression was used to estimate associations between genetic variants and risk of VTE.We utilized ioinformatics analysis of the top signalsto identifiy expression quantitative trait loci (eQTLs) in whole blood and we investigate the mRNA expression differences between VTE cases and controls.Results:Genome-wide significant associations were identifiedon chromosome 7 (rs73692310, p=1.73x10-9) and chromosome 18 (rs28496996 and rs58952918, p<1.1x10-8) and replicated SNP associations on chromosome 20 (rs2144940 and rs1998081, meta-analysis p<5x10-8) which increased VTE risk by ~2.20 fold. These risk variants were found at higher frequency among AAs (>20%) compared to other ethnic groups (<8%). We demonstrate that chromosome 20 SNPs are *cis*-eQTLs for thrombomodulin (THBD) – a key player in the regulation of coagulation, and also show the expression of THBD is lower among VTE cases compared to controls (p=9.87x10-6). The direction of these associations supports the role of decreased TMBD in VTE risk.Conclusion: We have identified and replicated common novel polymorphisms associated with increased risk of VTE in two independent AA cohorts. In addition, our study provides further evidence that the well-established risk variants among Caucasians (rs6025, prothrombin G20210A, and ABO variants) are not the major cause of VTE in AAs. Our findings provide new molecular insight into a mechanism regulating VTE susceptibility in AAs; a population disproportionately affected by this disease.

593T

Genome-wide Association Study with 1000 Genomes Imputation Identifies 7 new loci Associated with Blood-Pressure Traits in African-American Population. *J. Liang[1], D. Edwards[2], B. Tayo[3], E. African-Americans are more susceptible to high blood pressure (BP) and complications associated with high BP than any other ethnic group in the United States. Many large BP genome-wide association studies (GWASs) have been reported with common variants associated with BP in different ethnic populations, although the BP variation accounted for by the associated variants is still modest. The published GWASs are less successful in African ancestry populations than other populations, possibly due to relatively small sample size and different linkage disequilibrium patterns. We reported a GWAS using genotypes imputed from the 1000G Phase I Integrated Release Version 3 or recent including 30,086 individuals for 17 African American and one Nigerian cohorts. We observed nine independent loci (*BC041459, HBG2, RUFY4 (CXCR2P1), NDST4/TRAM1L1, GPR20, PTH2R/MAP2, ZNF621/CTNNB1, EVX1/HOXA, CDH17*) significantly associated with one or multiple BP traits (systolic BP, diastolic BP, pulse pressure and hypertension status) ($p < 5.0 \times 10\text{-}8$). Two of them have been reported previously (*EVX1/HOXA, CDH17)*. Among the nine index SNPs, two were also studied in our previous report (Franceschini et al. AJHG, 2013) but with less significance. Fine mapping, functional follow-up analysis and replication analysis are ongoing to further confirm the findings. Our study strongly suggests that searching for genetic variants underlying complex traits in African ancestry populations can be fruitful when variants are imputed to the 1000 Genomes reference panel.

594F

Identification of genetic loci associated with heart rate variability by the V$_g$HRV consortium. *I.M. Nolte[1], L.M. Muñoz[1], V. Tragante[2], R. Jansen[3], A. Vaez[1], . Background: Reduced cardiac vagal control reflected in low heart rate variability (HRV) is associated with greater risk of cardiac morbidity and mortality. Heritability of HRV ranges from 34-53% for the standard deviation of normal-to-normal intervals (SDNN), from 36-71% for the root mean square of successive differences (RMSSD), and from 25-63% for peak-valley respiratory sinus arrhythmia and high frequency power (pvRSA/HF) in the spectral decomposition of heart rate (HR).**Objective:** to identify loci associated with HRV at rest by performing meta-analysis of genome-wide association studies (GWAS).**Design:** The VgHRV consortium performed three two-stage meta-analyses of GWAS in 53,542 individuals of European ancestry for the HRV measures SDNN, RMSSD, and pvRSA/HF. These traits were determined from 10s to12h heart beat recordings, preferably under sitting/supine resting conditions. Independent SNPs that reached genome-wide significance after replication were followed-up in 11,234 Hispanic and 6,899 African American individuals. Post-GWAS analyses included *in silico* sequencing and annotation, eQTL analysis in whole blood, genetic risk score analysis, genetic correlation analysis between HRV and HR, and functional network analysis.**Results:** We identified 11 independent SNPs in eight loci that were significantly associated with at least one of the three HRV measures. These hits together accounted for 0.8-0.9% of the variance in HRV in the general European population. Replication in Hispanic and African American samples confirmed association for seven and six hits, respectively, in six of the loci. Five of the identified SNPs were previously associated with resting HR, but six were unique to HRV including

our top finding (p=4.6x10-46). Two of our hits were either themselves or in high LD with non-synonymous SNPs and three were eQTLs. LD Score regression showed that genetic correlation is almost 1 between the HRV traits and is around -0.6 between HRV and HR. Genes near our hits were broadly related to two categories of significantly enriched biological processes: 1) cellular signaling and response (e.g. to glucagon) and 2) metabolic processes in the cell (e.g. glycosylation).**Conclusion:** The VgHRV consortium identified 11 independent SNPs in eight loci that were genome-wide significantly associated with HRV explaining 0.9% of its variance. Post-GWAS analyses yielded interesting functional clues providing insight into the biology underlying cardiac vagal control.

Genome-wide association analysis of self-reported blood clots in 6,135 research participants identifies 8 loci associated with thrombosis. *M. Sabater-Lleal[1], D.A. Hinds[2], A. Buil[3], A. Martinez-Perez[4], R. Malik[5], L. Folkersen[6], D. Ziemek[1,7], A. Malarstig[1,7], N. Bing[7], J.M. Soria[4], J.C. Souto[4], A. Franco-Cereceda[8], A. Hamsten[1], E.T. Dermitzakis[3], J.Y. Tung[2], METASTROKE.* 1) Cardiovascular Genetics and Genomics, Department of Medicine, Karolinska Institutet, Stockholm, Sweden; 2) 23andMe, Inc; 3) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 4) Hospital de la Santa Creu i Sant Pau, IIB-Sant Pau, Barcelona, Spain; 5) Institute for Stroke and Dementia Research, Klinikum der Universität München, Ludwig-Maximilians Universität, Munich, Germany; 6) Center for Biological Sequence Analysis, Department of Systems Biology, Technical University of Denmark, Denmark; 7) Pfizer Worldwide R&D; 8) Cardiothoracic Surgery Unit, Department of Molecular Medicine and Surgery, Karolinska Institutet, Karolinska University Hospital Solna, Stockholm, Sweden.

Venous thromboembolism (VTE), which includes deep-vein thrombosis (DVT) and pulmonary embolism (PE), is a complex disease determined by well-established environmental factors and genetic risk factors. To add insights into the genetic regulation of thrombotic disease, we conducted a genome-wide association study (GWAS) of self-reported blood clots in 6,135 VTE cases and 252,827 controls of European ancestry belonging to the 23andMe cohort of research participants.Eight loci that exceeded genome-wide significance were revealed. Our study replicated previously known VTE loci near *F5, FGA-FGG, F11, F2, PROCR, FVIII* and *ABO* genes, and the more recently discovered loci near *SLC44A2*, and *TSPAN15*.In addition, we present data showing common genetic risks factors for stroke and coronary artery disease.Analyses of expression profiles and expression quantitative trait loci (eQTL) across different tissues suggested three plausible candidate genes for the chromosome 19 locus, the first thrombosis-related locus that does not harbour seemingly coagulation-related genes. Finally, our resultsprovide evidencethat self-reported data for VTE GWAS yield results comparable with those using clinically diagnosed VTE. This observation opens up the potential for larger meta-analyses, which will enable elucidation of the genetics of thrombotic diseases, and serves as an example for the genetic study of other diseases.

Platelet production is a tightly controlled developmental process indicative of the important role platelets play in hemostasis and thrombosis. Identifying genetic determinants of platelet count (PLT) and mean platelet volume (MPV), two common clinical blood count measurements, may elucidate mechanistic insights into platelet production, release, clearance, and their possible roles in chronic disease. Previous genome-wide association and exome chip studies have identified both common and rare genetic variation that influences PLT and MPV. Here, using platelet phenotypes and exome chip genotype data collected in 21 different studies, we performed a meta-analysis on PLT and MPV association results in 131,857 and 41,529 individuals, respectively. Individual study exome chip association results, completed using RareMetalWorker or RVTests, were combined with RareMetals for single variant tests and burden testing using Variable Threshold (VT) and SKAT.For PLT, we confirm association of many known rare (e.g., *JAK2*, *TUBB1*, *MPL*, and *SH2B3*) and common (e.g., *CABLES4*, *TMCC2*, *ARHGEF3*, and *SH2B3*) loci (p<2.07x10-7). Similarly, we replicate several known associations between rare (e.g., *TUBB1*, *KARLN*, and *IQGAP2*) and common (e.g., *GCSAML*, *WDR66*, and *JMJD1C*) loci with MPV (p<2.20x10-7). In addition to recapitulating the association of many known loci, we also identify novel loci currently undergoing conditional analyses and replication efforts. These include novel platelet associations of several genes associated with red and white blood cell (e.g. *TMPRSS6*, *ST5*, and *HFE*) traits previously in the literature and in concurrent analyses in the Blood Cell Consortium, which may reflect influences in common hematopoietic or clearance pathways. We also identify novel associations of genes (*PEAR1* and *MRVI1*) previously associated with platelet reactivity as well as several lipids associated genes including *APOH* and *LDLRAP1*. In addition to these novel associations of previously identified hematological or cardiovascular related genes, we find novel association with *ZMIZ2* (p=3.09x10-17), a known factor in androgen receptor mediated transcription and mesodermal development. Our results demonstrate the utility of exome chip data and increased sample size in genetic discovery for quantitative blood cell traits. Future work will seek to confirm the novel loci and examine the importance of novel coding variation and genes on platelet biology using animal and cellular models.

Simvastatin and RORα Ligands Increase AMP-Activated Protein Kinase (*AMPK*) Level *In vitro*. *N. Coban, C. Gulec, O. Yildirim, N. Erginel-Unaltuna.* Genetics, Institute for Experimental Medicine, Istanbul University, Istanbul, Turkey.

Aim: AMP-activated protein kinase (*AMPK*) is a trimeric enzyme comprising a catalytic α-subunit and regulatory β, γ subunits. *AMPK* was first identified as an upstream kinase that phosphorylates and hence inactivates 3-hydroxy-3-methylglutaryl coenzyme A reductase, the key enzyme controlling cholesterol biosynthesis. Cholesterol is known to be one of the natural ligands of nuclear receptor *RORα*, and *RORα*-mediated control of *AMPK* expression level was shown to play role in metabolism in the mice. Since cholesterol looks like to act as a linker in *RORα-AMPK* pathway, we aimed to test whether this cholesterol-based pathway is effective in human macrophages which play crucial role in atherosclerosis.**Methods:** To test the dependence of *AMPK* on cholesterol level and *RORα* aktivity in the macrophages, we measured the expression levels of *AMPK* and it's downstream gene *SREBF2* in THP-1 macrophages treated with simvastatin and/or synthetic *RORα* ligands. **Results:** We observed that simvastatin increased the expression of *AMPK*, and that this increment was partially enhanced by *RORα* ligands. Simvastatin was also found to increase the expression of *AMPK* target gene *SREBF2*. The latter increment, however, was partially reduced by *RORα* ligands. **Conclusion:** *AMPK* has emerged as a new target for the treatment of cardiometabolic diseases. *RORα* has also potential to be used as a target in cardiometabolic diseases. Statins, on the other hand, have been used in the treatment of cardiovascular diseases for decades. In recent study, we aimed to test the interrelationship between *AMPK* and *RORα* in macrophages. Our results suggest that cholesterol might play role in regulation of *RORα-AMPK* pathway in human macrophages, and this regulation can be modulated by administration of simvastatin and synthetic *RORα* ligands. These results offer *RORα-AMPK* pathway as a potential therapeutic target not only for metabolic disorders, but also for atherosclerosis.

Better Characterization of Coronary Artery Disease Across Multiple Tissues Achieved through Improvement of Bayesian Networks Using Causal Inference Testing. *A. Cohain[1], O. Franzen[1], R. Ermel[2], Y. Mo[1], H. Talukdar[3], H. Foroughi[3], J. Skogsberg[3], K. Hao[1], C. Betsholtz[5], J. Kovacic[6], T. Michoel[4], A. Ruusalepp[2,7], E.E. Schadt[1,7], J.L.M. Björkegren[1,2,6,7].* 1) Department of Genetics & Genomic Sciences, Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Cardiac Surgery, Tartu University Hospital, Tartu, Estonia; 3) Department of Medical Biochemistry and Biophysics, Karolinska Institutet, Stockholm, Sweden; 4) Division of Genetics and Genomics, The Roslin Institute, University of Edinburgh, Edinburgh, UK; 5) Deptartment of. Immunology, Genetics and Pathology, Uppsala University, Sweden; 6) Cardiovascular Institute, Icahn School of Medicine at Mount Sinai, New York, NY; 7) Clincial Gene Networks AB, Stockholm, Sweden.

Given the huge societal impact of Coronary Artery Disease (CAD) around the world, extensive genome-wide association studies (GWAS) have been pursued to elucidate the complexity of this highly heritable disease, resulting in the identification of >150 loci that collectively explain <10% of the expected genetic variance. The genetic architecture and downstream mechanisms of CAD required to translate genetic loci into opportunities for diagnosis, therapy and prevention, have been resolved for only a few of these disease-associated loci. To improve our understanding of CAD in light of these genetic findings, the Stockholm-Tartu Atherosclerosis Reverse Network Engineering Team (STARNET) sequenced RNA from 9 disease-relevant tissues, genotyped DNA, and collected extensive phenotypic information from a total of 700 patients who either underwent coronary artery bypass graft surgery ("cases") or other forms of open heart surgery ("controls").To move beyond viewing the complexity of the human system and disease as a combination of isolated genetic loci and genes, we carried out a multi-tissue systems approach to integrating the extensive STARNET dataset to better define the molecular underpinnings of CAD. First, we detected causal interactions among gene expression traits and between these traits and clinical phenotypes by employing causal inference techniques that leverage DNA variation common to these traits as a perturbation source. Systematic application of this causal inference procedure among all gene expression traits and clinical features across all CAD loci reveals the complex architecture of both upstream and downstream effects of these disease associated SNPs. Using the results of the causal relationships predicted across all tissues in STARNET as structure priors, we constructed Bayesian networks that provide a highly integrated, directed, multi-tissue view of disease that enables data-driven predictions relating to the pathophysiology of CAD. We believe these disease networks are the most comprehensive and informative representations of the regulatory and molecular landscape of CAD to date and as such should provide significant insights into novel therapeutic points of intervention and novel therapies for CAD.

From Death to Life/Back to the Future: Detailed premorbid clinical and family history can save the lifes and adress the final diagnosis in Sudden Unexplained Deaths with negative autopsy. *S.G. Temel[1,2], C.L Baydar[3], B. Turkgenc[4,5], M. Ozen[6], S. Usar Incirli[7], C. Conkbayir[8], M.C Yakicier[4,9].* 1) Near East University, Faculty of Medicine, Department of Histology & Embryology, Nicosia, North Cyprus; 2) Uludag University, Faculty of Medicine, Department of Medical Genetics, Bursa, Turkey; 3) Near East University, Faculty of Medicine, Departmen of Forensic Medicine, Nicosia, North Cyprus; 4) Acibadem Genetic Diagnostic Center, Istanbul, Turkey; 5) 2. Marmara University, Faculty of Medicine, Department of Medical Biology and Genetic, Istanbul, Turkey; 6) Dr. Nalbantoglu State Hospital, Department of Pathology, Nicosia, North Cyprus; 7) Dr. Nalbantoglu State Hospital, Department of Neurology, Nicosia, North Cyprus; 8) Near East University, Faculty of Medicine, Department of Cardiology, Nicosia, North Cyprus; 9) Acibadem University, Faculty of Science, Department of Molecular Biology and Genetic, Istanbul, Turkey.

Sudden cardiac death is responsible for a large proportion of sudden deaths in young individuals. In forensic medicine, many cases remain unexplained after routine postmortem autopsy and conventional investigations. These cases are called sudden unexplained deaths (SUD). İnherited cardiac disorders such as Long Qt, Brugada syndrome and cardiomyopaties comprise a substantial proportion of SUD cases. In this study, two forensic SUD case and their family members are investigated for inherited cardiac disorders. We report a 35 and 31 years old unrelated asymptomatic forensic SUD males died suddenly during asleep. There was another SUD individual in the first case's family and second case had a syncope history. Postmortem examinations excluded the extracardiac causes of sudden death as well as the absence of structural abnormalities. Because we had no available material for the first case, detailed cardiologic examination was performed to the sibling of him. She was positive for ajmaline test and diagnosed as Brugada syndrome; intracardiac defibrillator was planned and implanted. Targeted sequencing was performed to the sibling of the first and the second forensic SUD case on ion Personel Genome Machine using Ion Ampliseq Panel comprising 68 genes known to be associated with cardiological arrhythmias. Torrent Suite Software was used for data analysis. Three heterozygote missense variations were identified in the sibling of the first SUD case; c.3611C>T (p.Pro1204Leu) in TRPM4 gene, c.109G>A (p.Val37Ile) in RANGRF gene, paternally inherited and c.11229G>C (p.Met3743Ile) in AKAP9 gene, maternally inherited. Molecular autopsy of the second SUD case was revealed 3 missense variations; c.1889G>A (p.Arg630Gln) in KCND3 gene, maternally inherited and c.5369T>G (p.Val1790Gly) in AKAP9 gene, c.325G>A (p.Val109Ile) in KCNE1 gene, paternally inherited. RANGRF variation was novel, KCNE1 and TRPM4 variations were reported as pathogenic allele and the remaining 2 were reported as "unknown" allele. Carriers were identified in two families, also. For future directions functional analysis of found variations are under estimated. Irrespective of genetic testing; all SUD family required detailed clinical testing to identify relatives who may be at risk. Molecular autopsy and detailed premorbid clinical and family history can survive family members of SUD cases.Acknowledgements: İnherited arrhythmia panel is supported by grant from SANTEZ Project (0253.STZ.2013-2), Turkey.

Multivariate genome-wide association analysis of circulating cellular adhesion protein levels in the Multi-Ethnic Study of Atherosclerosis. *N.B. Larson[1], P.A. Decker[1], C.L. Wassel[2], J.S. Pankow[3], W. Tang[3], N.Q. Hanson[4], M.Y. Tsai[4], S.J. Bielinski[1].* 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA; 3) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 4) Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN.

The cellular adhesion pathway is critical in the pathophysiology of atherosclerosis, and genetic factors contributing to regulation of circulating levels of related proteins may be relevant to risk prediction of cardiovascular disease. Moreover, the regulatory genetics and corresponding effects of the cellular adhesion pathway may be race/ethnicity-specific and could contribute to disparities in disease incidence. In contrast to conducting separate protein quantitative trait loci (pQTL) analyses of each individual protein, joint genetic association analyses of multiple quantitative traits can leverage cross-trait co-variation and identify simultaneous regulatory effects on protein levels across the pathway. In this study, we conducted a multi-pQTL analysis of 15 proteins related to cellular adhesion assayed on n = 2313 from the Multi-Ethnic Study of Atherosclerosis (MESA). Genetic data consisted of the Affymetrix Genome-Wide Human SNP Array 6.0 supplemented by the Illumina Exome BeadChip, Cardio-MetaboChip, and the iSelect ITMAT/Broad/CARe (IBC) Chip. We applied the MQFAM multivariate association analysis method in PLINK on normalized residuals derived from univariate linear regression, adjusting for age, sex, genetic ancestry, BMI, and smoking status. Participants were African (n = 519), Chinese (n = 594), non-Hispanic white (n = 613), and Hispanic American (n = 587), and analyses were conducted stratified by race/ethnicity. Analysis results were also combined across race/ethnicity by meta-analysis using Stouffer's combined Z-score approach. Stratified analyses identified multiple significant (P<5e-08) loci associated with co-variation of protein levels, many of which were in proximity to coding genes of the assayed proteins and varied in statistical significance by strata. However, we additionally identified consistent SNP associations across race/ethnicity in genes *ABO* [MIM 110300] and *FUT2* [MIM 182100], which respectively encode the protein defining the ABO blood group system and a Golgi stack membrane protein involved in the creation of H-antigen precursor.Supplementary analyses suggested the *ABO* multi-pQTL SNP associations to be driven by ABO blood type. These results indicate the biological relevance of blood group antigens on regulation of circulating cellular adhesion pathway proteins while also demonstrating race/ethnicity-specific genetic regulatory effects.

Differential mRNA and miRNA gene expression in hypertensive and non-hypertensive women is influenced by race. *D.F. Dluzen, N.N. Hooten, Y. Zhang, K.D. Jacob, A.B. Zonderman, M.K. Evans.* National Institute on Aging, National Institutes of Health , Baltimore, MD.

Essential hypertension occurs more frequently among African Americans (AA) than any other population sub-group, has earlier onset, and more frequently results in end-organ complications. In addition, AA women have the highest incidence and hospitalization rates for hypertension in the United States. Previous data suggests that gene expression patterns may increase individual susceptibility to selected chronic diseases. Therefore, we hypothesized that differential gene expression may influence the disproportionate incidence and prevalence of hypertension among AAs. Transcriptional profiling of peripheral blood mononuclear cells (PBMCs) from AA or White, normotensive or hypertensive females identified thousands of mRNAs differentially expressed by race and/or presence of hypertension. Since microRNAs (miRNAs) are well-known post-transcriptional regulators of mRNA expression levels, and recent data indicates that miRNAs play an important role in the etiology of cardiovascular disease, we wanted to examine whether changes in miRNA abundance influence mRNA changes in hypertension. To test this, we profiled global miRNA expression in the same cohort. Analysis of microarray expression changes using Ingenuity Pathway Analysis identified mRNA-miRNA regulatory networks in hypertension-related pathways, i.e. the renin-angiotensin system, nitric oxide signaling, and actin-cytoskeletal signaling pathways, which differ by race and hypertension status. mRNA and miRNA gene expression changes were validated using RT-qPCR in an expanded cohort and gene functionality and miRNA target validation was investigated *in vitro* using primary human umbilical vein cells. We have identified several miRNAs, including miRs *20a-5p, 30c-5p, 4763-5p, 4709-3p* and *4717-3p*, which are significantly ($P<0.05$) and differentially expressed by race and/or presence of hypertension. Together, these findings identify several pathways and miRNA gene candidates whose expression differ with race and may contribute to hypertension-related health disparities.

Discovery of gene networks in monocytes with evidence of mediating the protective effects of HDL-cholesterol on monocytes function. *R.A. Verdugo[1], F.A. Medina[1], K. Orostica[1], T. Zeller[2], P.S. Wild[3,4], T. Munzel[3], K. Lackner[5], E. Ninio[6], D.A. Tregouet[6], F. Cambien[6], S. Blankenberg[2], L. Tiret[6].* 1) Programa de Genética Humana, Facultad de Medicina, Universidad de Chile, Chile; 2) Department of General and Interventional Cardiology, University Heart Center Hamburg; 3) Department of Medicine II, University Medical Center Mainz; 4) Center for Thrombosis and Haemostasis, Clinical Epidemiology, University Medical Center Mainz; 5) Institute for Clinical Chemistry and Laboratory Medicine, University Medical Center Mainz; 6) INSERM UMR_S 1166, Pierre and Marie Curie, Paris, France.

Although high-density lipoprotein (HDL) cholesterol is a known protective factor against atherosclerosis, the molecular mechanisms mediating its effects are not well understood. The objective of this study is to identify gene networks whose expression may explain such protective effect in humans. We tested graphical models of causality on 17,186 genes expressed in monocytes from 1,466 participants of the Gutenberg Health Study. There were 3,596 genes whose expression was associated with either HDL, 258 with number of atherosclerotic plaques, and 129 were associated to both (FDR < 0.1). Independent component analysis (ICA) identified 163 components in 500 runs. Of these, 44 were selected because high stability across runs, were not explained by outliers, and were not correlated with technical variables. Nine independent patterns of expression were significantly associated to HDL cholesterol level in blood. The rows of matrix A from ICA were used as independent expression patterns called metagenes. The structure of causal associations among the expression of nine metagenes, HDL, sex, smoking, and number of plaques were investigated by Bayesian Networks. Graphical models were scored by the BIC score and the space of models was explored by the hill-climbing algorithm. The process was repeated in 1000 bootstraps and the causal structure was represented as the average networks across boot replicates using the bnlearn R-package. The average causal model identified Meta31 (ADRB2 gene in the center) as a parent of HDL in the network, and therefore it's a causal candidate to modify cholesterol uptake or efflux from monocytes. By contrast, Meta29 and Meta119, with genes PACSIN1 and DEFA4 in their respective centers, were the only children of HDL, suggesting that HDL directly regulates the expression of these modules in the monocyte. Meta31 was the most correlated metagene to HDL cholesterol (r2=0.045) and it had the highest proportion of genes with expression correlated to this lipoprotein (50%) and to number of atherosclerotic plaques (10%). The gene module associated to this pattern contained 340 genes that were enriched for the "response to wounding" and "immune response" GO terms. Meta29 contained 258 genes that were enriched for the "response to endoplasmic reticulum stress" GO term and code mostly "integral to membrane" proteins. We investigate gene-level models of causality that can be tested experimentally.

Extensive Transcriptional Changes in Hypertrophied Cardiomyocytes Derived from Human iPSCs. *W. Li[1], P. Aggarwal[1], A. Turner[1], A. Matter[1], E. Storvick[1], D. Arnett[2], S. Hunt[3], B. Lewis[2], U. Broeckel[1].* 1) Dept. of Pediatrics, Medical College of Wisconsin, Milwaukee, Wisconsin, US; 2) Dept. of Epidemiology, University of Alabama at Birmingham, Birmingham, Alabama, US; 3) Cardiovascular Genetics Division, School of Medicine, University of Utah, Salt Lake City, Utah, US.

Rationale. Left ventricular hypertrophy (LVH) is a significant risk factor for cardiovascular disease. Cardiac hypertrophy is accompanied by significant gene expression changes in cardiomyocytes (CMs). However, our knowledge on gene expression patterns is largely focused on the net transcript abundance level. So far, we have limited knowledge about the level of alternative splicing (AS) and associated isoform expression changes. To gain insight into the transcriptional changes associated with cardiac hypertrophy, we perform RNA-sequencing on CMs with or without hypertrophy stimulation. We identify splicing patterns and differential isoform expression unique to CM hypertrophy. **Methods.** We developed a model of human CM hypertrophy using induced, pluripotent stem cell derived CMs (hiPSC-CMs). Four lines of CMs were included in our study. Stimulating the hiPSC-CMs with Endothelin1 induced characteristic changes consistent with the development of LVH, *e.g.*, an increase in cell surface area and elevated expression of well-established LVH markers. Transcripts were assembled using STAR and Bowtie2. Transcripts abundance was quantified using Cufflinks2. Splice sites with at least 10 uniquely mapped reads were pursued for further analysis. **Results.** Upon hypertrophic induction, 446 to 982 genes show differential expression at isoform level. A significant portion of the differentially expressed isoforms (DES) is specific to each cell line. Distinct functional motifs are found in these unique DESs. For each CM line, between 160 and 1131 genes exhibit altered splicing sites (SSs) specific to hypertrophic CMs. 11% to 25% of these SSs produce novel exons that are concentrated in highly expressed genes. Compared to annotated exons, a dominant portion (42%-72%) of the novel exons are created through alternative 5' splicing. Interestingly, AS and differential isoform expression are enriched in genes involved in hypertrophic cardiomyopathy and cardiac contraction. **Conclusions.** We reveal extensive transcriptional changes upon hypertrophy induction in our cellular model of LVH. Compared to normal CMs, hypertrophied CMs have a distinct profile of AS and isoform expression patterns. Our study suggest that alterations at both splicing and isoform-expression levels are an important regulatory component of cardiac hypertrophy. Further, unique SSs and isoform expression may serve as biomarker candidates for future investigations.

604W

Increased mutational burden is associated with more severe presentation in left ventricular noncompaction. *M. Bainbridge[1], K. Miszalski-Jamka[2], W. Mazur[3], J. Jefferies[4], S. Jhangiani[1], D. Muzny[1], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College Med, Houston, TX; 2) Department of Cardiology, Congenital Heart Disease and Electrotherapy, Silesian Center for Heart Disease, Zabrze, Poland; 3) Ohio Heart and Vascular Center Cincinnati, OH; 4) The Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Left ventricular non-compaction (LVNC) is traditionally understood to be a dominant, monogenic disease that is typified by spongy, non-compacted myocardium, and hypertrabeculation. LVNC has a prevalence of ~1/5000 and is believed to be a compensatory mechanism for impaired myocardial function. We extensively phenotyped and whole exome sequenced 190 subjects with LVNC or hypertrabeculation and identified possible contributory variants (CVs) in 113 subjects (59.4%), in 55 genes that are known to cause LVNC, muscular dystrophy or non-LVNC cardiomyopathy. The most commonly mutated gene was TTN with 17 truncating variants followed by MYH7 with 10. Multiple variants were found in genes not previously associated with LVNC including long-QT genes KCNH2, KCNE1, KCNQ1, KCNJ2, myopathy gene FLNC and coronary artery disease gene MEF2A. Of the 113 subjects with at least one CV, 37 (32.7%) had 2 or more, including a pair of siblings with 4 CVs. We found increased mutational burden in these genes between our LVNC cohort and an unselected control population. We also found strong correlation between mutational burden in individual patients and measured phenotypes of cardiac dysfunction, including left ventricular ejection fraction ($p<0.001$) and non-compacted to compacted myocardium ratio ($p<0.001$). These findings remained even when considering variants with minor allele fractions that would normally be considered too high to cause a rare, dominant, monogenic disease (0.1-1%). Our findings indicate that LVNC may be caused by, and its phenotype exacerbated by, multiple, uncommon variants that act epistatically. These findings have a profound impact in LVNC genetic diagnosis and help to explain the variable penetrance of LVNC seen in families.

Dilated cardiomyopathy-associated long intergenic non-coding RNAs in zebrafish cardiac transcriptome. *L. Wang[1], Y. Shih[2], X. Xu[2], Y. Zhang[1].* 1) Division of Biostatistics and Bioinformatics, University of Maryland Greenebaum Cancer Center, and Department of Epidemiology and Public Health, University of Maryland School of Medicine, Baltimore, MD; 2) Division of Cardiovascular Diseases, Department of Biochemistry & Molecular Biology, Mayo Clinic, Rochester, MN.

The long intergenic non-coding RNAs (lincRNAs) have been found to serve as key regulators of many cellular processes, such as genomic imprinting, chromatin regulation, mRNA regulation and nuclear organization. Because of temporospatial-specific expression property, it is important to investigate lincRNAs in the context of various tissue types. In this study, we aimed to identify heart-specific lincRNAs using a genome-wide transcriptome analysis. Specifically, we focused on lincRNAs that express in zebrafish heart at embryonic and adult stages, an emerging vertebrate model to study cardiomyopathy and heart failure. We identified 120 known lincRNAs from zebrafish heart, including 68 at embryonic stage, 94 at adult stage, and 42 overlapping lincRNAs at both stages. Among these lincRNAs, 55 lincRNAs are cardiac specific without expression in zebrafish muscle. Furthermore, we identified 592 putative novel lincRNAs using our computational bioinformatics pipeline. The co-expression analysis indicated that certain lincRNAs were potentially functionally associated with dilated cardiomyopathy genes in zebrafish. Our studies suggest that lincRNAs play crucial biological roles during heart development and may serve as potential key regulators in biological processes that are closely related to heart disease.

Adams-Oliver syndrome (AOS) is a rare developmental disorder characterized by the presence of both aplasia cutis congenita (ACC) of the scalp vertex and terminal limb reduction defects, such as brachydactyly, oligodactyly, syndactyly, hypoplastic nails or transverse amputations. Cardiovascular anomalies, comprising pulmonary hypertension, ventricular septum defects, tetralogy of Fallot and anomalies of the great arteries and their valves are also frequently observed. Mutations in five genes have been identified as a cause for AOS prior to this report. Mutations in *EOGT* and *DOCK6* cause autosomal recessive AOS, whereas mutations in *ARHGAP31*, *RBPJ* and *NOTCH1* lead to the autosomal dominant form of AOS. As *RBPJ*, *NOTCH1* and *EOGT* are all involved in the Notch signaling cascade, we hypothesized that mutations in other genes involved in this pathway may also be implicated in AOS pathogenesis. Using a candidate gene based approach, we prioritized *DLL4*, a critical Notch ligand, due to its essential role in vascular development and angiogenesis in the context of cardiovascular features in AOS patients. Targeted resequencing of the *DLL4* gene using a custom enrichment panel was performed in 89 independent families, in which we found seven mutations. In addition, a defect in *DLL4* was also detected in two pedigrees with whole exome/genome sequencing. In total, nine heterozygous mutations in *DLL4* were identified, including two nonsense variants, which are predicted to lead to nonsense mediated decay, and seven missense variants. These missense variants encompass four mutations that replace or create cysteine residues, which are likely critical for maintaining the structural integrity of the protein and three mutations that affect conserved amino acids in two functional domains of the protein. These functional domains include the DSL domain and the MNNL domain, which are both involved in binding of the ligand to the Notch receptor. Affected individuals with *DLL4* mutations present with variable clinical expression and incomplete penetrance with no emerging genotype-phenotype correlations. Our findings demonstrate *DLL4* mutations as an additional cause of autosomal dominant AOS or isolated ACC and provide yet further evidence for a key role of Notch signaling in the etiology of this disorder.

607W

Recessive *MYH6* mutations in hypoplastic left heart with reduced ejection fraction. *J. Theis, M. Zimmermann, J. Evans, B. Eckloff, E. Wieben, M. Qureshi, P. O'Leary, T. Olson.* Mayo Clinic, Rochester, MN.

The molecular underpinnings of hypoplastic left heart (HLH) are poorly understood. Staged surgical palliation has dramatically improved survival, yet eventual failure of the systemic right ventricle necessitates cardiac transplantation in a subset of patients. We sought to identify genetic determinants of HLH with latent right ventricular dysfunction in individuals with a Fontan circulation. Evaluation of cardiac structure and function by echocardiography in patients with HLH and their first degree relatives identified five individuals with right ventricular ejection fraction ≤40% following Fontan operation. Whole genome sequencing (WGS) was performed on DNA from 21 family members, filtering for genetic variants with allele frequency <1% predicted to alter protein structure or expression. Secondary family-based filtering for *de novo* and recessive variants revealed rare inherited missense mutations on both paternal and maternal alleles of *MYH6*, encoding myosin heavy chain 6, in two patients who developed right ventricular dysfunction >10 years postoperatively. Parents and siblings who were heterozygous carriers had normal echocardiograms. Protein modeling of the four highly conserved amino acid substitutions, residing in both head and tail domains, predicted perturbation of protein structure and function. In contrast to dominant *MYH6* mutations with variable penetrance identified in other congenital heart defects and dilated cardiomyopathy, this study reveals compound heterozygosity for recessive *MYH6* mutations in patients with HLH and reduced systemic right ventricular ejection fraction. These findings implicate a shared molecular basis for developmental arrest and latent myopathy of left and right ventricles, respectively.

608T

Novel *FLNC* truncation variants found in a large cohort of dilated cardiomyopathy cases. *R.L. Begay[1], S.L. Graw[1], D.B. Slavov[1], F. Brun[2], K.L. Jones[1], K. Gowan[1], D. Miani[2], G. Sinagra[2], L. Mestroni[1], M.R.G. Taylor[1].* 1) Department of Medicine, University of Colorado - CU Cardiovascular Institute, Aurora, CO; 2) University of Trieste Hospital, and S. Maria della Misericordia Hospital, Udine, Italy.

Background –Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy and frequently leads to heart failure. In cases without an environmental etiology, variants in over 50 genes have been linked to this DCM disease. However, genetic causes are only suspected in about ~30-40% of DCM cases. Therefore, it is crucial to continue the search for novel DCM disease-causing genes to understand this link between genetics and heart disease. One such potential gene is *Filamin-C* (*FLNC*), which encodes for a structurally important actin-binding protein located within the sarcomere of heart and skeletal muscle. Mutations in this gene are known to cause skeletal myopathies, and more recently has been associated with hypertrophic cardiomyopathy in the absence of skeletal muscle pathology. In a previous study (manuscript in preparation), we used Whole Exome Sequencing to discover a *FLNC* splicing mutation in two Italian DCM families and suggested haploinsufficiency of the resulting *FLNC* protein as the pathological mechanism. In this current study, we decided to pursue these findings in a larger DCM population. *Methods and Results* – To gain an understanding of the gene mutation spectrum in patients with DCM, we identified and analyzed 187 DCM affected individuals utilizing Illumina TruSight One Sequencing Panel, which queries 4,813 genes associated with clinical phenotypes. Following a bioinformatic filter, we detected six families with *FLNC* truncation mutations (three stopgain and three splicing), for a frequency of ~3.2%. These individuals tested presented with a DCM phenotype with lack of skeletal muscle abnormalities. In addition, these mutations are absent from the 1000 Genomes Project and NHLBI Exome Sequencing Project, which suggests novelty.*Conclusion* – *FLNC* truncation mutations have been inadequately understood with respect to cardiac muscle. This study provides additional findings that *FLNC* truncation mutations can lead to dilated cardiomyopathies without the presence of skeletal muscle defects. Currently, studies are ongoing to recapitulate the DCM phenotype seen in humans caused by *FLNC* truncations in a zebrafish model. As a result of this model, we can better understand the pathological mechanism of these truncation mutations.

609F

A unique case of multisystemic smooth muscle dysfunction syndrome with expanding genotype-phenotype correlations. *G. Bhat[1], R. Ji[2], W. Zou[2], D. Penny[2], F. Yuxin[2], P. Levy[1].* 1) Division of Medical Genetics, Montefiore Medical center, Albert Einstein College of Medicine, Bronx, NY; 2) John Welsh Cardiovascular Diagnostic Laboratory, Department of Pediatrics, Texas Children's Hospital, Baylor college of Medicine.

ACTA2 located at 10q23.31 is an actin isoform that encodes for vascular smooth muscle alpha-actin (#OMIM 102620). *ACTA2* mutations were initially found to be associated with familial thoracic aortic aneurysm, however in recent years the phenotypic spectrum has become increasingly diverse. Multisystemic smooth muscle dysfunction (MSMD [MIM 613834]) syndrome is on the severe end of the spectrum of *ACTA2* mutations with earlier onset and higher penetrance. Characteristic presentation includes hypoperistalsis, hypotonic bladder, pulmonary hypertension, congenital mydriasis, cerebrovascular abnormalities, stroke and PDA. Mileciwz et al in 2010 identified R179H mutation as causative in a cohort of 7 patients with MSMD syndrome. We report on a 27 year old female with MSMD syndrome caused by a missense R179C mutation in *ACTA2* and expand the genotype-phenotype correlations.Our proposita was born full term to a non-consanguineous couple of Puerto Rican ancestry. She had a complicated newborn course due to recurrent pneumonia, intestinal malrotation requiring surgery and PDA repair in infancy. Congenital mydriasis was noted at birth. She has persistent transient ischemic attack-like episodes first noted at 7 years of age, characterized by hand numbness and mutism. Her MRI of brain and angiogram showed bilateral cortical infarcts, with bilateral supraclinoid carotid artery occlusions, extensive collaterals, encephalomalacia, white matter signal abnormalities and extensive volume loss. CT of the thorax showed lucency of the left lung, emphysematous changes and areas of bronchiectasis. Echocardiogram showed right ventricular dilatation and pulmonary hypertension. The patient has a history of cholelithiasis and a unique finding of small left kidney, not previously described with MSMD syndrome. Sequence analysis identified a heterozygous missense mutation c.535C>T in one copy of the *ACTA2* gene. This nucleotide change predicts an amino acid change from arginine to cysteine (p.R179C). The only other patient with heterozygous p.R179C substitution in *ACTA2* associated with a MSMD phenotype was reported by Meuwissen et al in 2012. The patient had additional findings of malformations of corpus callosum and died at 3 years of age due to complications from PDA repair surgery. In conclusion, our case supports the hypothesis that the p.R179C mutation in *ACTA2* leads to a more extensive involvement with multiple comorbidities as compared to the more common p.R179H mutation.

610W

Genome-wide rare copy number variations contribute to genetic risk for transposition of the great arteries. *G. Costain[1,2], L. Ogura[1], C.R. Marshall[3], S.W. Scherer[3,4], C.K. Silversides[5], A.S. Bassett[1,5,6,7,8,9].* 1) Clinical Genetics Research Program, CAMH, Toronto, Ontario, Canada; 2) Residency Training Program in Medical Genetics, University of Toronto, Toronto, Ontario, Canada; 3) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) McLaughlin Centre and Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 5) Division of Cardiology, Department of Medicine, University Health Network, Toronto, Ontario, Canada; 6) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 7) Department of Psychiatry, and Toronto General Research Institute, University Health Network, Toronto, Ontario, Canada; 8) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 9) The Dalglish Family Hearts and Minds Clinic for 22q11.2 Deletion Syndrome, Toronto General Hospital, University Health Network, Toronto, Ontario, Canada.

Background: Transposition of the great arteries (TGA) is an uncommon but severe congenital heart malformation of unknown aetiology. Rare copy number variations (CNVs) have been implicated in other, more common conotruncal heart defects like tetralogy of Fallot (TOF), but there are as yet no CNV studies dedicated to TGA. **Methods:** Using high-resolution genome-wide microarrays and rigorous methods, we investigated CNV in a group of prospectively recruited adults with TGA (n=102) from a single centre. We compared rare CNV burden to well-matched cohorts of controls and TOF cases, adjudicating rarity using 10,113 independent population-based controls and excluding all subjects with 22q11.2 deletions. We identified candidate genes for TGA based on rare CNVs that overlapped the same gene in unrelated individuals, and pre-existing evidence suggesting a role in cardiac development.**Results:** The TGA group was significantly enriched for large rare CNVs (2.3-fold increase, p=0.04) relative to controls, to a degree comparable with the TOF group. Extra-cardiac features were not reliable predictors of rare CNV burden. Smaller rare CNVs helped to narrow critical regions for conotruncal defects at chromosomes 10q26 and 13q13. Established and novel candidate susceptibility genes identified included ACKR3, IFT57, ITGB8, KL, NF1, RERE, SLC8A1, SOX18, and ULK1.**Conclusions:** These data demonstrate a genome-wide role for rare CNVs in genetic risk for TGA. The findings provide further support for a genetically-related spectrum of congenital heart disease that includes TGA and TOF.

611T

Analysis of rare variants and CNVs in non-syndromic tetralogy of Fallot. *J. Goodship[1], M. Miossec[1], D. Brown[1], I. Wilson[1], L. Sutcliffe[1], A. Topf[1], K. Devriendt[2], A. Rauch[3], D. Winlaw[4], F. Bu'Lock[5], S. Bhattacharya[6], M. Lathrop[7], B. Keavney[8], M. Santibanez-Koref[1].* 1) Inst Genetic Medicine, Univ Newcastle upon Tyne, Newcastle on Tyne, United Kingdom; 2) Paediatric Cardiology, University of Leuven, Leuven B-3000, Belgium; 3) Institute of Medical Genetics, University of Zurich, Zurich-Schwerzenbach CH-8603, Switzerland; 4) Heart Centre for Children, The Children's Hospital at Westmead, Sydney NSW 2145, Australia; 5) East Midlands Congenital Heart Centre, Glenfield Hospital, Leicester LE3 9QP, UK; 6) Department of Cardiovascular Medicine and Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, UK; 7) McGill University and Génome Québec Innovation Centre, Montréal (Québec) Canada H3A 0G1; 8) Institute of Cardiovascular Sciences, Manchester University, Manchester M13 9NT, UK.

Tetralogy of Fallot (TOF) is the commonest cyanotic congenital heart disease requiring surgery in infancy. The majority of cases do not occur as part of a syndrome. We have investigated rare nucleotide variants and copy number variants (CNVs) in over 800 non-syndromic TOF cases. For nucleotide variants we filtered for variants with MAF <1% in 1000 genomes and EVS, not shared between cases and 500 UK10K individuals, not present in more than 1% of individuals in a set and not falling within a segmental duplication. Clustering of variants in transcripts and in exons was ascertained using Poisson distribution. Correcting for the difference in sample numbers in the two groups, the number of clusters when considering synonymous variants was very similar in the TOF cases and UK10K individuals. In contrast, there was an excess of clusters in TOF cases when considering truncating, predicted deleterious and non-synonymous variants. Clusters were found in genes previously associated with TOF and novel candidate genes. CNVs were called for the same TOF cases on PCA corrected SNP array intensities (Cooper et al. Hum. Mol. Genet 2014), which enabled the joint analysis of case and control data while allowing for batch effects. Penncnv and quantiSNP were used for CNV calling on the corrected data and the controls for this work were as previously reported (Soemedi et al Am. J. Hum. Genet 2012). This enabled detection of additional smaller CNVs than reported in our earlier work.

Congenital heart disease (CHD) is a severe birth defect that is often associated with extra-cardiac manifestations such as neurodevelopmental disabilities (NDD) and congenital anomalies (CA). Known genetic syndromes that cause CHD with extra-cardiac manifestations account for less than 10% of cases. We used whole exome sequencing to identify *de novo* mutations in 1,220 CHD case and 900 control parent-offspring trios. Using an adapted statistical framework for the analysis of *de novo* mutations, we found a marked excess of protein-damaging mutations in CHD cases, especially in genes highly expressed in the developing heart (enrichment 2.4x; p=1.6e-24) and brain (enrichment 2.2x; p5e-8). Mutations were enriched in genes involved in morphogenesis, chromatin modification, and transcriptional regulation, including *RBFOX2*, which regulates mRNA splicing. We found a significant overlap between genes mutated in our CHD cohort and in cohorts ascertained for NDD; moreover, CHD patients with these mutations were enriched for NDD. *De novo* mutations contributed to 19.5% of CHD with both NDD and CA but only 2.5% of isolated CHD. These findings reveal shared genetic contributions to CHD, NDD, and CA and suggest opportunities for improved assessment of neurodevelopmental prognosis and early therapeutic intervention in CHD patients.

613W

Utilization of Whole-Exome Sequencing to Identify Causative Mutations in Familial Congenital Heart Disease. *S. LaHaye[1,2,3], D. Corsemeier[4], J.L. Bowman[2,5], S. Fitzgerald-Butt[1,2,5], G. Zender[1], K. Bosse[1], K.L. McBride[1,2,5], P. White[4,5], V. Garg[1,2,3,5].* 1) Center for Cardiovascular and Pulmonary Research, Nationwide Children's Hospital, Columbus, OH; 2) The Heart Center, Nationwide Children's Hospital, Columbus, OH; 3) Department of Molecular Genetics, The Ohio State University, Columbus, OH; 4) Biomedical Genomics Core, Nationwide Children's Hospital, Columbus, OH; 5) Department of Pediatrics, The Ohio State University, Columbus, OH.

Congenital heart disease (CHD) is the most common type of birth defect, affecting ~8 out of every 1,000 live births, but there remains a limited understanding of the etiology for the majority of cases of CHD. Familial and population based studies have identified a strong genetic component to CHD, and familial cases of almost every type of CHD have been reported. The goal of this study was to identify pathogenic segregating variants in multiplex CHD families by whole-exome sequencing (WES). Target capture was performed using the Agilent SureSelectXT Target Enrichment kit, followed by WES on an Illumina HiSeq2500, on members from 9 families with Mendelian inherited CHD. Sequence alignment, post alignment processing, variant calling, and genotyping was performed with the Churchill pipeline. Tertiary analysis and annotation consisted of identifying rare (<1% mean allele frequency in the population) segregating variants, prioritizing by matching to a CHD gene list, and predicting pathogenicity via 12 different utilities. This strategy utilized a list of 69 CHD genes selected under strict criteria and allowed for prioritization of the variants. Predicted pathogenic mutations were identified in 3 of the 9 families. A splice donor site mutation was identified in *MYH11* (c.4599+1delC) in a family with autosomal dominant patent ductus arteriosus that is predicted to cause a 71 amino acid deletion, affecting functionality of the coiled-coil tail domain. A *GATA4* mutation, p.G115W, was identified in a family with autosomal dominant atrial septal defects (ASD) and is predicted to affect the transactivation ability of *GATA4*. A p.I263V mutation in *TLL1* was identified in a family with autosomal dominant ASD; as this mutation was located in the astacin-like metalloprotease catalytic domain it is predicted to affect the enzymatic efficacy of *TLL1*. In summary, our findings demonstrate the clinical utility of WES to successfully identify causative mutations in familial CHD and support the use of a CHD candidate gene list to allow for a more streamlined approach that enables rapid prioritization and identification of pathogenic variants from large WES data sets.

614T

Search for Novel Mutations Predisposing to Ventricular Fibrillation Without Overt Cause. *J.T. Leinonen[1], H. Swan[2], N. Junna[1], A. Lahtinen[3], M. Viitasalo[2], K. Kontula[3], E. Widen[1].* 1) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki, Finland; 2) Heart and Lung Center, Helsinki University Hospital, Helsinki, Finland; 3) Department of Medicine, University of Helsinki and Helsinki University Hospital, Helsinki, Finland.

Ventricular fibrillation (VF) is a major cause of sudden cardiac death. In 5-10% of the cases the arrhythmia remains idiopathic, the patient presenting spontaneous VF in the absence of known ischemic, electrical, infectious or structural heart disease. While the pathology underlying idiopathic VF is likely variable and complex, the condition seems to have a heritable component. For example, a haplotype containing the gene *DPP6* associates with idiopathic VF in Dutch families, and a missense mutation in *SEMA3A* has been associated with idiopathic VF in a Japanese study.In the current study, we sought to identify mutations predisposing to idiopathic VF in Finland, by sequencing the exomes of a nation-wide cohort of patients resuscitated from out-of-hospital VF during 1999 – 2011. Standard clinical examinations in the primary hospitals had failed to identify any cause for the VF. The study comprised altogether 38 subjects (16 males and 22 females, age at diagnosis <55). Exome sequencing was carried out using Nimblegen SeqCap v2 kit.We restricted our analyses to 91 candidate genes previously associated with cardiac channelopathies, or cardiomyopathy. We screened the genes for rare (MAF < 0.0005 in the ExAC (http://exac.broadinstitute.org/) and Sequencing Initiative Suomi (http://www.sisuproject.fi/) databases) and likely damaging missense and nonsense variants. Based on these criteria, we identified mutations in 5/38 patients. Two of the patients had novel missense mutations in the CPVT-associated gene *RYR2,* whereas one patient carried a de novo missense mutation in *CACNA1C*, a gene previously associated with long QT-syndrome. One of the patients carried a rare nonsense mutation in the cardiomyopathy-associated limb-girdle muscular dystrophy gene *FKRP*, whereas the fifth patient carried a truncating mutation in the cardiomyopathy gene *TTN*. Interestingly, the subject with the *FKRP* mutation had family history of muscular dystrophy, and the *TTN* mutation-carrier had two cousins previously diagnosed with cardiomyopathy. Current work is underway to characterize the segregation of the identified mutations in the families, and to assess the current cardiac status of the patients and their relatives.Our data suggest that even if part of idiopathic VF patients may carry potentially pathogenic mutations in genes associated both with channelopathies and cardiomyopathy, such mutations are unlikely to be a major cause of idiopathic VF associated with sudden cardiac death.

615F

Whole exome sequencing identified known and novel genetic causes for pulmonary arterial hypertension. *L. Ma[1], C. Gonzaga-Jauregui[2], A. Sawle[3], Y. Shen[4], A. King[2], EB. Rosenzweig[5], JG. Reid[2], J. Overton[2], AR. Shuldiner[2], F. Dewey[2], WK. Chung[1].* 1) Molecular Genetics, Columbia Univ, New York, NY; 2) Regeneron Genetics Center Regeneron Pharmaceuticals Tarrytown, New York, USA; 3) Herbert Irving Comprehensive Cancer Center Columbia University Medical Center New York, New York, USA; 4) Departments of Systems Biology and Biomedical Informatics Columbia University Medical Center New York, New York, USA; 5) Department of Pediatrics Columbia University Medical Center New York, New York, USA.

Pulmonary arterial hypertension (PAH) is a rare disease characterized by distinctive changes in pulmonary arterioles that lead to progressive elevation of pulmonary artery pressure, pulmonary vascular resistance, right sided heart failure, and a high mortality rate. Mutations in *BMPR2* and a few other genes have been implicated in families with PAH, however ~20% of cases remain unexplained. To identify additional genetic causes of PAH, we performed whole exome sequencing in 60 PAH patients and when possible both parents, including 48 pediatric PAH probands. The study included 17 hereditary PAH, 43 idiopathic PAH, 8 congenital heart disease (CHD)-PAH, 2 hereditary hemorrhagic telangiectasia (HHT)-PAH, and 2 patients with syndromic PAH including either autism or a connective tissue disorder. We identified known and novel mutations in 18 of 48 (37.5%) patients with pediatric onset PAH. Seven of the 18 (38.9%) were due to *de novo* mutations. The genes identified, number of patients for each gene and their associated phenotypes are listed in Table 1. The high yield of whole exome sequencing in pediatric-onset PAH and the fact that novel genes were identified suggests that this is a useful strategy for gene identification and genetic diagnosis in children with PAH. Furthermore, the identification of novel genes for PAH provide insights into pathophysiology and potential new drug targets for treatment and prevention.Table 1. List of genes identified, number of patients for each gene and their associated diseases.

Gene	Number of Variants	Number of patients	Disease	Whether known/ novel PAH gene
ABCC8	5	5	Pediatric PAH, one autism-PAH	Novel
ACVRL1	1	1	HHT-PAH	Known
BMPR1B	1	1	Pediatric PAH	Known
BMPR2	2	2	Pediatric PAH	Known
EIF2AK4	1	1	Adult PAH	Known
ENG	1	1	Pediatric PAH	Known
SMAD6	1	1	Pediatric PAH	Known
TBX4	6	6	Pediatric PAH, one CHD-PAH	Known
ZFPM2	2	1	Pediatric PAH	Known

Whole exome sequencing in 41 Czech families with inherited cardiovascular disorders: initial data from a representative Central European population. *M. Macek[1], N. Ptakova[3], A. Krebsova[2], L. Piherova[3], M. Kubanek[2], V. Stranecky[3], M. Macek Sr.[3], J. Kautzner[2], S. Kmoch[1], V. Melenovsky[1].* 1) Department of Biology and Medical Genetics, 2nd Faculty of Medicine and University Hospital Motol, Prague, Czech Republic; 2) Institute of Inherited Metabolic Disorders, 1st Faculty of Medicine and VFN, Prague, Czech Republic; 3) Department of Cardiology, Institute of Clinical and Experimental Medicine Prague, Czech Republic.

Whole exome sequencing (WES) fosters establishment of etiological diagnostics in hereditary forms of rare cardiovascular disorders, enables genetic stratification and may eventually facilitate introduction of precision medicine-based therapies. Altogether 96 families with ≥ 2 affected individuals were characterized based on established center care and using international clinical / laboratory standards. WES was carried out in a total of 41/96 families (TruSight Exome, Illumina, USA): 23/41 families suffered from dilated cardiomyopathy (DCM), 1/41 - non-compaction cardiomyopathy (LVNC), 14/41 - hypertrophic cardiomyopathy (HCM), 1/41 -arythmogenic cardiomyopathy (ACM) and 2/41 had unexplained cardiac arrest (UCA). Detected variants were confirmed by Sanger DNA sequencing and by segregation analysis. Pathogenic variants were revealed in 22/41 (64%) of studied families: 12/22 (54%) in DCM, 1/1 LVNC, 13/14 (92%) HCM, 1/1 ACM and in 1/2 familes with UCA. The most frequently affected gene in DCM was *TTN* (23%) and in HCM the *MYH 7* (29%). In case of LVNC, the likely pathogenic variants were identified in the *OBSC*, for ACM in *PKP2* and in the family with UAC in *SCN5A* genes, respectively. Although all disease genes were already identified, most variants were novel, thereby substantiating a population specific diagnostic strategy. In summary, obtained results are in accordance with other European studies and validate the integrated clinical care and genomic diagnostics in our country, whose genomic variation is representative of other Central European populations. Supported by: FNM 00064203, CZ.2.16/3.1.00/24022, NF-CZ11-PDP-3-003-2014, LD14073, IGA NT13770.to M.M. and IKEM 00023001 to V.M.

Investigating the role of somatic mutation in congenital heart disease. *D.E. Miller[1, 2, 3], G. Twist[1], N.A. Miller[1], D.C. Bittel[1], E.G. Farrow[1], J.E. O'Brien[1], G.S. Shirali[1], R.S. Hawley[2, 3], S.F. Kingsmore[1, 4].* 1) Children's Mercy Hospital, Kansas City, MO; 2) Stowers Institute for Medical Research, Kansas City, MO; 3) University of Kansas Medical Center, Kansas City, KS; 4) University of Missouri Kansas City, Kansas City, MO.

Mutations that arise during development (congenital somatic mutations) are an understudied cause of human genetic disease. Although it is well understood that germline mosaicism produces offspring with new mutations not apparent in the parental somatic tissue, less is known about the impact of mosaicism within a particular individual. The falling cost of whole-genome and exome sequencing makes it feasible to sequence multiple tissues from a single individual in an effort to understand the impact of somatic mutations on the incidence of congenital disease. Hypoplastic left heart syndrome (HLHS) is a devastating condition in which the left ventricle of the heart does not fully develop. Although HLHS shows evidence of heritability, suggesting a genetic cause, very few genes or loci have been implicated in its development. To understand the role that somatic mosaicism may have in the development of HLHS, we generated exome (average depth of coverage: 180x) and whole-genome data (average depth of coverage: 50x) from both cardiac tissue and blood, as well as transcriptome data (cardiac tissue only, average depth of coverage: 350x) from four individuals with HLHS to determine if there is a role of somatic mutation in the development of this disorder. We do not find support for the hypothesis that a de novo variant present in cardiac tissue that is not found in blood may be causative for HLHS. Alternatively, we do find several examples of alleles found at low frequency in both blood and cardiac tissue that are suggestive of mutations that occurred during early development. Our study is a proof-of-concept pilot for the identification and analysis of de novo mutations present in one or few tissues in a single individual and forms the foundation of a larger analysis of the role of somatic mutation in congenital heart disease.

Exome Analysis in 36 Unrelated Patients with Pregnancy-Associated or Peripartum Cardiomyopathy Demonstrates a Rare Variant Basis. *A. Morales[1], D.D. Kinnamon[1], D. Wheeler[1], M. Bamshad[2], D. Nickerson[2], R.E. Hershberger[2].* 1) The Ohio State University, Columbus, US; 2) University of Washington Center for Mendelian Genomics, Seattle, WA.

The underlying cause of peripartum cardiomyopathy (PPCM), a subtype of dilated cardiomyopathy (DCM), remains enigmatic with multiple etiologies suggested. PPCM is defined as DCM of unknown cause occurring in the last month of pregnancy or 5 months after delivery. Pregnancy associated cardiomyopathy (PACM) occurs earlier than the last month of pregnancy. To test the hypothesis that PPCM/PACM may have an underlying genetic etiology, we undertook exome sequencing of 37 PPCM/PACM DNA samples in our study (35 from unrelated cases and 2 from the same family). Exome sequencing was conducted at the University of Washington Center for Mendelian Genomics; 19 PPCM/PACM cases had been previously Sanger sequenced for 1-14 candidate genes. GATK (v.1.6) and GEMINI (v0.6.3.2) were used for sequence processing, variant calling and variant prioritization. Missense variants and indels were prioritized based on allele frequency <0.5% (1K Genomes or Exome Variant Server), GERP score >2 or conservation (Phastcons), and segregation among affected relatives with DCM or PPCM. Using a DCM variant adjudication scheme developed by our group, pathogenicity was assigned following ClinVar terminology: pathogenic (P), likely pathogenic (LP), or variant of uncertain significance (VUS). The analysis of variants from 40 previously identified DCM genes is presented here. Of 36 unrelated cases (27 PPCM, 9 PACM), 20 had familial DCM (f-DCM), and 16 had non-familial DCM (nf-DCM). The median age of onset was 26.5 years; 27 presented with heart failure; the mean LVEDD Z-score was 4.9, and the mean ejection fraction was 24%. A total of 43 unique variants were identified in 28 unrelated cases (2 P, 9 LP, 32 VUS). Pathogenic variants were identified in *PSEN2* and *SCN5A*. Likely pathogenic variants were identified in *LMNA, MYBPC3, MYH7, TNNT2*, and *TTN*. LP variants were identified in 2 nf-DCM cases. P/LP variants were identified in 10 f-DCM cases. Multiple variants were identified in 6 nf-DCM cases and 4 f-DCM cases. In 6 previously reported PPCM/PACM cases assayed with Sanger sequencing, no additional variants were found with stronger evidence favoring pathogenicity. We conclude that a proportion of PPCM/PACM, a subtype of DCM, has a rare variant genetic basis. Hence, a genetic evaluation is indicated for women diagnosed with PPCM/PACM, which includes genetic testing, as well as cardiovascular screening and predictive testing of at-risk relatives.

619W

Connective tissue disorders presenting severe arterial tortuosity in the perinatal period. *H. Morisaki[1], M. Horiuchi[2], J. Yoshimatsu[2], T. Yokoyama[3], M. Iwasa[3], Y. Takahashi[4], Y. Kawazu[5], N. Okamoto[5], T. Morisaki[1,6].* 1) Dept of Bioscience and Genetics, National Cerebral and Cardiovascular Ctr (NCVC), Osaka, Japan; 2) Div Perinatology and Gynecology, NCVC, Osaka, Japan; 3) Dept Pediatrics, Japanese Red Cross Nagoya Daini Hospital, Nagoya, Japan; 4) Dept Pediatrics, Chiba Univ. Grad Sch Medicine, Chiba, Japan; 5) Osaka Medical Ctr and Research Inst for Maternal and Child Health, Osaka, Japan; 6) Dept Molecular Pathophysiology, Osaka Univ Grad Sch Pharm Sci.

Arterial tortuosity (AT) is often accompanied with heritable connective tissue disorders (CTD), including arterial tortuosity syndrome caused by *SLC2A10* mutations, autosomal recessive cutis laxa type IB by *FBLN4* mutations, and Loeys-Dietz syndrome (LDS) by *TGFBR1/2* mutations. Diagnosis of these conditions is not easy in early childhood, though it is not difficult to diagnose them in adulthood. We experienced 5 cases with severe AT during prenatal and early infantile period, showing heart or respiratory failure as a main symptom. First case was a 2-year-old boy with compound heterozygous *SLC2A10* mutations, presenting dyspnea due to pulmonary emphysema after RSV infection. MRA showed annulo-aortic ectasia (AAE) and severe AT and elongation of the aorta and medium-sized arteries in both brain and abdomen. Second case was a 3-month-old boy with compound heterozygous *FBLN4* mutations, developing severe aortic regurgitation, dilatation of ascending aorta with isthmal narrowing and poststenotic dilatation, micro-thrombosis in the brain arteries. He underwent a successful surgical replacement of ascending aorta at age 2. Third case was a female fetus with *FBLN4* mutations presenting hydrops fetalis due to dysplastic tricuspid valve with an elongated aorta at 32 weeks gestation. The pregnancy ended in intrauterine death at 33wk. Autopsy revealed severe AT of total aorta with thickened wall and narrow lumen along with kinky aneurysm in subclavian and iliac arteries. The fourth case was a newborn baby with *TGFBR1* mutation, prenatally diagnosed as DORV and interrupted aortic arch with severe pulmonary artery dilatation, highly tortuous aorta and cervical arteries. He had emergency pulmonary banding followed by dilatation of descending aorta but died on 21st day. Fifth case was a 4-month-old girl with *TGFBR2* mutation, diagnosed as LDS with cleft palate, club foot and arachnodactyly. Ultrasound study showed severe AT, AAE and ASD/PDA. Her bronchi were depressed by dilated pulmonary artery. She subsequently died of respiratory failure due to cervical spine dislocation. None of these 5 cases presented any typical CTD features like cutis laxa, chest deformity or joint hypermobility during perinatal period, while AT was a sole symptom towards proper diagnosis. Prognosis was generally poor but early intervention was effective in some cases. It is important to consider CTD in such very young patients with AT.

620T

Whole exome sequencing, blood lipids, and cardiovascular outcomes in 31,000 participants in the Regeneron Genetics Center – Geisinger Health System (DiscovEHR) human genetics collaboration. *C. O'Dushlaine[1], J.B. Leader[2], C. Van Hout[1], S. Mukherjee[1], S.A. Pendergrass[2], D.R. Lavage[2], L. Habegger[1], O. Gottesman[1], A. Lopez[1], C. Gonzaga-Jauregui[1], S. Hamon[1], A. Verma[3], J. Wallace[3], S. Dudek[3], M.D. Ricthie[2], D.J. Carey[2], M.F. Murray[2], D.H. Ledbetter[2], J.D. Overton[1], J.G. Reid[1], A. Baras[1], A.R. Shuldiner[1], H.L. Kirchner[2], F.E. Dewey[1].* 1) Regeneron Genetics Center, Tarrytown, NY; 2) Geisinger Health System, Danville, PA; 3) The Center for Systems Genomics, The Pennsylvania State University, State College, PA.

Low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, and triglyceride levels are heritable risk factors for cardiovascular disease. Sequencing the protein coding regions of the genome (exome) enables discovery of rare mutations that may exert large effects on lipid traits and cardiovascular disease risk.We sequenced the exons of 18,951 protein-coding genes in 31,058 participants of predominantly European ancestry in the Regeneron Genetics Center-Geisinger MyCode-DiscovEHR collaboration. Tests of association were performed for ~350,000 individual variants with minor allele count ≥ 20 and for non-synonymous and putative loss-of-function (LoF) variants aggregated by gene with median lifetime lipid levels extracted from electronic health records (EHR) of 22,400 individuals. Lipid-associated variants and genes were tested for associations with coronary artery disease (CAD) in 8,496 cases and 22,562 controls. Phenotypic associations were expanded with a phenome-wide association study (PheWAS) of ~1,700 discrete disease traits.Analysis of this sample as discovery (n=~12,400) and replication (n=~10,000) strata for lipid levels identified 50 replicated coding variant associations in 32 genes that were also associated with lipid levels in joint analysis at P < 1.4x10-7, including multiple coding variants not previously associated with lipid levels. Gene-based association tests identified collections of rare non-synonymous and LoF variants in 8 genes that were reproducibly associated with lipid levels in staged analysis and also in joint analysis at P<1.3x10-6. In addition to known coding variant associations, these results implicated novel protein-disrupting mutations in 4 known lipid loci (*ABCA1, LCAT, SCARB1, LIPC*). Two novel lipid-associated variants were associated with CAD risk at P < 0.05. Multivariate testing for lipid traits identified additional coding variants with evidence for substantial effects on all multiple traits. PheWAS of these loci revealed multiple additional known and previously undiscovered disease associations.Using whole-exome sequencing in over 31,000 individuals with EHR-derived clinical phenotypes, we confirmed previous coding variant associations with lipid levels, and identified new associations between collections of rare, protein-disrupting mutations, lipid levels, and coronary artery disease. These results implicate rare protein-disrupting variation in the genetic architecture of lipid traits and CAD.

621F

Identification of Novel Risk Genes for Venous Thromboembolism using Rare Coding Variant Burden Analysis in the GIFT and ELATE/DODS Cohorts. *A. Ozel[1], K. Desch[2], M. Germain[4], C. Willer[1], D. Siemeniak[3], D. Tregouet[4], P. Reitsma[5], D. Ginsburg[1,3], J. Li[1].* 1) Department of Human Genetics, University of Michigan - Ann Arbor, Ann Arbor, MI; 2) Department of Pediatrics, University of Michigan - Ann Arbor, Ann Arbor, MI; 3) HHMI, University of Michigan - Ann Arbor, Ann Arbor, MI; 4) INSERM, Università Pierre et Marie Curie, Paris, France; 5) Leiden University Medical Center, Leiden, Netherlands.

Venous thromboembolism (VTE) affects ~1 million individuals in the United States and is the third most common cause of cardiovascular death. It is a highly heritable disease with ~60% of the lifetime risk attributable to genetic factors. While genome-wide association studies (GWAS) validated the involvement of common variants in the*Factor 5*(*F5*) and*ABO*genes, which account for 30% of the overall attributable risk for VTE, they are not suited to discover rare causal variants. The unique biology of VTE and the complex interactions between the hemostatic and host defense systems lead us to hypothesize that a limited number of rare, high-impact coding variants might help explain the remaining portion of the inherited risk. In this study, we compared the per-gene aggregate rare variant burden between 392 VTE patients from the GIFT, ELATE/DODS cohorts and 342 non-VTE subjects of the same ancestry (European). After joint calling of coding and splicing variants using exome sequencing data of these samples, we conducted case/control gene burden tests while accounting for the technical heterogeneity between the controls and cases by using the each gene's synonymous variant count as the background variant discovery rate. We used multiple annotations to define deleterious variants: (1) PolyPhen2, (2) CADD >= 10, (3) CADD >= 20, (4) CONDEL, (5) PhyloPNH, and performed the burden analysis at several minor allele frequency (MAF) thresholds: 0.01, 0.05, 0.10, 0.15 and 0.50. We analyzed all genes as well as 95 candidate genes that were implicated in VTE according to prior literature. As a positive control, we confirmed the known association of the Factor 5 Leiden (R506Q) mutation with VTE (p=8.7E-19, odds ratio=8.7; 95 % CI: 4.8 – 16.8). Among the 95 candidate genes, rare variants (MAF <= 5%) in *F5*, *SERPINA1*, *GP1BA* and *HNF4A*had significantly higher burden (p<0.00053) in VTE cases with a majority of the deleterious variant definitions. Among all 20,000 genes, rare variant burden in*F5*, *SELP*, *VWF* and *GP1BA* rank among the top 3% with at least two of the definitions. Our results suggest the aggregate contribution of rare variants in both known and unknown genes to the overall VTE risk. Additional analyses are underway to use publicly available exome control data to replicate these findings.

Aortic structural integrity is dependent on the activity of lysyl oxidases, which are extracellular copper enzymes that catalyze crosslinking of elastin and collagens. Mammals have five lysyl oxidase genes with highly similar catalytic domains, including the prototypic *LOX*. Deletion of *Lox* in mice leads to loss of 80% of lysyl oxidase activity in the aorta, and the mice die shortly after birth of aortic rupture. Exome sequencing was performed using DNA from two affected individuals from family TAA602 with autosomal dominant inheritance of thoracic aortic aneurysm and dissection. Using previously described filtering strategies, the possible causative variants were narrowed to 10 candidates. A variant in *LOX* was the best candidate for causing disease in TAA602 because of the established role of lysyl oxidase in aortic integrity. The variant, p.Ser280Arg, disrupts a highly conserved residue within the catalytic domain of the enzyme, is predicted to be damaging by 5 of 7 functional predictors, and segregates with aortic disease in the family. Exome and Sanger sequencing of 395 unrelated probands with familial thoracic aortic disease identified three additional rare *LOX* variants that were predicted to be damaging (p.Gly202X, p.Thr248Ile, p.Ser348Arg); one leads to haploinsufficiency and two are located in the catalytic domain and predicted to be damaging. Notably, the ESP database had no *LOX* nonsense or indel variants and only one rare variant in the catalytic domain in the European Americans. To determine if these variants in the catalytic domain disrupt enzymatic activity, expression plasmids of *LOX* wildtype (WT) and the missense variants were constructed and transfected into Hela cells and lysyl oxidase activity assayed. Based on equal protein amounts assayed, Hela cells transfected with p.Ser280Arg, p.Ser348Arg, and p.Thr248Ile mutant LOX constructs showed increased lysyl oxidase activities that were significantly lower compared to the WT LOX plasmid transfected cells by 58% (p=.002), 33% (p=.003), and 10% (p=0.003), respectively. The clinical disease in all families is characterized by fusiform aneurysms involving the root and ascending aorta and ascending aortic dissections and bicuspid aortic valves in 28% of mutation carriers. In conclusion, loss-of-function *LOX* mutations are a rare cause of familial thoracic aortic aneurysms.

623T

Clinically relevant variants identfied in thoracic aortic aneurysm patients by research exome sequencing. *J.A. Schubert[1,2], B.J. Landis[3], A.R. Shikany[3], R.B. Hinton[3], S.M. Ware[1,2].* 1) Indiana University School of Medicine, Indianapolis, IN; 2) University of Cincinnati College of Medicine, Cincinnati, OH; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Thoracic aortic aneurysm (TAA) is a genetically heterogeneous disease involving subclinical and progressive dilation of the thoracic aorta, which can lead to life-threatening complications such as dissection or rupture. Genetic testing is important for risk stratification and identification of at risk family members, and clinically available genetic testing panels have been expanding rapidly. However, when past testing results are normal, there is little evidence to guide decision making about when and in whom to pursue additional clinical genetic testing. Results from research based genetic testing can help inform this process. Here we present 10 TAA patients who have a family history of disease and who enrolled in research-based exome testing. Nine of these ten patients had previous clinical genetic testing, all of which was negative. We sought to determine the number of rare variants in 23 known TAA associated genes identified by research-based exome testing. In total, we found 13 rare variants in 7 patients, with no rare variants in these 23 genes in 3 patients. Likely pathogenic variants included one patient with a *TGFB2* variant and another with a *SMAD3* variant. These variants have been reported previously in individuals with similar phenotypes. In addition, novel variants in both *MYLK* and *MFAP5* were identified in a third patient. In total, clinically reportable rare variants were found in 5/10 (50%) patients, with at least 2/10 patients having likely pathogenic variants identified. These results highlight the importance of re-testing TAA patients with previous negative or inconclusive testing on a broader scale, as the field rapidly expands.

624F

Association of a single nucleotide polymorphism variant in the *SCUBE1* gene with Coronary Artery Calcium score in the *ClinSeq*® Study. *H. Sung[1], B. Suktitipat[1], K. Lewis[2], D. Ng[2], SG. Gonsalves[2], JC. Mullikin[3,4], LG. Biesecker[2], AF. Wilson[1], NISC Comparative Sequencing Program.* 1) Genometric Section, NIH/NHGRI/CSGB, Baltimore, MD; 2) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 4) National Institutes of Health Intramural Sequencing Center (NISC), National Human Genome Research Branch, NIH, Bethesda, MD.

ClinSeq® is a large-scale medical sequencing study designed to investigate associations of rare sequence variants with traits related to Coronary Artery Disease (CAD). The study currently includes more than 1000 non-smoking participants between the ages of 45 and 65 with normal to severe coronary artery calcification scores. About 200 traits related to CAD were measured at the NIH Clinical Research Center in Bethesda, MD. Exome sequencing was performed with the Agilent SureSelect 38Mb and 50Mb capture kits for 387 and 325 individuals, respectively, at the NIH Intramural Sequencing Center. Single nucleotide variants (SNVs) common to both capture regions having a call rate > 98% and minor allele frequency (MAF) > 1% were used to check for cryptic relatedness and for population stratification by multidimensional scaling analysis. After removing samples failing this screening, 635 unrelated European Americans (EAs) remained. For each capture kit with EAs only, SNVs without at least one homozygote or a call rate less than 50% were excluded. Then samples sequenced with the two capture kits were merged, leaving 439,807 shared SNVs. Of these SNVs, 74% and 46% had MAFs < 0.01 and < 0.001, respectively. SNVs with MAF < 0.01 were collapsed into a single derived variant for each genomic region defined using hotspot boundaries. Collapsed variants were coded as the proportion of minor alleles occurring within each region; common variants were coded as the proportion of minor alleles (scaled from 0 to 1). Tests of association of each variant with Coronary Artery Calcium (CAC) score (available in 550 samples, excluding samples with stents), were performed on log-transformed CAC with simple linear regression, adjusting for age, sex, BMI and cholesterol lowering medication use. The derived collapsed variant incorporating rs73420094 (MAF=0.0056) in the exon and rs193288922 (MAF=0.0018) in the intron of the *SCUBE1* gene was found to have a suggestive significant association at the level of 1e-05. All seven samples having a non-reference allele (A) of rs73420094 have a CAC score within the top 14% of the distribution. The next most significant variant, rs3751058 in the *SCUBE2* gene, was found to have an association at the 1e-04 level. Inhibition of *SCUBE1* was found by Wu et al. to protect against thrombosis in mice and *SCUBE2* is found by Ali et al. to be involved in atherosclerotic plaque progression via Hedgehog signal transduction.

625W

Arterial Tourtosity in two Turkish pediatric patient; with novel homozygous missence mutations in the SLC2A10 gene. *F. Uysal[1], S.G Temel[2,3], O.M Bostan[1], D. Proost[4], L.V Laer[4], B. Loeys[4], E. Cil[1].* 1) Uludag University, Faculty of Medicine, Department of Pediatric Cardiology, Bursa, Turkey; 2) Near East University, Faculty of Medicine, Department of Histology & Embryology, Nicosia, North Cyprus; 3) Uludag University, Faculty of Medicine, Department of Histology & Embryology, Bursa, Turkey; 4) Center for Medical Genetics, Antwerp University Hospital and University of Antwerp, Antwerp, Belgium.

Arterial tortuosity syndrome (ATS) is a rare autosomal recessive connective tissue disorder, mainly characterized by tortuosity and elongation of the large and medium-sized arteries with predisposition to stenosis and aneurysm. ATS is caused by mutations in the *SLC2A10* gene, encoding for the facilitative glucose transporter 10 (GLUT10) and is described typically in pediatric patients. We report two unrelated boys (2 and 1 year old) with ATS who initially presented with a cardiac murmur and respiratory distress, respectively. In the first proband echocardiography at the age of one month demonstrated dilatation of the aortic root (15mm, Z-score=) and tortousity in the descending aorta. The main clinical findings included elongated face, saggy cheeks, micrognathia, malar hypoplasia, joint hypermobility and hyperextensible skin. Follow-up echocardiography showed an increase of the diameter of the aortic root to 32mm and 35 mm at the age of 8 months and 2 years old, respectively. Angiography and computerized tomography angiography showed fusiform aneurysmal dilatation of ascending aorta, marked tortuosity of both pulmonary arteries and thoracic aorta, stenosis in vena cava inferior. For the second proband, echocardiography at the age of one week dilatation in ascending aorta and anomaly suspicion in pumonary artery (pumonary sling). He had an ileus and operated at the age of one month. The main clinical findings included elongated face, saggy cheeks, migrognathia, pectus excavatum and hyperextensible skin. Anjography showed dilatation in ascending aorta, tortuosity of arch branching arteries and 'S' like tortuosity in descending aorta and normal pulmonary arteries. Sequencing of the *SLC2A10* gene in the probands revealed the presence of two novel pathogenic homozygous missense variants (c.727C>A/c.395C>A). Heterozygous *SLC2A10* mutations were confirmed in both mothers and fathers. The pathogenic variants lead to a p.Gln243Lys and p.Arg132Gln change in the seventh transmembrane domain and endofacial loop of GLUT10, respectively. The first proband underwent aortic root replacement surgery. ATS resembles Loeys-Dietz and Marfan related disorders, so timely differential diagnosis is extremely important for early diagnosis and intervention of aneurysms to prevent serious vascular complications.

Towbin[17].* 1) Pediatrics, Indiana University, Indianapolis, IN; 2) Pediatrics, Wayne State University, Detroit, MI; 3) Pediatrics, Harvard Medical School, Boston, MA; 4) Biostatistics, New England Research Institutes, Watertown, MA; 5) Pediatrics, Washington University, St. Louis, MO; 6) Pediatrics, Children's Hospital at Montefiore, Bronx, NY; 7) Pediatrics, Vanderbilt Heart & Vascular Institute, Nashville, TN; 8) Pediatrics, Denver Children's Hospital, Denver, CO; 9) Pediatrics, Stollery Children's Hospital, Edmonton, AB, Canada; 10) Pediatrics, New York-Presbyterian Morgan Stanley Children's Hospital, New York, NY; 11) Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 12) Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA; 13) Pediatrics, Northwestern University, Chicago, IL; 14) Pediatrics, University of Miami Hospital, Miami, FL; 15) University of Cincinnati College of Medicine, Cincinnati, OH; 16) Pediatrics, Columbia University, New York, NY; 17) Cardiology, Le Bonheur Children's Hospital, Memphis, TN.

Consensus guidelines recommend genetic testing in children and adults for hypertrophic cardiomyopathy (HCM), and consideration of testing for dilated or restrictive cardiomyopathy (DCM, RCM). Cardiac surveillance is recommended in first degree relatives, and genetic testing for a known familial mutation (KFM) is indicated. Despite these recommendations, payer reimbursement rules, family choice, and practice barriers to testing and screening exist, and uptake in the pediatric population, where the disease is rare and causes are heterogeneous, is unclear. We evaluated genetic testing practices for 154 consecutively enrolled pediatric patients with cardiomyopathy at 11 sites as part of a large, prospective NHLBI-funded study. Inclusion criteria included patients with familial or idiopathic disease or unconfirmed myocarditis. Patients with known genetic syndromes, inborn errors of metabolism, mitochondrial disease, or neuromuscular disease were excluded. A pedigree was obtained, and clinical genetic testing reports were collected if applicable. All patients provided blood samples for research-based exome sequencing. In this preliminary sample of the target cohort, 48% (n=74) had previous clinical genetic testing, with 25% (n=41) of the cohort having a likely pathogenic or pathogenic variant. At enrollment, 38% had a family history of cardiomyopathy. The rate of clinical testing by phenotype was 72% for HCM, 36% for RCM, 45% for DCM, and 7% for LVNC/unknown. All variants reported by clinical genetic testing were also identified by research-based exome. Filtering exome results for 35 genes available on clinical cardiomyopathy panels revealed 49 additional clinically actionable results, 38 of which were in previously untested patients. Overall, 79/154 patients had positive findings (51%), including 75% with HCM, 71% with RCM, and 35% with DCM. Importantly, the 38 patients with newly identified genetic disease had 148 first degree relatives for whom KFM testing can now be offered, allowing risk stratification and further cascade screening. This is the first multisite evaluation of clinical genetic testing practices in the pediatric cardiomyopathy population. The results demonstrate testing is currently underutilized, show a high diagnostic yield across phenotypes, and indicate an opportunity to significantly impact cascade screening and risk stratification for family members.

627F

Identification of Second-hit Mutations in Known CHDs Causative genes in 22q11DS Patients with Conotruncal Heart Defects by Whole-exome Sequencing. *T. Guo[1], JH. Chung[1], D. McDonald-McGinn[2], WR. Kates[3], T. Wang[4], B. Emanuel[2,5], B. Morrow[1].* 1) Department of Genetics, Albert Einstein College of Medicine, Bronx, NY; 2) 2Division of Human Genetics, Children's Hospital of Philadelphia and Department of Pediatrics, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania; 3) 3Department of Psychiatry and Behavioral Sciences, and Program in Neuroscience, SUNY Upstate Medical University, Syracuse, New York; 4) Department of Epidemiology and Population Health, Albert Einstein College of Medicine, Bronx, New York; 5) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

The 22q11.2 deletion syndrome (22q11DS, velo-cardio-facial/DiGeorge) is the most common microdeletion disorder, occurring in 1:4,000 births. Most of the patients have a similar deletion on chromosome 22q11.2, but approximately 60% have congenital heart defects (CHD), mostly of the conotruncal type, while 40% have normal cardiac anatomy. We hypothesize that 22q11DS patients with CHD have second-hit mutations in known CHD genes reported in the literature. To test this, whole exome sequencing was performed on DNA samples from 184, 22q11DS subjects including 89 cases with CHD and 95 controls without. Rare variants (MAF < 0.001 in 1000 Genome and ESP6500 projects) that are predicted to be damaging in any of the 5 specific predictions (SIFT, Polyphen2 HVAR, MutationTaster, MutationAssessor, FATHMM and scaled CADD) were retained for analysis. We compiled 66 pathogenic, CHD-causing CNVs (copy-number variations) from the Copy Number Variation in Disease database (PMID: 22826268). These 66 CHD-causing CNVs encompass 782 genes which we tested for rare deleterious variants. A total of 259 genes had at least one deleterious mutation in either a case or control with 22q11DS. Among the 259 genes, we identified 6 cases (5 with tetralogy of Fallot (TOF); 1 with aortic arch artery anomalies) with deleterious heterozygous mutations in the *FRY* (FURRY) gene, but none in controls (Fisher extract p value=0.01). *FRY* is located on chromosome 13q13.1-q13.2, which is the CHD critical region of the 13q deletion syndrome (also called monosomy 13q syndrome). Among 35 reported patients with chromosomal deletions of 13q13.1-q13.2, 8/11 cases were reported to have conotruncal heart defects (PMID: 20598760). Furry (Fry) is an evolutionarily conserved protein of ~300 kDa that contains multiple HEAT/Armadillo-like repeats in the N-terminal region. Mammalian Fry plays crucial roles in chromosome alignment and bipolar spindle organization during mitosis, critical for asymmetric cell division, regulation of cell shape and early embryonic development, implicating it as a strong candidate gene within the region to explain the basis of CHD in patients with chromosome 13q13.1-q13.2 deletions and as a modifier of this phenotype in 22q11DS.

Sequence Data Processing and Analysis of the first 20,000 Human Genomesin the NHLBI TopMed Program. *G.R. Abecasis[1], D. Applebaum-Bowden[2], K. Barnes[3], T. Blackwell[1], J. Blangero[4], E. Burchard[5], A. Correa[6], P. Ellinor[7], C. Fox[2], S. Gabriel[7], W. Gan[2], C. Jaquish[2], H.M. Kang[1], S. Kathiresan[7], C. Laurie[8], S. McGarvey[9], B. Mitchell[10], D. Nickerson[8], J. O'Connell[10], G. Papanicolau[2], P. Qasba[2], R.S. Vasan[11], S. Redline[12], K. Rice[8], E. Silverman[13], J.D. Smith[8], P. Srinivas[2], S. Weiss[14], J. Wilson[6] for the National Heart Lung and Blood Institute's TopMed Program.* 1) University of Michigan, Ann Arbor, MI; 2) National Heart Lung and Blood Institute, Bethesda, MD; 3) Johns Hopkins University, Baltimore, MD; 4) University of Texas Rio Grande Valley, Rio Grande, TX; 5) University of California San Francisco, San Francisco, CA; 6) University of Mississippi Medical Center, Jackson, MS; 7) Broad Institute of Harvard and MIT, Cambridge, MA; 8) University of Washington, Seattle, WA; 9) Brown University, Providence, RI; 10) University of Maryland, Baltimore, MD; 11) Boston University School of Medicine, Framingham, MA; 12) Harvard Medical School, Boston, MA; 13) Brigham and Women's Hospital, Boston, MA; 14) Partners Health Care, Boston, MA.

The National Heart Lung and Blood Institute's Trans-Omics for Precision Medicine (TopMed) initiative aims to stimulate discovery of the fundamental mechanisms that underlie heart, lung, blood and sleep disorders by integrating high quality phenotypes, whole genome sequence data and other genomic information. The first phase of the effort will generate deep whole genome data for ~20,000 diverse samples (a majority with non-European ancestries traditionally under-represented in genomic research) and represents a collaboration between diverse groups of scientists, 4 genome sequencing centers, a project data coordination center, an informatics research center, staff at the National Institutes of Health and the National Center for Biotechnology Information (NCBI). Future phases of the program will include additional cohorts, genome sequencing and other omics data.Here, we describe efforts at the project's Informatics Research Center (IRC)to integrate sequence data across participating studies and sequencing centers and their initial results. As of abstract submission, >19,800 samples are prioritized for sequencing, with data for >1,000 samples received at the IRC. Sequencing is expected to be complete by February 2016; sequence data for >5,000 samples is expected by October 2015. To date, we have achieved an average sequencing depth of 36.9 (after duplicate removal), resulting in >98% of the genome covered at depth ≥10. We have evaluated alternatives for transfer and storage of sequence data, including file formats, quantization of base quality scores and others, to achieve reasonable costs for data processing and to allow the project to scale to even more samples. Deep sequencing, PCR-free sample preparation, and harmonized data processing already allow us to achieve <0.2% difference in SNP callsets when a sample is sequenced at different sites. Although more differences are observed for indels, these are concentrated in low complexity regions of sequence, such as short tandem repeats.A primary goal of the project is to allow investigators exploring diverse study designs and phenotypes to benefit from access to high-quality sequence data and analysis. There are also many opportunities from combined analysis of the data being generated, including a diverse catalog of genetic variation, a resource of controls for association studies, and an imputation reference panel. We discuss some of these opportunities and associated logistical and technical challenges.

629T

Identifying low frequency and rare coding variation influencing cardiometabolic traits through whole exome sequencing of 20,000 Finns: the FinMetSeq Study. *A.E. Locke[1], K. Meltz Steinberg[2], S. Service[3], V. Ramensky[3], M. Pirinen[4], H.M. Stringham[1], A.U. Jackson[1], M. Kurki[5], D.E. Larson[2], L.J. Scott[1], R.S. Fulton[2], D.C. Koboldt[2], J. Nelson[2], T.J. Nicholas[2], S. Ripatti[4,6,7], V. Salomaa[8], A. Palotie[4,5,7], M. Laakso[9], N. Freimer[3], R.K. Wilson[2], M. Boehnke[1].* 1) Center for Statistical Genetics and Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) McDonnell Genome Institute, Washington University School of Medicine, St. Louis, MO; 3) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 5) Broad Institute of MIT and Harvard, Cambridge, MA; 6) Department of Public Health, Hjelt Institute, University of Helsinki, Helsinki, Finland; 7) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 8) National Institute for Health and Welfare, Helsinki, Finland; 9) Department of Medicine, Kuopio University Hospital and University of Eastern Finland, Kuopio, Finland.

Due to recent population bottlenecks, low frequency, deleterious variants are enriched in the Finnish population. The resulting increase in power and the large population studies ongoing in Finland provide an excellent resource for complex trait genetics.We are sequencing the exomes of 20,000 individuals from two large population-based longitudinal studies of metabolic and cardiovascular disease in Finland: METSIM and FINRISK. Currently, we have completed sequencing for the first 10,628 individuals. Using an integrated variant discovery and genotyping approach across three sites -- McDonnell Genome Institute, University of Michigan, and UCLA -- we identified more variable sites (>1.5M SNPs) and achieved greater overall genotype accuracy than any single sequence analysis pipeline.We performed single-variant and gene-based association tests using EMMAX for >30 cardiometabolic phenotypes, identifying 46 apparently independent associations at exome-wide significance ($p<5x10-7$) at 26 loci in 9 different traits. While most observed associations, known and novel, were common, seven index SNPs had a minor allele frequency (MAF) <5%, and four <1%. We replicated low frequency non-synonymous variants in *PCSK9* (rs11591147) associated with decreased levels of total and LDL cholesterol and ApoB levels, in *HNF4A* (rs1800961) associated with lower HDL cholesterol, and a non-synonymous variant in *LPA* (rs3798220) with MAF~1% associated with total cholesterol. All of these variants are equally or more frequent in our cohorts than in other European populations.Finally, we identified a non-synonymous variant with MAF<0.5% in *LCAT* associated with significantly lower HDL cholesterol, which is known to convert cholesterol and phosphatidylcholines to cholesterol esters on HDL particles. Mutations in *LCAT* are also known to cause Fish-eye and Norum diseases, both of which are characterized by significantly altered lipid profiles and corneal opacity. This particular variant has not been implicated in either Fish-eye or Norum disease, so we plan to re-contact carriers to identify vision problems and more fully examine their lipid profiles.The population history of the Finnish people, the diverse array of phenotypes, and the large-scale but focused nature of this exome sequencing study allow us a unique opportunity to identify coding variation influencing cardiometabolic traits, and we plan to follow up candidate variants by collecting additional phenotypes.

630F

POSSIBLE PATHOLOGICAL EVENTS INVOLVED IN DILATED CARDIOMYOPATHY. *M.L. Satyanarayana[1], C. Narsimhan[2], N. Pratibha[1].* 1) Department of Genetics, Osmania University, Hyderabad, Telangana State, India; 2) CARE Hospitals, Hyderabad, Telangana State, India.

Dilated cardiomyopathy (DCM) is characterized by ventricular chamber dilation and diminished cardiac contractility, the most common cause of chronic heart failure (CHF) and cardiac transplantation. The underlying etiology of DCM varies due to genetic factors, viral (myocarditis), mitochondrial, and metabolic disorders. To date, candidate gene screening led to the identification of numerous heterozygous mutations in more than 40 different genes. The present study is an attempt to elucidate the interactions between the sarcomeric/cytoskeletal and the modifier gene(s), by screening *MYH7, MYBPC3, ANKRD1, EDN1, NOS3, IL-1B, TNF-A, HSP-70* gene variations, in order to understand the underlying pathogenesis of DCM, accounting to the phenotypic and genetic heterogeneity.The *MYH7 (G377R, E1258D)* mutations were predicted to disrupt actin-myosin binding and cross-bridge function, as localized to the LMM region. *MYBPC3 (V158M)* mutations resulted in the disruption of the sarcomeric assembly, posttranslational modifications which can cause alterations in myosin crossbridge architecture leading to **'defective force production'**. The novel protein truncation *(E583X)* mutation of *MYBPC3* produces a truncated protein **lacking titin and myosin binding sites.** *MYH7* mutations *(E1258D, A1379T and K1537N)* disrupting the sarcomere assembly with cytoskeletal protein network resulting in **reduction of force transmission**. Further, *ANKRD1 (D304H)* mutation resulted in the loss of one of the ankyrin repeats, hence altering the sarcomere interaction with cytoskeletal proteins **titin** and **myopalladin**, leading to reduced force transmission.*Injury to the myocardial cell* may results in the release of cytokines *(IL-1Δ,TNF-α)*, which can be detrimental to cardiac function, leading to overt congestive heart failure in a DCM phenotype. *Oxidative stress* and *heightened peripheral vasoconstriction* are other key features, wherein *NOS3* and/or *EDN1* gene variations can cause abnormal and excessive remodeling of the peripheral vasculature by imposing pressure on the ventricles. *Apoptosis* is believed to play an important role in the continuous loss of myocardial cells during chronic heart failure. Hence compensatory mechanisms like anti-apoptotic pathway can also be triggered, wherein *HSP70* plays a key role.Thus, suggesting the implication of sarcomeric/cytoskeletal gene mutations with epistatic interactions of modifier genes, accounting to complexity and multifactorial mode of inheritance of DCM.

631W

Effects of rare coding variants at *NOS1AP* and other genes encoding intercalated disc proteins on the electrocardiographic QT interval. *A. Kapoor[1], K. Bakshy[1], L. Xu[1], P. Nandakumar[1], D. Lee[1], E. Boerwinkle[2], M.L. Grove[2], D.E. Arking[1], A. Chakravarti[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, 21205, USA; 2) Division of Epidemiology, Human Genetics and Environmental Sciences, University of Texas Health Science Center, Houston, Texas, 77030, USA.

We have previously shown that *NOS1AP* (MIM 605551), the major genetic regulator of the QT interval (MIM 610141) explaining ~1% of its variation, is localized to cardiomyocyte intercalated discs (ID) in the human heart and that its overexpression in cardiomyocytes leads to altered cellular electrophysiology. We also showed that noncoding sequence variants mapping in and around (±10kb) 175 genes encoding ID proteins are enriched for associations greater than that observed for genome-wide comparisons. Specifically, at false discovery rate (FDR) of 5% we identified 27 ID genes at which noncoding variants were significantly associated with QT interval. Thus, we sought to assess whether coding variants at these 28 ID genes, including *NOS1AP*, affect QT interval variation. We used data on exome sequencing in 4,469 ARIC cohort individuals of European ancestry to focus on 2,393 rare (MAF <0.01) missense, splice-site and stop-gain variants and tested their effect on standardized QT interval residuals corrected for heart-rate, age, sex and genotypes of 34 known common QT interval GWAS hits. Single variant association tests performed using PLINK identified 6 missense variants (3 in *TTN* (MIM 188840) and 1 each in *ANKRD30A* (MIM 610856), *LRFN2* (MIM 612808) and *SIPA1L1* (MIM 610484)) at FDR of 5%: all were observed as singletons and thus need testing in larger sample sizes for replication. Gene-based burden tests performed using seqMeta identified 3 marginally significant genes: *CAV2* (MIM 601048) (P=0.038), *LRFN2* (P=0.046) and *TLN1* (MIM 186745) (P=0.025). *TTN* encodes for titin that is a large and abundant protein of striated muscle and plays a key role in its assembly and functioning. Rare coding mutations in *TTN* are known to be associated with cardiomyopathies. *CAV2* encodes caveolin-2 that is a caveolin family member and related to *CAV1* and *CAV3*. Caveolin proteins have been proposed to act as scaffolding proteins within caveolar membranes and the 3 caveolins are known to interact in cardiac tissue. Rare coding mutations in *CAV3* are known to be associated with long QT syndrome and cardiomyopathies. *SIPA1L1* encodes a Rap GTPase activating protein that plays a role in non-canonical Wnt signaling and development. Common variants at *SIPA1L1* locus are known to be associated with QRS interval duration. In summary, using a functionally enriched gene set we have identified association of QT interval with 6 potential candidates that need to be replicated using larger sample sizes.

632T

Rare Exome Sequence Variants in *CLCN6* Reduce Blood Pressure Levels and Hypertension Risk. *B. Yu[1], S.L. Pulit[2,3], C. Newton-Cheh[3,4], A.C. Morrison[1] on behalf of the CHARGE Blood Pressure Working Group and NHLBI Exome Sequence Project.* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX, USA; 2) Department of Medical Genetics, University Medical Centre Utrecht, The Netherlands; 3) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 4) Cardiovascular Research Center and Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, USA.

Genetic effects of rare variants on blood pressure (BP) are not yet well characterized. We performed whole exome sequencing on DNA samples from 9,950 and 4,547 individuals of European and African ancestry to examine the impact of rare variants on hypertension and four BP traits: systolic and diastolic BP (SBP, DBP), pulse pressure (PP), and mean arterial pressure (MAP). Single variant tests of common variants (minor allele frequency, MAF, ≥1%, conducted in ~170,000 common variants, statistical significance $P \leq 2.9 \times 10\text{-}7$) and gene-based tests of rare variants (MAF<1%, conducted in ~17,000 genes, statistical significance $P \leq 2.9 \times 10\text{-}6$) were evaluated for each trait and ancestry separately, followed by multiethnic meta-analyses. Rare coding variants (defined as splicing, stop-gain, stop-loss, nonsynonymous variants, or indels) in *CLCN6* were associated with lower DBP (cumulative MAF = 1.3%, b = -3.20, $P = 4.1 \times 10\text{-}6$), and the effect was consistent in both ancestries. These effects persisted after conditioning on a nearby common variant (rs17367504), known to be associated with BP. The variants in *CLCN6* were also associated with lower SBP (b = -4.11, $P = 2.8 \times 10\text{-}4$), MAP (b = -3.50, $P = 8.9 \times 10\text{-}6$), and reduced risk of hypertension (odds ratio = 0.72, P = 0.017). The association with DBP was corroborated by two independent samples of European ancestry. By meta-analyzing the two-stage discovery samples, *CLCN6* was shown to be associated with lower DBP at exome-wide significance (cumulative MAF = 1.1%, b = -3.30, $P = 5.0 \times 10\text{-}7$). Our findings implicate the effect of rare coding variants in *CLCN6* in BP variation, and by highlighting a single gene at a prior known locus offer new insights into BP regulation.

633F

First evidence of association between MTHFR C677T polymorphism and Rheumatic Mitral Value Disease. *S. Justin Carlus[1], Khalid. Al Harbi[2], Ghadeer. Saleh Mossad AlHarbi[3], Atiyeh. Abdallah[3].* 1) King Faisal Specialist Hospital & Research Center, Jeddah, Saudi Arabia; 2) Pediatric Cardiology, College of Medicine, Taibah University, Madina, Saudi Arabia; 3) Centre for Genetics and Inherited Diseases (CGID), Taibah University, Madina, Saudi Arabia.

Background: Rheumatic heart disease (RHD) is a serious complication of rheumatic fever (RF). *Plasma homocysteine (Hcy) levels are* increased in RHD patients. MTHFR catalyzes the irreversible conversion of 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate and plays a vital role in Hcy metabolism.However, the role of *MTHFR* polymorphisms in RHD has not been evaluated to date.*We therefore* conducted a case-control study to test the hypothesis that *MTHFR* C677T polymorphisms are associated with the risk of developing RHD.**Methods:** Eighty-six patients with RHD and 130 matched controls without a history of RHD were eligible for study. The diagnosis of RHD was made according to modified Jones' criteria and echocardiography. Using echocardiography, RHD patients were further divided into mitral valve lesion (MVL) and combined valve lesion (CVL) groups. *MTHFR* C677T polymorphisms were genotyped by DNA sequencing. The chi-squared test was used to evaluate differences in genotypes.**Results:** Control genotypes were in Hardy-Weinberg equilibrium. The C677T homozygous genotype (OR=4.09; 95% CIs 1.16-14.44; *P*=0.020) and recessive model (TT vs. CC+CT; OR=4.05; 95% CIs 1.17-14.04; *P*=0.019) were significantly associated with MVL RHD.**Conclusions:** This is the first study to investigate the association between the *MTHFR* C677T polymorphism and risk of RHD. The *MTHFR*C677Tpolymorphism is associated with RHD in patients with MVLs, perhaps via an Hcy-mediated cytokine effect.

634W

A phenome-wide scan to detect pleiotropic effects of the loss of function R46L variant in *PCSK9*. *M.S. Safarova[1], E.E. Austin[1], M. de Andrade[2], B.J. Coombes[2], T.G. Lesnick[2], M.S. Williams[3], M.D. Ritchie[4], K.M. Borthwick[5], S.J. Hebbring[6], E.B. Larson[7], A. Scrol[7], G.P. Jarvik[8,9], J.C. Denny[10], D.J. Schaid[2], I.J. Kullo[1], the electronic MEdical Records and GEnomics (eMERGE) Network.* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 3) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 4) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA; 5) The Henry Hood Center for Health Research, Geisinger Health System, Danville, PA; 6) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 7) Group Health Research Institute, Center for Health Studies, Seattle, WA; 8) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 9) Department of Genome Sciences, University of Washington, Seattle, WA; 10) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN.

Objectives. Proprotein convertase subtilisin/kexin type 9 (PCSK9) plays a key role in regulating plasma low-density lipoprotein cholesterol (LDL-C) levels. Since drugs targeting PCSK9 are expected to be in clinical use in the near future, we undertook an agnostic scan of the phenome to identify pleiotropic effects of a *PCSK9* variant (R46L) known to be associated with lower LDL-C levels.**Methods.** We performed a phenome-wide association study (PheWAS) of the missense mutation R46L (rs11591147) in *PCSK9* with 1802 binary clinical phenotypes in 45,654 individuals (44.5% males) from the electronic MEdical Records and GEnomics (eMERGE) Network. A comprehensive range of phenotypes available in the electronic health record (EHR) was mapped using a hierarchical ICD-9 code-based PheWAS software (R statistical package PheWAS). A control set for each phenotype was constructed by selecting all patients that did not have the phenotype or closely related phenotypes. After standard quality control steps, R46L was imputed using IMPUTE2. Logistic regression with adjustment for age, sex, and race was used to test for associations between R46L and individual phenotypes. Bonferroni correction was applied to account for the testing of multiple phenotypes.**Results**. The study cohort included European Americans (34,960; 76.6%), African Americans (7731; 16.9%), Asian/Pacific Islanders (252; 0.6%), and individuals with unknown ethnicity (2711, 5.9%). The imputation accuracy score (INFO) for R46L was 0.73 and the overall frequency of this variant was 0.64%. In PheWAS analyses, we replicated the association of this variant with hypercholesterolemia (odds ratio (OR) 0.56; p=8.6x10-6). Additionally R46L was associated with osteoporosis (OR 1.78; p=1.3x10-5) and acute bronchitis/bronchiolitis (OR 2.63; p=1.2x10-5).**Conclusion**. In an EHR-based study, PheWAS analysis found evidence of pleiotropy for the *PCSK9* R46L variant. In addition to replicating the known association with lipid traits, we discovered novel associations of R46L with skeletal and pulmonary traits. Further validation of these findings as well as *PCSK9*-wide level analyses are underway.

635T

Leveraging the uniqueness of family studies in the search for coding variants for Blood pressure: An exome array study in African American cohorts. *X. Zhu[1], H. Wang[1], P. Nandakumar[2], F. Tekola-Ayele[3], B. Tayo[4], E. Ware[5], C. Gu[6], M. Fornage[7], S. Kardia[8], C. Rotimi[3], R. Cooper[4], D. Rao[6], A. Morrison[9], G. Ehret[2], A. Chakravarti[2].* 1) Epidemiology & Biostatistics, Case Western Reserve Univ, Cleveland, OH; 2) Johns Hopkins University School of Medicine, McKusick - Nathans Institute of Genetic Medicine, Baltimore, MD; 3) Center for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 4) Public Health Science, Stritch School of Medicine, Loyola University Chicago, Maywood, IL; 5) School of Publish Health, University of Michigan, Ann Arbor, MI; 6) Division of Biostatistics, Washington University School of Medicine, St. Louis, Missouri; 7) Institute of Molecular Medicine and Human Genetics Center, University of Texas Health Science Center, Houston, TX; 8) Department of Epidemiology, University of Michigan, Ann Arbor, MI; 9) Human Genetics Center, University of Texas Health Science Center, Houston, TX.

High blood pressure (BP) is more prevalent, and is a major risk factor for cardiovascular disease (CVD), in African Americans than in any other US population. Although many large genome-wide association studies (GWAS) of BP have been conducted in individuals of European ancestry, studies of African Americans have lagged behind. Moreover, Family based linkage studies have been long ignored as GWASs became increasingly popular. However, family-based studies have greater power when rare variants underlie complex traits. Consequently, we performed genome-wide linkage analysis of blood pressure traits using the African-American families genotyped on the Illumina HumanExome BeadChip v1.1, for 242,901 variants in the Family Blood Pressure Program. We identified a genomic region on chromosome 1q with MLOD score 3.8 for pulse pressure, a region already implicated in prior studies of European ancestry families. Additional analyses using combined linkage and association studies identified 96 variants potentially accounting for the observed linkage evidence. Replication analysis in three independent African ancestral cohorts confirms the association evidence of these variants with all three BP traits (systolic, diastolic and pulse BP, $P < 0.039$). Single variant analysis and sliding window-based analysis both suggest the enrichment of BP variants in replication cohorts, with the most significant evidence observed in a window consisting of five variants with systolic BP (P=0.00044). Our study suggests that the chromosome 1q region harbors multiple genes contributing to BP variation and that family-based studies can be powerful in the search for rare functional variants within specific coding genes.

636F

Somatic/mosaic mutations are an important cause of sporadic vascular anomalies. *M. Vikkula[1,2,3], P. Brouillard[1], A. Mendola[1], J. Soblet[1], M. Schlögel[1], M. Amyere[1], N. Limaye[1], L.M. Boon[1,2].* 1) Human Molecular Genetics, de Duve Institute, Università catholique de Louvain, Brussels, Belgium; 2) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires Saint Luc, Brussels, Belgium; 3) WELBIO (Walloon Excellence in Lifesciences and Biotechnology), de Duve Institute, Università catholique de Louvain, Brussels, Belgium.

Purpose: Vascular anomalies are localized defects of the lymphatic or vascular system. They are most commonly observed on the skin, but can affect any body part. They are divided according to affected vessel type into arterial, capillary, venous, lymphatic and combined malformations. The etiology has remained unknown.Based on observed rare familial inheritance of some malformations, we have been able to identify underlying germline changes in several genes, including TIE2 for mucocutaneous venous malformations (VMCM), glomulin for glomuvenous malformations (GVM), and RASA1 for capillary malformation-arteriovenous malformation (CM-AVM). These familial cases are commonly characterized by multifocality of lesions that, in general, are small in size. Often, additional, small lesions develop with time. We have explained this by Knudson's double-hit theory, and demonstrated somatic second-hits in all three entities. These can be intragenic point mutations or deletions, or chromosomal anomalies, including deletions and acquired uniparental isodisomy.**Methods**: The frequent discovery of somatic 2nd hits made us study sporadic patients for eventual somatic changes. We screened frozen tissues from >100 venous malformations (VM), 30 capillary malformations (CM) and 20 lymphatic malformations (LM) for mutations in functional candidate genes. We used Ion Torrent PGM as technique to allow us to reach high vertical coverage (>1000x).**Results**: In the majority of the lesions, we have pinpointed a somatic mutation: 50% of the VMs have an activating TIE2 mutation, 50% of the CMs have an activating GNAQ mutation, and 80% of the LMs have an activating PIK3CA mutation. Syndromic forms, such as the CLOVES syndrome, is also characterized by a somatic PIK3CA mutation. Interestingly, some sporadic patients with multifocal lesions are mosaic in blood for an underlying mutation that seems to need a somatic second-hit. Moreover, in BRBN, also characterized by multifocal lesions, the somatic mutations in distant lesions are shared, even if the patient's blood is not mosaic for the underlying mutation.**Conclusion**: We conclude that somatic mutations are a common pathophysiologic cause of sporadic vascular anomalies, whether isolated or syndromic. In sporadic patients with multifocal lesions, mosaicism may play a role, yet in other, progenitor cell migration may underlie sharing of somatic mutations in distant sites.

637W

Large-scale analysis of population titin truncations reveals these variants are rarer than previously estimated. *O. Akinrinade[1], J. Koskenvuo[2,3], T. Alastalo[1,2].* 1) Children's Hospital, Institute of Clinical Medicine, University of Helsinki and Helsinki University Central Hospital Finland; 2) Blueprint Genetics, Helsinki, Finland; 3) Department of Clinical Physiology and Nuclear Medicine, HUS Medical Imaging Center, Helsinki University Central Hospital and University of Helsinki, Finland.

Background – Truncating titin (TTN) mutations account for 25% and 18% of familial and sporadic cases of dilated cardiomyopathy (DCM) respectively. However, distinguishing true pathogenic *TTN* truncating variants (TTNtv) from benign variants in clinical diagnostics and in research setting is challenging, as these variants are also present in control populations. We carried out systematic analyses of TTNtv in publicly available control populations, including, for the first time, data from Exome Aggregation Consortium (ExAC), in a bid to establish a more accurate estimate of prevalence of different TTNtv and to foster better clinical interpretation of these findings.**Methods and Results** – Using data from 1000 Genomes Project, Exome Sequencing Project (ESP) and ExAC, we estimated the prevalence of TTNtv in the population. Interestingly, 52-54% of population TTNtv were located either in exons with low expression in the left ventricle (LV) or exons present in few isoforms of the gene. The frequency of truncations affecting all transcripts in ExAC was 0.36% and 0.19% for those affecting the A-band. In the A-band region, the prevalences of frameshift, nonsense and consensus splice site variants were 0.057%, 0.090%, and 0.047% respectively. *Cga/Tga* (arginine/nonsense – R/*) transitional change at CpG mutation hotspots was the most frequent type of *TTN* nonsense mutation accounting for 91.3% (21/23) of arginine residue nonsense mutation (R/*) at *TTN* A-band region. Non-essential splice-site variants had significantly lower proportion of private variants and higher proportion of low-frequency variants compared to essential splice-site variants (respectively).**Conclusion** – Considering the rarity of A-band titin splice-site, nonsense and frameshift mutations in the population, we conclude that TTNtv are major causes of dilated cardiomyopathy. Our findings highlight the importance of the use of appropriate control population such as ExAC in filtering low frequency benign variants. Existing data supports classification of *TTN* truncations especially in A-band region likely pathogenic, and any individual tested positive should be considered to have elevated risk for dilated cardiomyopathy.

638T

Association of variation in 82 pharmacogenes with low-density lipoprotein cholesterol levels in the eMERGE-PGx project. *I.J. Kullo[1], E.E. Austin[1], M.S. Safarova[1], D.S. Kim[2,3], A.S. Gordon[2], P.D. Robertson[3], D.S. Hanna[3], D.S. Carrell[4], A. Scrol[5], M. de Andrade[6], S.J. Bielinski[6], K.F. Doheny[7], P.K. Crane[8], R. Li[9], S. Stallings[10], S.S. Verma[11], J. Wallace[11], M.D. Ritchie[11], M.O. Dorschner[3], E.B. Larson[5], D.A. Nickerson[3], J.G. Linneman[12], C. McCarty[13,14], D. Berg[14], G.P. Jarvik[2,3], D.J. Schaid[6], D.R. Crosslin[2,3], the electronic MEdical Records and GEnomics (eMERGE) Network.* 1) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Group Health Research Institute, Group Health Cooperative, Seattle, WA; 5) Group Health Research Institute, Center for Health Studies, Seattle, WA; 6) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 7) Center for Inherited Disease Research, Johns Hopkins University School of Medicine, Baltimore, MD; 8) Division of General Internal Medicine, University of Washington, Seattle, WA; 9) Division of Genomic Medicine, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 10) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 11) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, Pennsylvania, PA; 12) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, WI; 13) Essentia Institute of Rural Health, Duluth, MN; 14) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI.

Background and hypothesis. In the electronic MEdical Records and GEnomics (eMERGE)-PharmacoGenomics (PGx) study, ~9000 participants have been sequenced with the targeted Pharmacogenomics Research Network sequence platform (PGRNseq). This platform was designed to sequence the coding regions, UTRs, 2kb upstream, and 1kb downstream for 84 pharmacogenes. Common variants in five genes (*LDLR*, *HMGCR*, *NAT2*, *ABCA1,* and *APOA1*) on this platform are associated with low-density lipoprotein cholesterol (LDL-C) levels in genome wide association studies.**Aim.** We investigated whether any of the 82 Pharmacogenes (in particular the five candidate genes listed above) were associated with LDL-C levels in the eMERGE PGx study.**Methods.** We ascertained the median LDL-C level in the electronic health records (EHRs) for 3256 participants with lipid panel and targeted sequencing data. Population stratification factors were generated from a pruned set of all sequenced variants (minor allele frequency ≥ 0.05; linkage disequilibrium r2 <0.50). Covariate adjustments were made for age, sex, statin use, and population stratification. Gene level statistical significance was quantified with the adaptive sum of powered score (aSPU) test. This global test identifies significant associations of both rare and common variants in the presence of numerous non-associated rare variants. The adaptive feature of the test allows it to maintain high power across varying genetic architectures.**Results.** The median LDL-C level was available for 3256 participants across five eMERGE sites (Marshfield Clinic Research Foundation, Mayo Clinic, Northwestern University, University of Washington/Group Health, and Vanderbilt University). The mean (SD) age of participants was 56.5 (9.8) years, 48.6% were male. The mean (SD) LDL-C was 114.3 (29.3) mg/dL. The top five genes (aSPU *P*-value) ranked by statistical significance were *HMGCR* (0.001), *LDLR* (0.005), *TCL1A* (0.017), *NR3C1* (0.017), and *CRHR1* (0.019). Twelve of the 82 genes were found to be significant at a 0.05 level. Variation in *NAT2, ABCA1,* and *APOA1* was not significantly associated with LDL-C levels (aSPU *P*-values 0.612, 0.519, and 0.729, respectively)**Conclusion.** We replicated the association of *HMGCR* and *LDLR* with LDL-C levels and identified additional novel associations. Further studies are underway to include the larger anticipated sample size of ~9,000 individuals for gene and variant level analyses.

Defining the Genetic Landscape of Pulmonary Arterial Hypertension Using Whole-Genome Sequencing. *S. Gräf[1,2], M. Bleda[1], M. Haimel[1], C. Hadinnapola[1], N. Morrell[1] on behalf of the PAH National Cohort and the NIHR BRIDGE-PAH Consortium.* 1) Department of Medicine, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom; 2) Department of Haematology, University of Cambridge, Cambridge, Cambridgeshire, United Kingdom.

Pulmonary arterial hypertension (PAH) is a devastating rare disease with an estimated incidence of 2–3 per million of the adult population per year. Elevated blood pressure in the lung manifests from increased narrowing and stiffening of small pulmonary arteries. Individuals tend to present with symptoms late in the disease progression and die on average only 3–5 years after diagnosis from right heart failure. About 75% of familial cases and approximately 20% of sporadic cases without a known family history can be attributed to deleterious mutations in the bone morphogenetic receptor type 2 gene. Although several additional disease genes have been identified recently using candidate gene approaches or whole-exome sequencing, a genetic cause for the majority of cases remains to be identified.We have established an international consortium comprising PAH specialist centres in the UK and abroad with the aim of sequencing the whole genomes of more than 1,000 unrelated adults and children diagnosed with PAH as part of the NIHR BioResource–Rare Diseases (BRIDGE) 10,000 genomes project. When the patients are recruited to the study extensive phenotype data is recorded from the time of diagnosis. Participants are then followed up every 6 months for 5 years to monitor disease progression. In the case of familial PAH we are also recruiting family members to the longitudinal study to assess genetic penetrance and to determine additional environmental or genetic factors involved in this disease. Here we present the first account derived from the comparison of more than 400 sequenced PAH cases with more than 3,000 sequenced BRIDGE control samples.

640W

Testing causality in the association of plasma cortisol with risk of coronary heart disease: a Mendelian randomisation study. *A.A. Crawford[1, 2], N.J. Timpson[2], G. Davey Smith[2], B.R. Walker[1].* 1) University/BHF Centre for Cardiovascular Science, University of Edinburgh, Edinburgh, UK; 2) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK.

Coronary heart disease (CHD) is one of the leading causes of death in the developed world. Elevated morning plasma cortisol is associated with multiple cardiovascular risk factors in metabolic syndrome. Epidemiological studies have also reported a positive association between plasma cortisol and coronary heart disease (CHD), although not all estimates are statistically significant (OR 1.10 (95% CI 0.97 to 1.25)) (Davey Smith *et al.* Circulation 2005). Importantly, observational studies are unable to infer causality and results may be confounded. A two-sample Mendelian randomisation approach was used to estimate the causal effect of plasma cortisol on risk of CHD. Our genetic instrument for plasma cortisol comprised of three SNPs which were associated with plasma cortisol in the recent Cortisol Network (CORNET) genome wide association meta-analysis (GWAMA) (n=12,597) (Bolton *et al.* PLoS Genetics 2014). We investigated the association between our genetic instrument for plasma cortisol and risk of CHD in up to 22,223 cases/64,762 controls from the publicly available CARDIOGRAM consortium. Each standard deviation change in genetically elevated plasma cortisol was associated with an odds ratio of 1.27 (95% CI: 1.01 to 1.60) for CHD. The inconsistent results from observational studies may be explained by: the inverse association between cortisol and obesity, which confounded the positive association of cortisol with other cardiovascular risk factors; and the use of single 'snapshot' plasma cortisol measurement rather than cumulative measure of cortisol exposure provided by genetic prediction. A bi-directional Mendelian randomisation analysis between plasma cortisol and BMI may yield greater clarity. To improve the strength of our genetic instrument an expanded CORNET GWAMA is currently underway with the aim of recruiting 30,000 individuals. However, initial results suggest that measurements of cortisol may add value to predictions of CHD risk.

641T

Possibly Pathogenic Copy Number Variations Identified in Patients with Hemorrhagic Stroke. *A. Donatti[1], R. Secolin[1], F.R. Torres[1], L.E. Ferreira[2], P.H.C. França[2], V. Nagel[2], N.L. Cabral[2], I. Lopes-Cendes[1].* 1) University of Campinas, Campinas, SP, Brazil; 2) University of Joinville Region, Joinville, SC, Brazil.

Background: Stroke is the third most common cause of death or disability worldwide. Hemorrhagic stroke (HS) occurs in 15%-20% of patients and it features the disruption of cerebral blood vessels as main clinical characteristic. There are only a few genetic studies related to HS, due to its low population frequency and high mortality rate. To our knowledge no previous study examined the possible role of copy number variations (CNVs) in HS.**Objective:** To determine if CNVs could be involved in the etiology of HS.**Methods:** We obtained DNA sample from peripheral blood of 46 patients with HS and 41 age matched individuals without HS. All samples were obtained from the Joinville Stroke Biobank, as part of a population-based epidemiologic study. We detected CNVs using the Genome-Wide Human SNP 6.0 DNA chips (Affymetrix Inc.). We evaluated the presence of population stratification in the sample by principal component analysis (PCA) using 'affy' and 'limma' packages in R software. We analyzed CNVs data using Bayesian Robust Linear Model using Mahalanobis (BRLMM) and Canary algorithms by Genotype Console®Software (Affymetrix Inc.). Furthermore, we built gene networks using METACORE TM software to analyzed possible interaction among genes found within CNVs.**Results:** PCA analysis showed that the total sample did not present population stratification, which allows unbiased comparison between patients and controls. Using the matched controls as reference, we identified 378 CNVs present **only** in patients, including 139 losses and 239 gains. The CNVs encompassed 105 genes located within duplicated regions and 57 genes within deletions. According to gene network analysis, we found CNVs in several genes with functions related to blood pressure regulation, such as *DEFB103B*, *DEFB4B*and *PRODH.* We also found CNVs in genes related to vascular processes, coagulation and hypertension, and lipids metabolism (*ANXA8*, *HGSNAT* and *NOMO1*).**Conclusion:** We describe here patients with HS and CNVs in genes related to vascular process, coagulation, hypertension and lipid metabolisms. Furthermore, these CNVs were not detected in age-matched control individuals.Supported by CNPq and BRAINN-CEPID/FAPESP, BRAZIL.

Concordance in classification of hypertrophic cardiomyopathy variants is markedly higher among expert centers than among clinical labs. *A. Furqan[1], P. Arscott[2], F. Girolami[3], A. Cirino[4], M. Michels[5], S. Day[2], I. Olivotto[6], C. Ho[4], E. Ashley[7,8], C. Caleshu[7,9], SHaRe Consortium.* 1) California State University, Stanislaus, Turlock, CA; 2) University of Michigan Cardiology, Ann Arbor, MI, USA; 3) Genetics Unit, Careggi University Hospital Florence, Italy; 4) Cardiovascular Division, Brigham and Women's Hospital, Boston, MA, USA; 5) Department of Cardiology, Thoraxcenter, Erasmus Medical Center, Rotterdam, the Netherlands; 6) Referral Center for Myocardial Diseases, Azienda Ospedaliera Universitaria Careggi, Florence, Italy; 7) Stanford Center for Inherited Cardiovascular Disease, Stanford, CA, USA; 8) Division of Cardiovascular Medicine, Stanford Medical Center, Stanford, CA, USA; 9) Division of Medical Genetics, Stanford Medical Center, Stanford, CA, USA.

Background: It has become increasingly clear that there are often marked differences in how variants in Mendelian disease genes are classified by different laboratories. Efforts to improve variant classification strategies will be aided by a thorough understanding of why differences in classifications exist.**Aim:** To gain such insights, we examined discordance in sarcomere variant classifications in SHaRe, a consortium of multiple international centers with expertise in cardiomyopathy genetics. **Methods and results:** We evaluated the frequency of disagreement in variant classifications between centers submitting to SHaRe and compared it to the frequency of disagreement in classifications among clinical laboratories submitting to ClinVar. Of the 536 sarcomere variants in SHaRe, 120 were submitted by ≥1 center and 17 (14%) of those were classified differently by ≥2 centers. The frequency of discordance in ClinVar was three times higher; there were 2355 sarcomere variants, 680 had classifications by ≥1 clinical lab and 307 (45%) were discordant. We then assessed the severity of discordance as severe (i.e. (likely) benign vs. (likely) pathogenic), moderate (i.e. VUS vs. pathogenic or benign), or modest (i.e. VUS vs. likely benign or likely pathogenic). The majority of discordant classifications in SHaRe were modest (10/17), with 1/17 severe and 6/17 moderate. In contrast, discordant classifications in ClinVar were more severe; about half were moderate (155/307), 145/307 were modest and 7/307 were severe. To identify the sources of discordance in SHaRe, we compared the data and rationale that each center used in making their classifications. The frequent cause of discordance was differences in privately held data, either at the testing lab (12/17) or the clinical center (11/17). Additional causes of discordance included differences in published data used (8/17), in interpretations of the same published data (2/17), and in classification criteria (5/17).**Conclusions:** Taken together, these data suggest that variant classification can be improved by evaluation at specialized centers. The lower and less severe discordance among cardiomyopathy genetics centers may be due to classification of variants by experts or to more thorough follow-up of genetic findings including segregation analysis. Our findings also underscore the importance of sharing of privately held data as this was a frequent cause of discordance.

643W

Detection of eQTLs in Human Left Atrium and their association with Atrial Fibrillation Using Hidden Expression Factor Analysis. *M. Heydarpour, M.I. Sigurdsson, L. Saddic, T.W. Chang, S.K. Shernan, J.D. Muehlschlegel, S.C. Body, Center for Perioperative Genomics.* Anesthesiology, Brigham and Women's Hospital, Boston, MA.

Introduction: Risk alleles for atrial fibrillation (AF) have been identified by genome wide association study in ambulatory and surgical populations, notably found in or near the *PITX2*, *KCNN3* and *ZFHX3* genes. However, these associations have, to date, failed to be supported by biological mechanisms. We hypothesized that these variants may alter human left atrial gene expression as a mechanism in the genesis of AF. **Methods:** In 62 Caucasian patients in sinus rhythm, left atrial (LA) tissue samples were excised prior to mitral valve surgery and analyzed using mRNASeq. Quality control of gene expression data was performed by MatrixeQTL (Shabalin, 2012). Patients were genotyped using the HumanOmni2.5 array. Twenty one patients (34%) had AF postoperatively, and were generally older with a higher frequency of hypertension. We performed gene-expression differential analysis between 21 AF patients and 41 no-AF to detect genes with significant differences. Whole genome eQTL analysis was executed for 17,925 genes and 1,243,383 genetic-markers. A hidden expression factor analysis (HEFT) method (Gao et al. 2014) was used for detecting eQTLs while accounting for age, gender, BMI, and cardiopulmonary bypass time. Hidden factors selected by assessing the eigen spectrum of the overall gene expression covariance (>5% of total variance). **Results:** We identified 407 genes which significantly differential expressed [log2(expr-AF/expr-noAF) >0.5] between patient with AF and no-AF. 5,628 cis-eQTLs and 21,406 trans-eQTLs significant (P<1.0E-8) were identified through whole genome eQTL analysis. After integrated these results with 407 genes, we recognized 192 cis-eQTLs in 15 genes were overlapped. The most significant cis-eQTLs were identified for *ERAP2* (5q15), *MYOZ1* (10q22.1), *HLA-DQB1* (6p21.3), and *HLA-DQA1* (6p21.3). SNPs in each region were in high linkage disequilibrium (LD). We did not detect any significant eQTL for genes previously associated with AF such as *PITX2*, *KCNN3* and *ZFHX3.* The *SCN10A* gene previously associated with AF in ambulatory populations and PR interval was also significant (P=1.0E-10) in this study.**Conclusion:** We present a comprehensive eQTL analysis of gene expression in the human left atrium. These observations may help establish mechanisms for how common genetic variation predisposes to AF. The method that we used (HEFT) is able to reveal significant cis-eQTLs that are not detectable by linear regression, while providing strict false positive control.

644T

Co-Aggregation of Depression and Cardiovascular Diseases. *S. Knight[1,2], H.T. May[1], H. Coon[2,3], B.D. Horne[1,2].* 1) Intermountain Heart Institution, Intermountain Medical Center, Murray, UT; 2) Division of Genetic Epidemiology, University of Utah, Salt Lake City, UT; 3) Department of Psychiatry, University of Utah, Salt Lake City, UT.

Introduction: Studies have found greater risk of coronary artery disease (CAD) in individuals with depression, and greater risk of suicides in individuals who had a myocardial infarction (MI). These findings, and the fact that depression, CAD, and MI have strong genetic components, suggest possible co-aggregation of these diseases. The purpose of this project was to test for significant co-aggregation of depression with CAD and MI using a large genealogy registry, the Intermountain Genealogy Registry.Methods: The Intermountain Genealogy Registry (IGR) is a database of genealogical information from over 23 million individuals who lived or whose blood relatives lived in the Western Intermountain region of the United States. The IGR is linked to clinical records of over 650,000 (20%) patients in the Intermountain Healthcare system, an integrated healthcare delivery system which provides the majority (60%) of healthcare services in Utah. Two-way Genealogy Indices of Familiality (GIF) were generated for depression and CAD, and for depression and MI. One-way GIFs were also computed for depression, CAD, and MI individually. The GIF statistic is a measure of average relatedness (10,000x average kinship coefficient for all pairs) of individuals with a specified diagnosis in a population or a set of diagnoses. Significance was determine empirically using GIFs for age and sexed matched control sets (n=1000) of Intermountain patients in the IGR. Patients linked to the registry without ancestors were excluded, as these would not provide information for the GIF. The average GIF of the controls sets are reported. Results: There were 11,712 patients in IGR who had depression, 70,631 with CAD, and 16,113 with MI. After excluding founders, the sample sizes decreased to 7,780, 45,312, and 10,361, respectively. The one-way GIFs for each disease were 0.061 (control GIF=0.056; p=0.015) for depression, 0.085 (control GIF=0.048; p<0.001) for CAD, and 0.075 (control GIF=0.069; p<0.001) for MI. The two-way GIF for depression and CAD was 0.065 (control GIF=0.051; p<0.005), and for depression and MI it was 0.069 (control GIF=0.060; p<0.001).Conclusions: Significant co-aggregation of depression with both CAD and MI was found in a large clinical population genealogy. This supports previous evidence that these diseases may have a shared genetic cause and suggests further joint study of their genetic basis.

645F

Gene Frequencies of the *GSTT1* and *GSTM1* genes in Ramgarhia Sikh population of Amritsar district and association with Coronary Artery Disease. *N. Mahajan, G. Gandhi.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Introduction: Cardiovascular diseases (CVDs), the diseases of the heart and blood vessels, are predominant causes of morbidity and mortality and it has been estimated that by 2030 there will be >50% deaths due to cardiovascular diseases among non-communicable diseases. The types of CVD include heart beat irregularities, cardiac failure, coronary artery disease and sudden cardiac death. In coronary artery disease, damage of the coronary arteries lead to atherosclerosis/arteriosclerosis and so the disease is known as atherosclerotic heart disease or coronary artery disease (CAD) or coronary heart disease. Detoxification of metabolites produced by oxidative stress within the cell is carried out by **genetic variants of xenobiotic-metabolizing enzymes, such as** Glutathione S-transferases (GSTs) which protects the cells against injury and **may be associated with the risk of coronary artery disease (CAD)**. For the present study the contribution of polymorphism in the *GSTT1* and *GSTM1* genes in the development of coronary artery disease in *Ramgarhia Sikh* population of Amritsar district has been investigated.**Methodology:** DNA samples from CAD patients (n=200) and age-, sex- matched healthy controls (n=200) were genotyped for *GSTT1* and *GSTM1* polymorphism using multiplex polymerase chain reaction (PCR). Genotypic frequency of CAD patients were compared with genotypic frequency of controls using chi-square test.**Results**: Results of the present study showed significant (p<0.05) difference for genotypic frequencies of *GSTT1* and *GSTM1* genotype in cases as compared to controls. *GSTT1* null genotype was 2.3-folds higher in controls as compared to CAD patients, whereas *GSTM1* null genotype was 1.7-folds higher in CAD patients as compared to controls.**CONCLUSION**: *GSTT1* null genotype showed protection against CAD whereas *GSTM1* null showed susceptibility to CAD in *Ramgarhia Sikh* population of Amritsar.

646W

Differential genetic expression in ECG characterized normokinetic and akinetic/dyskinetic myocardium zones in humans. *O.A. Makeeva[1,3], V.E. Babokin[2,4], E.V. Kulish[1], V.M. Shipulin[2], V.P. Puzyrev[1].* 1) Research Institute of Medical Genetics, Tomsk, Russia; 2) Research Institute of Cardiology, Tomsk, Russia; 3) Research Institute for Complex Issues of Cardiovascular Diseases, Kemerovo, Russia; 4) Moscow Regional Research and Clinical Institute (MONIKI), Moscow, Russia.

The aim of the study was to investigate expression profiles in different zones of human left ventricular myocardium characterized by echocardiography (ECG) as (1)akinetic, (2)dyskinetic, (3)hypokinetic, and (4) normokinetic in patients who survived myocardial infarction.**Methods:** Myocardial biopsy was taken with diagnostic purpose during cardiosurgery for aneurism resection and left ventricular reconstruction. Total of 24 biopsy samples were investigated and divided into groups according to ECG characteristics.Total RNA was extracted using RNAeasy kit (Qiagen,Germany). Quality of RNA samples was evaluated using Agilent Total RNA 6000 chip (Agilent Technologies). 400 ng of total RNA were amplified with Illumina TotalPrep™ RNA Amplification Kit (Ambion). Whole genome expression analysis was conducted using Illumina HT-12v4 BeadChip. Data collection and analysis was performed using Illumina GenomeStudio, Gene Expression Module.**Results:** Samples from different zones of myocardium were compared in respect to differential expression. Samples from normokinetic zones differed from dyskinetic in expression of *FAM43B*, *FAP, GRB14*,and *SERPINEF1*. Normokinetic samples differed from akinetic in expression of the *GRB14* only. When akinetic and dyskinetic samples were combined in one group and compared to normokinetic, 3 genes with differential expression were detected: *CNN1, DIO2* and *GRB14*.**Discussion:** ECG characteristics well correspond to functional status of myocardium. Normokinetic zones present preserved wall thickness and normal contractility; hypokinetic zones correspond to reduced wall thickening and/or reduced longitudinal shortening in systole. Akinetic/dyskinetic segments are suggestive of myocardial scar due to old infarction.Normal myocardium had higher expression of *GRB14*. *GRB14* encodes a growth factor receptor-binding protein that interacts with insulin receptors and insulin-like growth-factor receptors. *GRB14* plays a role in signaling pathways that regulate growth and metabolism. Increased *GRB14* expression was previously described in adipose tissues of model animals and obese humans. *GRB14* associated with HDL-cholesterol, triglycerides, and fasting insulin gene expression levels in human tissues.Reviled differences in gene expression can lead developing new drugs to help post-infarction treatment and rehabilitation. Investigations are needed to explore whether the stimulation of *GRB14* expression in post-infarction myocardium can improve patients outcome.

647T

Heritability of age of onset of cardiovascular disease using large-scale Finnish health registry and genome-wide data. *C. Benner[1], M. Pirinen[1], V. Salomaa[3], J. Palmgren[1,2], S. Ripatti[1,4].* 1) Institute of Molecular Medicine Finland, Helsinki, Finland; 2) Karolinska Institutet, Stockholm, Sweden; 3) National Institute for Health and Welfare, Helsinki, Finland; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Whole genome sequencing is currently being performed on thousands of Finns as part of the Sequencing Initiative Suomi project (SISu). Combining genomic profiles of tens of thousands of Finns with health registry data provides a unique resource in the world to accomplish breakthroughs in modern human genomics with possibly important implications on public health. In particular, the information can be utilized to determine to what extent phenotypic variation in age of diseaseonsetis attributable to genetic effects. Recent methodological development has enabled heritability estimation for quantitative traits in population cohorts by estimating the proportion of genetic sharing among pairs of individuals from genome-wide marker data. The possibility to use population cohorts rather than family structures to assess heritability opens up a multitude of new avenues for genetic research of age of disease onset. However, connecting age of onset to big genomics data form large-scale population cohorts has so far not been feasible with hitherto existing methods.

We introduce a novel method that deals with prospective follow-up information from health registry data and permits heritability estimation and association testing based on millions of genetic markers and health registry events in tens of thousands of individuals with more than 20 years of follow-up time. Our approach implements a very flexible piecewise constant hazard model that contains an individual-specific Gaussian random effect with an arbitrary covariance structure. Computationally, we analyze the model in a Bayesian context by using a Markov Chain Monte Carlo algorithm. We compared our method on simulated data to a mixed effects Cox model, as implemented in the R package ‘coxme’. Compared to the mixed effects Cox model, our method produced lower mean squared error of variance and regression parameters under varying proportion of variance explained in the genotype, different number of simulated causal variants and sample size as well as high censoring rates. Using over 10000 unrelated Finns from the National FINRISK study, we also estimated that the heritability of cardiovascular disease (defined as coronary heart disease and ischaemic stroke) in terms of relative risk of disease due to genetic effects is 27% (95% CI: 6-51%).

648W

Genetic polymorphism of *P2RX7* can be a predictive biomarker for responsibility to long-term effect of infliximab against Crohn's disease. *M. Yoshimura[1], D. Mukai[1], Y. Fukumitsu[1], T. Inamine[1], S. Kondo[1], S. Urabe[2], K. Matsushima[2], H. Isomoto[2], T. Ishida[3], R. Uehara[2], T. Honda[2], H. Minami[2], H. Machida[2], Y. Akazawa[2], C.C. Chen[2], N. Yamaguchi[2], K. Ohnita[2], F. Takeshima[2], K. Nakao[2], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Dept Gastroenterology and Hepatology, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 3) Oita Red Cross Hospital, Oita, Japan.

Purpose: Infliximab (IFX) is a chimeric anti-tumor necrosis factor-a monoclonal antibody exerting the therapeutic effect against Crohn's disease (CD). However, some CD patients, who treated with IFX, showed the secondary loss of response to IFX at long-term treatment of 1 year although they have achieved remission at short-term treatment of 10 weeks. Therefore, in order to identify any biomarkers to predict the therapeutic effect of IFX, we investigated a candidate gene-based association study between single nucleotide polymorphisms (SNPs) in a cell surface ATP receptor, P2X7 receptor (P2RX7, encoded by *P2RX7*) and response to IFX at the 1-year treatment period in Japanese CD patients.**Methods:** A total of 116 CD patients, who showed response to IFX at the 10-week treatment period in Oita Red Cross Hospital or Nagasaki University Hospital, were divided into two groups, responders and non-responders, based on the presence of IFX effect at the long-term period of 1 year after IFX administration. Eleven tag SNPs in *P2RX7* were analyzed by PCR-restriction fragment length polymorphism or -high resolution melting curve analysis. The frequencies of alleles and genotypes of each SNP between responders and non-responders at the 1-year treatment period were compared in three different inheritance models using chi-squared or Fisher's exact test.**Results:** The genetic analyses indicated that the frequency of a minor allele homozygous G/G genotype of rs3751143 in *P2RX7* in the minor allele recessive model was significantly decreased in responders in comparison to that in non-responders (P = 0.001, odds ratio = 0.143), implicating ~7.0-fold secondary loss of response to IFX. Conversely, a T/T or T/G genotype of rs3751143 indicated 7.0-fold response to IFX.**Conclusions:** Our results suggest that the G/G genotype of rs3751143 in *P2RX7* may affect the gain-of-function of P2RX7, thus leading to the activation of the signals in the Ras signaling pathway in the intestines of CD patients. The activation of Ras signals can lead to the perpetuation of the chronic intestinal inflammatory process, thereby resulting in the secondary loss of response to IFX at the 1-year treatment period. Thus, *P2RX7* appear to be a genetic determinant for response to IFX at the 1-year treatment period against Japanese CD patients, and to be a target molecule for new therapeutic drugs overcoming the secondary loss of response to IFX treatment.

649T

Association between *KCNJ6* (*GIRK2*) gene polymorphism rs2835859 and postoperative analgesia, pain sensitivity, and nicotine dependence. *D. Nishizawa[1], K. Fukuda[2], S. Kasai[1], Y. Ogai[1], J. Hasegawa[1], N. Sato[3,4], H. Yamada[4], F. Tanioka[5], H. Sugimura[4], M. Hayashida[6], K. Ikeda[1].* 1) Psychiatry and Behavioral Science (Addictive Substance Project), Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Dental Anesthesiology, Tokyo Dental College, Tokyo, Japan; 3) Department of Clinical Nursing, Hamamatsu University School of Medicine, Hamamatsu, Japan; 4) Department of Tumor Pathology, Hamamatsu University School of Medicine, Hamamatsu, Japan; 5) Department of Pathology, Iwata City Hospital, Iwata, Japan; 6) Department of Anesthesiology & Pain Medicine, Juntendo University School of Medicine, Tokyo, Japan.

Background: G-protein-activated inwardly rectifying potassium (GIRK) channels are expressed in many tissues and activated by several Gi/o protein-coupled receptors, such as opioid and dopamine receptors, and thus are known to be involved in the modulation of opioid-induced analgesia, pain, and reward. **Methods**: We focused on a GIRK channel subunit that plays a pivotal role in the brain, GIRK2, and investigated the contribution of genetic variations of the *GIRK2* (*KCNJ6*) gene to individual differences in the sensitivity to opioid analgesia using a two-stage analysis in 355 healthy patients who were scheduled to undergo cosmetic orthognathic surgery for mandibular prognathism at Tokyo Dental College Suidoubashi Hospital and provided informed, written consent for the genetics studies, followed by additional association analyses using other samples. **Results**: In our initial linkage disequilibrium (LD) analysis, a total of 27 single-nucleotide polymorphisms (SNPs) were selected in the whole exon and intron region as well as 5'- and 3'- flanking regions (~10kbp) of the *KCNJ6* gene. Among them, the rs2835859 SNP was selected in the exploratory study as a potent candidate SNP for the further confirmatory association study. The association with opioid analgesic sensitivity was confirmed for this SNP, in which the carriers of the C allele of this SNP required less analgesics compared with non-carriers after painful cosmetic surgery. We also found that the carriers of the C allele of this SNP were less sensitive to both cold and mechanical pain in healthy volunteers. Moreover, we found that homozygous carriers of the C allele of this SNP showed higher score in Tobacco Dependence Screener (TDS), an index of nicotine dependence, and required a greater number of trials until attaining successful smoking cessation. **Conclusions**: The rs2835859 SNP could serve as a marker that predicts sensitivity to analgesic and pain and severity of nicotine dependence.

650W

Genetic polymorphisms in the neuroplasticity-related genes contribute to the therapeutic effect of antidepressants for major depression. *Y. Kawafuchi[1], T. Kurokawa[1], Y. Arata[1], K. Keya[1], T. Araki[1], S. Ijichi[1], T. Inamine[1], S. Kondo[1], N. Kurotaki[2], K. Nishiwaki[3], K. Tsukamoto[1].* 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 2) Dept Neuropsychiatry, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki, Japan; 3) Nishiwaki Hospital, Nagasaki, Japan.

Purpose: Major depression (MD) is a common psychiatric disorder in substantial proportion of the worldwide. As MD is a multifactorial disease, a variety of genetic and environmental factors contribute to its etiology and development. Neuroplasticity and neuroinflammation contribute to the pathogenesis of MD as well as responsibility to antidepressants. We investigated a candidate gene-based association study between single nucleotide polymorphisms (SNPs) in neuroplasticity-related genes (*GRIN1*, *MAPK1*, *ARC*, *FGFR1*, *FRS2*, *FRS3*, *BDNF*) and response to antidepressant(s) at the short-term treatment of 8 weeks in Japanese MD patients.**Methods:** A total of 105 MD patients were treated with antidepressants including serotonin reuptake inhibitors (SSRIs) and serotonin noradrenaline reuptake inhibitors (SNRIs) in Nishiwaki Hospital, and were divided into two groups, responders and non-responders, based on the presence of SSRI or SNRI effect at the 8-week treatment period. Thirty-four tag SNPs among 7 candidate genes were analyzed by PCR-restriction fragment length polymorphism, -direct DNA sequencing, or -high resolution melting curve analysis. The frequencies of alleles and genotypes of each SNP between responders and non-responders to SSRIs or SNRIs were compared in three different inheritance models using chi-squared or Fisher's exact test.**Results:** The frequency of a heterozygous C/T or a minor homozygous T/T genotype of rs6474354 in *FGFR1* in the minor allele dominant model was significantly increased in responders to SSRIs in comparison to that in non-responders ($P = 0.044$, odds ratio (OR) = 6.61), showing ~6.6-fold response to SSRIs. Conversely, the frequency of a minor homozygous T/T genotype of rs3804281 in *FRS3* in the minor allele recessive model was significantly decreased in the responders to SSRIs as compared with that in non-responders ($P = 0.007$, OR = 0.08), indicating ~12.5-fold loss of response to SSRIs. **Conclusions:** Our results suggest that the activation of the signals in the FGF signaling pathway due to these polymorphisms of *FGFR1* and *FRS3* may accelerate synaptic plasticity and neurogenesis induced by SSRIs, thereby resulting in good response to SSRIs. Thus, *FGFR1* and *FRS3* appear to be genetic determinants of responsibility to SSRIs in Japanese MD patients. Moreover, these molecules in the FGF signaling pathway may become targets for novel drug discovery for MD patients.

651T

Genetic risk factors for β-lactam antibiotic-induced cutaneous adverse drug reactions in Japanese population. *T. Ozeki[1], T. Mushiroda[1], A. Takahashi[2], M. Kubo[3].* 1) Laboratory for Pharmacogenomics, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan; 2) Laboratory for Stastical Analysis, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan; 3) Laboratory for Genotyping Development, RIKEN Cen. Integr. Med. Sci., Yokohama, Kanagawa, Japan.

β-lactam antibiotics, e.g. penicillin and cephem, are known to show incidences of cutaneous adverse drug reactions (cADRs) including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN) and drug-induced hypersensitivity syndrome (DIHS). To identify a gene(s) susceptible to β-lactam antibiotic-induced cADRs, we conducted a genome-wide association study (GWAS) and subsequent HLA typing in 92 cases of β-lactam antibiotic-induced cADRs and 879 subjects of a general population in Japanese. Among the SNPs analyzed in the GWAS, suggestive SNPs were located in the *HLA* loci. Thus, we genotyped the individual *HLA-A*, *-B*, *-C* and *–DRB1* alleles and found that *HLA-B*44:03* and *HLA-DRB1*13:02* was present in 31.5% (29/92) and 25.6% (23/90) of the cADR cases, but in 12.1% (106/879) and 10.5% (92/879) of the general population controls, respectively (odds ratio (OR) = 3.4 and 2.9, 95% confidence interval (CI) = 2.1-5.4 and 1.7-4.9, $P = 3.91 \times 10\text{-}6$ and $1.24 \times 10\text{-}4$, respectively).

652W

PCSK9 variants are associated with LDL-C response to statin therapy in African-Americans. *Q. Feng[1], WQ. Wei[2], CP. Chung[3], R. Levinson[4], L. Bastarache[2], JC. Denny[2], CM. Stein[1,5].* 1) Division of Clinical Pharmacology, Department of Medicine, Vanderbilt University, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 3) Division of Rheumatology, Department of Medicine, Vanderbilt University, Nashville, TN; 4) Vanderbilt Genetic Institute, Vanderbilt University, Nashville, TN; 5) Department of Pharmacology, Vanderbilt University, Nashville, TN.

Background Statins (HMG-CoA reductase inhibitors) lower low-density lipoprotein cholesterol (LDL-C) and prevent cardiovascular disease (CVD). Despite the overall benefits of statins, there is wide individual variation in LDL-C response. Drugs targeting proprotein convertase subtilin/kexin type 9 (PCSK9) lower LDL-C and are likely to be used with statins. PCSK9 plays a critical role in the degradation of LDL receptors; statins up-regulate both LDL receptors and PCSK9. Therefore, individuals with loss-of-function (LOF) *PCSK9* variants would be expected to have an increased LCL-C response to statins because LDL receptor degradation would be reduced.The gene encoding PCSK9 is highly polymorphic and several LOF and gain-of-function (GOF) variants have been identified. However, the relationship between *PCSK9* variants and statin response remains unclear. We examined the hypothesis that functional *PCSK9* variants affect statin response. **Methods** We studied 669 African Americans (AAs) treated with a statin in clinical practice. The LDL-C response to statin treatment (difference between natural log of baseline and on-treatment LDL-C) was extracted from the electronic health record. Genotypes for 11 *PCSK9* variants known to be functional were obtained using the MetaboChip. Association analysis was performed with adjustment for age, sex, baseline LDL-C, principal components of ancestry, statin type and dose with a Bonferroni-adjusted significance threshold of $p< 0.0045$. We also analyzed the collective effect of 11 known *PCSK9* functional variants using a burden test.**Results** One LOF variant, rs11591147 (p.R46L) was significantly associated with LDL-C response to statin (p=0.00236). In the 3 patients with the minor allele of the variant there was a 55.6% greater LDL-C reduction compared to non-carriers. This SNP has previously been associated with LDL-C response to rosuvastatin in 6989 Caucasians (JUPITER) with locus-wide significance. Another functional variant, rs298362261(p.N425S), which has been associated with baseline LDL-C in a large AA cohort, was associated with statin response with a borderline p-value (p=0.0064). The collective effect of the 11 known *PCSK9* functional variants was also of borderline significance (P=0.06).**Conclusion** Some functional *PCSK9* variants are associated with the LDL-C response to statin therapy. Further analysis in larger populations of African Americans will be important for a more thorough evaluation of the effect size of these SNPs.

653T

Identification of genetic and environmental factors that influence time to achieve target INR and time in therapeutic range with warfarin. *M.R. Botton[1], P.P. Viola[1], M.R. Meireles[1], P. Zuchinali[2], E. Bandinelli[1], L.E. Rohde[2], T.L.L. Leiria[3], J.Y.Y. Salamoni[2], A.P. Garbin[2], M.H. Hutz[1].* 1) Departamento de Genética, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil; 2) Serviço de Cardiologia, Hospital de Clínicas de Porto Alegre, Porto Alegre, Rio Grande do Sul, Brasil; 3) Instituto de Cardiologia - Fundação Universitària de Cardiologia, Porto Alegre, Rio Grande do Sul, Brasil.

Warfarin is an oral anticoagulant widely prescribed to prevent and treat thromboembolic disorders. It has a narrow therapeutic window and must have its effect controlled. Prothrombin test, expressed as INR values, is used for follow up. Time to reach target INR and time in therapeutic range (TTR) are important outcomes and several factors might influence them. The aim of this study was to identify genetic and environmental factors that can potentially influence time to reach target INR and TTR. A total of 422 patients using warfarin were investigated. Genotypes for VKORC1 -1639G>A, CYP2C9*2 and CYP2C9*3 were detected by TaqMan assays by real-time PCR. Furosemide co-medication and presence of chronic renal failure were associated with more time to reach target INR whereas VKORC1 -1639GA and -1639AA genotypes were associated with less time to reach INR. Regarding TTR, glibenclamide co-medication, male gender and presence of CYP2C9*2 allele were associated with more percentage of TTR, while amiodarone and enalapril co-medication were associated with less percentage of TTR. Our results suggest that TTR is not influenced by the same factors that alter time to reach INR. Other studies must be developed to confirm these results.

654W

SNP-based HLA tagging, imputation, and association in adverse drug reaction of epilepsy patients from Hong Kong. *S.S. Cherny[1 2 3], H. Gui[2], M. Kwok[4], P.C. Sham[1 2 3], L. Baum[1], P. Kwan[4 5].* 1) Department of Psychiatry, The University of Hong Kong; 2) Centre for Genomic Sciences, The University of Hong Kong; 3) The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong; 4) Department of Medicine & Therapeutics, The Chinese University of Hong Kong; 5) Department of Neurology, Royal Melbourne Hospital, Melbourne, Australia.

Human leukocyte antigen (HLA) genes control the regulation of the human immune system and are involved in infection and autoimmune-related complex diseases. Some HLA alleles (B*15:02, A*31:01 and B*57:01) have been associated with increased risk of cutaneous adverse drug reaction (cADR) in epilepsy patients taking antiepileptic drugs like carbamazepine and abacavir. However, traditional serotyping or Sanger sequencing for HLA genotyping may not be cost-effective for clinical application. A more efficient way may be to look for single nucleotide polymorphisms (SNP) that can tag HLA risk alleles with high sensitivity and specificity. Since haplotype structure is population-specific due to different linkage disequilibrium patterns, an investigation on pairwise SNP-HLA relationships was conducted in the Hong Kong population. This analysis arose from our program of research on epilepsy genetics and pharmacogenomics, for which we have built an in-house database including classical HLA serotyping, genome-wide SNP arrays, exome sequencing, and whole-genome sequencing. The discovery panel employed included 144 patients with both genome-wide SNP-array data and HLA*B or HLA*A serotypes, which enable a greedy search of highly correlated pairs of HLA risk alleles and SNPs through use of pairwise LD statistics. Common variants rs9265348, rs2532923, and rs114025781 were found to tag HLA risk alleles B*15:02, B*58:01, and B*13:01, respectively, with 100% sensitivity and >95% specificity. No HLA-A risk allele was found to be tagged by any single SNP. The results are being replicated in an independent sample, for which both HLA and SNP genotypes can be called directly from exome or whole genome sequencing. In addition, SNP2HLA was used to construct a Hong Kong population-specific reference dataset for HLA imputation. Using the GWAS sample, complete HLA-A and HLA-B allele information was inferred for a total of 408 epilepsy patients whose cADR status upon taking aromatic antiepileptic drugs was recorded. To determine how HLA genes affect cADR individually and jointly, this data will be combined with Caucasian populations from the International League Against Epilepsy Consortium on Complex Epilepsies for an overall trans-ethic meta-analysis.

Differential allele and haplotype frequencies in the ADME genes *ABCB1* and *NAT2* in Mexican population. *A.V. Contreras, V. Bonifaz-Peña, J.C. Fernández-López, M.E. Tejero.* National Institute of Genomic Medicine, Mexico City, Mexico.

Genetic polymorphisms in genes related to drug absorption, distribution, metabolism and excretion (ADME genes) influence how humans respond to commonly used drugs. However, the effect of the polymorphisms to drug response can differ in magnitude or can be absent depending on the ethnic origin of the population being studied. Most of the Mexican population results from an admixture of any of 65 Native American groups with European ancestry individuals, and to a lesser extent, Africans. To characterize the distribution of relevant genetic markers for pharmacogenomics in *ABCB1* and *NAT2* in Mexican population, we genotyped eight SNPs and inferred haplotypes from individual genotypes. The sample included 250 self-identified Mestizo individuals (MES) from 5 states located in geographically distant regions in Mexico and 45 Native American Zapotecos (ZAP). We evaluated the extent of genetic differentiation (measured as Fst values) of the genetic markers genotyped between Mexican and parental populations. We observed alleles showing large frequency differences in both genes studied. The *ABCB1* 2677G>A/T (rs2032582) TT and the *ABCB1* 3435C>T (rs1045642) TT genotypes was enriched in ZAP (frequency: 46.7 and 53.3%, respectively) compared to MES (frequency: 14.3 and 20.2%, respectively). Moreover, comparative analysis with parental populations evidenced different allele frequencies, including the *ABCB1* 1236C>T (rs1128503) TT genotype (frequency: 11.86% in CEU, 48.88% in ZAP, and 22.32% in MES). In MES and ZAP, the *NAT2*4* (rapid phenotype) was highly prevalent (frequency: 39.2 and 51.5%, respectively), and the frequency showed regional variations related to ancestry. Haplotype distribution for *NAT2* alleles associated with slow phenotype, such as *NAT2*5B*, *NAT2*6A* and *NAT2*7B*, also showed differences between distant regions in Mexico and parental populations. Our results indicate differences in the distribution of allele and haplotype frequencies by the admixture history of Mexican population. Thus, these analyses may be of relevance to better design pharmacogenomic studies leading to a more rational use of drugs in the Mexican population.

Molecular Markers of Blood Pressure Response to Thiazide Diuretics Identified Through Whole Transcriptome RNA-Seq Analysis. *A. Costa Sa[1, 2], A. Webb[3], Y. Gong[1], C.W. McDonough[1], T.Y. Langaee[1], S.T. Turner[4], A.L. Beitelshees[5], A.B. Chapman[6], E. Boerwinkle[7], J.G. Gums[8], S. Scherer[9], R.M. Cooper-DeHoff[1, 10], W. Sadee[3], J.A. Johnson[1, 2, 10].* 1) Center for Pharmacogenomics and Department of Pharmacotherapy and Translational Research, College of Pharmacy, University of Florida, Gainesville, FL; 2) Graduate Program in Genetics and Genomics, Genetics Institute, University of Florida, Gainesville, FL; 3) Department of Pharmacology, College of Medicine, Ohio State University, Columbus, OH; 4) Division of Nephrology and Hypertension, Mayo Clinic, Rochester, MN; 5) Division of Endocrinology, Diabetes and Nutrition, University of Maryland, Baltimore, MD; 6) The Renal Division, Department of Medicine, Emory University, Atlanta, GA; 7) Division of Epidemiology, University of Texas at Houston, Houston, TX; 8) Department of Community Health and Family Medicine, University of Florida College of Medicine, Gainesville, FL; 9) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 10) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, Gainesville, FL.

Hypertension (HTN) is the most significant risk factor for cardiovascular disease, affecting about 1 billion individuals worldwide. Thiazide diuretics are among the most commonly prescribed first line anti-HTN medications, however less than 50% of treated patients achieve BP control. Therefore, the purpose of this study is to identify novel molecular determinants of thiazide diuretics BP response by exploring transcriptome profiling in hypertensive participants treated with hydrochlorothiazide (HCTZ) and chlorthalidone from PEAR (Pharmacogenomics Evaluation of Antihypertensives Response) and PEAR-2 studies, respectively. This study assessed whole genome expression levels in whole blood samples from 150 participants with extremes of BP response (responders and non-responders) to thiazide diuretics (50 whites from PEAR; 50 whites and 50 blacks from PEAR-2). RNA-Seq generated reads (100 bp) were aligned to the human reference genome (Hg19) with TopHat2. Abundance comparisons between responders and nonresponders were carried out using Cufflinks and reported as fragments per kilobase per million reads (FPKM). A t-test was performed to evaluate significance of the difference in FPKM (responders/non-responders). In addition, genome-wide genotyping was determined in 228 white participants, from PEAR and 417 participants from PEAR-2 via Illumina Human Omni 1M-Quad Chip and 2.5M-8 BeadChip, respectively. At FDR adjusted p-value <0.05, we identified 14, 20 and 55 genes that were differentially expressed in relation to HCTZ BP response in whites, and chlorthalidone BP response in whites and blacks, respectively. For each differentially expressed gene in PEAR or in PEAR-2 whites and blacks, we attempted replication in the other race and drug groups. *CEBPD* and *TSC22D3* were differentially expressed in all 3 cohorts, while *SERINC5, PPP2R5C, TFCP2* and *FOS* identified in the PEAR-2 whites participants' cohort, replicated only in PEAR-2 blacks. Of note, rs1004249 was the top significant genetic variant in *SERINC5* where variant allele carriers had poor chlorthalidone BP response vs non-carriers (P=1.8x10-4; b=-3.1 mmHg). Additionally, rs1203488 in *PPP2R5C* was also associated with chlorthalidone BP response in whites (P=3.7x10-4; b=-4.0 mmHg). Further evaluation of these genes may provide new insights into molecular mechanisms underlying BP response to thiazide diuretics.

657T

Distribution of allele frequencies for clinically relevant pharmacogenes in Mexican population. *J.C. Fernandez-Lopez[1], V. Bonifaz-Peña[1], A.V. Contreras[2], A. Hidalgo-Miranda[3].* 1) Computational Genomics Consortium, Instituto Nacional de Medicina Genómica, Mexico City; 2) Nutrigenetics and Nutrigenomics Laboratory, Instituto Nacional de Medicina Genómica, Mexico City; 3) Oncogenomics Consortium, Instituto Nacional de Medicina Genómica, Mexico City.

Pharmacogenomics markers can differ in magnitude or be completely absent depending on the population being assessed. Recently, the frequency distribution of relevant polymorphisms in Absorption, Distribution, Metabolism, and Elimination genes have been described in Mexican mestizo using pharmacogenomic microarray technology (Affymetix DMET array). In this work, we explore allele frequencies and genetic differentiation (*FST* statistic) of 25 polymorphisms (SNPs) in 8 genes: *CYP2C19, CYP2C9, CYP2D6, CYP3A5, DPYD, SLCO1B1, TPMT* and *VKORC 1.* According to the pharmacogenomics knowledge resource (PharmGKB) these genes have been reported to have the highest clinical level of evidence for pharmacogenetics implementation (Clinical Annotation Level 1A). We analyzed these 25 SNPs on three data sets: 320 unrelated Mexican mestizo with mainly Native American and European ancestry (57.4% and 39.1%, respectively); HapMap samples of 60 Europeans, 208 Africans individuals; and 45 Native Americans Zapotecas from Oaxaca, Mexico. Our results showed that allele frequencies and *FST* values for most of SNPs analyzed were similar for Europeans and Mexican mestizo. However, some SNPs showed high allele frequency differences, *CYP3A5* rs776746 with 6% in Europeans and 21% in Mexican mestizos, and *FST* value of 0.05 (p=1.99x10-05). As a matter of fact, this farmacogenomic marker has been reported to have the highest *FST* value between European and African populations (*FST*=0.64). Other genetic variants with important allele frequency differences were *CYP2C19* rs12248560, 22% in Europeans and 9% in Mexican mestizos, and *FST*=0.03 (1.94x10-4); the *CYP2C9* rs1799853, 5% in Mexican mestizos and 15% in Europeans, and *FST*=0.026 (p=4.4x10-4); *CYP2D6* rs3892097 24% in Europeans and 11% in Mexican mestizos, and *FST*=0.026 (p=3.3x10-3). In summary, the allele frequencies for drug related pharmacogenes studied here are in many cases two or four-fold higher between Europeans and Mexican mestizos. This information may help clinicians decide on dosages for populations with large Native American ancestry, as Mexico and other Latin-American countries.

658W

Influence of genetic variability on platelet aggregation in clopidogrel-treated patients of the International Clopidogrel Pharmacogenomics Consortium (ICPC). *J. Lewis[1,2] on behalf on the International Clopidogrel Pharmacogenomics Consortium.* 1) Endocrinology, Diabetes & Nutrition, University of Maryland, Baltimore, Baltimore, MD; 2) Program for Personalized and Genomic Medicine, University of Maryland, Baltimore, Baltimore, MD.

Dual antiplatelet therapy (DAPT) is critical in preventing recurrent cardiovascular events in patients with coronary artery disease (CAD) and other related disorders. While inhibition of platelet aggregation is most commonly achieved with aspirin and clopidogrel, other agents are available (i.e. ticagrelor and prasugrel) and allow for the possibility of more effective and personalized patient care. To better understand the genetic determinants of clopidogrel efficacy, we evaluated the impact of 32 previously reported single nucleotide polymorphisms (SNPs) on ADP-stimulated platelet aggregation in 4175 CAD patients of the International Clopidogrel Pharmacogenomics Consortium (ICPC). Consistent with prior investigations, we observed strong association between the loss-of-function *CYP2C19**2 [rs4244285] variant and increased on-clopidogrel ADP-induced platelet aggregation (P = 1.97 x 10-52, b = 0.46). In contrast, on-clopidogrel ADP-stimulated platelet aggregation was substantially lower in carriers of the loss-of-function *CES1* G143E variant (rs71647871; P = 4.27 x 10-17, b = -0.72) as well as the *CES1* intronic variant rs2244613 (P = 7.84 x 10-4, b = -0.09). While CAD patients who carried the well-described gain-of-function *CYP2C19**17 variant (rs12248560) initially appeared to have better clopidogrel response (P = 7.04 x 10-9, b = -0.17), this association did not remain statistically significant after adjustment for *CYP2C19**2 (P = 0.02, b = -0.07), suggesting that linkage disequilibrium between these SNPs was driving the association with *CYP2C19**17 (D' = 1.0, r2 = 0.05). Genetic variants in other candidate genes (e.g. *PON1* [Q192R (rs662) and L55M (rs854560)], *ABCB1* C3435T [rs1045642] and C1236T [rs1128503]), *ITGB3* [rs5918]), and other CYP enzymes including *CYP2B6*, *CYP2C9*, and *CYP1A2* were not associated with ADP-stimulated platelet aggregation in clopidogrel-treated patients after correction for multiple testing. Taken together, in addition to *CYP2C19**2, our data suggest that genetic variants in *CES1*, encoding the primary enzyme responsible for degrading clopidogrel into biologically inactive carboxylic acid metabolites, significantly influence platelet aggregation in patients on clopidogrel therapy.

Investigating Genetic Variants of *IL-1β*, *IL-2*, *IL-6*, *TSPO*, and *BDNF* in Association with Treatment Response to Duloxetine and Placebo Treatment in Patients with Major Depression. *V.S. Marshe[1,2], M. Maciukiewicz[1], A.K. Tiwari[1], N. Freeman[1], S. Rotzinger[3], J.A. Foster[4], J.L. Kennedy[1,2,5], S.H. Kennedy[3,5], D.J. Müller[1,2,5].* 1) Pharmacogenetics Research Clinic, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, Faculty of Medicine, University of Toronto, Ontario, Canada; 3) Department of Psychiatry, University Health Network, Toronto, Ontario, Canada; 4) Department of Psychiatry and Behavioral Neurosciences, McMaster University, Hamilton, Ontario, Canada; 5) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada.

Major depressive disorder (MDD) is a prevalent psychiatric disorder treated with antidepressant medication such as duloxetine. In addition, placebo treatments have been shown to improve depressive symptoms in a subgroup of patients. This study examined the role of genetic variation of inflammatory markers (*IL-1b*, *IL-2*, *IL-6*, and *TSPO*) including brain-derived-neurotrophic factor (*BDNF*) in response to duloxetine and placebo. Twenty single nucleotide polymorphisms (SNPs) across *IL-1b*, *IL-2*, *IL-6*, *TSPO* and *BDNF* were genotyped in 215 patients receiving duloxetine and 235 patients receiving placebo for 8 weeks. Samples were obtained through a partnership between the Canadian Biomarker Integration Network for Depression (CAN-BIND) and Lundbeck. Interleukin SNPs (r2 = 0.8, MAF > 0.05) covered ~100% of the common genetic variation. For ANCOVAs, we used quantitative and binary response variables. Quantitative response was defined as percentage change in MADRS score from baseline to endpoint. Binary response versus non-response was defined by at least 50% of reduction of MADRS scores from baseline. Two SNPs, rs2066992 (p=0.047) and rs10242595 (p=0.028), in the *IL-6* gene were associated with response to duloxetine after 6 weeks of treatment. *IL-6* variant rs2066992 was also significantly associated with response to placebo after 6 weeks (p=0.026). When dichotomizing response into response vs. non-response, *IL-6* variant rs10242595 was also found to be associated with response to duloxetine (p=0.003), but not placebo. Therefore, SNPs across *IL-6* may play a role in response to duloxetine and placebo.

660W

Spindle and Kinetochore Associated Complex Subunit 2 (SKA2) May Play a Role in Response to Citalopram. *A.J. Lisoway[1], C.C. Zai[1,3], A.K. Tiwari[1], D.J. Müller[1,2,3], Z.A. Kaminsky[4], J.L. Kennedy[1,2,3].* 1) Neurogenetics Section, Campbell Family Research Institute, Centre for Addiction and Mental Health, Toronto, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Canada; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins University, Baltimore, MD; 4) Department of Psychiatry, University of Toronto, Toronto, ON.

Background: Major Depressive Disorder (MDD) has a strong genetic component and is characterized by a number of physiological impairments, including diminished ability of the HPA axis to mediate stress response. The current process used to determine pharmacological treatments is markedly inefficient, with more than 50% of antidepressant treated patients failing to reach remission. Genetic and epigenetic variation in SKA2 (Spindle And Kinetochore Associated Complex Subunit 2) is implicated in mediating HPA axis function, and has recently been associated with suicidal behaviour. We hypothesized that genetic variation in SKA2 may play a role in predicting response to antidepressant medication.**Methods:** 492 Caucasian MDD patients were selected from the STAR*D sample. Change in HAMD-17 score was used to measure response to citalopram. Linear regression analysis was used to model the relationship between seven single-nucleotide polymorphisms (SNPs) in SKA2 and antidepressant response.**Results:** Marker rs7208505 was not significantly associated with antidepressant response (p=0.573) or baseline score on the HAMD-17 suicidality item (p=0.409). rs9892425, located in the 5' region of SKA2, was nominally associated with antidepressant response (p=0.017, pcorr=0.051). This finding was significant for males (p=0.003, pcorr=0.009), but not for females (p=0.396, pcorr=1.000). A trend was observed using a three marker haplotype window encompassing rs9892425 (p=0.068).**Conclusions:** The results provide some evidence that SKA2 genetic variation may be a predictor of therapeutic response to antidepressant medication, particularly in male patients with MDD. Further work incorporating epigenetic information is warranted in larger samples.

Genetic Risk, Smoking Cessation, and the Clinical Benefits of Pharmacotherapy. *L. Chen[1], T. Baker[2], L. Bierut[1].* 1) Psychiatry, Washington University School of Medicine, St. Louis, MO; 2) Tobacco Research and Intervention, University of Wisconsin, School of Medicine, Madison, WI.

Background: Multiple genetic variants have been associated with the risk of nicotine dependence and heavy smoking with genome wide significance. In this study, we tested whether or not these variants could predict the probability of smoking abstinence in a treatment trial and identify those individuals who derive greater clinical benefit from cessation pharmacotherapy.Methods: Using a randomized controlled trial of smoking cessation (N = 1282) we studied the association of a genetic risk score based on 7 genetic variants with smoking abstinence at end of treatment, adjusting for traditional clinical risk factors. We then investigated the genetic prediction of smoking abstinence stratified by treatment condition.Findings: In smokers receiving placebo, the genetic variants significantly improved the prediction of the smoking abstinence at end of treatment. The area under curve (AUC) was 0.56 with clinical predictors (age, sex, cigarettes smoked per day), and increased significantly to 0.71 (p=0.018) when genetic variants were added to the clinical predictors. In contrast, these genetic variants do not improve the prediction of cessation. Smokers with the highest genetic risk derive the greatest benefit from the cessation pharmacotherapies tested.Interpretation: A genetic risk score identified individuals at increased risk for failed smoking cessation amongst those given placebo. People with the highest burden of genetic risk derived the largest relative and absolute clinical benefit from cessation pharmacotherapy.

662W

A common missense variant of *LILRB5* is associated with statin intolerance: A GoDARTS study. *M.K. Siddiqui, A. Veluchamy, R. Tavendale, F. Carr, C. Maroteau, E.R. Pearson, H.M. Colhoun, A.D. Morris, E. Dow, J. George, A. Doney, C.N.A. Palmer.* Division of Cardiovascular & Diabetes Medicine, University of Dundee, Dundee, United Kingdom.

There are approximately 12 million statin users in the United Kingdom. Approximately 9% of users present with intolerance to statins, manifesting as muscle ache, fatigue or more seriously, muscle breakdown leading to myopathy. Creatine phosphokinase (CK) levels are used as a biomarker of statin-induced muscle damage. Variants in *LILRB5* and *CKM* were shown to be associated with CK levels irrespective of statin usage. This study aims to analyse the association of these variants with statin intolerance.Genotype information was gathered for two missense variants, rs12975366 (*LILRB5:* Asp247Gly) and rs11559024 (*CKM*: Glu83Gly) in the GoDARTS study cohort of Scottish Caucasian individuals in the Tayside and Fife areas. We found both variants were associated with CK levels in statin users and non-users, but that only Asp247Gly was associated with our definition of statin intolerance (raised CK and accompanying prescribing changes) : OR 0.48, p value 7.7 x 10 -5 and 95% CI (0.28, 0.65).This demonstrates that the *LILRB5* locus is associated with statin intolerance-related raised CK levels, whereas *CKM* is purely a marker of constitutional serum CK levels. This study also highlights the probability that statin intolerant individuals may not have raised CK levels for genetic reasons.This study presents a novel genetic factor associated with statin intolerance and raises considerations for the usage of CK as a biomarker. It encourages further investigation into the physiology of statin-induced muscle damage, inter-individual variability in CK levels and response to muscle damage.

663T

Fucosyltransferase 2 polymorphism (FUT2, rs492602) associates with vitamin B12 deficiency, but may be independent with proton pump inhibitor or metformin usages, diabetes mellitus, and thyroid diseases. *H. Mo[1], L. Bastarache[1], J.A. Pacheco[2], Y. Xu[1,3], J. Pathak[4], W.K. Thompson[5], J.C. Denny[1,6].* 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Center for Genetic Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) Department of Biostatistics, Center for Quantitative Sciences, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Health Sciences Research and Center for the Science of Health Care Delivery, Mayo Clinic, Rochester, MN; 5) Center for Biomedical Research Informatics, NorthShore University HealthSystem, Chicago, IL; 6) Department of Medicine, Vanderbilt University, Nashville, TN.

GWAS have suggested plasma vitamin B12 concentration is associated with SNP rs492602-C in fucosyltransferase 2 (*FUT2*)(Nat Genet 2008;40:1160). Medical conditions (e.g., diabetes mellitus [DM], thyroid diseases, and use of proton pump inhibitors [PPI], and metformin) are also found to associate with B12 deficiency. However, it has not been established if this SNP associates with B12 deficiency as a disease state, nor is it known if the effect on B12 is a result of interactions between medications or other diseases, rather than representing an independent effect. Thus, we performed an association analysis between rs492602 and B12 deficiency, and also did an interaction analyses between the SNP and related medical conditions. **Methods:** We used rs490602 data from 29,929 European-ancestry individuals genotyped on the Illumina Exome array with traits defined by VUMC electronic health records. We ascertained B12 deficiency cases and matched them with controls (as described in Lam 2013,JAMA,310:2435), and their related comorbid status (DM, thyroid diseases) and medication usages (PPIs, metformin). Associations between B12 deficiency and the SNP or medical conditions were computed using logistic regression, and each interaction was tested as a gene-environment interaction term (GxE). **Results:** In our genotyped population, we identified 524 B12 deficiency cases, and 3509 controls. SNP rs492602-T associates with higher risk of B12 deficiency (OR=1.40, p=5.1e-7), and with abnormally low plasma B12 levels (OR=1.35, p=3.1e-7). We found associations between 3 of the 4 medical conditions and B12 deficiency, and we did not find an interaction with rs492602-C and any of the medical conditions.

Associations between B12 deficiency and medical conditions

	OR	p	GxE OR	GxE p
DM	1.64	1.4e-6	1.05	0.73
Thyroid diseases	1.29	0.012	0.98	0.86
PPI use	1.32	0.07	1.07	0.76
Metformin use(in DM patients)	1.83	0.0028	0.86	0.60

We also tested B12 deficiency and these medical conditions adjusted with rs492602, but none of the new ORs or p-values dramatically changed. **Conclusion:** We found rs492602-T associates with clinically significant B12 deficiency, and replicated known associations between B12 and 2 diseases and 1 medication. We did not find any evidence of rs492602 either confounding or potentiating the association between B12 deficiency and DM, thyroid diseases, PPI use, or metformin use. Thus, we suggest *FUT2* polymorphism is an independent factor of vitamin B12 deficiency.

Applying genetics in inflammatory disease drug discovery. *L. Folkersen[1], S. Biswas[2], K.S. Frederiksen[3], P. Keller[3], B. Fox[2], J. Fleckner[3].* 1) Department of Systems Biology, Copenhagen, Denmark; 2) Department of Molecular Immunology, Novo Nordisk, Seattle, WA, USA; 3) Department of PharmacoGenetics, Novo Nordisk, Novo Nordisk Park, Måløv, Denmark.

Recent groundbreaking work in genetics has identified thousands of small-effect genetic variants throughout the genome that are associated with almost all major diseases. These genome-wide association studies (GWAS) are often proposed as a source of future medical breakthroughs. However, with several notable exceptions, the journey from a small-effect genetic variant to a functional drug has proven arduous, and few examples of actual contributions to drug discovery exist. Here, we discuss novel approaches of overcoming this hurdle by using instead public genetics resources as a pragmatic guide alongside existing drug discovery methods. Our aim is to evaluate human genetic confidence as a rationale for drug target selection.

665T

Novel genetic loci for Resistant Hypertension discovered through a Genome-wide Association approach (GWAS) in the INternational VErapamil SR-Trandolapril STudy (INVEST) and the Secondary Prevention of Subcortical Strokes (SPS3) Study. *N. El Rouby[1], CW. McDonough[1], Y. Gong[1], LA. McClure[2], BD. Mitchell[3,4], RB. Horenstein[3,5], RL. Talbert[7], A. Takahashi[8], T. Tanaka[8], M. Kubo[8], CJ. Pepine[9], RM. Cooper-DeHoff[1,9], OR. Benavente[6], AR. Shuldiner[3,4,5], JA. Johnson[1,9].* 1) Department of Pharmacotherapy and Translational Research and Center for Pharmacogenomics, University of Florida, Gainesville, FL; 2) Department of Biostatistics, School of Public Health, University of Alabama, Birmingham, AL; 3) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 4) Geriatric Research and Education Clinical Center, Veterans Administration Medical Center, Baltimore, MD; 5) Program for Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD; 6) Department of Neurology, University of British Columbia, Vancouver, British Columbia, Canada; 7) College of Pharmacy, University of Texas at Austin, Austin, Texas; 8) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 9) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, Gainesville, FL, USA.

Resistant hypertension (RHTN) is a clinically important pharmacogenomic phenotype defined as a blood pressure (BP) ≥140/90 mm Hg despite use of ≥ 3 antihypertensive medications or BP <140/90 mm Hg using ≥ 4 drugs. RHTN is associated with increased risk for adverse cardiovascular outcomes. We sought to identify novel genetic variants of RHTN through a genome wide association study (GWAS). A discovery cohort of hypertensive participants (N=657 whites) from INVEST-GENES were included as RHTN cases (defined above) or controls defined as BP<140/90 using ≤3 drugs. Participants were randomized to a β-blocker strategy (BB) or a calcium channel blocker strategy (CCB) and had genotype data from the Illumina OmniExpressExome chip. Multiple logistic regression was conducted using an additive genetic model, adjusting for clinical predictors of RHTN, principle components for ancestry and BP treatment arms. Suggestive signals ($p < 1x10-5$) were tested for replication in 263 whites from SPS3-GENES. Three SNPs in the discovery phase met the suggestive p, and two were tested for replication (third SNP absent in SPS3 dataset). The Bonferroni-adjusted p was set at 0.025 to account for multiple comparisons. A combined meta-analysis was also performed between INVEST-GENES and SPS3-GENES for replicated SNPs or SNPs that had consistent association in the two datasets with nominal significance. An intronic SNP in the AQP4-antisense RNA 1 *(AQP4-AS1)* was identified in INVEST-GENES and met the criteria for replication. The A allele of rs630495 was associated with reduced risk for RHTN (OR=0.55, p=1.9 x10-6 in INVEST-GENES; OR=0.6, p=0.023 in SPS3-GENES; meta-p= 3.3 x10-7). rs630495 is an eQTL for the aquaporin-4 (*AQP4)* gene in brain tissue according to the GTex Portal database. *AQP4* is a member of the aquaporin family and functions at the basolateral side of the renal collecting tubule. *AQP4* is highly expressed in the brain and is thought to play an important role in edema production in cerebrovascular diseases. The other SNP near *UPK2* gene (rs647769) was associated with increased risk of RHTN in INVEST-GENES (OR= 2.0, p= 1.6 x 10-7) and was directionally consistent though not significant in SPS3-GENES (OR=1.4, p=0.069). The meta-analysis OR was 1.8 and p= 1.5 x 10-7. In conclusion, we identified *AQP4-AS1* as a novel gene region associated with RHTN, and *UPK2* as a suggestive gene region. These associations, if further validated, may help identify those patients at risk for RHTN.

A Genome-wide Association and Admixture Mapping Study of Bronchodilator Response in African Americans with Asthma. *M.L. Spear[1, 4, 5], M. Pino-Yanes[2, 3], C. Eng[4], S. Huntsman[4], D.G. Torgerson[4], E.G. Burchard[4, 5] on behalf of the SAGE and GALA II Investigators.* 1) Biomedical Sciences Graduate Program, University of California, San Francisco, San Francisco, CA 94158, USA; 2) Research Unit, Hospital Universitario N.S. de Candelaria, Tenerife, Spain; 3) CIBER de Enfermedades Respiratorias, Instituto de Salud Carlos III, Madrid, Spain; 4) Department of Medicine, University of California, San Francisco, San Francisco, CA; 5) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA.

Short-acting b2-adrenergic receptor agonists (SABAs) are the most commonly prescribed asthma medications. Response to SABAs is measured as bronchodilator response (BDR), which varies among racial/ethnic groups in the US. Common variants have been associated with BDR through genome-wide association studies (GWAS), with studies performed in European Americans and Latinos. However, knowledge of genetic variation that contributes to BDR has never been studied in African Americans with asthma. We performed a GWAS in African American children from the Study of African Americans, Asthma, Genes & Environments (SAGE). We included 757 individuals with asthma, genotyped with the Axiom LAT1 array (World Array 4, Affymetrix, Santa Clara, CA) followed by imputation using 1000 Genomes phase 3 data. We performed linear regression adjusting by age, sex, BMI and genetic ancestry to test for an association between BDR and genotype at single nucleotide polymorphisms (SNPs). To complement this analysis, we performed genome-wide admixture mapping to identify regions whereby local African or European genetic ancestry is associated with BDR. We identified a region of candidate SNPs on chromosome 3 as being associated with BDR. For variants with minor allele frequency (MAF)≥5%, the minimum p-value was 10-6; including low frequency variants (1%≤MAF≤5%) we identified SNPs with $p < 5x10-8$ as being associated with differences in BDR. This region is located proximal to *KCNH8*, a member of a family of genes whose functions include regulating smooth muscle cell contraction. Candidate SNPs in *SPATS2L* that previously associated with BDR in Caucasians showed a similar trend of association in African Americans. From our admixture mapping analysis, we identified a peak on chromosome 2 (p=0.0003) where African ancestry was associated with lower BDR. We replicated this effect in Latinos from the Genes-environments and Admixture in Latino Americans (GALA II)study (p=0.005). Overall, our GWAS for BDR in African Americans with asthma identified regions containing common and low frequency variants as being associated with differences in BDR for follow-up study.

667T

Pharmacogenetics of Acute Coronary Syndrome. *P. Yin[1], A. Jorgensen[1], A. Morris[1], R. Turner[2], R. Fitzgerald[2], R. Stables[3], A. Hanson[2], M. Pirmohamed[2].* 1) Department of Biostatistics, INSTITUTE OF TRANSLATIONAL MEDICINE, Liverpool, United Kingdom; 2) Department of Molecular and Clinical Pharmacology, INSTITUTE OF TRANSLATIONAL MEDICINE, Liverpool, United Kingdom; 3) Liverpool Heart and Chest Hospital, Liverpool, United Kingdom.

Coronary heart disease (CHD) is a major global public health burden. It is a recurrent disease that is treated by multiple drugs, including aspirin, clopidogrel, statins, beta-blockers, and ACE inhibitors. There is significant inter-patient variability in the response to cardiovascular drugs, which may have a heritable basis. We have therefore undertaken a genome-wide association study (GWAS) to identify loci associated with response to cardiovascular drugs in 1470 patients recruited to a UK prospective pharmacogenetic study of acute coronary syndrome (PHACS).Index hospital admission was defined non-ST elevation acute coronary syndrome. Patients were treated with a range of cardiovascular drugs, including statins (93%) and clopidogrel (83%), and followed up prospectively for up to 48 months. Approximately 8% of the patients had another cardiovascular event including myocardial infarction (MI) or stroke, in some cases resulting in death. We defined a binary outcome corresponding to the occurrence of any of these events in one year after hospital discharge. We began by considering clinical risk factors for drug response. Several risk factors were related: age (p=3.2x10-7), prior MI (p=0.0048), diabetes (p=0.032), ACE inhibitor use pre-admission (p=0.0072), aspirin use at discharge (p=0.0066) and gender (p=0.12).Patients were genotyped using the Illumina OmniExpress array. After quality control, the genotype scaffold was imputed up to the 1000 Genomes Phase I reference panel (all ancestries, March 2012 release). We tested for association of SNPs with outcome under an additive dosage model in a logistic regression framework after adjusting for the clinical factors identified above and principal components to account for population structure. Variants mapping to the *LRPPRC* gene demonstrated strong evidence of association: lead SNP rs65544733, minor allele frequency 0.37, odds ratio (95% CI) 1.96 (1.49-2.63), p=2.9x10-7. When stratifying the analysis by drug, the association with this variant was strongest in patients treated with statins (p=6.5 x10-8). *LRPPRC* encodes a leucine-rich protein with, as yet, unknown role. Mutations in the gene have previously been associated with Leigh syndrome, which causes lowered levels of cytochrome C oxidase, a key enzyme in aerobic metabolism. Our study highlights that variants mapping to *LRPPRC* are associated with response to cardiovascular drugs in CHD patients, in particular those treated with statins.

668W

Using polygenic risk scores to guide antipsychotic dosage in a geriatric schizophrenia population. *N. Hettige[1,2], C. Cole[1], V. De Luca[1,2].* 1) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada.

Antipsychotic medications are commonly used to treat elderly patients with delirium, agitation and psychosis due to Alzheimer's disease, and schizophrenia. Schizophrenia is a debilitating mental healh disorder that once diagnosed, remains throughout the lifetime. The first line of treatment for individuals with schizophrenia is to administer antipsychotic medication which aims to reduce the severity of psychotic symptoms, such as hallucinations and paranoia. As individuals with schizophrenia may be required to take antipsychotic medication for the duration of their life, antipsychotic dosage must be adjusted accordingly due to age-related neurobiological changes or symptom severity. The purpose of our study was to calculate the polygenic risk scores for the risk alleles that reached genome-wide significance from the recent genome-wide association study by the Psychiatric GWAS Consortium for Schizophrenia. We hypothesized that individuals with a high risk score would potentially represent increased symptom severity and therefore require higher antipsychotic dosage. Polygenic risk scores were used to predict whether individuals with a higher score also require higher antipsychotic dosage. In our preliminary sample of 83 European Caucasian individuals, we found that the risk score was not significantly predictive of antipsychotic dosage. Incorporating the polygenic score in our model, however, better explained the variance in dosage compared to age and sex alone. The polygenic risk score may be a useful way of translating the knowledge aquired from GWA studies to predict clinical outcomes and related endophenotypes.

669T

Partitioning the polygenic inheritance of paclitaxel-induced peripheral neuropathy. *E.A. Khramtsova[1], H.E. Wheeler[1], D.L. Kroetz[2], K. Owzar[3], H.L. McLeod[4], N.J. Cox[5], M.E. Dolan[1], B.E. Stranger[1], L.K. Davis[1].* 1) Department of Medicine, The University of Chicago, Chicago, IL; 2) Department of Bioengineering and Therapeutic Sciences, University of California San Francisco, San Francisco, CA; 3) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC; 4) Personalized Medicine Institute, Moffitt Cancer Center, Tampa, FL; 5) Division of Genetic Medicine, Vanderbilt University School of Medicine, Nashville, TN.

Peripheral neuropathy is one of the most common side effects of paclitaxel treatment affecting 20-40% patients receiving the chemotherapy. Previous studies have identified several single nucleotide polymorphisms (SNPs) and genes associated with increased susceptibility to peripheral neuropathy development, but individual SNP replication is lacking, so we sought to look for polygenic traits. Whole genome estimates of heritability have been challenging due to small sample size, although a previous study has shown that if gene sets are analyzed separately, the axonogenesis GO Term set had significant estimates of heritability close to 20%. We performed an analysis of paclitaxel-induced neuropathy heritability in the CALGB40101 (Alliance) trial, but in contrast to previous analysis of these datasets, we performed a more stringent population stratification analysis and included the X chromosome in the analysis. Principal component analysis of genetic data revealed a small group of closely-related individuals which formed a separate cluster from all of the individuals of European ancestry. These 10 individuals in the CALGB40101 cohort were excluded from further analysis. Thus, our study sample consisted of 204 cases with neuropathy grade 2 and 3, and 640 controls. Using GCTA, we estimated the whole genome heritability of paclitaxel-induced peripheral neuropathy in this cohort to be 0.49 (se=0.42, P=0.114). Partitioning heritability by allele frequency revealed that the minor allele frequency group of >0.4-0.5, which comprises 18.7% of total SNPs, contributes the most to heritability (h2=0.45, se=0.25, P=0.038). Partitioning heritability by chromosome showed that chromosomes 2 (h2=0.22, se=0.12, P=0.037) and 10 (h2=0.19, se=0.10, P=0.032) contribute the most to heritability. We did not find any contribution to heritability from the X chromosome. Genome-wide association analysis of neuropathy cases versus controls did not reveal any genome-wide significant SNP-trait associations. However, the strongest signals (P<10-6.5) were for SNPs in the *ESPNL* and *UBE2F-SCLY* genes. While chromosomes 2 and 10 explained the greatest proportion of phenotypic variance, there were no SNPs with P<10-8 on those chromosomes, suggesting that individual effect sizes are small but cumulatively important. Taken together, our findings are consistent with a polygenic model for chemotherapy-induced neuropathy.

670W

A Variant in *UGT2A1/2* is Associated with Sex-Specific Clopidogrel Response. *A.S. Fisch, J.P. Lewis, L.M. Yerges-Armstrong, A. Parihar, H. Xu, J.R. O'Connell, K.A. Ryan, R.B. Horenstein, B.D. Mitchell, A.R. Shuldiner.* Program for Personalized and Genomic Medicine, Division of Endocrinology, Diabetes, and Nutrition, University of Maryland School of Medicine, Baltimore, MD.

Coronary artery disease (CAD) is the leading cause of death in the United States, with reported event rate disparities across sexes. Clopidogrel is an antiplatelet agent for high-risk CAD treatment. Clopidogrel response variability is established, and previous investigations show a genetic component to the variability, including the well-described *CYP2C19*2* variant. However, *CYP2C19*2* accounts for 12% of the ~70% heritability of clopidogrel response, suggesting undiscovered genetic determinants of the trait. To identify these variants, we genotyped 647 individuals from the Pharmacogenomics of Anti-Platelet Intervention (PAPI) Study using the Affymetrix Drug Metabolizing Enzymes and Transporter (DMET) chip. We then examined the effect of 643 polymorphic SNPs with MAF ≥ 0.01 (multiple testing-corrected significance threshold of P=7.43x10-5) on clopidogrel response, defined as maximal platelet aggregation change between pre- and post-clopidogrel treatment for one week (300 mg loading dose, 75 mg maintenance dose). Associations were analyzed with a multivariable linear regression model adjusting for age, sex, and relatedness. We observed significant associations between clopidogrel response and *CYP2C19*2* (rs4244285; P=5.34x10-13) as well as the novel intronic variant rs11249454 in UDP glucuronosyltransferase 2A1 and 2A2 (*UGT2A1/2*), with the minor allele associated with a 24% decrease in clopidogrel response (b=-10.3±2.4; P=2.92x10-5). Based on the roles of UGT2A1/2 in androgen and estrogen metabolism, a sex stratified association analysis was performed, showing significance in 325 PAPI women (P=8.40x10-6) and no association in 322 men (P=0.21). The results of a SNP x sex interaction analysis were significant (P = 0.049). Sex-specific differences remained after *CYP2C19*2* adjustment (Pwomen=8.12x10-5; Pmen=0.14). This study suggests that genetic variation in *UGT2A1/2* affects clopidogrel response in a sex-dependent manner. These findings are consistent with other groups' data regarding sex-specific effects of sex hormone metabolizing UGTs, and may connect to prior reports of altered *UGT2A1/2* expression by substrate level and biological sex. In light of previous findings regarding sex hormone effects on platelet aggregation, UGT2A1/2 may be a key regulator of sex-specific clopidogrel response. Continued studies are needed to replicate our findings and understand mechanisms by which rs11249454 affects UGT2A1/2 function and, ultimately, clopidogrel response.

671T

Prevalence of CYP2D6*4 allele in a Northern Mexican Mestizo population for the assessment of tamoxifen metabolism. *J.E. Gaytán-Arocha[1], K.L. Valdés-Morales[1], R.D. Arellano-PérezVertti[1], D. Delgadillo-Guzmán[1], R.I. de la Cruz-Granados[1], J.R. Argüello[1,2], F.F. González-Galarza[1].* 1) Faculty of Medicine, Autonomous University of Coahuila, Torreon, Coahuila, Mexico; 2) Institute of Science for Genomics Medicine, Torreon, Coahuila, Mexico.

In recent years, the use of different technologies such as microarrays has allowed scientists to perform cost-effective association studies in different fields, including pharmacogenomics. Tamoxifen has been a widely studied drug that is used in breast cancer therapy which needs the CYP2D6 enzyme to be metabolized into its active form. From the 155 alleles that have been identified in the CYP2D6 gene at present, CYP2D6*4 is the most common allele with inactive enzyme activity. Thus, in this study, we analyzed one-hundred randomly-selected individuals from the North Area of Mexico that were SNP genotyped using the Illumina array technology with more than 600,000 SNPs. To evaluate the allele coverage of the DNA chip, we used an in-house software tool to perform the sequence alignment. We also calculated genotype and allele frequencies and evaluate the CYP2D6 gene diversity in Mexicans compared to other populations. Interestingly, the allele CYP2D6*4 was present in 12.9% of the individuals. We believe that the use of these findings may provide a useful resource for scientists and assist physicians when deciding to prescribe tamoxifen.

672W

A longitudinal genome-wide association study of anti-tumor necrosis factor response among Japanese patients with rheumatoid arthritis. *D. Jawaheer[1], I. Hallgrimsdottir[2], K. Honne[3], C. Wu[4,5], R. Sebro[6], N. Jewell[7], T. Sakurai[8], M. Iwamoto[3], S. Minota[3].* 1) Children's Hospital Oakland Research Institute, Oakland, CA, USA; 2) Integrative Biology, UC Berkeley, CA 94720, USA; 3) Rheumatology and Clinical Immunology, Jichi Medical University, Shimotsuke, Tochigi, Japan; 4) Institute of Clinical Research, University of Southern Denmark, Odense, Denmark; 5) Dept of Obstertics & Gynecology, Odense University Hospital, Odense, Denmark; 6) Radiology Dept, University of Pennsylvania, Philadelphia, PA 19104, USA; 7) School of Public Health, UC Berkeley, CA 94720, USA; 8) Inoue Hospital, Takasaki, Gunma, Japan.

Introduction: Studies of patients with rheumatoid arthritis (RA) to identify genetic biomarkers of anti-tumor necrosis factor (TNF) response have used response at a single follow up time point as the phenotype with which single nucleotide polymorphisms (SNP) associations have been tested. There has been little overlap in findings across studies, most of which have been conducted in Caucasian populations. We report here the first genome-wide association study (GWAS) to identify genetic biomarkers of anti-TNF response among Japanese RA patients, using anti-TNF response at 2 time-points for a more reliable clinical outcome over time.Methods: Disease Activity Scores based on 28 joint counts and C-reactive protein (DAS28CRP3) were assessed at baseline (before initial therapy), and after 3 and 6 months in 487 Japanese RA patients starting anti-TNF therapy for the first time or switching to a new anti-TNF agent. A genome-wide panel of single nucleotide polymorphisms (SNPs) was genotyped and additional SNPs were imputed. Using change in DAS28 scores from baseline (ΔDAS28) at both 3 and 6 months as the response phenotype, a longitudinal genome-wide association (GWA) analysis was conducted using Generalized Estimating Equations (GEE) models to accommodate the repeated measures of the outcome, adjusting for baseline DAS28, time since initiation of therapy, type of anti-TNF agent and concomitant methotrexate.Results: A total of 4,253,138 autosomal SNPs passed quality thresholds for association analysis. Suggestive evidence of association ($p<1x10-6$) with ΔDAS28 was observed at 3 chromosomal regions (6q15: rs284515, p=6.6x10-7; 6q27: rs75908454, p=6.3x10-7 and 10q25.3: rs1679568, p=8.1x10-7), extending to numerous SNPs in linkage disequilibrium (LD) across each region. Potential candidate genes in these regions include *MAP3K7* (6q15) a key player in TNFα-mediated inflammatory pathway signaling, *GFRA1* (10q25.3) which was associated with anti-TNF response in an independent study, and *WDR27* (6q27).Conclusion: In this first GWAS of anti-TNF response among Japanese RA patients using a longitudinal analysis approach, three genomic regions demonstrated suggestive association with response to anti-TNF therapy. Using more than one assessment of response enhanced the power to detect these associations.

Meta-analysis of the genome wide association studies (GWAS) on the intolerance of angiotensin converting enzyme inhibitors (ACEIs). *C.N.A Palmer[1], S.H Mahmoudpour[2], M.K. Siddiqui[1], A. Veluchamy[1], F.W. Asselbergs[3], P.C. Souverein[2], C.E. de Keyser[4], A. Hofman[4], B.H. Stricker[4], A. de Boer[2], A.H. Maitland-van der Zee[2], PREDICTION-ADR.* 1) Medical Research Institute, University of Dundee, Dundee, United Kingdom; 2) 1Div. of Pharmacoepidemiology & Clinical Pharmacology, UIPS, Utrecht University, Utrecht, the Netherlands; 3) Div. of Heart & Lungs, Dept. of Cardiology, UMC Utrecht, Utrecht, The Netherlands; 4) Dept. of Epidemiology, Erasmus MC, Rotterdam, The Netherlands;.

BackgroundACEIs are frequently used to treat hypertension and heart failure. Cough and angioedema are the two main adverse drug reactions (ADRs) associated with ACEI use that occur in up to 20% of the patients and are the main reason of therapy discontinuation1.**Aims**To identify single nucleotide polymorphisms (SNPs) associated with switching of an ACEI to an angiotensin receptor blocker (ARB) as a marker for ADRs.**Methods**A cohort of patients starting ACEIs was identified within the Rotterdam Study in the Netherlands and the GoDARTS study in Scotland. Cases were subjects that switched from an ACEI to an ARB while controls were subjects who used ACEIs for at least 2 years and did not switch. The validity of using switching as a marker for ACEI-induced adverse drug reaction (ADR) was investigated in a subset of users that had the primary care records available. A GWAS using an additive model was performed and results were meta-analyzed using METAL2. **Results/Conclusions** In total 5109 ACEI starters were included in the study of which 959 were cases. The validation of switch as marker for ACEI-induced ADRs showed the positive predictive value of 90.5% for at least possible ADRs within a subset of 1132 patients. Ten SNPs within four genes reached the GWAS significance level in the meta-analysis. The strongest associated SNP was located on chromosome 17q25 (MAF=0.16, OR=1.52 [95%CI: 1.32-1.76], p=6.2x10-9). These results indicate a substantial contribution of genetic variation in determining the risk of ACEI-induced ADRs, and warrant further studies in larger populations.**References:**Morimoto T, Gandhi TK, Fiskio JM, Seger AC, So JW, Cook EF, et al. Identifying a Novel Hypertension Genetic Signature Influencing the Blood Pressure Response to Hydrochlorothiazide Treated Patients. *M.H. Shahin[1], A.C. Sa[1], A. Webb[2], Y. Gong[1], T. Langaee[1], C.W. McDonough[1], A.L. Beitelshees[3], A.B. Chapman[4], J.G. Gums[1], S.T. Turner[5], R.F. Frye[1], S.E. Scherer[6], W. Sadee[2], R.M. Cooper-DeHoff[1], J.A. Johnson[1].* 1) Pharmacotherapy and Translational Research, University of Florida, Gainesville, Florida; 2) Program in Pharmacogenomics, Department of Pharmacology, The Ohio State University, Columbus, Ohio; 3) Department of Medicine, University of Maryland, Baltimore, Maryland; 4) Department of Medicine, Emory University, Atlanta, Georgia; 5) College of Medicine, Mayo Clinic, Rochester, Minnesota; 6) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas.

Hypertension is a global public health burden and a significant contributor to heart attack, stroke, and kidney failure, making its control of critical importance. Hydrochlorothiazide (HCTZ) is among the most commonly prescribed first line antihypertensives in the US, yet, less than 50% of HCTZ treated patients achieve blood pressure (BP) control. A recent meta-analysis, including gene expression profiles of ~7000 individuals, revealed 34 genes explaining ~9% of the inter-individual variability in BP (PMID:25785607). We hypothesized that those genes might also influence the BP response to HCTZ and give us more insight in the BP lowering mechanism underlying this therapy. The primary analysis included clinical data and biological samples from 228 white hypertensives recruited as part of the Pharmacogenomic Evaluation of Antihypertensive Response (PEAR) trial, with BP determined at baseline and after 9 weeks of HCTZ treatment. A total of 216 Single nucleotide polymorphisms (SNPs), within the candidate regions (transcript ± 2kb) of the 34 BP susceptible genes, were extracted from the Illumina Omni 1M-Quad Chip. A Bonferroni threshold of 2.3x10-4 (0.05/216) was used to account for multiple comparisons of the SNP association analysis. Illumina© HiSeq 2000 was used to conduct RNA-Seq on PEAR white baseline blood samples of extreme HCTZ BP response (25 responders and 25 non-responders). RNA-sequencing reads were aligned to the reference genome (homo sapiens Hg19) with TopHat2, and gene expression levels were calculated using cufflinks/cuffdiff. We adjusted for age, gender, and baseline BP in all analyses. First, out of the 216 tested SNPs, we identified rs6750487 SNP within the *ARHGAP15* (Rho GTPase activating protein 15) gene as a significant predictor of HCTZ BP response where A allele carriers had a better BP response than non-carriers (DSBP/ΔDBP:-19.8/ -11.4 vs -7.5/-4.1 mmHg, respectively, DSBP p=8x10-6 and ΔDBP p=1x10-4). Additionally, *ARHGAP15* baseline expression levels were significantly correlated with HCTZ BP response (DSBP r=-0.37 p=9x10-3, ΔDBP r=-0.36 p=1x10-2). This study aligns with recent studies showing the importance of *ARHGAP15* in hypertension and BP regulation. Additionally, our results suggest that *ARHGAP15* might be an important determinant of HCTZ BP response.

675T

Robust Heritability Estimation of Anti-TNF Treatment Response Phenotypes in Rheumatoid Arthritis. *K.A. Standish[1,2], C.C. Huang[4], M. Curran[4], N.J. Schork[1,2,3].* 1) Human Biology, J. Craig Venter Institute, La Jolla, CA; 2) University of California, San Diego; 3) The Translational Genomics Institute, Phoenix, AZ; 4) Janssen R&D, LLC.

Several classes of drug have been approved to treat rheumatoid arthritis (RA); however, there is heterogeneity in patients' response to different treatments, including anti-TNF agents. Identifying an effective treatment early can slow disease progression and result in better overall outcomes for patients. Pharmacogenetics studies aim to identify genetic predictors of treatment response in order to better understand the underlying mechanisms of response variability and to inform more efficient treatment decisions. Previous studies attempting to estimate the heritability of anti-TNF treatment response have certain limitations. While patients can be stratified into "responder" and "non-responder" groups, continuous response phenotypes (e.g., disease activity state, swollen or tender joint counts) provide a more robust alternative; however, many genetic association methods make assumptions about the distributions of the phenotype variables. In particular, these parametric approaches assume that the data are normally distributed and heteroscedastic. In reality, the response phenotypes often do not conform to these assumptions. Furthermore, previous studies relied on a single pre-treatment measurement and a single follow-up measurement to determine the degree of response, failing to account for variability among repeated measurements. Here, we address these limitations as we make use of a longitudinal clinical data set and whole-genome sequencing in a cohort of rheumatoid arthritis patients treated with an anti-TNF drug. First, we find that transforming data to better conform to the basic assumptions of parametric association methods increased the heritability estimates for several metrics and resulted in greater levels of significance. Next, we show the variability between single measurements and confirm an increase in power when making use of repeated measurements before and/or after treatment. We find consistently higher heritability estimates when making use of averaged response metrics. Additionally, we demonstrate that the use of more subjective measurements, such as swollen and tender joint counts, can be confounded by placebo response. Finally, we validate our findings using permutation testing to calculate p-values relating to each heritability estimate. Overall, our work provides an example of the importance of robust estimation of phenotype heritability to pharmacogenetics studies.

***CYP2D6* Gene Variants and Effectiveness of Adjuvant Tamoxifen in Breast Cancer: A Population-Based Case-Control Study.** *C.S. Richards[1], K.E. Richert-Boe[2], K.A.B. Goddard[2], C. Chen[2], S. Punj[1], D. Schwarzkopf[2], M. Kalter[2], S. Weinmann[2].* 1) Department of Molecular and Medical Genetics, Knight Diagnostic Laboratories, Oregon Health & Science University, Portland, OR; 2) Center for Health Research, Kaiser Permanente Northwest, Portland, OR.

Tamoxifen, a cornerstone of adjuvant therapy for hormone-receptor-positive breast cancer, is metabolized to the active metabolite endoxifen through enzymatic activity of cytochrome P450 2D6. *CYP2D6* has numerous alleles that affect metabolizing phenotype. Among women who take tamoxifen, those homozygous for inactive alleles (poor metabolizers) have lower levels of serum endoxifen than those with two functional alleles (extensive metabolizers). We conducted a population-based case-control study in the Kaiser Permanente Northwest integrated health plan to evaluate the hypothesis that, after adjuvant tamoxifen treatment for breast cancer, women with *CYP2D6* genotypes associated with poor metabolism of tamoxifen have an elevated risk of breast cancer recurrence compared to women with *CYP2D6* genotypes associated with extensive metabolism of tamoxifen. Study subjects were diagnosed between 1980 and 2011 with hormone-receptor positive breast cancer who received at least 180 days of adjuvant tamoxifen treatment and for whom stored formalin-fixed paraffin-embedded (FFPE) normal tissue was available for laboratory analysis. The Oregon Health & Science University Molecular Genetics Laboratory extracted genomic DNA from stored FFPE tissue blocks and performed allelic discrimination assays and pyrosequencing to accurately determine *CYP2D6* variant status for the alleles, *3, *4, *5, *10, *17, and *41. We also collected data from medical records and from pharmacy, laboratory, tumor registry, and membership health plan databases. Statistical analysis will include multivariable logistic regression analysis to assess CYP2D6 functional status and activity score in relation to breast cancer recurrence. We identified 358 cases with breast cancer recurrence. Randomly selected controls (833), without breast cancer recurrence, were matched to cases on tumor stage, diagnosis year, diagnosis age, race/ethnicity, and patterns of health plan membership. All assays have been completed and study subjects have been categorized according to CYP2D6 metabolizer phenotype (poor, intermediate, extensive) and activity score (0-2). Based on the ethnicities in our study population, the *CYP2D6* allele frequencies are in Hardy-Weinberg equilibrium, and the frequencies of the predicted metabolizer phenotypes also fall within the expected range. Preliminary logistic regression results will be presented.

Assessment of Knowledge and Comfort of Healthcare Providers in the Development of a User-Friendly Pharmacogenomics Report. *C.A. Campbell[1], A.E. Kwitek[1], M. Kimble[1], D.L. Kolbe[1], C. Nishimura[1], M.A. Mansilla[1], S.O. Mason[1], T. Bair[1], K.L. Knudtson[1], O. Shchelochkov[1], D.J. Murry[2], M. Sorenson[3], M.J. Brownlee[3], R.J.H. Smith[1].* 1) Iowa Institute of Human Genetics, University of Iowa, Iowa City, IA; 2) University of Iowa College of Pharmacy, Iowa City, IA; 3) University of Iowa Hospitals and Clinics Pharmacy Department, Iowa City, IA.

As genetic tests are ordered more frequently by non-geneticists, it is imperative the results are understandable and useful. The Iowa Institute of Human Genetics (IIHG) offers a clinical pharmacogenetics (PGx) test, so our goal was to create a result report that is an informative educational tool to aid providers in the use of PGx in the management of their patients. The purpose of this study was to ask healthcare providers about PGx test reports to see whether the medical and genetic terminology used in the reports is understandable to the average healthcare provider. The original report contained a brief summary of results and recommendations. Clinical recommendations are based on the Clinical Pharmacogenetics Implementation Consortiumguidelines and written in collaboration with pharmacists at the University of Iowa. The report also contained appendices of result and methodology details, and educational materials. A genetic counselor conducted brief interviews with eight surgeons who had previously used the PGx test on 53 patients. Responses were transcribed and analyzed. Questions covered understanding of results, content preferences, points of confusion, PGx implementation challenges, and comfort explaining results. Providers were also shown results reports from other clinical testing labs for comparison. The report was modified, and additional interviews are being conducted with pharmacists, residents, and internists. Results of the interviews indicated all of the providers understood the report. In general, providers; 1) liked the report's brief summary and clinical recommendations; 2) appreciated education information in the appendices; and 3) were comfortable explaining results to patients. One interviewee stated, the report has "to speak to both the clinician and layperson. The clinician is going to read this like a layperson, but needs to understand what it means for the medicine so he can appropriately treat his patient." Providers expressed frustration with; 1) non-intuitive pharmacogenetics nomenclature; and 2) lack of insurance reimbursement. In summary, stakeholder interviews aided in the development a user-friendly PGx report that can serve as an educational resource for non-genetics providers. Feedback on return of genetic test results, and utilization of clinical pharmacogenetics testing from non-geneticists providers is critical if pharmacogenetics testing is to be implemented as part of a precision medicine program.

Development and comparison of warfarin dosing algorithms in stroke patients. *S. Cho[1], K. Lee[2], J. Choi[3], K. Lee[1].* 1) Departments of Laboratory Medicine, Gangnam Severance hospital, Yonsei University College of Medicine, Seoul, Korea; 2) Departments of Neurology, Gangnam Severance hospital, Yonsei University College of Medicine, Seoul, Korea; 3) Departments of Laboratory Medicine, Severance hospital, Yonsei University College of Medicine, Seoul, Korea.

Purpose: The genes for cytochrome P450 2C9 (*CYP2C9*) and vitamin k epoxide reductase complex subunit 1 (*VKORC1*) have been identified as important genetic determinants of warfarin dosing and have been studied. We developed warfarin algorithm for Korean patient with stroke and compared the accuracy of warfarin dose prediction algorithms based on the pharmacogenetics.**Material and Methods**: A total of 101 patients on stable maintenance dose of warfarin were enrolled. Warfarin dosing algorithm was developed using multiple linear regression analysis. The performance of all the algorithms was characterized with coefficient of determination, determined by linear regression, and the mean of percent deviation predicted doses from the actual dose. In addition, we compared the performance of the algorithms using percentage of predicted dose falling within ±20% of clinically observed doses and dividing the patients into a low-dose group (≤3mg/day), an intermediate-dose group (3-7mg/day), and high-dose group (≥7mg/day).**Results**: A newly developed algorithms including the variables of age, body weight, and *CYP2C9* and *VKORC1* enotype. Our algorithm accounted for 51% of variation in the warfarin stable dose. The predicted doses using algorithms derived from Anderson and this study showed the best correlation with actual warfarin doses. Our algorithm performed best in predicting dose within 20% of actual dose and intermediate-dose.**Conclusion:** Our warfarin dosing algorithm may be useful for Korean patients with stroke. Further studies to elucidate clinical utility of genotype-guided dosing and find the additional genetic association is necessary.

679T

The identification of hematologic adverse drug events using the electronic health record in the eMERGE PGx cohort, in relation to pharmacogenetic variation. *D. Crosslin[1,2], A. Gordon[1], D. Carrell[3], P. Robertson[2], A. Scrol[3], J. Ralston[3], A. Hartzler[3], K. Leppig[3], M. de Andrade[4], J. Grafton[3], D. Kim[1,2], A. Burt[1], K. Doheny[5], P. Crane[6], S. Stallings[7], M. Dorschner[8], D. Nickerson[2], E. Larson[3], J. Denny[7], M. Ritchie[9], M. Williams[10], M. Palmer[11], I. Kullo[12], T. Manolio[13], G. Jarvik[1,2], The electronic Medical Records and Genomics (eMERGE) Network.* 1) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Group Health Research Institute, Center for Health Studies, Seattle, WA; 4) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 5) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 6) Division of General Internal Medicine, University of Washington, Seattle, WA; 7) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 8) Department of Pathology, University of Washington, Seattle, WA; 9) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, Pennsylvania State University, University Park, PA; 10) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 11) Department of Urology, University of Washington, Seattle, WA; 12) Division of Cardiovascular Diseases, Mayo Clinic, Rochester, MN; 13) Division of Genomic Medicine, National Human Genome Research Institute, Bethesda, MD.

Using the electronic health record (EHR), we are attempting to algorithmically identify adverse drug events (ADEs) in ~9000 eMERGE participants that have been sequenced with the targeted Pharmacogenomics Research Network sequence platform (PGRNseq). This platform was designed with the coding regions, UTRs, 2kb upstream, and 1kb downstream for 82 pharmacogenes. The goals are to assess a trend in ADEs in this cohort overall and stratified by ancestry/sex, and to assess the possible association with pharmacogene(s). Network-wide recruitment is ongoing (~6000), and we are developing the algorithm on a pilot set of ~900 mixed-ancestry participants from the Group Health, Seattle. The algorithm harnesses information from demographic, laboratory, and prescription data derived from the outpatient EHR. Using laboratory data, we assess patterns of change in hematological counts that could suggest an ADE, and assess patterns of change in platelets to identify thrombocytopenia due to multiple mechanisms. These events, coupled with prescription data patterns, could further support the identification of ADEs. Once these patterns are identified, we will assess the association of these events with genetic variation identified by PGRNseq, overall and stratified by ancestry/sex. As proof of concept, we assessed 900 persons for platelet count < 2 standard deviations of the median for that participant. We evaluated all prescriptions from the prior 7-28 days. The most frequent drug identified was Acetaminophen/Hydrocodone with 11 events for 5 participants. Using guidelines from PharmGKB, we focused on variation in *ABCG2*, *CYP2D6*, *G6PD*, *HLA-B*, and *UGT1A1*. A total of 8 variants were identified (7 missense, 1 splice-acceptor) and found in *ABCG2* (n=2), *CYP2D6* (n=5), and *UGT1A1* (n=1). Notably, *ABCG2* is involved in metabolism and transport of acetaminophen in the liver. Next steps are to refine the EHR algorithm with a sliding window for patterns of hematologic changes, and a custom prior prescription window per blood cell index. We also will expand to the entire eMERGE PGx cohort as enrollment approaches ~9000. Identification of AEs using the EHR and the pattern of enrichment of these events with pharmacogenes in the eMERGE cohort could inform on drug selection and dosing guidance overall, and by ancestry.

Kingsmore[2,3,4].* 1) Clinical Pharmacology, Toxicology & Therapeutic Innovation, Children's Mercy Kansas City, Kansas City, MO, USA; 2) Center for Pediatric Genomic Medicine, Children's Mercy Kansas City, Kansas City, MO, USA; 3) Department of Pediatrics, Children's Mercy Kansas City, Kansas City, MO, USA; 4) Department of Pathology, Children's Mercy Kansas City, Kansas City, MO, USA; 5) School of Medicine, University of Missouri-Kansas City, Kansas City, MO, USA; 6) Department of Pediatrics, University of New Mexico Health Science Center, Albuquerque, NM, USA; 7) Clinical Translational Science Center, University of New Mexico, Albuquerque, NM, USA; 8) Division of Computer Science and Electrical Engineering, School of Computing and Engineering, University of Missouri-Kansas City, Kansas City, MO, USA.

Background: Whole genome sequencing (WGS) has the potential to inform drug choice and dosing after identifying genetic variation in pharmacogenes in a patient's genome. The highly polymorphic *CYP2D6* gene encodes one of the most important and highly polymorphic drug metabolizing enzymes. Due to the complexity of the gene locus, genotype analysis is challenging and often only includes common variants. Here we describe Constellation, a probabilistic scoring algorithm, which enables automated ascertainment of *CYP2D6* phenotype from WGS data. **Methods:** The Study was approved by the Institutional Review Board of Children's Mercy–Kansas City and included 61 subjects (7 HapMap; 54 patients/parents). Constellation uses a probabilistic scoring system to determine the most likely diplotype of a WGS sample for each locus. Data inputs included (vcf) files, a gene directory with chromosomal position, and allele definition files (allele definitions according to *CYP2D6* nomenclature at cypalleles.ki.se/. Constellation was implemented in Java. WGS was performed on HiSeq 2500 instruments (depth ~120GB; 2x100nt reads; TruSeq DNA PCR-Free kits). Variants were called with GSNAP 2012-`7-12 and GATK 1.6. All samples were genotyped using long-range (XL) PCR, TaqMan assays and a quantitative CNV assay. A subset of 34 subjects were Sanger sequenced to confirm or resolve differences between genotyping and Constellation calls.**Results:** When compared with genotyping (consisting of SNV, CNV and XL-PCR analysis) and Sanger sequencing, Constellation correctly called *CYP2D6* diplotypes for 56 of 61 subjects. Phenotype prediction between genotype, Sanger and WGS/Constellation were consistent for 57 subjects. Constellation also accurately identified 5 samples carrying a gene deletion and 2 subjects with a gene duplication. When combined with rapid WGS methods, Constellation can provide provisional *CYP2D6* phenotype prediction within 30 hours.**Discussion:** Although this study focused on *CYP2D6*, Constellation is generally extensible to other ADMER genes, and can be performed at marginal incremental cost in the setting of diagnostic WGS. Constellation depends on the quality of data input, i.e. sequence data and haplotype definition sets. Advancing NGS technology and refining allele/haplotype definitions will further improve the accuracy of Constellation-based phenotype prediction. Prospective studies of the clinical and cost effectiveness of WGS-clinical pharmacogenomics are, however, warranted.

Comprehensive study of NAT2 acetylation status in the Greenlandic population. *F. Geller[1], B. Soborg[1], A. Koch[1], E. Birch[1], K. Bjorn-Mortensen[1], M. Blaszkewicz[2], K. Golka[2], J. Hengstler[2], S.W. Michelsen[1], L. Carstensen[1], A.C. Nordholm[1], M.M.B. Johansen[1], M.L. Børresen[1], B. Feenstra[1], M. Melbye[1,3,4].* 1) Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Leibniz Research Centre for Working Environment and Human Factors, Dortmund, Germany; 3) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 4) Department of Medicine, Stanford School of Medicine, Stanford, CA, USA.

N-acetyltransferase 2 (NAT2) is a well-studied phase II xenobiotic metabolizing enzyme relevant in isoniazid drug metabolism. Greenland has a high incidence of tuberculosis and isoniazid is widely used both in prevention and treatment of tuberculosis. Polymorphisms in the coding region of *NAT2* explain 88 % of the variability in isoniazid clearance. Individual enzyme activity is divided into three main categories as slow, intermediate and rapid and the distribution of NAT2 acetylation status is highly variable across the world.A recent clinical trial investigated a *NAT2* genotype guided treatment of tuberculosis, suggesting that a personalized dosage of isoniazid can improve both the safety and the efficacy of treatment. Therefore, we decided to study NAT2 acetylation status in 1,556 individuals from Greenland.As a first step, we determined NAT2 status based on four established SNP panels and the tagging SNP rs1495741. There was good concordance between the NAT2 status inferred by the different SNP combinations. Overall, the observed fraction of slow acetylators of 17.5% was one of the lowest in the world. The Greenlandic population is admixed with two major components: an Inuit part reaching back to the first migration waves from North America and a Northern European part that was introduced over the last 300 years. We split the study group in three parts according to the percentage of Inuit ancestry and observed a frequency of 12.2 % slow acetylators among individuals with a high percentage (>70%) of Inuit ancestry, which is substantially lower than the 25.6 % observed in individuals with low (< 50%) Inuit ancestry.Additional rare variants associated with slow acetylation are known, and we cannot rule out that these variants and maybe even Inuit-specific variants are present in Greenland. Thus, we currently investigate the agreement between the inferred NAT2 acetylation status and actual enzyme activity by measuring caffeine metabolites in urine. If prediction of NAT2 status by the applied genotype panel is good, our findings could lead to a practicable pharmacogenetics-based tuberculosis therapy in Greenland.

Rapid implementation of a system-wide, high-throughput, EHR-integrated pharmacogenetics clinical service through cloud-based software automation. *M. Landsverk[1], M. Italia[2], M. Cornwell[1], L. Fricke[1], A. Rajendra[2], D. Schoolmeester[1], C. Larson[1], M. Mellacheruvu[1], V. Williams[1], C. Chan[1], A. Heid[2], A. Hsu[2], J. Hirsch[2].* 1) Sanford Health, Sioux Falls, SD; 2) Syapse Inc, Palo Alto, CA.

Adoption of precision medicine has the potential to improve quality of care while reducing toxicity, unnecessary treatments, and cost. In particular, availability of pharmacogenetics (PGx) data about a patient before a drug is ordered can improve patient safety. Sanford Health is one of the largest health systems in the nation with 43 hospitals and nearly 250 clinics in 9 states and 3 countries. In 2014, we initiated a program to integrate genomic medicine into adult primary care. A top priority was to implement a system-wide PGx clinical service with 3 components: 1) Fast-turnaround in-house analysis of a panel of drug metabolism genes, 2) delivery of clinically actionable results to Sanford Health's electronic health record (EHR) system, and 3) integration of PGx results into clinical workflow via real-time EHR alerts at the time of drug ordering. To ensure accurate decision support based on clinically valid gene-drug relationships, the panel run by Sanford Health's clinical molecular genetics laboratory only contains genes with clear clinical dosing guidelines published by the Clinical Pharmacogenetics Implementation Consortium (CPIC), including CYP2C19, CYP2D6, CYP2C9, CYP3A5, VKORC1, TPMT, and DPYD. Syapse Precision Medicine Platform (PMP) software was used to automate receipt of test orders from the EHR, convert nucleotide-based genotyping results to corresponding star (*) alleles, and convert star alleles to enzyme metabolizer status. These results were then automatically delivered back to the EHR. To determine the efficacy of Syapse PMP for clinical PGx services, we compared manual entry, data review, and result reporting of 60 samples submitted to our laboratory for PGx panel testing to automated processing by Syapse PMP. The manual process had a 5% error rate and took over 20 person-hours. One sample had an incorrectly spelled last name, one had the incorrect gender, and another was reported as wild-type for CYP2C19 instead of *1/*2 and thus would have been misreported as an extensive metabolizer instead of intermediate. Using Syapse PMP, no manual sample entry was required, eliminating the need for paper requisition forms. Data review and reporting were reduced to 2 hours, with no processing errors. Automation with Syapse PMP enabled Sanford Health to implement a clinical PGx service in less than 5 months and trigger best-practice alerts with patient-specific decision support content to fire upon ordering of a corresponding drug in the EHR.

Exome sequencing outperforms chip-based testing for clinically useful pharmacogenetic variant interrogation: Implications for pre-emptive pharmacogenetic evaluation. *D. Ng[1], L.N. Singh[1], C.S. Hong[1], J.J. Johnston[1], J.C. Mullikin[2,3], L.G. Biesecker[1,2], NISC Comparative Sequencing Program.* 1) Medical Genomics & Metabolic Genetics Branch, MGMGB, NHGRI, NIH, Bethesda, MD; 2) NIH Intramural Sequencing Program, NHGRI, NIH, Bethesda, MD; 3) Comparative Genomics and Cancer Genetics Branch, NHGRI, NIH, Bethesda, MD.

One of the great challenges of pharmacogenetics is that the testing delays treatment decisions. The gold standard for testing is chip-based analysis of specific variants associated with these traits. While pharmacogenetic testing is not commonly performed, exome sequencing is increasingly used in research and clinical care for a variety of indications. Our objective was to pilot a future scenario where exome or genome sequencing is routine and could be used for pre-emptive pharmacogenetic screening. We set out to assess the utility of exome and genome sequencing for pre-emptive pharmacogenetic screening by comparing exome and genome sequence accuracy and coverage of 203 clinically-relevant pharmacogenetic variant positions selected from the Pharmacogenomics Knowledgebase and Clinical Pharmacogenetics Implementation Consortium and identify copy number variants in cytochrome P450 2D6 *(CYP2D6)* that affect the metabolizer phenotype. We recruited participants from the Washington DC metropolitan region to study the clinical application of next gen sequencing for precision medicine. We performed exome sequencing and baseline clinical testing on 973 volunteers. We also performed genome sequencing and genotyping with a pharmacogenetic chip assay on five of these 973. As expected genome sequencing had the highest sensitivity (1,003/1,015) for the interrogated variants. Surprisingly, exomes had very good sensitivity (875/1,015) and outperformed chip-based testing (260/1,015). Exomes had high genotype concordance (99%) with chip-based genotyping. *CYP2D6* copy number variants were identified in 57/973 exomes using XHMM and were validated by qPCR in 19/21 high confidence calls. Exomes outperformed chip-based genotyping in capturing more important pharmacogenetic variant positions and *CYP2D6* copy number variants for preemptive pharmacogenetic screening. The agnostic design of exomes enables it to capture a large proportion of pharmacogenetic variants, outperforming the current standard chip-based assay. These data suggest that pre-emptive next-gen sequencing will allow pharmacogenetic evaluation to become routine, as this sequencing is more widely deployed in clinical care.

684W

PGRN-seq v.2: A second-generation capture-sequencing reagent for prospective targeted sequencing of clinically relevant pharmacogenetic loci. *S. Scherer[1], X. Qin[1], A. Gordon[2], R. Fulton[3], E. Wieben[4], E. Mardis[3], D. Nickerson[5], R. Gibbs[1], the PGRN.* 1) HGSC/Mol & Human Gen, Baylor Col Med, Houston, TX; 2) Institute for Personalized Medicine, Mt. Sinai School of Medicine, New York, NY; 3) McDonnell Genome Institute, Washington University, St. Louis, MO; 4) Dept. of Biochemistry, Mayo Clinic, Rochester, MN; 5) Genome Sciences, University of Washington, Seattle, WA.

Using feedback garnered from users of the first version of this reagent, the Pharmacogenomics Research Network's Deep Sequencing Resource (PGRN-DSR) worked together with PGRN network members, pharmacogenomic community experts and NimbleGen to design a second generation capture-sequencing probe set that builds on successes realized with PGRN-seq v.1. Primary modifications to the target list reflect advances in the field of pharmacogenomics, address loci left unaddressed in the original and emphasizes clinical relevance. To this end, targets now include all of the current Clinical Pharmacogenetics Implementation Consortium (CPIC) drug-gene pairs with published clinical guidelines as well as genes with high CPIC priority and PharmGKB clinical annotation scores. The new 76 gene panel targets the entire CYP2D6 locus, critical HLA tag SNPs and once again includes probes aimed at all of the ADME and DMET microarray sites while maintaining the original design's low cost thus enabling both common and rare variant reporting. Initial data produced from a broad panel of Coriell trios exhibits outstanding performance. We will present further studies outlining performance and validation metrics for this new addition to the pharmacogenomic translation toolkit.

685T

Pharmacogenetics of antipsychotic dosing. *V. De Luca, A. Perreira Silva, G.H. Franca de Moraes, N. Hettige.* Dept Neurogenetics, Univ Toronto, Toronto, ON, Canada.

In the present contribution, we expand the work that we have done in the past using the CPZ dose equivalent standardization. The primary mode of treatment for schizophrenia is through the administration of antipsychotic (AP) medications. A major concern for physicians aiming to treat patients is to improve treatment outcome and reduce side effects associated with AP medication. Many studies have investigated the genetic polymorphisms of AP drug metabolizing enzymes, focusing mostly on drug response while few have investigated a genetic influence on AP dosage. For this study, we selected a panel of candidate genes, focusing on AP receptors and genes implicated in the neurobiology of schizophrenia to increase the gene coverage from Hettige et al (2014). We recruited 266 patients from the Centre for Addiction and Mental Health (CAMH) between the ages of 18 and 75. Participants' current AP and dosage were collected at the time of the interview and standardized according to Chlorpromazine equivalents (CPZe) as seen in Gardner et al (2010). We selected 185 SNP markers from 38 candidate genes involved in the neurobiology and pharmacological treatment of schizophrenia. The 185 SNP panel was genotyped using a customized Illumina Bead Chip. We corrected for ethnicity using the Principal Component Analysis to include only those of European ancestry. The top SNP was the rs13182501 in the HTR4 gene (p=0.003). While we demonstrate potential significant targets, after multiple testing correction none of the SNPs were associated with CPZe standardization. This suggests that different candidate genes involved in AP mechanism(s) should be investigated for this phenotype. Nevertheless, AP dosage is a valuable phenotype in psychiatric pharmacogenetics because it is clinically relevant and can be normalized using standard criteria.

A Missense Mutation in *SVEP1* Influences On-Clopidogrel Platelet Aggregation in a Sex-Specific Manner. *J. Backman, R. Horenstein, B. Mitchell, J. O'Connell, A. Shuldiner, L. Yerges-Armstrong, J. Lewis.* Division of Endocrinology, Diabetes & Nutrition, University of Maryland at Baltimore, Baltimore, MD.

Clopidogrel therapy, often with aspirin, is standard of care for reduction of recurrent cardiovascular events in patients with acute coronary syndromes. Previous investigations have found genetic variation to be a significant determinant of on-clopidogrel platelet reactivity and incidence of clinical outcomes. Furthermore, while sex-specific differences in on-treatment platelet reactivity have been documented, identification of polymorphisms that contribute to gender-specific differences in clopidogrel efficacy has been limited.We perform sex-stratified analyses of exome chip (Illumina Inc.) data in 545 participants of the Pharmacogenomics of Anti-Platelet Intervention (PAPI) study to identify novel genetic variants that influence on-clopidogrel *ex vivo* platelet aggregation in a sex-specific manner. Extensive phenotype data was collected in all participants pre- and post-clopidogrel exposure (300 mg loading dose + 75 mg/d for 7 days). Platelet function was assessed in platelet-rich plasma by optical aggregometry using a PAP8E aggregometer (Bio/Data Corp.) after stimulation with adenosine diphosphate (20 μM). Association analyses were performed under a variance component framework that models the effect of genotype as an additive effect on the quantitative trait, while simultaneously adjusting for the effects of age, BMI, baseline platelet aggregation, and participant relatedness.Exome-wide analysis identified a variant in the Sushi, Von Willebrand Factor Type A, EGF, and Pentraxin Domains-Containing 1 (*SVEP1*) gene to be significantly associated with increased ADP-stimulated platelet aggregation post-clopidogrel exposure in females (rs10980419, P = 2.04 x 10-8, N=278), resulting in an approximate doubling of platelet aggregation between homozygote groups (maximal platelet aggregation = 33.3 for CC homozygotes, 44.1 for CT heterozygotes, and 68.0 for TT homozygotes). In contrast, no significant association was observed between rs10980419 and platelet aggregation in men (P = 0.23, N=267). A significant SNP x gender interaction was observed (P = 0.008).In this investigation, we identified a genetic variant in *SVEP1* that influences on-clopidogrel platelet aggregation in a sex-specific manner. *SVEP1* expression is known to be regulated by 17b-estradiol, strengthening our confidence in these results. Additional studies are required to replicate our finding as well as to determine the effects of this variant on recurrent cardiovascular events in women.

687T

Effect of SLCO2B1 Gene Polymorphism on the Lipid Lowering Effect of Rosuvastatin in Hypercholesterolemic Patients. *T.-E. Kim[1,2], D.-S. Shin[2,3], N. Gu[2,4], J. Choi[5], B. Jung[5], K.-S. Yu[2], I.-J. Jang[2], J.-Y. Cho[2].* 1) Department of Clinical Pharmacology, Konkuk University Medical Center, Seoul, South Korea; 2) Department of Clinical Pharmacology and Therapeutics, Seoul National University College of Medicine and Hospital, Seoul, Republic of Korea; 3) Clinical trials center, Gil hospital, Incheon, Republic of Korea; 4) Department of Clinical Pharmacology and Therapeutics, Dongguk University College of Medicine and Ilsan Hospital, Goyang, Gyeonggi-do, Republic of Korea; 5) Molecular Recognition Research Center, Korea Institute of Science and Technology, Seoul, Republic of Korea.

Rosuvastatin is an HMG-CoA reductase inhibitor widely used for the treatment of hypercholesterolemia. It is well known that the polymorphism of solute carrier organic anion (SLCO) 1B1 gene may affect the pharmacokinetics and pharmacodynamics of HMG-CoA reductase inhibitors. However, the effect of genetic polymorphism of SLCO2B1 has not been reported. The aim of this study was to investigate the effect of SLCO2B1 polymorphism on the lipid lowering effect of rosuvastatin in hypercholesterolemic patients.A total of 21 patients whose low density lipoprotein (LDL) level was over 130 mg/dL were participated in this study. For the subjects, three single nucleotide polymorphisms (SNPs) of SLCO2B1, c.935G>A, c.1457C>T and c.601G>A were evaluated. For 8 weeks subjects were administered 20 mg of rosuvastatin once a day. Lipid lowering effect of rosuvastatin was evaluated by the measurements of total cholesterol, LDL, high density lipoprotein (HDL), triglyceride (TG), apoprotein B (apo B) and apoprotein A1 (apo A1). Blood samples were taken before dosing and after finishing dosing of 8 weeks. The comparisons between genotypes were performed by Mann-Whitney U test. The genotyping were performed in 19 subjects. Among 19 subjects, 14 were CC and 5 were CT for c.1457C>T. As for c.935G>A, GG, GA and AA types were 7, 9 and 3, respectively. In the case of c.601C>T, all the subjects showed wild-type except one subjects of GA type. There was no significant difference in lipid lowering effect between genotypes with c.1457C>T and c.601G>A polymorphisms. However, in the case of c.935G>A, there were statistically significant difference between wild-type and variant-type in the lowering effect of LDL and ApoB. The LDL was decreased after the 8-week dosing by 62.8 ± 6.8% (mean ± SD) in wild-type (c.935GG) and 50.3 ± 11.5% in variant-type (c.935GA or AA) (p=0.035). The ApoB was decreased by 52.1 ± 7.1% in wild-type and 42.8 ± 9.1% in variant-type (p=0.039).In this study, it was demonstrated that SLCO2B1 polymorphism of c.935G>A can influence on the lipid lowering effect of rosuvastatin in hypercholesterolemic patients.

688W

Genotyping of New ADME Variants in a Phase 2 Axitinib Trial to Understand Exposure Variations. *J.C.M. Marshall[1], Y.P. Pithavala[1], B.J.S. Smith[2], L.W. Wood[1], S.L. Li[1], A.W. Williams[3], P.E. English[1].* 1) Pfizer, Groton, CT; 2) Gilead, San Mateo, CA; 3) Genentech, San Francisco, CA.

Axitinib is a selective 2nd generation inhibitor of vascular endothelial growth factor receptors (VEGFR) 1, 2, and 3 that is approved for the 2nd line treatment of patients with advanced renal cell carcinoma. This study undertook a retrospective analysis of a clinical trial set with AUC and CL data to understand if newly described genotypes could be used to predict variability in axitinib plasma exposure. Data from a Phase 2, randomized, double-blind study (n= 213 patients) with axitinib in treatment-naïve renal cell carcinoma (RCC) were used for this analysis. Patients (n=112) who were eligible for dose titration, based on pre-specified criteria were randomly assigned (1:1) to receive in combination with 5-mg BID either masked titration with axitinib or placebo. Patients who did not meet the criteria continued at 5 mg BID axitinib. The study met its primary endpoint of statistically significant higher objective response rate with active axitinib titration (54% ORR) versus placebo titration (34% ORR). A previously described population pharmacokinetic model was used to obtain post hoc oral clearance (CL/F) and steady-state AUC24 in each patient at the 5 mg BID starting dose. DNA from 172 patients was extracted from blood samples taken at enrollment. Genotyping for CYP3A4*22, CYP3A5*3,*6,*7 and POR*28 was carried out using TaqMan assays run on a QuantStudio 12K Flex system. The following genotyping frequencies were recorded for each gene of interest: CYP3A5 predicted poor metabolizer (PM) 77.9%, intermediate metabolizer (IM) 19.8%, extensive metabolizer (EM) 2.3%; CYP3A4 IM 7%, EM 93%, no individuals were PM (*22/*22). For POR*28, 51% patients were wild type (C/C), 41% were heterozygote (C/T) and 8% were homozygote variant (T/T). Multivariate statistical analysis was carried out to assess genetic effect for each gene polymorphism on AUC and CL after adjusting for important baseline characteristics.AUC analysis for POR*28 approached statistical significance (p = 0.0747 for higher AUC in TT vs. CC) no genotype was statistically significant for AUC or CL. While POR*28 shows potential, there is insufficient evidence from genotyping evaluated in this population to completely explain patient to patient differences in axitinib plasma exposure. Analysis of this population therefore indicated that genotype-based dose adjustment is not warranted for RCC patients receiving axitinib.

Profiling of miRNA expression in Immune thrombocytopenia patients before and after Qishunbaolier (QSBLE) treatment. *B. Borjigin[1], E. Eerdunduleng[1], W. Huo[1], C. Gong[1], H. Gaowa[1], L. Long Mei[1], M. Li[1], X. Zhang[1], S. Wang[1], Y. Liu[2], H. Bai[1,3].* 1) Affiliated Hospital of Inner Mongolia University for the Nationalities, tongliao, China; 2) Department of Developmental Biology, Washington University in St. Louis School of Medicine, St. Louis, MO 63110, USA; 3) School of Life Science, Inner Mongolia University for the Nationalities, Tongliao, Inner Mongolia 028000, China.

Immune thrombocytopenia (ITP), also known as idiopathic thrombocytopenic purpura, is an autoimmune disease characterized by low platelet count and increased bleeding tendency. Currently, glucocorticoid and splenectomy are the main therapies for ITP but with obvious side effects including tendency of relapse and risk of internal bleeding. Searching for a safer alternative treatment from traditional medicine represents an active research direction. Mongolian medicine Qishunbaolier (QSBLE) (also called Xuebaowan or Shengxuekang) has been successfully developed for treatment of ITP, Aplastic Anemia, Allergic Purpura, myelodysplastic syndromes, and other bleeding disorders since the 1960s. QSBLE is a compound preparation made of gardenia, bezoar, Cornu Bubali, bear gall, saffron, Lithospermum, and Rubia. We followed closely 32 cases of ITP patients administrating QSBLE and found that QSBLE can not only significantly increase the number, quality, and life span of platelets, but also improve the immunity and hematopoietic function of ITP patients. We did not observe any side effect that normally associated with glucorticoids treatment including nausea, vomiting, increased heart rate et al.To better understand the ITP pathogenesis and therapeutic basis of QSBLE, we profiled miRNA expression in the blood sample of ITP patients and identified 44 miRNAs that are differentially expressed in ITP patients before and after QSBLE treatment. Interestingly, 25 of them are expressed in control subjects and are downregulated in ITP patients, whereas treatment with QSBLE restores their expressions to the level of control subjects. This result suggests that abnormal expression of these 25 miRNAs might be connected to the pathogenesis of ITP. Furthermore, 14 of those 44 miRNAs are predicted to target at least once on 31 ITP associated genes, indicating the possible mechanism of QSBLE on ITP therapy. This work is supported by the grants for the Key Project in the Chinese National Science & Technology Pillar Program during the Twelfth Five-year Plan Period (2012BAI27B02).

690W

Rare variants in ALOX5 may be associated with the risk of hypersensitivity reaction to penicillin . *R. Pellegrino, B. Almoguera, L. Vazquez, D. Abrams, T. Watanabe, L. Tiang, J. Garifallou, F. Mafra, J. Conolly, F. Mentch, P. Sleiman, H. Hakonarson.* CAG, Childrens Hospital of Philadelph, Philadelphia, PA.

Penicillin allergy is the most commonly reported medication allergy and it limits these antibiotics' use. There is evidence that genetic factors play a significant role in the risk of penicillin allergy and several efforts have been applied to identify genetic candidate genes such as *IL4*, *IL6*, *IL10* or *TNF*. However, results to date have not been replicated and genetic risk factors remain largely unknown. Here we investigate the role of rare variation in 82 genes related to the disposition of a variety of drug compounds in the risk of penicillin allergy. Cases with penicillin allergy were defined by specific **ICD9 codes V14.0, E930.0, and 995.27**, as documented in their electronic health records and allergic symptoms being consistent with hypersensitivity reaction, such as anaphylaxis, hives, angioedema, or respiratory symptoms. Control population was defined as subjects exposed to penicillins and no documentation of allergic symptoms. Sequencing of the complete coding and nearby regulatory regions of the 82 genes was performed using a custom-sequencing panel developed by the Pharmacogenomics Research Network (PGRN). For rare variant gene-level association analysis, we used three complementary algorithms: the Sequence Kernel Association Test, the Variant Threshold test and the Combined Multivariate and Collapsing test. Single variant analysis was also conducted using a Logistic Score Test. 125 subjects with penicillin allergy and 58 controls of European ancestry were identified for the study. We found *ALOX5*, a gene located in chromosome 10 approaching statistical significance (p=6.50E-04). The *ALOX5* gene is a member of the lipoxygenase gene family with a role in the synthesis of leukotrienes from arachidonic acid, which are important mediators of inflammatory and allergic conditions. These results show great promise in the identification of the genetic underpinnings of penicillin allergy and we are currently undergoing replication in an additional cohort.

691T

Next generation sequencing technologies improve pharmacogenetic-guided drug dosing. *I. Cohn[1,8], T. Paton[6], C.R. Marshall[2,6,7], R. Basran[4,7], P.N Ray[2,4,6,7], N. Monfared[2], P. Sinajon[3,7], R.D. Cohn[2,3,4,5,6], S. Ito[1,5,8].* 1) Division of Clinical Pharmacology and Toxicology, The Hospital for Sick Children, Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada; 2) Center for Genetic Medicine,The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada; 4) Department of Molecular Genetics, University of Toronto, Ontario, Canada; 5) Department of Pediatrics, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 6) The Center for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Department of Pediatric Laboratory Medicine, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 8) Program in Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada.

Pharmacogenetics provides opportunities to optimize drug treatment and prevent adverse drug events. Currently, targeted genotyping strategies are used clinically to screen markers in genes with well-characterized drug-gene interactions. Next generation sequencing (NGS) technologies carry the promise to identify known and novel pharmacogenetic variants that are not covered by existing clinical panels. Here, we determined the accuracy of variant calls from NGS platforms and investigated additional variants of potential pharmacotherapeutic benefit. We performed a systematic comparison of 74 pharmacogenetic variant loci from whole genome sequencing (WGS, Complete Genomics) and mass spectrometry (Agena Biosciences) for 98 pediatric patients of varying ethnicities. Additionally, 11 patient samples of this cohort underwent whole-exome sequencing (WES, Illumina HiSeq2500).The 74 loci were sequenced to an average read depth of 20X or greater across the 98 samples that underwent WGS. However, there was considerable variability in coverage between cases, with 32 loci exhibiting low read depth (5X or less) or poor variant-quality reads, mostly within the CYP2D6 gene. However, these variant loci were not always required for metabolizer status assignment, as they are used to further subtype functional classifications. In contrast, WES exhibited superior coverage in the majority of the 74 loci (3 loci are in non-coding regions). Surprisingly, discordant genotypes were identified for 7 variants in the WGS data but only 1 variant in the WES data when compared to the mass spectrometry platform. At present, detection of copy number variants in the CYP2D6 gene cannot be easily interpreted from NGS and require separate testing by qPCR. In the WGS data, we identified 3 coding variants with potential clinical implications that change the metabolizer status or dosage recommendation in CYP2C9, CYP2D6 and DPYD.As WGS/WES becomes more routine for identification of primary diagnoses there is opportunity to gain relevant information about pharmacogenetic markers. Our data demonstrate that clinically important pharmacogenetic variants covered by targeted genotyping are accurately called by NGS platforms. Additionally, functional variants of potential clinical pharmacogenetic significance could be missed by using targeted genotyping panels, indicating that NGS technologies need to be considered for a more genome-wide approach to pharmacogenetic testing of individual patients.

692W

Comprehensive exploration of the high-risk rare variants for the cold medicine–related Stevens-Johnson syndrome/ toxic epidermal necrolysis (CM-SJS/TEN) with severe ocular complications. *Y. Hitomi[1], S. Khor[1], M. Ueta[2,3], H. Sawai[1], K. Zawlatt[1], C. Sotozono[3], S. Kinoshita[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Frontier Medical Science and Technology for Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan; 3) Department of Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan.

Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) are acute inflammatory vesiculobullous reactions of the skin and mucous membranes, and these reactions are reported to be caused by inciting drugs, viral infections, or malignant tumor. Although the occurrence of SJS/TEN is rare at about 1-6 cases per million, mortality rates are higher than other drug rush (SJS: 3%, TEN: 27%). In addition, Quality-of-life of the most survivors is often low, as severe ocular surface complications are often developed as the aftereffect.*HLA-A* and *IKZF1* have been recently reported as susceptible genes for Cold Medicine–Related SJS/TEN (CM-SJS/TEN) in Asian populations by genome-wide association study (GWAS). However, other genetic factors of CM-SJS/TEN including rare variants and structural variants remains to be discovered.In order to identify the functional variants for CM-SJS/TEN with severe ocular complications, whole-exome sequencing was performed in 128 Japanese CM-SJS/TEN patients with severe ocular complications using next generation sequencer (NGS) - ion Proton (Thermo-Fisher Scientific). After data cleaning, the following average scores per individual were acquired: 7.23±1.09 billion bases; 42.5±6.0 million reads; 169±7.59 of read length; 94.8±0.8 % of on target reads; 89.6±3.0 % of uniformity; x115.5±17.7 of coverage. Finally, 50,722±736 variants were called by Torrent suite software with appropriate parameters using NCBI hg19 as the reference.In order to evaluate the accuracy of variant calling, we compared the genotypes of approximately 5,000 variants which were overlapped on the Axiom chip (Affymetrix) from our previous GWAS using same CM-SJS/TEN sample set (Ueta M *et al., J Allergy Clin Immunol* 2015). The concordance rate of genotypes between GWAS and exome sequencing was over 99%.The identification of high-risk rare variants which have extreme effect on the pathogenesis of CM-SJS/TEN are carried out by comparing variants identified with approximately 1,000 Japanese individuals whole-genome sequencing database (Tohoku-Medical Megabank). In addition, pathway analysis will be carried out by SNP-set Kernel Association Test (SKAT) software. In this presentation, we will report the preliminary result of the identification of high-risk rare variants. This study may illustrates novel diagnostic and therapeutic methods for CM-SJS/TEN.(Equally contributed: Hitomi Y, Khor SS, Ueta M).

693T

Investigation of the role of rare variation in eighty-two pharmacogenes in the risk of vincristine-induced peripheral neuropathy in children. *B. Almoguera, L. Vazquez, D. Abrams, T. Watanabe, L. Tiang, R. Pellegrino, J. Garifallou, F. Mafra, J. Connolly, F. Mentch, P. Sleiman, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

The dose-limiting toxic effect of vincristine, a drug prescribed to over 50% of children with cancer, is peripheral neuropathy, characterized by neuropathic pain and sensory and motor dysfunction. There is evidence that genetic factors play a significant role in the risk of neuropathy, however the precise risk factors remain elusive. In this study we investigated the role of 82 genes related to the disposition of a variety of drugs in the risk of developing vincristine-induced neuropathy in children. Phenotyping was performed by direct mining of the electronic health records (prescription of vincristine + ICD9 code for neuropathy, 355x) and identified 96 individuals with vincristine neuropathy and 52 controls that were exposed and confirmed negative by chart review. Sequencing of the complete coding and nearby regulatory regions of the 82 genes was performed using a custom-sequencing panel developed by the Pharmacogenomics Research Network (PGRN). For rare variant gene-level association analysis, we used three complementary algorithms: the Sequence Kernel Association Test, the Variant Threshold test and the Combined Multivariate and Collapsing test. Single variant analysis was also conducted using a Logistic Score Test. Neuropathy was classified and analyzed as autonomous, sensory, and motor symptoms, and also as a continuous trait. Preliminary results on 43 cases and 23 controls evidenced that *CYP3A4*, which is directly involved in vincristine metabolism, was nominally significantly associated with the risk of neuropathy (p=1.10e-03). Also, *SLC6A6*, a taurine transporter, was associated with the risk of sensory neuropathy (p=7.91e-04) Absence of *SLC6A6* in mice has been demonstrated to lead to several neurologic deficits and sensory losses. These results show great promise in the identification of the genetic underpinnings of vincristine-induced neuropathy and are currently undergoing replication in an additional cohort of 53 cases and 29 controls.

694W

Deep Sequencing of Genes Associated with Glucocorticoid Response in Asthma. *Q.L. Duan[1], M.H. Cho[1], J.A. Su[1], K.G. Tantisira[1,2], S.T. Weiss[1,3].* 1) Channing Division of Network Medicine, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 2) Pulmonary Division, Brigham & Women's Hospital, Boston, MA; 3) Partners Center for Personalized Genetic Medicine, Partners Health Care, Boston, MA.

Glucocorticoids (GCs) have potent, anti-inflammatory effects, and are commonly used for treatment of diseases including asthma, which occurs in over 300 million individuals worldwide. However, there is substantial inter-individual variability in GC response, with 25% of patients non-responsive. Multiple genetic loci have been associated with GC response but account for only part of the variability. We hypothesize that deep sequencing of loci from genome-wide association studies (GWAS) will identify novel genetic variations that could constitute part of the missing heritability of GC response. To test this hypothesis, we identified top associated genes from a meta-GWAS of four asthma clinical trials (N=723) and whole exome sequencing (WES) in an asthma cohort of extreme GC responders (N=188). In the meta-GWAS, linear regression was performed in PLINK using an additive model, with covariate adjustments (height, age and gender) and GC response measured as a percent change in lung function (baseline pre-bronchodilator forced expiratory volume in one second) following 4-8 weeks of therapy. WES data used the NimbleGen SeqCap EZ human exome v2.0 capture array and sequenced on the Illumina Hi-Seq 2000. Sequence alignment used BWA, and variants were called with Samtools. Our primary analysis included 75,655 coding (non-synonymous, splice, or stop) variants based on annotations from SnpEff, and used a per-gene burden test in SKAT, adjusted for covariates (gender, age, and height, and baseline FEV1). In total, we identified 46 genes from the meta-GWAS ($P < 0.001$), that were nominally associated ($P < 0.05$) with extreme GC response in our gene-based test. Our results include *KCNQ5,* which encodes a potassium channel in airway smooth muscle cells from human bronchioles and regulate airway constriction as well as members of a multidrug transporter family (*ABCA4* and *ABCC1*). Targeted sequencing of 30 such genes, prioritized by P values and biological plausibility, is underway in three asthma clinical trials (N=984) for validation analysis. In summary, we identified potentially deleterious variants from WES within loci previously associated with GC response in GWAS of asthmatics.Please address all inquiries to qingling.duan@channing.harvard.edu.

695T

Influence of common and rare genetic variation on warfarin dose among African Americans and European Americans using the exome-array. *N. Liu[1], A. Patki[1], M. Irvin[4], D. Zhi[1], T. Brown[3], C. Hill[5], M. Beasley[1], D. Nickerson[6], N. Limdi[2].* 1) Dept Biostatistics, Univ Alabama at Birmingham, Birmingham, AL; 2) Department of Neurology, University of Alabama at Birmingham, AL; 3) Division of Cardiovascular Diseases, University of Alabama at Birmingham, AL; 4) Department of Epidemiology, University of Alabama at Birmingham, AL; 5) Department of Pathology and Laboratory Medicine, Emory University, Atlanta, GA; 6) Department of Genome Sciences, University of Washington, Seattle, WA.

Personalized management of warfarin, the most widely used oral anticoagulant, is challenging. The large inter-patient variability in warfarin dose requirements and narrow therapeutic index make warfarin a "top offender" accounting for 33.3% of all adverse-drug-related hospitalizations in the US, with hemorrhage representing 63.3% of admissions. Achieving therapeutic anticoagulation rapidly and predictably is critical for safe and effective therapy. To this end multiple investigations have identified the influence of clinical, demographic and genetic factors on warfarin dose. To date, candidate gene and genome-wide associations studies (GWAS) have confirmed that the majority of the genetic influence is accounted by single nucleotide polymorphisms (SNPs) in two genes: *CYP-2C9*and *VKORC1*. Cytochrome P450 4F2 (*CYP4F2*) was recently shown to account for a small but significant proportion of variability in warfarin dose among European Americans.We hypothesize that novel coding SNPs (common and rare) may harbor additional clues that can explain variaiblity in warfarin dose. Toward this end, we assessed 247,870 SNPs using the Illumina Exome Array in 1,240 warfarin users (701 European Americans, 539 African Americans).Results show *VKORC1* (rs9923231) was the single most important genetic influence on warfarin dose in both European-Americans ($p<9.28E-45$) and African-Americans ($p<1.80E-8$). This association explains 22.8 % of the variance in dose among European-Americans 6.5% in African-Americans.Among European-Americans the single most important *CYP2C9* SNP was rs4086116 ($p= 1.24E-19$) as reported previously, *CYP2C9*3* (exm844046; $p=1.01E-13$) demonstrated significant influence on warfarin dose as did *CYP2C9*2* (exm-rs1799853; $p=2.34E-7$). Although significant ($p=0.03$), inclusion of rs4086116 explains little additional (0.6%) variance in warfarin dose, similar to that explained by *CYP4F2* (0.6%; $p=0.004$).Among African-Americans no *CYP2C9* SNP demonstrated statistically significant association with dose. The SNP rs12777823 identified in the GWAS of African-American was marginally significantly associated with dose ($p=1.93E-5$ with FDR adjusted q-value = 0.184) explaining an additional 4% of the variance in warfarin dose. *CYP4F2* did not demonstrate significant influence on dose.In addition, we identified novel significant association of single markers. We are validating our findings in an independent cohort.

Rescuing the un- sequenceable: using Exome Sequencing and HRM to reliably and cost-effectively genotype non-trivial loci. *M.D. Napier[1], R.P. Loewe[2].* 1) Agilent Technologies, Santa Clara, CA; 2) Genewake GmbH, Neuried, Bavaria, Germany.

To move beyond the modest drug responses seen in oncology and immunology today, cutting edge researchers must generate better answers by changing the mode of questioning in clinical research. We should shift gears away **from** genomic biomarker associations with drug response, **toward** haplotype associations with drug response phenotypes. To tackle this challenge we must overcome two research obstacles: (1) obtain the proper tools to scan the exome comprehensively and (2) enrich cancer exome studies with targeted qPCR for fine loci mapping. Special emphasis in our study was given to: the tyrosine kinase family especially to EGFR and ERBB2 and the cytochrome p450 family for their pharmacogenomics utility. Together these two techniques will rescue loci that were previously unavailable or under-represented to the genetic researcher. The methods utilized include: Sure Select Human All Exon v6for exome capture followed by Next Generation Sequencing(NGS), qPCR as well as high resolution melting (HRM). Our study's objective was to find improved patient stratification methods for research. Our combined methodology gives a viable and easy option for a standard laboratory to venture deeper into the cancer and immunology genome. This workflow enables fine mapping of loci using NGS complemented with qPCR for accelerating clinical research beyond the event horizon of what is currently known.

Novel genotyping algorithms for multiallelic and copy number ADME variants. *J.P. Schmidt, J. Gollub, D. Oliver, R. Varma, J. Brodsky, C. Bruckner, B. Eynon, S. Malakshah, M. Mittmann, A.H. Roter, B. Wong, M.H. Shapero, T. Webster.* Informatics, Affymetrix, Santa Clara, CA.

There are many well-known and well-characterized, clinically relevant mutations in genes associated with drug absorption, distribution, metabolism, and elimination (ADME). Most of these variants are biallelic single nucleotide polymorphisms (SNPs) or short insertion/deletion (indel) variants, and thus amenable to standard genotyping assays and calling algorithms. However, copy number variations (CNVs) in critical genes, as well as multiallelic SNPs or indels, can be more challenging to genotype. We have developed novel probe design methods and calling algorithms to address these variants with Axiom® Genotyping Solution.Genotyping multiallelic variants requires the design of a set of probes, each specific to a single allele. This is straightforward for SNPs, but more complex when indel alleles may be present. Under the assumption of diploidy, genotype calling proceeds in three steps, using the signals from those probes: 1) background estimation for each allele; 2) all-by-all biallelic clustering of appropriate samples for initial genotype assignment; 3) final assignment to a genotype "cluster" using an N-dimensional Gaussian mixture model with posterior distributions informed by the initial assignments in (2) and conjugate priors that may be either generic or trained on previous data. Using this unique approach we are able to address the underlying variations for important alleles such as CYP2C8*7 and *8, or CYP2D6*8 and *14.CNV calling in the ADME context presents challenges that are in some ways both easier and more difficult than those in exploratory analysis. There are only a small number of defined regions of interest, so probe design and analysis parameters can be optimized for them, and precise determination of breakpoints is not essential. However, the regions are smaller than normal for CNV calling, and in some cases the presence of highly homologous pseudogenes or extremes of GC content reduce specificity. We have developed new methods for the design and selection of maximally informative probes, correction of signals using a variety of covariate factors, and signal summarization and thresholds for calling copy number states from zero (homozygous deletion) to three or more (amplification) in five genes of great relevance to ADME: CYP2A6, CYP2D6, GSTM1, GSTT1, and UGT2B17.

Variable read-through by small molecule drugs in Leber Congenital Amaurosis (LCA16) suggests need for personalized approach to read-through strategies. *D.M. Pillers[1, 2], P. Shahi[1, 2], V. Bakhutashvili[3], S. Brar[1, 2], R. Gatti[4,5], B.R. Pattnaik[1, 2, 6].* 1) Pediatrics, University of Wisconsin-Madison, Madison, WI; 2) McPherson Eye Research Institute, University of Wisconsin-Madison, Madison, WI; 3) School of Medicine and Public Health, University of Wisconsin-Madison, Madison, WI; 4) Pathology & Laboratory Medicine, UCLA, Los Angeles, CA; 5) Human Genetics, UCLA, Los Angeles, CA; 6) Ophthalmology and Vision Sciences, University of Wisconsin-Madison, Madison, WI.

Introduction: Leber congenital amaurosis (LCA [MIM 204000]) is asevere vision disorder that presents in infancy with progression to blindness. We studied LCA16 [MIM614186] which is due to defects in the Kir7.1 ion channel encoded by *KCNJ13* [MIM 603208].We sought to determine the response to small molecule read-through drugs by measuring their physiologic response as a marker for improvement in function. **Methods:** Chinese Hamster Ovary (CHO-K1) cells were transfected with N-terminal GFP-fused wild-typeor W53X (c.158 G>A)or R166X (c.496C > T) mutant plasmids. The cells were treated with 5 μM and 10 μM of the read-through compounds Gentamicin, PTC-124, RTC-13,or RTC-14 after eight hours of transfection, and the cells were incubated with these drugs for 36 hours. Whole-cell patch clamp electrophysiology was performed on the transfected cells. Function of the Kir7.1 channel was measured in the presence of Cs+ to block function, or the highly permeant Rb+ to enhance current. The students T-test was used and significance was determined at the $P<0.05$ level.**Results:** Both W53X and R166X transfection resulted in non-measurable Kir7.1 current as compared to the wild-type Kir7.1 channel, and the cells were depolarized. Upon treatment with Gentamicin, PTC-124 and RTC-13,we detected no measurable difference in either the current amplitude or the resting membrane potential (Vm). In contrast, RTC-14 showed partial rescue of both the Kir7.1 current amplitude and Vm. R166X expressing cells responded to RTC-14 treatment by a 15 mV hyperpolarizing shift in Vm (-25.92 ± 2.7 to -40.16 ± 4.05 mV; $P<0.02$) and an increase in current amplitude measured at -150 mV from -98.5 ± 24.7 to -122.8 ± 28.15 pA, $P = 0.52$. W53X, however, showed a 33 mV hyperpolarization shift in Vm (-29.37 ± 3.55 to -61.94 ± 2.9 mV; $P<0.001$). We also noticed a four-fold augmentation in both inward (-80.4 ± 11.2 to -316.16 ± 60.8 pA at -150 mV; $P<0.01$) and outward (-7.4 ± 2.4 to 33.3 ± 11 pA at -40 mV; $P<0.02$) current amplitude. **Conclusions:** We have shown that a measurable outcome such as the electrophysiology of the Kir7.1 ion channel at the cellular level can serve as a useful marker in the visual system to detect a response to translational read-through drugs. We have also shown that different mutations within the same gene may have very different responses to the same read-through drugs. This suggests that small molecule read-through therapies should beexplored using a personalized approach.

***in silico* analyses of complex systems for the development of novel therapeutics in rare and orphan diseases.** *K. Nguyen[1,4], D. Li[1], L. Tian[1], R. Pellegrino da Silva[1], C. Kao[1], R. Pandey[1], M. Bakay[1], P. Sleiman[1,2,3], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Center for Dynamic Data Analytics, Rutgers University, Piscataway, NJ.

We introduce a structural approach that incorporates modeling, simulation, and drug design to our translational, precision, and network medicine pipeline for the purpose of discovering novel therapeutics in rare and orphan diseases. The importance of an accurate model, whether acquired through experimental or computational methods, is vital to this approach. Once validated, the structure, dynamics, and energetics are calculated to determine if the overall conformation has converged enough using molecular simulation and high performance and parallel computing. It has been reportedthat modeling alone is not accurate enough and does not adequately represent the conformational space of the system in question – especially when it is the prerequisite for virtual screening and structure-activity relationships. Once the simulated structure has been validated through established metrics, determining targets for ligands/drugs for therapeutic purposes, elucidating ligand-receptor interactions, and linking those results to function are the final steps before analytical and instrumental validation. Of course, these steps may take several iterations, but are necessary to determine a successful set of candidates. Here, we present an overview of two systems using the resources described in our pipeline – ephrin type-B receptor 4 (EPHB4) and C-X-C chemokine receptor type 1 (CXCR1, also known as interleukin 8 receptor – alpha, IL8RA) - both of which represent novel disease associations with supporting functional data.

Variation in transcriptional response to Vitamin D and LPS in monocytes. *S.N. Kariuki, J.D. Blischak, D. Witonsky, A. DiRienzo.* Human Genetics, University of Chicago, Chicago, IL.

Vitamin D plays an important immunomodulatory role, regulating genes in the monocyte microbicidal pathway involving toll-like receptors (TLRs). Activation of TLRs by bacterial ligands such as lipopolysaccharide (LPS) results in production of 1,25-dihydroxyvitamin D3 (1,25D), which induces transcription of genes. Studies have shown correlations between low vitamin D levels and risk of various diseases, but the mechanisms underlying these observations are poorly understood. We aim to characterize inter-individual and inter-ethnic variation in monocyte transcriptome-wide response to 1,25D and LPS*in vitro*.Primary monocytes obtained from 10 African-American (AA) and 10 European-American (EA) healthy donors were treated with 1,25D, LPS, and ethanol for 24 hours. Transcript levels of RNA were measured on the Illumina HumanHT12 microarray. Genome-wide differential expression (DE) was analyzed using linear mixed-effect models and a joint Bayesian analysis to identify patterns of shared and differential response across treatments.At a false discovery rate (FDR) < 0.01, we identified 2888 and 4461 genes that were significantly DE in response to 1,25D and LPS respectively, while4720 genes were significantly DE in response to1,25D plus LPS. The joint Bayesian analysis identified four broad patterns: non-DE genes, and DE genes responsive to 1,25D, LPS, and 1,25D plus LPS. Gene ontology analysis of these patterns showed enrichment of metabolic processes and immune response pathways among the 1,25D responsive genes, while cell proliferation and fatty acid oxidation pathways were enriched in LPS responsive genes. We identified 12 genes with differences in response to 1,25D plus LPSacross the two ethnic groups at an FDR < 0.10, including*PPAP2B,*which encodes a member of the phosphatidic acid phosphatase (PAP) family, and*AKNA*which encodes a transcription factor that activates expression of the CD40 receptor and ligand.In summary, we identified genes that were significantly DE in response to 1,25D and LPS, and were significantly enriched for immune response and metabolic functions. Treatment of monocytes with both 1,25D and LPS resulted in greater transcriptional response, increasing our power to detect genes with significant inter-ethnic DE within our small sample set. We speculate that the inter-ethnic differences in response to vitamin D in the presence of LPS could contribute to inter-ethnic disparities in immune-related diseases.

Association of gene polymorphism in detoxification enzymes and urinary 8-OHdG levels in traffic policemen exposed to vehicular exhaust in Telangana State. *P.Reddy Penagaluru[1], B. Siva Prasad[1], C. Prashanth[1], P. Vidyullatha[2], T. Gudimella Vani[2], P. Rekha V. Devi[3], P. Usha Rani[2], M. Hema Prasad[2].* 1) Genetics, Bhagwan Mahavir Medical Research Centre, Hyderabad, Telangana State, India; 2) Institute of Genetics and Hospital for Genetic Diseases, Osmania University, Begumpet, Hyderabad; 3) Toxicology Unit, Biology Division, Indian Institute of Chemical Technology, Tarnaka, Habsiguda, Hyderabad.

Abstract Context: With rapid economic growth and massive development of transportation, the number of automobiles has greatly increased. Traffic police are the one of the vulnerable groups predominantly exposed to vehicular exhaust during traffic control. Objective The present study is aimed to study the relation between occupational exposure to vehicular exhaust and oxidative stress (OS) in traffic police. We investigated the levels of 8- hydroxydeoxyguanosine (8-OHdG), one of the most sensitive biomarkers for measuring OS and the association between polymorphisms in Cytochrome P450 (CYP) and Glutathione S-Transferase (GST) genes that are known to play a significant role in the activation and detoxification of xenobiotics. Materials and methods: 148 non smoking male traffic policemen and 135 control subjects were selected for this study. The 8-OHdG levels were analyzed by liquid chromatography with electrochemical detection method. Gene polymorphism was detected by multiplex PCR and RFLP method. Results: 8-OHdG levels were found to be increased in traffic police with increase in the years of service in traffic control ($p = 0.02$) when compare to the controls. The results showed a significant increase in urinary 8-OHdG levels in mutated CYP1A1m1 ($p < 0.007$) and null GSTM1 ($p < 0.01$) genotypes. However the genotype frequencies of CYP1A1 m2 and GSTT1 genes did not vary in both exposed and control groups. Conclusion: Our study suggests that exposure to vehicular exhaust over a period of time increases oxidative stress and subsequently induces oxidative DNA damage in traffic policemen. Preventive and therapeutic strategies may be considered for traffic policemen to minimize the adverse effects due to vehicular exposure.

Molecular Modelling and Docking Analysis of *katG* and *rpoB* Genes in Clinical Isolates of Multi Drug Resistant Tuberculosis Patients from Sahariya Tribe of North Central India. *R. Prakash[1], R. GUPTA[1], V.M. KATOCH[2,3], P.K. TIWARI[1].* 1) CENTRE FOR GENOMICS, MOLECULAR & HUMAN GENETICS, JIWAJI UNIVERSITY, GWALIOR, MADHYA PRADESH, India; 2) DEPARTMENT OF HEALTH RESEARCH, MINISTRY OF HEALTH AND FAMILY WELFARE, GOVT. OF INDIA, NEW DELHI; 3) INDIAN COUNCIL OF MEDICAL RESEARCH, NEW DELHI INDIA.

Tuberculosis caused by *Mycobacterium tuberculosis*, requires a multi-drug therapy approach. Isoniazid and Rifampicin are two potent first line drugs. Alteration in drug binding due to mutation in *katG* and *rpoB* genes is an important factor for resistance to isoniazid and rifampicin. To investigate the drug-drug target interactions for these two clinically important drugs, mutations in *katG* and *rpoB* genes, of MDR-TB patients from Sahariya tribe were identified and molecular models were prepared. Multiple sequence analysis revealed three mutations (Arg463Leu, Asp529Thr and Asp529His) for *katG* gene and one most common mutation (Ser-531Leu) in *rpoB* gene. The docking analysis showed that isoniazid binds to wild type katG protein at one of its active site residue HIS108 with one hydrogen bond formation, whereas, the drug binds to different positions for two of its mutant forms, i.e., Arg463Leu and Arg463Leu & Asp529Thr, with formation of one hydrogen bond at different residues, LYS274 and HIS270, respectively. The drug binds to third mutant (Arg463Leu & Asp529His, a semi conservative substitution) at TYR229 and VAL230 residues forming 2 hydrogen bonds. Interaction of rifampicin with wild type rpoB protein revealed formation of 1 hydrogen bond at LYS799 residue along with the formation of 1 oxygen bond at THR829 residue, a hypothesized active site for rifampicin binding, since no crystal structure is available for rpoB protein till date. Whereas, its interaction with mutant protein (one of the most common mutation in 81bp RRDR) resulted formation of 1 hydrogen bond at ILE522 residue with bond distance of 2.23 Å, smaller than bond distance at THR829 residue 2.46 Å. Functioning of drug mainly depends on its binding on active site or residues. In mutant models, the inhibition of drug function may be due to change in binding residues or difference in formation of hydrogen bonds, which needs further investigations. Thus, the knowledge of structural mechanism of drug resistance could pave the way for design of new drug targets to tackle the situation of multi-drug resistant tuberculosis.

Preliminary analysis of polymorphisms in the *ABCB1* and *ABCC1* genes associated to virological failure to antiretrovirals in a Mexican Mestizo population. *F.F. González-Galarza, I.J. Varela-Marrufo, D. Delgadillo-Guzmán, R.D. Arellano-Pérez Vertti, F.C. López-Márquez, J.R. Argüello.* Center for Biomedical Research, Autonomous University of Coahuila, Torreon, Coahuila, Mexico.

In recent years, there has been a significant increase in the number of studies that are being performed to understand the pharmacogenomics of highly active antiretroviral therapy (HAART). This treatment is commonly used in HIV infections by promoting the suppression of virus replication. The antiretroviral effect has been shown to vary among individuals of different ethnicities in which the existing polymorphism in the *ABCB1* and *ABCC1* genes has been suggested to provide evidence for the heterogeneity of the response. At present, many of these studies have been primarily carried out in individuals of Caucasian ancestry. Thus, there is a lack of analysis carried out in populations from other ethnic groups such as in the Mexican Mestizo population. In this study, we analyzed the prevalence of two SNPs (rs1045642 and rs212091) associated to virological failure to HAART in one hundred randomly-selected individuals from the Comarca Lagunera region that were SNP genotyped using the commercially-available Illumina HumanOmniExpress BeadChip. We found that the genotype frequencies for the rs1045642 were: AA-31%, GG-31% and AG-38%. In the case of the rs212091 the CT genotype was present in 20% and TT in 80% of the individuals whereas the CC genotype was absent. Additionally, 150 HIV patients have been included to evaluate the prevalence of these SNPs which may help researchers and clinicians in the personalized treatment of HIV infected patients in Mexico.

704W

X-linked genes with novel rare variants identified by WGS in ASD patients are involved in Neurodevelopment. *V. Chini[1], K. Shalaby[1], Y. Al-Sarraj[1], R. Taha[1], M. Kambouris[2,3], H. El-Shanti[1,4].* 1) Medical Genetics Center, Qatar Biomedical Research Institute, Doha, Qatar; 2) Pathology-Genetics, Sidra Medical and Research Center, Doha, Qatar; 3) Genetics, Yale University School of Medicine, New Haven, CT, USA; 4) Pediatrics, University of Iowa, Iowa City, IA, USA.

Two boys with Autism Spectrum Disorder (ASD) from two unrelated consanguineous families of Arabic origin were studied by Whole Genome Sequencing (WGS) together with their parents. The WGS data of the X chromosome were analyzed to identify possible predisposing X-linked variants. Comparative analysis of the WGS data for X-linked recessive inheritance identified the following three strong candidate gene variations, in order of priority; Family 1: *IL1RAPL2* c.206G>C/p.S69T; Family 2: *SHROOM4* c.3370C>G/p.Q1124E, and *SYTL5* c.1370G>A/p.R457Q. All variations validated by Sanger Sequencing, co-segregate with the disease phenotype within each family and are absent in known polymorphism databases, as well as in 1800 ethnically matched control chromosomes, genotyped by TaqMan assays and Real-Time PCR.In Family 1: *IL1RAPL2* is associated with non-syndromic X-linked ID and/or ASD and the protein is detected at low levels in fetal and adult brain (particularly in the frontal lobe, temporal lobe and cerebellum). In Family 2: *SHROOM4* plays a role in cytoskeletal architecture and it is considered an XLMR gene, as mutations have been linked to Stocco dos Santos Syndrome. Deleterious mutations might affect the morphology of the neural cells and eventually the neural development. The *SYTL5* encoded protein belongs to the synaptogamin-like protein family and seems to play a role in protein transportation in specific tissues, as it is expression is restricted to placenta and liver. Maybe during embryonic development its expression is required for downstream gene control that plays a role in neural development.Genes function and suggested mechanisms, as well as the absence of the mutations from the ethnically matched control population and publically available databases, indicate that these novel rare variants identified are strong candidates for predisposition to the development of ASD. Future studies on transcriptome analysis and gene expression will enable to confirm the indications and the mechanisms might justify their involvement to ASD.

705T

Inherited missense variation in Pfam protein domains contributes to autism risk. *S. Fu[1,2], M. Fromer[2,3], A. Goldberg[1,2,3], J. Buxbaum[1,2,3,4,5,6].* 1) Seaver Autism Center for Research and Treatment, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 2) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 3) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 4) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 5) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, New York, USA; 6) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, New York, USA.

Autism spectrum disorder (ASD) is a neurodevelopmental disorder affecting 1% of the population, with a large fraction of risk conveyed by genetic variation. The genetic architecture of ASD involves the interplay of common and rare variation affecting hundreds of genes. Gene function is defined by the structure of the resulting protein, with protein domains defining key functional and structural elements of the protein. Previous studies by the Autism Sequencing Consortium (ASC) and others have demonstrated that (1) *de novo* and (2) inherited loss of function (LoF) mutations and (3) *de novo* probably damaging missense (mis3) mutations all play a role in ASD risk. Here we hypothesized that inherited missense mutations could also contribute to autism risk by disrupting specific protein domains. Published rare variants identified with whole exome sequencing (WES) by the ASC and in the Simon Simplex Collection (SSC) in more than 17,000 individuals from seventeen sample sources were annotated with Pfam, which is a database of conserved protein domain families that is widely used to annotate and classify proteins. We analyzed both case-control and family data, incorporating the latter by using cases and pseudo-controls. *De novo* variants were analyzed separately.We grouped missense mutations into three categories based on polyphen2 annotation: mis1 (benign), 2 (possibly damaging), and 3 (probably damaging). Case-control burden was estimated using odds ratios from corresponding 2x2 tables, and significance was assessed using permutation that controls for population structure. We found that, when considering case-control and case-pseudo-control data, mis3 variation as a whole did not show excess burden (P=0.31;OR=0.96). In contrast, mis3 variation disrupting Pfam domains show excess burden in cases (P=0.02;OR=1.02). No corresponding signal was observed in mis1 and mis2 variation (P>0.3). For *de novo* variation, strong burden was found in mis3 (P=0.015). However subsetting down to the mis3 variants overlapping pfam did not show a strong signal.We next assessed whether specific Pfam domains could be implicated in these analyses. Although nothing survived correction for multiple testing across 4178 unique Pfam domains, the top hit was the nucleosome assembly protein family, consistent with previous findings of alterations in chromatin remodeling in risk factor for ASD. Further studies will group domains functionally and will incorporate additional ASD whole exome datasets.

706F

Whole genome sequencing of pedigrees with a high burden of autoimmune disease. *P. Bronson[1], J. Sitrin[1], T. Bhangale[1], L. Criswell[2], P. Gregersen[3], R. Graham[1], T. Behrens[1].* 1) Human Genetics, Genentech, Inc., South San Francisco, CA; 2) Dept. of Rheumatology, Univ. of California, San Francisco, CA; 3) Boas Center for Genomics & Human Genetics, Feinstein Institute for Human Genetics, Manhasset, NY.

Collectively, autoimmune diseases affect >23M Americans, and can be severely debilitating. Though the etiology of autoimmunity remains largely unknown, evidence supports a substantial genetic component, particularly with HLA. To date, ~400 genetic loci have been reported. However, common risk alleles account for only a fraction of heritability, and the role of rare causal variants is unknown. We undertook a combined sequencing and linkage screen to identify potential rare variants. We selected 75 pedigrees with a high burden of autoimmune disease (≥2 cases with rheumatoid arthritis (RA), inflammatory bowel disease (IBD), type 1 diabetes (T1D), multiple sclerosis (MS) or systemic lupus erythematosus (SLE)) out of 265 multiplex autoimmune disease pedigrees collected by the Multiple Autoimmune Disease Genetics Consortium (MADGC). We sequenced one or two cases from each pedigree (73 WGS, 50 exome, total N = 123). Individuals in the 75 pedigrees with available DNA were genotyped on the Illumina 660K or 1M SNP chip (N = 669). After calling reads with GATK, we removed variants that were present in WGS data (mean 30x coverage) available for 583 European Americans, the 1000 Genomes Project, or the NHLBI Exome Sequencing Project. For families with two cases sequenced, variants that were only present in one case were removed. To prioritize rare variants, we first restricted our search to ~400 known autoimmune loci. We also undertook a nonparametric genome-wide linkage scan (N = 5,132 common SNPs) to identify regions of the genome that segregate with disease within families. We identified 850 linkage intervals, and are using these family-specific linkage intervals to prioritize variants for follow-up genotyping. A private exonic missense (R>K) mutation in the SH2B adaptor protein 3 (*SH2B3*, chr12:111,882,571**A*) was identified in both affecteds from a single pedigree. *SH2B3* is important for hematopoiesis and T cell receptor signaling. *SH2B3* is pleiotropic for autoimmunity, and is a significant GWAS locus for T1D, RA, Celiac disease, ankylosing spondylitis, primary biliary cirrhosis, juvenile idiopathic arthritis, vitiligo and primary sclerosing cholangitis. Further work is being conducted to genotype this variant in additional affected and unaffected members of this pedigree, and to identify additional rare variants.

707W

The exome sequencing identified the YARS2 mutation as a nuclear modifier for the phenotypic manifestation of Leber's hereditary optic neuropathy-associated mitochondrial DNA mutation. *M. Guan[1], P. Jiang[1], X. Jin[1], Y. Peng[1], M. Wang[1], X. Liu[2], X. Zhou[2], J. Qu[2], T. Huang[3].* 1) Genetics, Zhejiang University, Hangzhou, Zhejiang, China; 2) Ophthalmology, Wenzhou Medical University, Wenzhou, Zhejiang, China; 3) Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA.

Leber's hereditary optic neuropathy (LHON) is one of the most common inherited optic neuropathies, with maternal inheritance. The MT-ND4 m.11778G>A mutation is the most prevalent LHON-associated mitochondrial DNA mutation. The m.11778G>A mutation is a primary factor underlying the development of blindness but insufficient to produce a blindness phenotype. Nuclear modifier genes were proposed to modulate the phenotypic manifestation of the m.11778G>A mutation. However, none of modifier gene(s) has been identified. An exome sequencing of four members in a Chinese family carrying m.11778G>A mutation identified a missense mutation (highly conserved 191 glycine to valine) (p.191Gly>Val) at the catalytic domain of mitochondrial tyrosyl-tRNA synthetase, encoded by YARS2. The Sanger sequence analysis of YARS2 in 307 symptomatic matrilineal relatives and 271 asymptomatic matrilineal relatives of 167 Chinese families carrying the m.11778G>A mutation showed that all matrilineal relatives carrying both homozygous YARS2 p.191Gly>Val and m.11778G>A mutations exhibited optic neuropathy. It was proposed that the YARS2 p.191Gly>Val mutation alters its structure and function. Functional analysis showed that homozygous YARS2 p.191Gly>Val mutation altered the aminoacylation and steady-state levels of tRNATyr. The failure in tRNATyr metabolism impaired mitochondrial translation, especially for polypeptides with high content of tyrosine codon such as MT-ND4, MT-ND5, MT-ND6 and MT-COX2. The primary defect of m.11778G>A mutation was the reduced activity of complex I. However, the YARS2 p.191Gly>Val mutation worsened the respiratory phenotypes associated with m.11778G>A, especially reducing activities of complex I and IV. The respiratory deficiency then caused the reducing efficiency of the mitochondrial ATP synthesis and increasing the production of reactive oxygen species. Thus, biochemical defects caused by the YARS2 p.191Gly>Val mutation aggravate the mitochondrial dysfunction associated with the m.11778G>A mutation, exceeding the threshold for expressing the blindness phenotype. These findings indicate that the mutated YARS2, acting as a nuclear modifier, modulates the phenotypic manifestation of the LHON-associated mtDNA mutations.

708T

Exome analysis of rare and common variants within the NOD receptor pathway. *G. Andreoletti[1], E.G. Seaby[1], T. Coelho[1,2], N.A. Afzal[2], A. Batra[2], R. Haggarty[3], R.M. Beattie[2], S. Ennis[1].* 1) University of Southampton, Southampton, Hampshire, United Kingdom; 2) Southampton Children's Hospital, University Hospital Southampton NHS Foundation Trust, Southampton General Hospital, Tremona Road, Southampton, SO16 6YD, UK; 3) NIHR Nutrition Biomedical Research Centre, Southampton Centre for Biomedical Research, University Hospital Southampton NHS Foundation Trust (Mailpoint 218), Southampton General Hospital, Southampton, SO16 6YD, UK.

Objective: This study looks at the burden of coding mutation in PIBD patients within the genes comprising the NOD2 pathway using data derived from exome sequencing.**Methods**: 143 cases and 96 controls were recruited through tertiary referral clinics at University Hospital Southampton for whole-exome sequencing. For all exomed patients, genomic DNA was extracted using the salting out method. Data were aligned and tested for quality control using an in-house pipeline and customized scripts. Burden of mutation testing was conducted across all genes in the NOD2 pathway using the SKAT-O test.**Results**: We observed mutations in 39 of 40 genes comprising the NOD2 pathway. Despite the small sample size, SKAT-O test identified five genes as significantly associated with disease status (*NFKB1* p= 0.008; *BIRC3* p=0.016; *IL6* p=0.022; *BIRC2* p=0.030, and *NOD2* p=0.033). The evidence contributing to the association signal for these genes is primarily driven by rare variants that would not have been assessed in previous GWA studies.**Conclusion**: Within a modest cohort of children with IBD we successfully applied burden of mutation testing that includes common and rare variants. Three of the implicated genes (*NFKB1*, *NOD2* and *IL6*) had been previously identified using only common variant association but two previously unreported genes (*BIRC2* and *BIRC3*) were also detected. *BIRC2* and *BIRC3* are members of the inhibitor of apoptosis familywhich plays an important role in IBD pathogenesis.

709F

Identification of novel disease-causing genes expands molecular genetic diagnosis of Osteogenesis Imperfecta. *S. Fahiminiya[1], F. Rauch[2], J. Majewski[1].* 1) Department of Human Genetics, Faculty of Medicine, McGill University and Genome Quebec Innovation Center, Montreal, Quebec, Canada; 2) Shriners Hospital for Children and McGill University, Montreal, Quebec, Canada.

Background: Sequencing of protein coding regions of human genome (Whole Exome Sequencing; WES) has been successfully used to unravel the mystery behind several inherited human genetic diseases, in the past few years. We applied this approach to uncover novel genetic cause of Osteogenesis Imperfecta (OI). OI is a group of genetically heterogeneous disorders characterized mainly by variable degree of bone fragility and most often is caused by mutations in COL1A1 or COL1A2, the genes that code for collagen type I alpha 1 and alpha 2 chains. Other clinical manifestations include tooth abnormalities (dentinogenesis imperfecta), hearing loss and blue or gray sclera. Here, we present the results of our WES studies that led to the identification of several novel disease-causing genes in OI patients. We also show that analyzing only rare variants in coding regions is not always conclusive and the involvement of non-coding variants and copy number variations (CNV) should not be ignored during bioinformatics analysis of WES. **Method**: WES was performed on 69 patients diagnosed with different types of OI in our center at the Shriners Hospital for Children in Montreal, for whom the result of initial molecular screening of known or potential candidate genes was negative. **Results**: We successfully identified novel disease-causing mutations in coding regions of SPARC and WNT1 in patients with clinical diagnosis of OI type IV. Additionally, we showed that variants in non-coding regions and CNV carry important information and should be considered during bioinformatics analysis of WES data. For instance, we identified pathogenic variants in 5'UTR of IFITM5 (OI type V) resulting in the production of longer protein or in 3'UTR of BMP1, affecting the polyadenylation signal and impaired procollagen type I C-propeptide cleavage. In a patient with OI type VII, CNV in CRTAP was identified as the main cause of the diseases. In addition to new gene discovery, we also identified mutations in Known OI genes (COL1A1, COL1A2, FKBP10 and SERPINF1), which highlight the importance of using WES as an efficient and sensitive diagnosis tools in OI patients. Finally, promising candidate genes were found in a few other patients, however validation in unrelated patients is needed. **Conclusion**: Our study highlights that WES is a powerful molecular approach for discovery pathogenic and novel gene(s) and will help to establish more specific diagnostic panel and improve clinical diagnosis of OI patients.

Utility of VAAST in targeted case-control sequencing of candidate genes in childhood onset Crohn disease. *J. Chen[1], Y. Yu[1], S. Watkins[2], H. Hu[1], L. Denson[3], S. Kugathasan[4], C. Huff[1], S. Guthery[5].* 1) Epidemiology, MD Anderson Cancer Center, Houston, TX; 2) Department of Human Genetics, Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT; 3) Gastroenterology, Hepatology, and Nutrition, Cincinnati Children's Hospital Medical Center, and The University of Cincinnati College of Medicine, Cincinnati, Ohio; 4) Department of Pediatrics, Emory University School of Medicine and Children's Health Care of Atlanta, Atlanta, Georgia; 5) Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Crohn disease is a heritable disease characterized by chronic inflammation of the gastrointestinal tract. Although over 100 common susceptibility variants have been identified from genome-wide association studies (GWAS), the role of rare genetic variation in Crohn disease susceptibility is less clear. To search for rare variation contributing to Crohn disease risk, we sequenced 205 childhood onset parent-offspring trios and 194 unaffected controls in nine genes previously implicated in GWAS: *NOD2*, *IL23R*, *ATG16L1*, *IRGM*, *CARD9*, *STAT1*, *IRF1*, *IL5*, and *SLC22A4*. Our single marker analysis replicated two common missense susceptibility variants, in *ATG16L1* (T300A, rs2241880, p = 0.0006) and *NOD2* (P268S, rs2066842, p = 0.0019). The risk allele effect sizes were consistent with effect sizes reported in adult onset populations, with per allele odd ratios [OR] of 1.63 (95% confidence interval [CI] = 1.2 – 2.2) and 1.60 (95% CI = 1.2 – 2.2) for rs2241880 and rs2066842, respectively. To evaluate evidence for rare variant association, we performed gene-based tests using VAAST 2.1 for variants with population minor allele frequencies (MAF) lower than 0.05. VAAST identified a statistically significant association for rare nonsynonymous variants in *NOD2* (p = 2.1 x 10-5). The association signal at *NOD2* was driven primarily by three variants: G908R (rs2066845, MAF = 0.01, OR = 4.7, 95% CI 1.6 to 13.9), R702W (rs2066844, MAF = 0.05, OR = 2.0, 95% CI 1.2 to 3.4), and A1006fs (rs2066847, MAF = 0.025 OR =3.86 95% CI 1.9 to 7.7). Our results replicate the association of rare nonsynonymous variation in *NOD2,* affirm the utility of the probabilistic approach implemented in VAAST in complex genetic traits, and provide a framework for assessing rare variation in other genes implicated in Crohn disease.

711T

LONP1 is A Novel Gene for Congenital Diaphragmatic Hernia. *L. Yu[1], L. Shang[1], J. Wynn[1], AD. Sawle[2], M. Tarnopolsky[3], M. Geraghty[3], A. Larson[3], A. Safdar[3], A. Nazli[3], GB. Congenital diaphragmatic hernia (CDH) is a life-threatening birth defect characterized by the incomplete formation of diaphragm. The incidence of CDH is approximately 1 in 3,000 births. CDH can occur as an isolated defect or in the presence of one or more anomalies including congenital heart, brain, renal, and genitourinary malformations in 40% of CDH. Chromosomal anomalies and mutations in several genes have been implicated in the etiology of CDH. We identified a *de novo* variant (p.T638M) in *LONP1* in a sporadic CDH patient using parental-child whole exome sequencing (WES). We then studied an additional 424 CDH patients using targeted next generation sequencing and Sanger confirmation to identify an additional 3 rare variants in *LONP1* that were either *de novo* or dominantly inherited. The p.T638M variant was found recurrently, once *de novo* and once inherited in a familial case and segregated with CDH and eventration of the right hemidiaphragm. An additional *de novo* missense variant p.R358W was identified in a sporadic CDH patient. Variant p.S866F segregated with disease in a pedigree with incomplete penetrance with CDH and mild eventration of the diaphragm. We also identified a splice variant c.639-1G>T in a familial case that was *de novo* in the proband's paternal grandmother. Analysis of mRNA shows that the splice variant results in aberrant splicing that produces a premature termination. Functional studies in fibroblasts from patients revealed defects in cytochrome *c* oxidase (COX) enzyme activity and COX subunit 2 protein aggregates with immunohisotchemistry. Our results provide the first genetic evidence for the role of *LONP1* in diaphragm development and suggest a novel mechanism for the development of CDH. Our results also suggest that there are subtle defects in diaphragm development that are not clinically apparent that can be associated with genetic causes of CDH.

712F

A Patient with Beaulieu-Boycott-Innes Syndrome, Illustrating the Utility of Whole Exome Sequencing. *J. Amos[1], S. Tang[2], K. Helbig[2], W. Alcaraz[2], R.R. Lebel[1].* 1) SUNY Upstate Medical University, Syracuse , NY; 2) Ambry Genetics Corporation, Aliso Viejo, CA.

A 19-year-old female, initially identified with developmental delays and anatomic abnormalities at infancy, presented for re-consideration. Her features include cleft palate, corpus callosum dysplasia, developmental delays, bilateral hearing deficit, hypothelorism, lordosis, retrognathia, and ventriculomegaly; this constellation of features was considered "non-syndromic," not fitting any currently identified syndromes. Previously, routine karyotype and subtelomere FISH had revealed a normal variant 2q deletion. Comparative genomic hybridization later revealed a 163 kb deletion at 10q21.3, which was shown to be of maternal origin but has uncertain clinical significance. A literature search had been performed (using London Dysmorphology Database) to identify candidate syndromes, without success. DNA was extracted from lymphocytes and subjected to whole exome sequencing in search of diagnostic insights; five mutations were found. Two significant novel mutations were found in the *THOC6* gene. One was a missense mutation causing a protein change T250P and the other was a nonsense mutation of R87 (stop codon). Other notable mutations were in the genes *ATR, FANCD2* and *NIPBL*; while they might have clinical importance, they are not thought to have any significance to the patient's phenotype since each is heterozygous and the conditions with which they are associated are autosomal recessive. Mutations of *THOC6* have been associated with Beaulieu-Boycott-Innes Syndrome (BBIS), an autosomal recessive condition (OMIM #613680); all four previously published cases were homozygous for Q46R inherited in an extended pedigree characterized by consanguinity. Comparing our patient's phenotype with previously reported patients, we note some overlap in features including intellectual disability, microcephaly, and retrognathia. Other features in our patient, such as brain anomalies found by MRI, submucous cleft palate, short stature, hypothyroidism, bilateral hearing deficit, strabismus and low-set ears, were not observed in previously reported patients. Mutations found in this patient are novel and likely causative of her adverse phenotype. Her divergence from previously observed phenotypes may be due to the differential effects of the specific mutations. We are in the process of obtaining follow-up information about the previously reported patients, seeking insight for this patient's optimum management.

713W

Searching for rare variants involved in fulminant hepatitis B virus infection using exome sequencing. *N. Chaturvedi[1,2], S. Asgari[1,2], P. Scepanovic[1,2], J. Fellay[1,2].* 1) Ecole Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland.

Background: Hepatitis B virus (HBV) infection is a global health problem causing around 1 million deaths every year. A rare and dramatic clinical presentation, observed in less than 1% of patients with acute HBV infection, is fulminant hepatic failure. We used exome sequencing in carefully selected patients to test the hypothesis that rare human genetic variants play a role in driving the course of HBV disease towards fulminant hepatic failure.Methods: A total of 21 liver transplant recipients who developed liver failure due to fulminant HBV infection were recruited in the Transplantation Units of Swiss and Australian University Hospitals. Exome capture and sequencing were performed using Agilent SureSelect technology and Illumina HiSeq2000 sequencer. We used *BWA* to align the short sequencing reads to the human reference genome, and *GATK* for variant calling and quality control. We used two sets of exomes as controls: an in-house set of 172 samples from patients co-infected with HIV and HBV (without any history of severe HBV infection), and the large collection of ~30,000 non-Finnish European exomes gathered by the Exome Aggregation Consortium (ExAC). We used principal component analysis to identify and exclude population outliers. Then, we ran a case-control association analysis of loss-of-function (LoF) and missense variants, collapsed by gene, using one-tailed and two-tailed Fisher's exact tests. We applied the mid-P correction to the two-tailed Fisher's exact test, and Bonferroni correction to control for multiple testing.Results and discussion: After quality control, we observed a total of 228,077 variants in the 21 cases, including 2,611 LoF and 60,822 missense variants. We compared the allele count of LoF variants, per gene, in fulminant HBV cases and in in-house and ExAC controls. While no significant difference was found in the comparison with in-house controls, we identified a total of 100 genes that were enriched in LoF variants in the HBV cases in comparison to the ExAC controls. Using this set of genes, we performed protein interaction analysis, disease pathway analysis and functional annotation clustering using DAVID, but did not observe any significant enrichment. We also obtained RNA-seq data from blood samples of the same set of fulminant HBV patients, and we are performing integrated genomic analysis to study the associational patterns between DNA variants and RNA expression levels.

714T

Sharing of sequence variants in multiple genes within and across multiplex nonsyndromic cleft lip/palate families supports a multifactorial model. *S.H. Blanton[1,2], P. Dillingham[2], S. Slifer[2], R.E. Plant[3], M.E. Serna[3], B.T. Chiquet[4], E.C. Swindell[3], J.T. Hecht[3].* 1) Dept of Human Genetics, Univ Miami, Miami, FL; 2) Hussman Institute for Human Genomics, Univ Miami, Miami, FL; 3) Dept of Pediatrics, UTHSC, Houston, TX; 4) Dept of Pediatric Dentistry, UTHSC, Houston, TX.

Nonsyndromic cleft lip/palate (NSCLP) is a common birth defect, with a birth prevalence of approximately 1/1000. While there is strong evidence for genetic underpinnings based on family and twin studies and GWAS in large samples, only a few specific genetic changes have been identified. Association studies have identified several candidate pathways involving HOX and WNT genes. We previously identified association to a novel gene, CRISPLD2, and have shown that it plays a role in orofacial development in zebrafish. To further explore its role, we knocked down CRISPLD2 in zebrafish and used RNA-seq to identify up and down regulated genes. In order to better capture the variants/genes involved in the etiology of NSCLP, we subjected a subset of 36 families from our large collection of multiplex NSCLP families to whole exome sequencing with the Agilent 50Mb Exome v5 + UTRs kit. After initial QC, there were thirty-four families with at least 2 affected individuals sequenced (range 2-6). We compiled a candidate gene list of 62 genes identified from association studies and our RNA-seq analysis. As an initial screen, we filtered variants by presence in our candidate genes, presence in all affected individuals within a family, and having a GERP score>4, or location in a predicted transcription factor binding site (TFBS), or a possibly or probably damaging functional prediction by Polyphen2. A total of 247 variants in 50 genes met these criteria. Multiple families had variants in the same gene(s). Individual families had variants in multiple genes, ranging from 15 to 34 genes; the number of segregating variants was not correlated with the number of affected individuals. 207 variants were exonic, 168 were rare or novel, 156 were TFBS, and 27 were possibly or probably damaging. Of the 57 nonsynonymous variants, 1 was in the 5'UTR, 53 were missense, 2 were splice donors and 1 was a gain of a stop codon. Variants in multiple genes are segregating in individual families as well as across families. This is consistent with the multifactorial trait threshold model proposed for NSCLP. We are currently developing multigenic haplotypes in our families.

715F

Whole genome sequencing in families to find new Alzheimer Disease genes: The analysis and current results from the Family Analysis Working Group of the Alzheimer's Disease Sequencing Project. *E. Blue[1,4], B. Kunkle[2,4], B. Vardarajan[3,4], J. Jaworski[2], Family Analysis Working Group of the Alzheimer's Disease Sequencing Project.* 1) Div Med Gen, Univ. of Washington, Seattle, WA; 2) Inst Hum Gen, Univ. of Miami, Miami, FL; 3) Neurology, Columbia Univ., New York, NY; 4) co-first author.

The Alzheimer's Disease Sequencing Project (ADSP) is a Presidential Initiative on Alzheimer's Disease (AD) with the goals of 1) identifying new genetic variants that influence risk for developing AD, 2) determining why some individuals with known risk factors for AD escape from developing the disease, and ultimately 3) identifying new pathways for the prevention of AD. Toward this goal, the Family-based Analysis work group of the ADSP is analyzing whole genome sequences generated as part of this initiative on 583 subjects from 111 families that contain multiple affected relatives with late-onset AD, and pre-existing SNP array data. These families were ascertained from multiple sites, and include 67 Caribbean Hispanic and 44 European-American and Dutch families. These data are publicly available through dbGaP.Families with multiple affected relatives can provide powerful information regarding the genetic underpinnings of AD. In particular, co-segregation of variants with the phenotype provides sharp focus to narrow the vast quantity of variation within whole genomes. Our previous linkage analyses of these families identified several regions of interest (ROI) with HLOD>4, including: 14q32.2 in European-Americans, 7p14.3 in Hispanics, and 11q12-14, a region previously associated with LOAD, in both ethnicities. Additionally, significant evidence for linkage was observed at 3q22 in European-American, Dutch, and Hispanic families. These results define our initial target ROIs for examination using the ADSP sequence results.Several complementary analyses of the sequencing data to find variants segregating with disease in these ROIs are underway, including: 1) linkage analyses using the full pedigree structures with and without accounting for local admixture, 2) prioritizing rare variants that co-segregate using IBD/linkage regions and functional annotation, 3) combined linkage and association analysis, 4) analyses of variants in known AD and dementia genes, and 5) gene-based analyses. Products of these analyses will be shared with the research community. These include 1) estimates of regional and global ancestry proportions in the Hispanic families, 2) inheritance vectors for identity-by-descent-based analyses computed from the complete pedigrees, and 3) variant imputation throughout the pedigrees. This presentation is meant to inform the research community of the resources available, and highlight our preliminary findings.

716W

Common and Rare Exonic Variants Associated with Type 2 Diabetes in Han Chinese. *G. Chen[1], Z. Zhang[2], A. Adeyemo[1], Y. Zhou[2], A. Doumatey[1], G. Liu[2], J. Zhou[1], D. Shriner[1], F. Tekola-Ayele[1], C. Wang[2], A. Bentley[1], C. Jiang[2], C. Rotimi[1].* 1) NHGRI/NIH, National InGuanjie Chenstitutes of Health, Bethesda, MD; 2) Suizhou Central Hospital, Suizhou, Hubei, China.

Type 2 diabetes (T2D) is a common health condition with a prevalence of over 10% in China and about a million new cases of T2D are projected to occur each year in the 21st century. Genome wide association studies (GWAS) performed in East Asians have identified several common variants associated with T2D. Although these findings have provided valuable insight into the pathogenesis of T2D, much of the heritability for this trait remains unexplained. It has been postulated that rare variants may explain some of this missing heritability. Here, we investigate the contribution of rare and common variants to susceptibility to T2D by analyzing exome array data in 1908 Han Chinese (917 cases) genotyped with Affymetrix Axiom® Exome Genotyping Arrays. A total of 57,704 autosomal SNPs within 18,455 genes passed quality control filters and were analyzed. Based on the joint common and rare variants analysis implemented in the Sequence Kernel Association Tests (SKAT), we identified significant associations between T2D and variants in *MUC5B* (p-value 1.01 × 10-14, 9 rare and 16 common variants). *MUC5B* encodes a member of the mucin family of proteins, which are highly glycosylated macromolecular components of mucus secretions. Emerging evidence indicates that diabetes is an independent risk factor for pulmonary dysfunction and that diabetes pulmonary fibrosis is a potential diabetic complication. Also, we replicated 8 (*NCNQ1, PEPD, ACHE, IGF2BP2, GPSM1, PCNXL2, ZPLD1, PSMD6*) of 46 genes previously associated with T2D in East Asian ancestry populations (GWAS catalog) using both rare and common variants with p value < 0.05. These findings provide potential insight into the role of rare and common variants in the pathogenesis of T2D in Chinese and provide an important evidence for understanding the mechanisms underlying diabetic pulmonary fibrosis.

717T

Genetics of normal cognitive and neurosensory variation in humans. *E.T. Cirulli[1], A.J. Bartholomew[1], D.B. Goldstein[2].* 1) Center for Applied Genomics and Precision Medicine, Duke Univ, Durham, NC; 2) Institute for Genomic Medicine, Columbia Univ, New York, NY.

While extensive efforts continue to be made to understand the genetics of human diseases, there has been much less serious effort dedicated to understanding the genetic bases of traits comprising everyday differences among healthy individuals, many of which are of great interest biologically and have the potential to further our understanding of diseases. We have administered a standard cognitive battery to more than 2,400 healthy volunteers and assessed more than 800 participants for their night visual acuity, face recognition ability, time perception, contagious yawn susceptibility, and auditory pitch discrimination; these are all traits that are relevant to disease, fairly easy to measure and involve neuronal processes. In addition to GWAS and exome chip genotyping, we have now sequenced the complete exomes of >100 of our participants. Our work provides a novel viewpoint into the biology underlying human diseases and the genetic architecture of human traits.

718F

Rare variation association testing in inflammatory bowel disease, using low coverage whole genome sequences. *K.M. de Lange, Y. Luo, C.A. Anderson, J.C. Barrett, UK IBD Genetics Consortium.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

The contribution of rare variants (MAF<1%) to complex disease has been difficult to study as they are poorly tagged by GWAS. Next generation sequencing studies can address this, but sample sizes have been modest, and mostly focused on the exome. Here we investigate the use of low coverage whole genome sequences to study rare variation in inflammatory bowel disease (IBD), an exemplar complex trait.Low coverage sequencing allows greater sample sizes (and increased power) for a fixed-cost, but yields less accurate individual genomes. Variation in read depth exists even in samples sequenced together and is exacerbated when combining existing datasets. Our IBD study has 3 groups with different mean depths: 1767 ulcerative colitis cases (UC; 2x), 2513 Crohn's disease cases (CD; 4x) and 3652 controls (6x).As read depth increases, sensitivity and specificity improves. If depth is correlated with phenotype two countervailing sources of error affect association tests: false positive calls (favors lower depth) and false negative calls (favors higher depth). When aggregating rare variants over a test region even tiny biases produce inflated test statistics. For common variation this bias can be reduced by joint-calling across large samples, and by using imputation improvement to borrow information from across individuals and correlated sites. However, our investigation suggests that for MAF<3% bias from read depth differences is not removed by joint-calling, as there is insufficient population-level information. Furthermore we discover that the bias in this range is worse after imputation improvement, which performs excessive smoothing on signals from sites with scarce information, making individual genotype probabilities poorly calibrated.We apply an approach based on Derkach et al's score test (2014), using expected genotypes given the data, and evaluating significance by bootstrapped permutation testing. Burden analyses are performed on rare variants in gene-coding regions and a signal is observed in the CD risk gene *NOD2* without inflation in other genes. The method is extended to non-coding regions (e.g active gene enhancers in immune-related cell types), where we find that the number of variants that may be included is limited by the corresponding increase in the aggregated bias. Analyses are ongoing, but it is clear that higher coverage sequencing of much larger sample sizes will be required to fully understand the role of rare variation in complex disease risk.

719W

Genetic epidemiology of ocular health and disease in the Jirel ethnic group of eastern Nepal: the Jiri Eye Study (JES). *M.P. Johnson[1], S.S. Thapa[2], K.L. Anderson[3], S. Laston[1], M.K. Shrestha[2], B. Towne[4], J. Subedi[5], J. Blangero[1], S. Williams-Blangero[1].* 1) South Texas Diabetes and Obesity Institute, School of Medicine, University of Texas Rio Grande Valley, Brownsville, TX; 2) Tilganga Institute of Ophthalmology, Kathmandu, Nepal; 3) Department of Ophthalmology, School of Medicine, University of Texas Health Science Center at San Antonio, TX; 4) Department of Community Health, Boonshoft School of Medicine, Wright State University, Kettering, OH; 5) Department of Sociology and Gerontology, College of Arts and Science, Miami University, Oxford, OH.

Approximately 90% (n=660 million) of the world's visually impaired reside in developing countries. Combating ocular-related health problems in these countries is critical if we are to reduce the global burden associated with visual impairment (VI). The primary objective of a new study established in eastern Nepal and focused on the Jirel ethnic group is to identify rare functional variants that influence VI. Nepal is a developing country where the prevalence of VI across regions ranges from 7% to 42%. Our family-based study design will recruit 2,000 members of the Jirel population to undergo an eye examination to document, in part, the prevalence of ocular diseases known to influence VI (e.g., cataract). We will use SOLAR to determine the underlying genetic architecture (heritability, pleiotropy) of all measured ocular-related traits and disease endpoints. An existing high-density SNP framework will be used to localize QTLs harboring ocular positional candidate genes. An exome sequencing strategy will be employed to objectively prioritize rare functional variants influencing ocular QTLs. An independent, population-based cohort (n=2,200) from the Bhaktapur District of Nepal will be used to replicate findings. The Jirels belong to a single extended pedigree containing >62,000 pair-wise relationships that are informative for genetic analysis. The Jirel pedigree has 80% power to detect an additive genetic heritability as low as 6.5%, a genetic correlation between two traits as low as 4.4%, and a genetic association explaining as little as 2.4% of the variation observed in a tested trait. The 316 founders of the Jirel pedigree could maximally transmit 10 to 112 copies of a private variant. The average probability that one of the Jirel founders disseminates 5 extra copies of a private variant ranges from 0.20 to 0.92. To date, 229 Jirel members have been recruited to the study. The mean (range) age, SBP and DBP are 45.7 (13-85) years, 129.9 (90-200) mmHg, and 81.2 (52-110) mmHg, respectively. Preliminary field diagnoses are: presbyopia, 28.8%; cataract, 18.3%; glaucoma, 7.9%; and hypertensive retinopathy, 5.7%. The Jirel population is ideal for identifying functional rare variants due to its genetic isolation and deep genealogical relationships. Results from our well-powered study design will explicitly implicate genes in causal biological pathways influencing VI trait variance and therefore, encourage testing of these genes in other global populations.

720T

***GRHL3* mutation screening identifies truncating mutations in patients with apparently nonsyndromic cleft palate.** *E. Mangold[1], A.C. Böhmer[1,2], P. Gültepe[1,2], H. Schuenke[1,2], J. Klamt[1,2], M.M. Nöthen[1,2], M. Knapp[3], K.U. Ludwig[1,2].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics; University of Bonn, Bonn, Germany; 3) Institute of Medical Biometry and Informatics and Epidemiology; University of Bonn, Bonn, Germany.

Van der Woude syndrome (VWS) is a common syndromic form of cleft lip and palate. Mutations in the interferon regulatory factor 6 (*IRF6*) gene account for ~70% of cases. Recently, grainy head-like 3 (*GRHL3*) was identified as a novel VWS gene. Individuals with a *GRHL3* mutation are more likely to have cleft palate and less likely cleft lip or lip pits than individuals with an *IRF6* mutation.Of note, VWS patients have lip pits as sole symptom in addition to clefting. These can be subtle and difficult to recognize. Thus VWS might sometimes appear as nonsyndromic clefting. We therefore evaluated apparently nonsyndromic cleft patients for mutations in *GRHL3*. We sequenced the complete coding region of *GRHL3* in 576 patients with nonsyndromic cleft lip with or without cleft palate (nsCL/P) and 96 patients with nonsyndromic cleft palate only (nsCPO). Observed rare variants were investigated with respect to *de novo* occurrence. Nineteen rare single-base variants were found, four of them can be regarded as pathogenic: 1 frameshift mutation (present in an affected mother and her child), 3 splice site mutations (two of them *de novo* in the affected families, one inherited from an unaffected mother to her two affected children). All seven mutation carriers had an apparently nonsyndromic cleft palate only (nsCPO). We re-contacted/re-visited them, and again they denied any VWS typical lip pits.Notably, common variants in the regulatory region of *IRF6* have been shown to confer risk for nsCL/P, which has a genetically complex background. We therefore investigated whether also common variants in the *GRHL3* region are associated with nsCL/P. Based on genome-wide imputed data from our previously published meta-analyses of GWAS data we tested ~1300 SNPs in the *GRHL3* coding region +/- 200kb for an association in patients. None of the association *P*-values in that region withstood correction for multiple testing (lowest *P*-value observed: rs10903069, *P*=0.013), suggesting that single common variants at the *GRHL3* locus do not contribute to nsCL/P. To identify whether common variants within the *GRHL3* gene region (coding region, introns, UTR) show evidence for association in aggregate, we performed a gene-based analysis for nsCL/P using VEGAS. No evidence for gene-based association was identified.In summary, we did not find evidence for common *GRHL3* variants being causative for nsCL/P. However, we demonstrated that rare mutations in the coding region of *GRHL3* can mimic nsCPO. .

Quality Control (QC) and Multi-Pipeline Genotype Consensus Calling Strategies for 578 whole genomes and 10,692 whole exomes in the Alzheimer's Disease Sequencing Project (ADSP). *A.C. Naj[1], H. Lin[2], B.N. Vardarajan[3], J. Dupuis[4], M. Schmidt[5], F. Sun[4], Y. Ma[6], A. Partch[7], W.J. Salerno[8], N. Gupta[9], S.H. Choi[4], D. Lancour[6], J.C. Bis[10], E.R. Martin[5], A.L. DeStefano[4], Alzheimer's Disease Sequencing Project (ADSP).* 1) Department of Biostatistics & Epidemiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 2) Department of Medicine, Boston University School of Medicine, Boston, MA; 3) Department of Neurology, Columbia University Medical Center, New York, NY; 4) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 5) John P. Hussman Institute for Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 6) Department of Biomedical Genetics, Boston University School of Medicine, Boston, MA; 7) Department of Pathology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 8) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 9) Medical and Population Genetics Program, Broad Institute, Cambridge, MA; 10) Department of Medicine, University of Washington, Seattle, WA.

To identify AD risk and protective variants the ADSP has sequenced whole genomes (WGS) of 578 samples from 111 multiplex families and whole exomes (WES) of 10,692 case/control samples at Baylor College of Medicine, Washington University-St. Louis, and the Broad Institute. WGS and WES from the 3 centers were centrally called using *GATK-HaplotypeCaller* at Broad and *Atlas V2* at Baylor. The ADSP QC Working Group applied a QC protocol to WGS VCFs from each pipeline and developed a novel consensus protocol to combine calls from both pipelines into a single high-quality genotype set.After initial sequencing-center-recommended filtering (variant-level filtering for *GATK*; genotype- and variant-level filtering for *Atlas*), additional variant-level metrics (e.g., call rate, average read depth) were computed across all subjects for each autosomal bi-allelic single nucleotide variant (SNV), and *a priori* filters were applied to exclude low-quality SNVs. Sample-level QC examined within-subject distributions of metrics (e.g., average read depth, Ti/Tv ratio), and outliers (by center or ethnic group) were noted, including correcting miscoded ethnicity for 5 pedigree members. The resulting QCed calls from each pipeline were then combined via a consensus protocol to integrate (a) genotypes concordant between pipelines and (b) high quality genotypes unique to one caller. For the consensus protocol, quality metrics from SNVs involved in Mendelian inconsistencies (MI) among parent-child pairs (n=67) were used to establish additional genotype-specific filters for *GATK* calls.Variant-level QC applied to WGS SNVs excluded ~12.0% and 14.5% of SNVs called by *GATK* and *Atlas*, respectively. After QC, ~91% of genotypes were concordant between pipelines, 4.23% of genotypes were exclusive to Atlas, 4.56% of genotypes were exclusive to *GATK*, and ~0.01% of genotypes were discordant between pipelines. Discordant genotypes were excluded. *GATK*-unique genotypes were kept if the genotype quality (GQ) score met specified thresholds. *Atlas*-unique genotypes were uniformly kept. Re-evaluation of MI in the final consensus set showed improvement in genotype consistency. The final WGS consensus data contains 27,896,774 bi-allelic autosomal SNVs. QC is ongoing for indels and WES.This protocol resulted in a single set of high-quality genotypes from 3 sequencing centers and 2 calling pipelines providing a robust pipeline applicable to other multi-center large-scale sequencing studies.

722W

Genome-wide analysis of stuttering susceptability. *L.E. Petty[1], S.J. Kraft[2], S. Shankaracharya[3], Y. Yu[3], J.M. Beilby[4], D.M. Munzy[5], S.N. Jhangiani[5], M.L. Grove[1], J.R. Lupski[6], R.A. Gibbs[5], E. Boerwinkle[1], C.D. Huff[3], J.E. Below[1].* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Communication Sciences and Disorders, Wayne State University, Detroit, MI; 3) Department of Epidemiology, MD Anderson Cancer Center, Houston, TX; 4) School of Psychology and Speech Pathology, Curtin University, Bentley, WA, Australia; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Stuttering is a speech and language disorder that is common in children and has a high estimated heritability, between 0.66 and 0.81. Prevalence in children is 5%, with higher regional reports, *e.g.* estimated prevalence in Australia is 11%. Existing research on the genetics of stuttering has been limited in both the number of studies and the size and context of those studies. To date, genes identified through candidate gene studies and linkage analyses have not replicated in the literature, suggesting the genetic architecture of stuttering remains largely undiscovered. We sampled 174 individuals comprising 95 families highly enriched for stuttering from Western Australia. From these families, all samples were chip genotyped on the Illumina HumanCore BeadChip, and two affected individuals from each of 25 families were whole exome sequenced in the Baylor Human Genome Sequencing Center through the Baylor Hopkins Center for Mendelian Genomics. Same chip data for additional population-based race-matched controls were drawn from the Childhood Autism Risks from Genetics and the Environment study, including genotypes for 48 HapMap CEU.Preliminary gene-based test analyses were performed using Pedigree-based Variant Annotation, Analysis, and Search Tool. Top results of chip and sequencing data include *CC2D2A* (p = 3.5 x 10-4), a gene related to formation of cilia, *DFFA* (p = 3.7 x 10-4), which has been linked to problems in apoptosis, *CYC1* (p = 2.4 x 10-3), which is involved in the mitochondrial respiratory chain, *DEFB128* (p = 4.1 x 10-4), and *ZNF467* (p = 3.5 x 10-3).To date, no GWAS have been published for stuttering susceptibility. Preliminary results of single variant GWAS controlled for relatedness identified a top signal, rs2516399 (p = 1 x 10-7), which was previously associated with eosinophil count and is intergenic between immune response genes *MICB* and *MCCD1*. Suggestive SNPs include rs10817858 (p = 2.4 x 10-5), rs3737787 (p = 5.9 x 10-5) located in the 3' untranslated region of *USF1*, which has prior associations with familial hyperlipidemia and Alzheimer disease, and rs948962 (p = 8.5 x 10-5) which is non-synonymous and exonic to *MYO7A*, a gene in which homozygous mutation causes Usher syndrome (deafness and diminished inner ear function).These top variants lend support to the idea that stuttering is associated with a pathway that causes structural brain changes. They also indicate new avenues of inquiry, including damage to hearing and the vestibular system.

723T

Genome-wide rare variant association study of extreme phenotypes of emphysema. *J.E. Radder, Y. Zhang, F.C. Sciurba, S.D. Shapiro.* Division of Pulmonary, Allergy, and Critical Care Medicine, Department of Medicine, University of Pittsburgh, Pittsburgh, PA.

Chronic obstructive pulmonary disease (COPD) is characterized by irreversible airflow limitation due to repeated exposures to noxious inhalants, most commonly cigarette smoke. To date, loci identified in genome-wide association studies (GWAS) have only explained a fraction of the heritability of this disease. We hypothesized that a portion of the unexplained heritability of COPD is attributable to rare variants and that we could detect some of this variation using extreme phenotypes of a well-defined subtype of COPD. To test this, we conducted a whole genome sequencing study of extreme traits of emphysema as measured by density histogram quantitative computed tomography and tested for association of rare variants with this phenotype.We selected 70 subjects with severe emphysema and obstruction (f-950 = 0.00455 ± 0.00006, FEV1%predicted = 97.9% ± 2.6%) and 70 subjects with no indication of emphysema or obstruction (f-950 = 0.27600 ± 0.03080, FEV1%predicted = 25.4% ± 1.6%) of similar age (years, emphy = 61.1 ± 1.4, controls = 63.7 ± 1.2) and with similar smoking histories (pack years, emphy= 53.5 ± 7.4, controls=48.6 ± 5.9) from the SCCOR cohort at the University of Pittsburgh. These 140 subjects underwent whole genome sequencing and 137 were analyzed following quality control. Alignment was performed using bwa and variant calling according to GATK's best practices. Genome-wide depth of coverage averaged 27.6X across these samples. We identified 15,819,411 SNPs and indels, 3,532,222 of which were novel (compared to dbSNP138). We filtered all SNPs with minor allele frequency (MAF) > 0.01 in 1000 Genomes and 6500 exomes European American populations. Any SNP with no MAF recorded in one of these databases was excluded with an empirical MAF > 0.01, leaving 5,423,566 rare SNPs (2,221,186 not in dbSNP138). We performed principal component analysis to adjust for ancestry on a pruned set of linkage independent SNPs using EIGENSOFT. We tested for association using SKAT-O in 30kb regions across the genome with age, sex, pack years, and the first two principal components of the ancestry analysis as covariates.The top genomic region associated with emphysema in our study was chr3:81840000-81869999 (P = 2.5x10-6). We are further validating this finding and investigating the genomic elements in this region for their potential functional effects on emphysema. .

724F

Comparing genetic, proteomic and clinical profiles of discordant monozygotic twins. *N. Vadgama[1,2], M. Simpson[6], N. Niranjanan[7], D. Gaze[7], K. Pearce[3], M. Kristiansen[3], P. De Rijk[8], E. Rees[5], G. Kirov[5], A. Pittman[1], S. Morgan[1], D. Lamont[4], J. Hardy[1], J. Nasir[2].* 1) Instituite of Neurology, University College London, London, United Kingdom; 2) Division of Biomedical Sciences, St. George's University of London, London, UK; 3) Instituite of Child Health, University College London, London, UK; 4) College of Life Sciences, University of Dundee, Dundee, UK; 5) Institute of Psychological Medicine and Clinical Neurosciences, Cardiff University School of Medicine, Cardiff, UK; 6) Department of Genetics and Molecular Medicine, King's College London, London, UK; 7) St. George's Hospital and Medical School, London, UK; 8) Applied Molecular Genomics Group, University of Antwerp, Antwerp, Belgium.

Discordant monozygotic (MZ) twins provide a unique opportunity to study the genetics of complex disorders. We carried out whole-exome sequencing, copy number variation (CNV) and proteomic analysis on 13 pairs of MZ twins discordant for a range of complex disorders, including dystonia, inclusion body myositis, and lactose non-persistence. Sequence reads that passed the quality control threshold were filtered for repetitive DNA and screened against a variety of databases, including our in-house database with over 1000 exome sequences. We next manually screened all SNPs that were either different or showed >15% mosaicism.One twin pair discordant for amyotrophic lateral sclerosis (ALS) was screened against a panel of 25 ALS-linked genes. The panel was designed using Illumina TruSeq Custom Amplicon and implemented on an Illumina MiSeq platform. A mutation in *SOD1* (c.65A>G; p.E22G) was identified in both the patients, suggesting epigenetic and/or environmental involvement in familial ALS.Data from Illumina HumanCore BeadChip was analysed using Illumina Genomestudio and PennCNV software, involving an assessment of calls in each of the twin pairs in order to identify unique CNVs in either the affected and unaffected twin. Novel CNV differences were identified within MZ twin pairs discordant for attention deficit hyperactivity disorder, Tourette's syndrome, schizophrenia, and inclusion body myositis.Proteomic profiling of serum samples obtained from an MZ twin pair discordant for ischemic stroke was analysed through a label-free pipeline using the Progenesis application. Potential quantitative and qualitative biomarkers were identified, including afamin and desmoglein-1. We performed pathway analysis using Cytoscape and PANTHER on those proteins, which showed statistically significant differences between the twin pair.We have identified clear-cut quantitative and qualitative differences at the genetic and proteomic levels between MZ twins. This adds to our recently published study on a comparison of blood chemistries of the MZ twins discordant for stroke, showing marked elevation of γ-glutamyltransferase (GGT) and erythrocyte sedimentation rate (ESR) levels in the affected twin.These novel findings support our original hypothesis of postzygotic *de novo* mutations during development to explain discordance in MZ twins. Our study also presents a theoretical framework for mosaicism detection and indicates potential weaknesses of existing variant detection tools.

725W

Sequencing Analysis of Interferon Lambda loci In Individuals with Spontaneous Hepatitis C Virus Clearance and Persistence. *C. Vergara[1], C. Thio[1], M. Taub[2], R. Latanich[1], G. Kirk[1], S. Mehta[1], A. Cox[1], D. Thomas[1], P. Duggal[2].* 1) Johns Hopkins University, School of Medicine, Baltimore, Maryland, USA; 2) Johns Hopkins University, Bloomberg School of Public Health, Baltimore, Maryland, USA.

Hepatitis C virus (HCV) infections affect ~170 million people and is one of the leading causes of cirrhosis and liver cancer. The infection either spontaneously is cleared or persists; persistence is more common in persons of African descent. Polymorphisms near the genes for interferon lambda (IFNL) are significantly associated with HCV persistence and enriched in persons of African descent but the causal DNA sequence and biological mechanisms are unknown. We aimed to determine the distribution of functionally annotated variants (SNVs, insertions, deletions) in and around the IFNL genes in African Americans (AA) and European Americans (EA) with HCV clearance and persistence. Whole genome sequencing was performed in 19 AA (11 clearance) and 18 EA (7 clearance) at 30X coverage using the Illumina HiSeq platform. Variants were annotated and predicted using Snpeff. We interrogated a 1Mb region on chromosome 19 (chr19:39002893-40006156) that includes the IFNL genes and tabulated the distribution of annotated variants between clearance and persistence groups.142 variants in 31 genes were observed in AA and 122 variants in EA (Table 1). Only missense variants were annotated in the IFNL genes. The total number of variants was higher in the persistence group compared with the clearance group for EA (71 vs 51) and AA (74 vs 68). In EA, the Non-synonymous coding variants were more frequent in the persistence group compared with the clearance group (70 vs. 40) although this was not distinct in the AA (69 vs. 67) Most of these variants were predicted to have moderate impact. Two high impact variants were observed in the EA clearance group compared to 1 in the EA persistence group. In AA, 1 variant of high impact was identified in the clearance group, and 4 variants in the persistence group. A higher number of annotated variants (mainly non synonymous coding) were present in individuals with HCV persistence independent of ethnic group. Overall, we observed a diversity of variants with functional impact in individuals with both HCV clearance and persistence. Further analysis will help to elucidate the role of these variants in the resolution of HCV infection.

Table 1. Annotated variants in IFNL with HCV clearance and persistence.

Annotation	European Americans			African Americans		
	Clearance	Persistence	Total	Clearance	Persistence	Total
Non Synonymous Coding	49	70	119	67	69	136
Stop Gained	0	1	1	0	0	0
Splice Site Donor	1	0	1	1	3	4
Codon Deletion	0	0	0	0	1	1
Start Lost	1	0	1	0	1	1
Total	51	71	122	68	74	142

726T

Systematic screening of known associated genes confirms Congenital Hypogonadotropic Hypogonadism is characterized by oligogenicity. *D. Cassatella[1,3], J. Liang[2], J.S. Acierno[3], C. Xu[3], S. Santini[3], A. Dwyer[3], C. Chambion[3], G. Sykiotis[3], M. Hauschild[3], F. Phan-Hug[3], J.G. Xhang[3], B.J. Stevenson[4], N. Pitteloud[3].* 1) Faculty of Biology and Medicine, University of Lausanne, Lausanne, Switzerland; 2) BGI-Shenzen, Shenzen, PRC; 3) Centre Hospitalier Universitaire Vaudois, Lausanne, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland.

Congenital Hypogonadotropic Hypogonadism (CHH [MIM 308700]) is characterized by incomplete puberty and infertility due to absent GnRH secretion. In 50% of cases, CHH is accompanied by absent sense of smell (anosmia) and termed Kallmann syndrome (KS); otherwise, it is referred to as normosmic CHH (nCHH). CHH is a rare, genetically heterogeneous disorder, with 26 genes known to underlie the phenotype, either alone or in combination.CHH shows incomplete penetrance and variable expressivity, both within and between families. Previous studies by our group and others have demonstrated oligogenicity (>2 genes mutated) in CHH, however smaller subsets of genes were evaluated. This study aims to comprehensively evaluate oligogenicity in a larger set of genes, using whole exome sequencing in a cohort of CHH probands.We evaluated 22 known CHH genes in 106 CHH probands and 416 controls from the CoLaus cohort to identify rare, pathogenic non-synonymous and splice acceptor/donor variants. Overall, 45.3% of CHH probands harbored at least one rare pathogenic variant—a frequency higher than reported in previous studies (22-35%).The frequency of digenicty (including bi-allelic changes in one or two genes) in CHH probands (8.5%) was statistically higher relative to controls (0%), which only harbored monoallelic rare variants (RVs) in known CHH genes (p=4.4x10-7); previous studies demonstrated digenicity in the range of 2.8-4.6%.Finally, 4.7% of CHH probands exhibited oligogenicity (RVs in >2 CHH genes), which was absent in controls (p=3.2x10-4). Oligogenicity in previous studies was markedly less, at approximate 1% on average.On a single-gene level, we found two genes with higher mutational rates in our cohort than previously reported; *FGFR1* RVs are present in the 15.1% of our CHH population, while its incidence has been previously reported at 6-10%, and *CHD7* had an incidence of 10.4%, higher than shown in previous studies (5-8%).In summary, as more genes are evaluated in CHH patients, the more striking the frequency of oligogenicity becomes. The complete oligogenic profile for CHH patients is critical for understanding the pathogenicity of this disease and for improving genetic counseling, and next-generation sequencing provides a cost-effective means to accomplish this task.

727F

Exome sequencing identifies *SLC36A4* and *SLC4A8* as novel genes influencing the distribution of HDL-cholesterol in West Africans and African Americans. *A.R. Bentley[1], D. Shriner[1], F. Tekola Ayele[1], A.P. Doumatey[1], J.C. Mullikin[2], . NISC Comparative Sequencing Pg[2], C. Adebamowo[3], J. Oli[4], O. Fasanmade[5], T. Johnson[5], A. Amoah[6], K. Agyenim-Boateng[7], B.A. Eghan Jr.[7], A.A. Adeyemo[1], C.N. Rotimi[1].* 1) Center for Research on Genomics and Global Health, NHGRI/NIH, Bethesda, MD; 2) NIH Intramural Sequencing Center, Bethesda, MD; 3) Department of Epidemiology and Public Health, School of Medicine, University of Maryland, Baltimore, MD; 4) Department of Medicine, University of Nigeria Teaching Hospital, Enugu, Nigeria; 5) Department of Medicine, University of Lagos, Lagos, Nigeria; 6) Department of Medicine and Therapeutics, University of Ghana Medical School, Accra, Ghana; 7) Department of Medicine, University of Science and Technology, Kumasi, Ghana.

Much of the genetic epidemiology of high-density lipoprotein cholesterol (HDLC) in individuals of African ancestry has focused on replicating findings identified in those of European ancestry, an approach which may miss African ancestry-specific variation. Also, HDLC is influenced by both genetic and non-genetic factors, motivating study of individuals with similar ancestry living in different environments, such as West Africans (WA) and African Americans (AA). We conducted whole exome sequencing on individuals at the extremes (5th and 95th percentiles) of the HDLC distribution of samples of WA (n=98 [low], n=100 [high]) and AA (n=57 [low], n=60 [high]). Consistent with previous observations, the mean HDLC was lower in WA than AA (low: 19 vs. 27 mg/dl; high: 75 vs. 96 mg/dl). Common variants (MAF > 0.05) were analyzed in regression models of risk of being in the low group after adjustment for age, sex, and the first principal component. No variants reached statistical significance in the analysis of either WA or AA. We conducted gene-based analysis using SKAT with covariates as described above and statistical significance set at p=2.3 × 10-6 (α=0.05/21,711 genes). Among the WA, *SLC36A4* was associated with HDLC (p=1.6 × 10-7). Variants in this gene were not associated with HDLC among AA, but variants in a different solute carrier, *SLC4A8*, were (p=3.9 × 10-7). Adjusting for body mass index reduced the statistical significance of the *SLC4A8* association in AA (p=1.0 × 10-3), but had virtually no effect on the *SLC36A4* association in WA. To our knowledge, this is the first report of the contribution of either *SLC4A8* or *SLC36A4* to HDLC distribution. The different findings among WA and AA despite ~80% genome-wide shared ancestry are of interest. A potential explanation is that the variants interrogated were not identical in the two groups (e.g., only 77% of the *SLC36A4* and 52% of the *SLC4A8* variants were observed in both WA and AA samples). Alternatively, the differences may result from the European admixture in AA or genetic effects that manifest differently depending on the environment (e.g. the obesogenic environment of AA). This work highlights the importance of studying the genetic determinants of HDLC in African ancestry populations, as it may reveal novel mechanisms that contribute to the distribution of this trait.

728W

Intraocular pressure and exome sequencing variation in the Beaver Dam Eye Study. *F. Chen[1], AP. KLEIN[1,2,3], KE. LEE[4], R. KLEIN[4], BEK. KLEIN[4], P. DUGGAL[1].* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, MD; 3) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI.

Intraocular pressure (IOP) is an important clinical parameter in the evaluation of ocular health. Elevated IOP is a major risk factor for primary open-angle glaucoma (POAG). This study aimed to identify novel gene candidates influencing IOP. A cohort of 139 individuals of European descent with extreme baseline IOP or refractive error measurements from the Beaver Dam Eye Study (BDES) underwent whole exome sequencing. Variants were called simultaneously across all samples by GATK Unified Genotyper and were filtered based on a number of quality control metrics, resulting in a total of 228,413 single nucleotide variants (SNVs) with a mean transition transversion ratio (Ti/Tv) of 2.62 and 11,500 small insertions/deletions (INDELs). In our preliminary analysis for IOP, we classified 15 unrelated individuals as “high IOP” with an IOP > 22 mmHg in at least one eye at baseline. We filtered all variants compared to the normal or low IOP individuals, and identified 3,467 SNVs and 48 small INDELs in exons that are unique to these high IOP individuals. We generated a list of genes with multiple exonic variants that were seen in more than one individual with elevated IOP excluding known false positive genes. The top two genes were *ADGRV1* (adhesion G protein-coupled receptor V1) on chromosome 5q13 (4 nonsynonymous and 2 synonymous SNVs) and *ZFHX3* (zinc finger homeobox 3) on chromosome 16q22.3 (2 non-synonymous and 4 synonymous SNVs). All identified SNVs of these two genes were singletons and 10 of 15 individuals with high IOP carried at least one SNV including four with glaucoma diagnoses. SNVs of these two genes in our study cohort each have a minor allele frequency (MAF) consistent with or higher than those in Europeans from the 1000 Genomes Project. The functional role of these two genes in the eye are unknown, however mutations in human *ADGRV1* are linked to Usher Syndrome type 2, and its homologous gene is associated with abnormal vision in mice. And *ZFHX3* is highly expressed in the retina. We will extend our analysis to other gene regions having multiple variants for low and high IOP as well as the known susceptibility loci for IOP and glaucoma from both GWAS and linkage studies.

729T

Whole-exome sequencing identifies mutations in *SQSTM1* and *VCP* genes in a series of 205 inclusion body myositis cases. *Q. Gang[1,2], C. Bettencourt[1], P.M. Machado[1,2], S. Brady[2,4], J.L. Objective: Sporadic inclusion body myositis (sIBM [MIM 147421]) is the most common myopathy in individuals aged over 45 years. The etiology of sIBM is unknown, but clinico-pathologically overlapping inherited disorders indicate that genetic factors might be involved.**Methods:** We used whole-exome sequencing in a large group of 205 IBM patients. Muscle tissue was pathologically evaluated and whole-transcriptome expression profiles generated.**Results:** We identified eight rare missense mutations in the *SQSTM1* (MIM 601530) and *VCP* (MIM 601023) genes in 10 IBM patients (5%). Five of the mutations have been previously reported in patients with other degenerative diseases, typically associated with denervation, as in amyotrophic lateral sclerosis (ALS [MIM 105400]) and frontotemporal dementia (FTD [MIM 600274]) with Paget's disease of bone (PDB [MIM 602080]). These patients exhibited increased p62 immunohistochemical staining in muscle tissue. MHC-I markers were up-regulated in the muscle of patients as compared to controls, both at the protein and mRNA level.**Conclusion:** In the past the occurrence of denervation found on muscle electromyography (EMG) and the deposition of neurodegeneration associated proteins in sIBM patients was always considered an unexpected finding. The occurrence of mutations in *SQSTM1* and *VCP* in IBM, ALS, FTD and PDB reinforces the link between these disorders, pinpointing converging pathogenic pathways resulting in impaired autophagy-lysosome processing, causing dysregulation of protein homeostasis. The MHC expression could indicate the differentiating factor that directs the clinical phenotype towards IBM as opposed to the other neurodegenerative conditions. We suggest that *SQSTM1* and *VCP* need further investigation in IBM and collaborative efforts will undoubtedly lead to a greater understanding of the pathogenesis of this disorder.

730F

Identification of novel candidate genes in Primary Congenital Glaucoma by Whole Exome Sequencing. *M. Kabra[1], AK. Mandal[2], S. Senthil[2], I. Kaur[1], S. Chakrabarti[1].* 1) Brien Holden Eye Research Centre, L.V. Prasad Eye Institute, Hyderabad, India; 2) Jasti V Ramanamma Children's Eye Care Centre, L.V. Prasad Eye Institute, Hyderabad, India.

PurposePrimary congenital glaucoma (PCG) is an autosomal recessive disorder of the eye characterized by abnormal development of the trabecular meshwork and anterior chamber angle. Mutations in the *CYP1B1* gene have been implicated in 20-100% of all PCG cases worldwide. In the present Southern Indian cohort, *CYP1B1* accounted for 40.47% cases exhibiting 27.47% homozygous and 13.00% heterozygous mutations. Thus, a large majority of PCG cases were either partially or completely unlinked to *CYP1B1* suggesting the involvement of other candidate genes in the disease pathogenesis. The present study was designed to identify the other novel genes by whole exome sequencing (WES) in cases devoid of mutations in the known candidate genes (*CYP1B1, LTBP2, MYOC* and *FOXC1*).**Methods**Ten trios consisting of affected children born out of consanguineous marriages and their unaffected parents underwent WES on an Ion Proton platform (Life Tech, CA). The preparation of DNA libraries, enrichment and sequencing (mean depth of 100x) was done as per the manufacturer's guidelines along with the standard quality control measures and the filtered reads were aligned to hg19 reference genome. An algorithm was designed to delineate the homozygous variants followed by filtering the dbSNP and 1000 genomes variants. Non-synonymous deleterious variants assessed by SIFT, PolyPhen and Grantham were finally analyzed for disease segregation in the trios.**Results**WES data revealed 50,000-90,000 variants in each trio of which on1y 1500-6000 variants were homozygous in the probands. Subsequent analysis indicated 396 novel variants that were not available in the public database and only 28 variants in 27 genes were found pathogenic. These variants were not reported in the HapMap database. Further prioritization of these genes was based on their interactions (STRING software) and published literature.**Conclusions**Among the novel candidate genes, four harbored the known glaucomatous loci *(GLC1I, GLC1L*, *GLC1N* and *14q21-q22*). Five developmental genes included two transcription factors, one of which was earlier implicated in anterior segment anomalies in animal model and the other was involved in the development of the neural crest by interacting with *PAX6*. One gene variant was common across two trios, which is known to induce autophagy in RGCs following IOP elevation leading to neuro-degeneration. Further functional validation of these genes understanding their precise role in PCG is in progress.

Understanding genetics of glucose and insulin dynamics in Mexican American individuals from Starr County, Texas. *M. Karhade[1], G. Jun[1], L.E. Petty[1], G. Bell[2], J.E. Below[1], C.L. Hanis[1].* 1) Human Genetics Center, The University of Texas Health Sciences Center, Houston, TX; 2) Department of Human Genetics and Department of Medicine, The University of Chicago , IL.

Oral glucose tolerance test (OGTT) is a procedure for diagnosis of impaired glucose tolerance (IGT) and type 2 diabetes (T2D). Genetic association studies typically assess fasting and 2-hour post-load glucose and insulin levels from OGTT, often ignoring in-between time points. To understand genetic components affecting glucose and insulin responses, we analyzed glucose, insulin, and C-peptide levels measured at 7 time points (0, 10, 20, 30, 60, 90 and 120 minutes) after oral glucose intake on 331 previously undiagnosed Mexican-American individuals from Starr County, Texas. For genetic analysis, we collected both whole exome sequencing data (Agilent Truseq capture reagents on Illumina HiSeq2000) and GWAS array data (Genome-Wide Human SNP Array 6.0 Affymetrix) for all 331 samples. In our preliminary analysis, we analyzed glucose, insulin, and C-peptide levels at baseline, and then extended our analysis to the differences in measurement levels between adjacent time points. In exome-wide single-variant association tests (MAC>5), no SNP reached genome-wide significance level of 5x10-8. Interestingly, top signals for glucose at rs17053612 (*DOCK5p*-value 4.6x10-7) and insulin at rs8178822 (*APOHp*-value 1.89x10-6) traits were both for changes between 10 and 20 minutes, which corresponds the to the effects of the first phase of insulin release.*APOH*&*DOCK5*have been previously implicated in T2D and in severe obesity respectively. The top signal rs112475035 (*ANKRD13Cp*-value 2.28x10-7) for C-peptide was for the change between 90-120 minutes. To assess contributions of rare variants, we performed gene-based tests using SKAT-O for variants with MAF<0.05. Given a gene-wise significance threshold of 2.5x10-6, one gene, *SPTBN5*was significantly associated with insulin changes between 0 and 10 minutes with*p*-value of 2.24x10-6.*SPTBN5*has been previously implicated in ischemic stroke. Glucose at baseline was found to be associated with the gene*OBSCN*with*p*-value 5.52x10-6. These intermediate time points provide novel insight into the biology of glucose tolerance.

Whole-exome sequencing identifies novel candidate genes for early-onset Alzheimer disease. *B.W. Kunkle[1], B. Vardarajan[2], P.L. Whitehead[1], S. Rolati[1], E.R. Martin[1], J.R. Gilbert[1], R.P. Mayeux[1], J.L. Haines[3], M.A. Pericak-Vance[1], G.W. Beecham[1].* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Taub Institute of Research on Alzheimer's Disease, Columbia University, New York, NY, USA; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH, USA.

BACKGROUND. Mutations in*APP*,*PSEN1*and*PSEN2*lead to early-onset Alzheimer disease (EOAD). These mutations account for ~11% of EOAD overall, leaving the majority of genetic risk for the most severe form of Alzheimer disease unexplained. METHODS. To search for rare variants contributing to risk for EOAD we performed Whole-Exome Sequencing (WES) in 50 Caucasian EOAD cases screened negative for*APP*,*PSEN1*, and*PSEN2*. Variant filtering for functional, damaging rare variants (MAF<0.1%) was performed. Damage prediction was performed using a Combined Annotation Dependent Depletion (CADD) score. Rare, damaging variants shared by multiple cases (+2) were then selected for follow-up protein-protein interaction analysis with known EOAD genes (*APP, PSEN1, PSEN2, GRN*,*MAPT*) using the program STRINGdb. Additionally, we performed a separate text-mining screen of this set of variants using Phenolyzer and the terms 'Alzheimer disease', 'dementia', and 'neurodegeneration'. RESULTS. We identified 51 rare, damaging variants in 46 genes in two or more EOAD cases. Gene network analysis of these 46 genes with known EOAD genes identified three candidate genes: HSPG2 (interacts with GRN and APP), CLSTN1 (interacts with PSEN1 and APP), and DOCK3 (interacts with PSEN1 and PSEN2). Five cases have a variant in HSPG2, a gene in a LOAD susceptibility region and potentially involved in amyloidogenesis and tau aggregation in AD. Four cases have a variant in DOCK3, a gene shown to regulate amyloid-İ secretion, and associated with neurofibrillary tangles in AD brains. Several other cases have shared variants in CLSTN1. Disruption of calsyntenin-1-associated axonal transport of APP by mutations in CLSTN1, a known APP interactor, have been identified as a potential pathogenic mechanism of Alzheimer's. Moreover, CLSTN1's potential as a regulator of synapse formation and neuronal development suggests other mechanisms through which it could be involved in development of dementia. Top scoring genes for the Phenolyzer analysis included the genes HSPG2, STAT1, a BACE1 interactor, and CNTNAP2, whose expression is down-regulated in AD patients. CONCLUSIONS. WES of EOAD cases identified several genes with potential roles in AD pathogenesis.

733F

Exome sequencing for identification of potential causal variants for diffuse cutaneous systemic sclerosis. *A.C.Y. Mak[1], L.F. Tang[2], C. Cleveland[3,5], M.K. Connolly[4], T. Katsumoto[3,5], P. Wolters[5], P.Y. Kwok[1,2,4], L.A. Criswell[3].* 1) Cardiovascular Research Institute, University of California, San Francisco, San Francisco, CA; 2) Institute for Human Genetics, University of California, San Francisco, San Francisco, CA; 3) Rosalind Russell Medical Research Center for Arthritis, University of California, San Francisco, San Francisco, CA; 4) Department of Dermatology, University of California, San Francisco, San Francisco, CA; 5) Department of Medicine, University of California, San Francisco, San Francisco, CA.

Scleroderma is a genetically complex autoimmune disease with substantial phenotypic heterogeneity. Previous genome-wide association studies (GWAS) have identified a large number of gene regions associated with disease risk. However, GWAS directly capture only common genetic variants that are presumably in linkage disequilibrium with causal variants, some of which may be rare variants more frequently found in the disease population. Our goal was to identify potentially causal variants by comparing whole exome sequencing data between cases and controls. We focused on patients with severe disease, and specifically those with diffuse cutaneous systemic sclerosis (dcSSc), to limit disease heterogeneity.We produced whole exome sequencing data from 32 dcSSc patients on the Illumina HiSeq2500 platform with the Nimblegen SeqCap EZ v3.0 exome enrichment protocol. Paired-end 2 X 100 bp sequencing reads were generated with a mean coverage of 51X on the 64Mb of targeted exome regions. Control data came from 17 healthy control subjects whose data were produced using comparable methods, and from the 1000 Genomes and the NHLBI-ESP6500 Projects. Exome sequencing reads were processed according to the GATK Best Practices for DNAseq variant analysis. Variants were annotated and filtered with ANNOVAR and Variant Tools. We applied a gene mutation burden test to identify genes that were enriched with deleterious variants in dcSSc patients compared to controls.We identified 96 genes that were enriched with deleterious variants in the dcSSc patients. Among the 96 genes, 10 genes (*NOTCH4, BANK1, BLK, GRB10, IRF8, KCNA5, NMNAT2 and TNFSF4*) are in previously identified scleroderma susceptibility loci or pathways implicated in scleroderma pathogenesis. In addition, we identified novel genes and 3 new pathways associated with scleroderma, including pathways related to ABC-family proteins mediated transport, extracellular matrix organization and the CD320-dependent methylmalonic aciduria.Using exome sequencing and gene mutation burden analysis, we identified 96 genes that contain functionally deleterious variants that may contribute to the development of dcSSc. This study demonstrates the potential value of whole exome sequencing for the identification of causal variants that contribute to scleroderma risk and/or severity. The candidate genes we discovered are potential targets for in-depth functional study or therapeutics development.

734W

Whole exome sequencing of probands from 158 idiopathic pulmonary fibrosis families identifies a telomere related gene network carrying potentially damaging mutations. *R. Mitra[1], Q. Wang[1], J.D. Cogan[2], J.A. Kropski[3], D.B. Mitchell[3], H. Yu[1], J.E. Loyd[3], Z. Zhao[1], J.A. Phillips III[2,4], T.S. Blackwell[3,5,6,7].* 1) Department of Biomedical Informatics; 2) Division of Medical Genetics and Genomic Medicine, Department of Pediatrics; 3) Division of Allergy, Pulmonary and Critical Care Medicine, Department of Medicine; 4) Department of Pathology, Microbiology and Immunology; 5) Department of Cancer Biology; 6) Department of Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN; 7) Department of Veterans Affairs Medical Center, Nashville, TN.

Idiopathic pulmonary fibrosis (IPF) is a progressive and often fatal lung disease of unknown etiology. So far, familial forms of IPF have been linked to genes involved in regulation of telomere length (e.g. *TERT*, *TERC*, and *RTEL1*) and those encoding surfactant proteins. Interestingly, even in the absence of telomerase mutations, short telomeres are frequently found in IPF patients and many of them lack a family history. To investigate the mechanisms of developing IPF, we examined exome-sequencing data from 158 unrelated familial IPF subjects. Exomes from 4300 European subjects from the NHLBI GO Exome Sequencing Project (ESP) database were used as a control population. To identify the sequence variants contributing to IPF risk, we analyzed rare (MAF < 0.01 in ESP) or intermediate (MAF < 0.05 in ESP) frequency variants that had a significantly higher minor allele frequency (MAF) in IPF compared to control data ($P < 0.05$, Fisher's exact test). Based on these criteria, we identified 200 potentially damaging variants that mapped to 214 genes. We selected 9 of these predicted damaging variants for Sanger resequencing, which successfully validated each variant. Enrichment analysis of these 214 genes using Pathway Commons prioritized 'mTOR signaling pathway' as the top-ranked pathway mutated in IPF. The relevance of this pathway in IPF development has been explained by previous studies. Assuming that mutated proteins may alter the function of their interactors, we constructed an IPF-specific network, which started with the mutated gene *ATM* linking to mTOR signaling pathway and then added curated protein interacting pairs. A subset of the ATM interactors was found to be linked to 'Telomere maintenance', 'Regulation of Telomerase', and 'mTOR signaling pathway', which formed a network we termed as backbone network. We further extended the backbone network based on the literature evidence such as known DNA binding protein interactions and obtained a network of 34 genes. Intriguingly, in this systematically derived network, 14/34 (41%) genes carried damaging variants and were observed in 59% of the affected IPF subjects, indicating that genetic variation related to telomere biology may underlie a large proportion of IPF risk. Overall, our network approach is promising to detect rare or intermediate damaging variants from exome-sequencing data with their potential roles in IPF.

735T

Whole exome sequencing analysis of HIV-1 African American elite controllers. *M. Montasser[1], J. O'Connell[1], M. Sajadi[2,3,4], A. Parsa[1].* 1) Department of Medicine, Program for Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD, USA; 2) Institute of Human Virology, University of Maryland School of Medicine, Baltimore, Maryland, USA; 3) Department of Medicine, University of Maryland School of Medicine, Baltimore, Maryland, USA; 4) Medical Care Clinical Center, VA Maryland Health Care Center, Baltimore, Maryland, USA.

HIV-1 continues to plague the world with 35 million infected individuals, 25 million of them in sub-Saharan Africa. While highly active antiretroviral therapy is very effective in limiting HIV-1 progression, it is limited by drug resistance/toxicity, the high cost of lifetime treatment, and it's ineffectiveness in eliminating the latent HIV-1 reservoir. Currently, there is a consensus that host genetics, rather than viral factors, plays a major role in determining the response to HIV-1 infection. Among populations of African ancestry, the MHC region explains ~ 25% of the variability in response to HIV-1 infection, while the remaining variability is still unknown. HIV-1 elite controllers (EC) represent the 1% of the HIV-1 infected population that have the ability to naturally suppress their viral infection for many years without treatment, and therefor may be instrumental in identifying protective genetic factors. We performed exome sequencing in 22 EC and 2 pools of 20 HIV-1 progressors. After QC, filtering, statistical testing, and biological prioritization, we identified 15 SNPs located in 13 genes with interesting biological links to HIV or the immune system. These SNPs have a MAF of 2% or less in the 1000 genomes African population, but are increased to 10-15% in our EC. Five SNPs were missense, 4 silent, 5 intronic, and one non-genic. The genes are: *CPSF3, PRG4, PSMD1, SETDB2, TAF4B, TPR, MPDZ, C1orf150, KIR-REL2, IGSF10, PIAS1, POLR3A,* and *DEFB110*. In an attempt to replicate these findings, we performed TaqMan genotyping for 11 SNPs in 42 EC (including the original samples to confirm the exome data), and 42 HIV-1 progressors. While we were able to confirm the exome data in the same samples with TaqMan, we identified the minor allele in no more than 1-2 additional replication samples. These findings did not refute nor convincingly confirm our initial findings, but rather showed that identifying the genetic basis of response to HIV infection is very challenging. The difficulty in identifying coding variants contributing to EC may indicate that there are many very rare coding causal variants, thus, requiring very large sample sizes to sufficiently power discovery. It may also indicate that the causal variants are non-coding regulatory variants and cannot be detected by exome sequencing. Multiomic studies that can layer data from transcriptomic, epigenomic, metabolomic, and genomic data may be warranted to elucidate the genetic components of EC status.

736F

Identification of novel candidate genes for tuberculosis susceptibility by identifying disease-causing mutations in individuals with PIDs. *M. Müller[1], N. Schlechter[1], E.G. Hoal[1], M. Schoeman[1], M. Urban[1], M. Esser[2], B.S. Petersen[3], A. Franke[3], C.J. Kinnear[1].* 1) SA MRC Centre for TB Research, DST/NRF Centre of Excellence for Biomedical Tuberculosis Research, Division of Molecular Biology and Human Genetic, Faculty of Medicine and Health Science, Stellenbosch University, Cape Town, Western Cape, South Africa; 2) Department of Pathology, Stellenbosch University, Cape Town, South Africa; 3) Institute for Clinical Molecular Biology, Christian-Albrechts University Kiel, Kiel, Germany.

Despite the fact that approximately 33% of the world's population is infected with *M. tuberculosis,* the causative agent of tuberculosis (TB), only 10% of infected individuals will develop active disease. While the genotype of invading strain and environmental factors have been shown to be crucial in disease outcome, host genetic factors are just as important. Several investigations have been undertaken to identify genes involved in TB susceptibility and many TB susceptibility genes have been reported. Nevertheless, it is certain that more susceptibility genes exist, but identifying these genes in a complex disease such as TB is challenging. We believe that the answers may lie in the genomes of individuals suffering from a group of inherited primary immunodeficiency disorders (PIDs) for which multiple infections with *M. tuberculosis* is a common feature. We hypothesise that the genes that cause these PIDs could be plausible candidate genes for increased TB susceptibility in the general population. We therefore aimed to identify novel TB susceptibility genes by finding gene mutations in patients suffering from PIDs characterised by increased TB susceptibility.Six PID patients between the ages of eight and 17 years were recruited for this study. Once written informed consent was obtained, their exomes were sequenced using the Illumina HiSeq. Bioinformatics techniques were used to identify variations from the reference human genome for each of the patients.Bioinformatics analysis of the sequence data identified a large amount of potential candidate genes in these patients. We subsequently prioritised the genes based on OMIM and HGMD database entries which resulted in 11 genes. At least one variant in the TAP1 gene has already been identified for which functional studies will be done in order to investigate its involvement in the disease. .

737W

Exome sequencing reveals *GNE*, *DYSF* and *CAPN3* as the major contributors of muscular dystrophy with potential roles of other genes in mediating disease progression. *B. Nallamilli[1], K. Gandhi[1], S. khadilkar[2], A. Bhutada[2], M. Hegde[1].* 1) Human Genetics, Emory University, Atlanta, GA; 2) Bombay Hospital institute of Medical Sciences Mumbai, India.

Muscular dystrophies (MDs) constitute a group of genetically and clinically heterogeneous diseases of progressive muscle weakness. Without prior protein analysis on muscle biopsies, and most frequently even after initial protein analysis, determining the disease subtype and the causative gene is difficult. To date, over 54 genes have been shown to be associated with MDs. A majority of these genes are expressed at the sarcolemma to form an integrative network serving to provide structural support to individual muscle cell. The clinical and genetic heterogeneities of MDs make disease diagnosis complicated and expensive. However, current next generation sequencing based approaches have tremendously improved our molecular diagnostic capabilities, allowing timely management and participation of affected individuals in clinical trials that have become increasingly available. Comprehensive exome sequencing analysis facilitates identification of disease subtype and causative genes in one single test. In this project, we performed exome sequencing (ES) on 100 clinically well characterized MD patients to identify the causative gene and disease subtype. Among these, molecular diagnosis could be established in 70 patients with the majority having mutations in either of three genes, *GNE*, *DYSF* and *CAPN3*, suggesting that these are the major contributors to MDs. More interestingly, in at least 50 individuals, mutations were detected in more than one MD genes. For example, one patient clinically diagnosed with LGMD2B but with an unexpected severe progression had mutations in both *DYSF* and *MYH2* genes. Heterozygous loss of MYH2 coupled with complete loss of DYSF could be contributing to the rapid disease progression and severe phenotype observed in this individual. Similar multigenic combinations of mutations were detected in *DYSF, CAPN3, SYNE2, GNE* and *LAMA2* in other individuals suggesting a possible role of synergestic heterozygosity and digenic contribution to disease presentation and progression. Using ES we have recently identified new disease causative genes including *DDOST*, *NGLY1* and *PIGL* and are currently investigating several new candidate genes, with functional studies. Application of ES to MD diagnosis has improved our understanding of the clinical spectrum of different MDs. Overall this project allowed us to understand the phenotypic overlap between different MDs.

738T

Exome sequencing analysis in a Primary Open Angle Glaucoma Brazilian Family. *P. V. Svidnicki[1], J. P. C. Vasconcellos[2], H. D. T. Caldeira[3], M. B. Oliveira[1], H. F. Nunes[1], B. S. Carvalho[4], M. G. Borges[4], P. A. O. R. Aguiar Araújo[4], I. T. L. Cendes[4], M. B. Melo[1].* 1) Center of Molecular Biology and Genetic Engineering, UNICAMP, Campinas, SP, Brazil; 2) Department of Ophthalmology, Faculty of Medical Sciences, UNICAMP, Campinas, SP, Brazil; 3) Centro Oftalmológico de Janaúba, Janaúba, MG, Brazil; 4) Department of Medical Genetics, Faculty of Medical Sciences, UNICAMP, Campinas, SP, Brazil.

Background: Glaucoma is the leading cause of irreversible blindness worldwide, characterized by loss of retinal ganglion cells leading to visual field deficits. Multiple loci have been associated with primary open angle glaucoma (POAG), the most common type of the disease. However, the etiology and pathogenesis of this trait are poorly understood. **Methods**: We have studied a Brazilian POAG family (four members, the father and three siblings) with no mutation in the MYOC gene, through whole exome sequencing (WES) using Illumina Nextera Rapid Capture Expanded Exome kit. Sequencing data were generated on Illumina HiSeq2500 at mean coverage depth of 70X. Reads were aligned to the human reference genome (GRCh38) using Burrows-Wheeler Aligner. Variants were called using GATK and annotations were performed using VEP. Filtering strategies were: variants segregating only in the affected individuals (father and one of the siblings), excluding common and synonymous variants. After filtering, 363 variants remained. Subsequently, variant prediction by SIFT and Polyphen-2, gene expression in ocular tissue databases, and finally text mining in NCBI and Pubmed were evaluated. Mutation segregation in candidate genes according to the phenotype was further investigated by Sanger sequencing in 13 other family members (7 affected and 6 non-affected individuals). **Results**: Affected members tested negative for the most common known genes in glaucoma, for instance, OPTN, NTF4, TBK1, WDR36, CAV1/CAV2, CDKN2B, TMCO1, SIX1/SIX6. According to our filtering criteria, we selected five variants in the following genes: ANKS6, CPAMD8, LTBP2, NUMA1 and UTRN. However, none of these variants segregated with the disease. Five other variants in 5 genes have been chosen and are being evaluated according to their segregation in family members. **Conclusion**: We selected possible new candidate genes for POAG, since patients do not carry any mutation in the known causative genes for glaucoma. Further resequencing and experimental verification are still needed to confirm the causative gene in this family. Supported by Fundação de Amparo á Pesquisa do Estado de São Paulo - FAPESP. Process: 2013/17958-2.

739F

Exome sequencing in families affected with age-related macular degeneration identifies rare variants in Complement Factor H associated with extramacular drusen and lower serum factor H levels. *E. Wagner[1,2], M. Triebwasser[3], E. Schramm[3], M. Daly[4,5], S. Raychaudhuri[4,5], J. Atkinson[3], J. Seddon[1,2].* 1) Ophthalmic Epidemiology and Genetics Service, Tufts Medical Center, Boston, MA; 2) Department of Ophthalmology, Tufts University School of Medicine, Sackler School of Graduate Medical Sciences, Tufts University, Boston, MA; 3) Washington University School of Medicine, Department of Internal Medicine, Division of Rheumatology, St. Louis, MO; 4) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 5) Partners HealthCare Center for Personalized Genetic Medicine, Division of Genetics, Brigham and Women's Hospital, Boston, MA.

Age-related macular degeneration (AMD) is the leading cause of blindness in people over the age of 65. It is a common disease with multifactorial etiology including environmental, behavioral, and genetic components. In this study, we investigated the genetic factors contributing to AMD risk in families that are densely affected with advanced AMD, have an earlier age at diagnosis (less than 75 years of age) and have a low genetic risk score as calculated using the known genetic factors. We performed exome sequencing on members of families who met the above criteria and applied a series of filtering parameters to screen for rare, damaging variants in genes known to be associated with AMD from genome-wide association study results and which segregate with AMD in the families. Our results showed that in two independent families, a novel, loss-of-function variant in the AMD gene, complement factor H, segregated with the disease. Both variants are predicted to be deleterious by prediction programs; one confers an amino acid change while the other abolishes a splice site, and both mutations occur in a highly conserved region of the gene that interacts with C3b, an important component of the innate immune system. Neither rare variant was found in public genomic databases, nor were they found in any of the other subjects in our AMD registry database. To assess the functional impact of these variants, factor H protein (FH) serum levels were quantified using radial immunodiffusion with anti-human antibodies specific for FH. Family members carrying the rare variants had decreased serum FH levels compared to those without the variants. Additionally, a detailed assessment of the retinal phenotypes revealed presence of extramacular drusen among family members carrying the rare variants but not among those without the variants. These results contribute to the catalog of rare, highly penetrant variants in known AMD genes and aid in expanding our understanding of the genetic architecture of this disease.

740W

Exome sequencing of a family–based cohort with polycystic ovary syndrome highlights variants in known and novel genes. *S. G. Wilson[1,2,3], V. Oo[1, 4], S. Liew[1,4], P. J. Campbell[1], B. H. Mullin[2], A. L. Weeks[2], S. J. Brown[1], R. J. Mead[4], E. M. Lim[1,5,6], B. G. A. Stuckey[1,2].* 1) Endocrinology & Diabetes, Sir Charles Gairdner Hospital, Nedlands, WA, Australia; 2) School of Medicine and Pharmacology, University of Western Australia, Nedlands, WA, Australia; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 4) School of Biological Sciences, Murdoch University, Murdoch, WA, Australia; 5) PathWest Laboratory Medicine WA, Nedlands, WA, Australia; 6) School of Pathology and Laboratory Medicine, University of Western Australia, Nedlands, WA, Australia.

Polycystic ovary syndrome (PCOS) is a heterogeneous hormonal disorder with a prevalence of 5-8% among women of reproductive age. The syndrome is characterised by elevated blood androgens, hirsutism, amenorrhoea and polycystic ovaries. This condition is also the leading cause of subfertility in women and increases the risk of metabolic complications. PCOS has a genetic basis and 11 loci have been identified to date from GWAS. Defining the underlying genetic mechanisms and functional variants for PCOS will be a key step in developing better understanding of the disease process and development of effective therapies. We recruited first degree relative pairs with physician diagnosed PCOS from a clinical-practice database, for an exome sequencing study. We prepared genomic DNA from the blood of 16 suitable study subjects and performed human exome capture and sequencing using Agilent SureSelect XT Human All Exon +UTR v5 (71Mb), 100 bp paired end sequencing (~5 Gb per sample), targeted 50x mapped coverage with SNV and Indel detection, on the Illumina HiSeq 2500 platform. Exome sequencing yielded an average 73. 4 Mb of DNA sequence per sample with median coverage achieved of 56. 2x across all targets (i. e. 21,522 genes across the genome). Analysis of sequence data of individuals in the study for functional changes in genes previously reported to be associated with PCOS phenotypes yielded results in the following genes: *THADA, INSR, LHCGR, DENND1A, HMGA2, SUOX.* Analysis of the data for variants in affected family members, to determine if private mutations observed were segregating with the disease and therefore presenting stronger evidence of a susceptibility locus for PCOS, identified 31 mutations of potential relevance across the families studied. Among the variants detected across the genome, missense variants in the following genes may be of particular interest: *WDFY3, MAP4K4*. GWAS for PCOS have identified genes of potential relevance, however the variants highlighted are often common SNPs and unlikely to be the causal variants. The results from this study demonstrate the ability of exome sequencing to detect potentially pathogenic variants in known genes and highlight novel genes with a possible role in PCOS, providing targets for additional study and functional characterisation. If functional relevance can be established, the findings may be of potential clinical value in molecular screening and in the creation of genetic risk scores for patients.

741T

Analysis of exome array markers with quantitative lung function measurements in the COPDGene study. *M. M. Parker[1], B. D. Hobbs[2,3], I. Ruczinski[4], R. A. Mathias[5], J. Crapo[6], E. K. Silverman[2,3], T. H. Beaty[1], M. H. Cho[2,3], COPD. Gene Investigators[1,2,3,4,5,6].* 1) Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 4) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore MD, USA 21202; 5) Johns Hopkins Asthma and Allergy Center, The Johns Hopkins University, Baltimore, MD; 6) National Jewish Health, Denver, CO.

Background: Spriometric measures including the forced expiratory volume in one second (FEV1) and the forced vital capacity (FVC) reflect the severity of airway obstruction, and predict population morbidity and mortality. These measures are heritable and substantial advances have been made in our understanding of genetic risk factors underlying lung function using GWAS and large-scale meta analyses. However, these associated genetic risk factors account for only a small fraction of the estimated heritability of lung function. **Methods**:To determine if rare coding variants play a role in lung function, we genotyped 9,858 Non-Hispanic White (NHW) and African American (AA) participants from the COPDGene study with Illumina's HumanExome Beadchip. We performed: 1) single nucleotide variant (SNV) analysis for polymorphic markers, and 2) gene-based analysis of rare variants collapsed within a gene using SKAT. SNV tests included only functional variants with a minor allele frequency (MAF) >0. 5%. Gene based tests included only functional, rare (MAF<5%) variants. All analyses were adjusted for age, gender, pack-years of smoking and principal components to control for population stratification. Statistical significance was determined by Bonferroni correction for the number of tests performed. **Results**:**Single variant tests:**We identified four significant associations between SNVs and spirometry, all of which were nonsynonymous mutations. Three of these four associations had been previously identified in GWAS as risk loci for lung function: rs16969968 in *CHRNA5* (MAF=36. 6%) and rs2070600 in *AGER* (MAF=4. 2%). We identified one novel association between a nonsynonomous SNV and FEV1 percent predicted in AA subjects (rs34664882, p=2. 42 x10-7, MAF=1. 7%). The associated SNV is in the gene encoding the ankyrin 1 (*ANK1*) protein and the minor allele (A) is associated with significantly lower FEV1 percent predicted (b = -11. 59). **Gene based tests:**We identified three significant gene associations with FEV1/FVC or FEV1 percent predicted using SKAT. Associated genes include: *AGER* on chromosome 6 (associated with FEV1/FVC in the NHW group, p=2. 01x10-9); *ProSAPiP1* on chromosome 20 (associated with FEV1 percent predicted in NHWs, p = 2. 63x10-6); and *ANK1* on chromosome 8 (associated with FEV1 percent predicted in AAs, p = 5. 27x10-6). Association signals in these genes were largely driven by a single rare, nonsynonomous variant with a large effect.

742F

Exome chip meta-analysis identifies novel low-frequency variants contributing to central body fat distribution. *K. L. Young[1,2], A. E. Justice[1], T. Karaderi[3], H. M. Highland[1], M. Graff[1], V. Central adiposity is a leading risk factor for metabolic and cardiovascular disease, and evidence suggests genetic factors contribute to fat distribution, measured as waist-to-hip ratio adjusted for BMI (WHRa), and to differences in central adiposity prevalence. To date, 49 loci have been associated with WHRa, based on studies of common [minor allele frequency (MAF) ≥5%] single nucleotide variants (SNVs) mostly in populations of European descent. Our aim was to identify low frequency (LFV: MAF <5%) and rare (RV: MAF <1%) coding variants associated with WHRa using Exome-Chip data from 299,666 individuals of European, African, Asian, and Hispanic/Latino ancestry. We performed fixed effects meta-analyses of study-specific WHRa associations stratified by sex and ancestry and then combined across strata for both SNV and gene-based results. We used a strict definition of non-synonymous and missense variants annotated as damaging by 5 algorithms to perform gene-based analyses using the sequence kernel association test (SKAT). Analyses included up to 236,047 SNVs (218,195 with MAF<5%), and 9,175 genes with at least one SNV that met our inclusion criteria. Five LFVs reached chip-wide significance (P<2. 5E-7) in our all ancestry sex-combined analyses, including one novel non-synonymous RV in *RAPGEF3* [MAF<0. 01, b (SE) = -0. 088 (0. 013), P=2. 1E-11]. Gene-based analyses identified *RAPGEF3* (P=1. 42E-11) and *ACVR1C* (P=1. 29E-7) as significantly associated with WHRa after correction for multiple tests (P<2. 5E-6). *RAPGEF3* also shows a significant association (b (SE) = 0. 05 (0. 01), p=4. 68E-12) in all ancestry, sex combined gene-based analysis of BMI. Both *RAPGEF3* and *ACVR1C* are expressed in subcutaneous and visceral adipose tissue, and have been implicated in insulin regulation. *RAPGEF3* plays a role in the GLP1 pathway, which controls insulin secretion in response to blood glucose concentration. In animal models, mice lacking the protein ALK7, coded by *ACVR1C,* show evidence of diminished production of adipokines in white fat cells and reduced energy expenditure by brown fat, both of which can negatively impact glucose homeostasis and insulin sensitivity. Our results highlight the importance of large-scale genomic studies for identifying LFV and RV influencing central fat distribution. Understanding these genetic effects may provide insights into the progression of central adiposity and highlight potential population-specific variants that increase susceptibility.

Caporaso[1], NCI DCEG Cancer Sequencing Working Group.* 1) Genetic Epidemiology Branch, DCEG, NCI, NIH, Bethesda, MD; 2) Hematology Branch, NHLBI, NIH, Bethesda, MD; 3) Cancer Genomics Research Lab, DCEG, NCI, NIH, Bethesda, MD; 4) Simulation, Analysis, and Mathematical Modeling Group, FNLCR, Leidos Biomedical Research, Inc, Frederick, MD; 5) Westat, Inc. , Rockville, MD; 6) Human Genetics Program, DCEG, NCI, NIH, Bethesda, MD; 7) Division of Cancer Epidemiology and Genetics, NCI, NIH, Bethesda, MD.

Chronic lymphocytic leukemia (CLL) shows strong familial aggregation and co-aggregates with other lymphoid malignancies. A number of genes with small to moderate effects have been identified by GWAS but no high-risk genes have been identified. We conducted whole exome sequencing in 69 patients/obligate carriers in 19 CLL families (discovery set), each with 3-5 patients or obligate carriers using a Nimblegen v. 3 exome capture library and paired end sequencing on the Illumina HiSeq2000. Alignment, variant discovery and calling of substitutions, insertions and deletions were performed using standard methods. Variants were analyzed, annotated and prioritized using ANNOVAR, Ingenuity Variant Analysis, and custom R scripts. Dominantly segregating, rare (≤ 1% frequency in European populations), coding or potentially functional variants were further prioritized based on predicted deleteriousness, conservation, and potential importance in lymphoid malignancy pathways. Possible technical sequencing artifacts were eliminated by filtering out variants found in >1% of samples from other non-hematologic cancer studies identically processed in our laboratory. Ten highest priority genes were selected for further targeted follow-up studies using a custom set of AmpliSeq primers on the Ion Torrent platform. For replication, we sequenced 28 additional families with 2 CLL patients plus 12 single patients from multiplex families. A missense mutation in the *ITGB2* gene was detected in one CLL family in the discovery set and was replicated in 3 additional smaller families plus 2 single patients from families with only one patient tested. The mutation has a frequency of 0. 007 in Europeans, is predicted to be damaging using computational tools, and is in a highly conserved region. A few other promising mutations were identified but appear to be “private”. The *ITGB2* gene codes for a B-cell surface marker, CD18, involved in leukocyte adhesion. Other studies in sporadic CLL patients have shown the expression of CD18 is reduced on CLL lymphocytes compared to normal cells and is also associated with disease progression. By flow cytometry, we found that the expression of CD18 in B-cells from patients with the mutation was significantly lower than in patients who did not carry the mutation ($p<0.02$). While the full functional consequences of this mutation are not yet known, our results suggest that it may account for susceptibility to CLL in 10% of high risk families.

744T

Assessment of rare loss of function variants in previously healthy children with pediatric sepsis. *A. Bittencourt Piccini[1], P. J. McLaren[1], I. Bartha[1], C. Berguer[2], J. Fellay[1], L. Schlapbach[3,4,5], Swiss Pediatric Sepsis Study.* 1) School of Life Science, EPFL, Lausanne, VD, Switzerland; 2) University Children’s Hospital Zurich, Zurich, Switzerland; 3) Paediatric Critical Care Research Group, Mater Research, University of Queensland; 4) Paediatric Intensive Care Unit, Lady Cilento Children’s Hospital, Brisbane Australia; 5) Department of Pediatrics, Inselspital, University of Bern Switzerland.

Background: Bacterial sepsis is a leading cause of childhood mortality globally. Sepsis due to community-acquired bacteria in children without clinical risk factors could represent the first manifestation of previously unrecognized primary immunodeficiency (PID). Through exome sequencing, we sought to identify rare human genetic variants that are responsible for an increased susceptibility to sepsis in previously healthy children. Methods: 89 previously healthy children admitted to hospital with sepsis due to community-acquired bacteremia in the absence of known risk factors were enrolled in the study. Inclusion criteria were: 1) age >1 month and <17 years 2) no immunosuppression, chronic disease, or central venal line infections 3) positive blood cultures for *Staphylococcus Aureus*, *Streptococcus Pneumoniae*, or Group A *Streptococcus* 4) systemic inflammatory response syndrome. Exonic regions were selected using the Agilent V5 51Mb enrichment kit and sequenced to high coverage on the Illumina HiSeq2000. Variant annotation was performed using SNPeff v4. 1. Analysis was restricted to rare variants (<1% in the healthy population) annotated as loss of function (LoF), assuming a recessive model of inheritance. Results: We observed 14 homozygous LoF variants (stop-gain, frameshift or splice site) in patients that were either not observed, or observed below 1% frequency in the ExAc reference data set and ~400 in-house controls. These included 3 single nucleotide variants and 11 insertion/deletion polymorphisms affecting 13 genes. Comparing these candidates to a curated list of 256 genes implicated in PIDs showed no overlap. Extending this analysis to include 3,085 genes predicted to be PID candidates through functional connectivity identified 2 genes, *HPR* and *MAP3K1*, where homozygous LoF genotypes were observed in a single individual each. In both genes, homozygous LoF genotypes are rare in the population, with one homozygote observed for *HPR* and none for *MAP3K1* in the ExAc reference data (N~60,000). Conclusions: In this study focusing on highly selected pediatric sepsis cases, no previously described PID was identified. Rare, homozygous LoF genotypes potentially related to PID were identified in two patients. The methodology may prove useful to rule out PIDs of relevance for SIRS survivors and their relatives. Functional testing of the candidates and analysis of enrichment for heterozygous variants and compound homozygotes are ongoing.

745F

Large-Scale Association Study of 4,898 Age-Related Macular Degeneration via Whole-Genome Sequencing. *A. Kwong[1], X. Zhan[1,6], L. G. Fritsche[1], J. Bragg-Gresham[1], K. E. Branham[2], M. Othman[2], L. Gieser[5], R. Ratnapriya[5], D. Stambolian[3], E. Y. Chew[4], A. Swaroop[5], G. R. Abecasis[1].* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI. , United States; 2) Department of Ophthalmology and Visual Sciences, University of Michigan Kellogg Eye Center, Ann Arbor, MI, United States; 3) Department of Ophthalmology and Human Genetics, University of Pennsylvania Medical School, Philadelphia, PA, United States; 4) Division of Epidemiology and Clinical Applications, National Eye Institute/National Institutes of Health, Bethesda, MD, United States; 5) Neurobiology-Neurodegeneration and Repair Laboratory, National Eye Institute/National Institutes of Health, Bethesda, MD, United States; 6) Southwestern Medical Center, University of Texas, Dallas, TX, United States.

Purpose: Age-related macular degeneration (AMD) is one of the major causes of blindness for the elderly. Past studies have examined the role of common variants in the disease, but there has not yet been a systematic study of the role of rare variants in this disease. We obtained whole-genome sequencing samples and plan to perform association studies on a set of variants that includes both SNPs and indels. Methods: We collected genetic samples from over 5,000 volunteers with European ancestry, balanced between cases and controls and matched by age and sex, from the Kellogg Eye Center at the University of Michigan, the Age-Related Eye Disease Study from the National Eye Institute, and the University of Pennsylvania. We used GotCloud to call SNPs and indels, beagle4 to phase the merged callset, and EPACTS to test associations between variants and disease. Results: So far, we have processed whole genomes of 4,898 samples (2,451 cases and 2,447 controls), representing >89 terabytes (8. 9 x 1013 bytes) of sequence data, corresponding to a total genomic coverage of ~30,000x and an average coverage of ~6x per sample. We estimate to have 95. 6% power to detect variants with minor allele frequency > 1%. From our current data, wecan already see an increase of total variants discovered when compared to the 503 European samples of 1000 Genomes Project (phase 3, version 5): for example, in the region around the known AMD risk locus *CFH* on chromosome 1 (195. 7-197. 8 Mb), the 1000 Genomes project contained 31,922 total variants, 151 non-synonymous SNPs, 1,275 deletions, 56 splice sites, and 5 stop gains, while our 4,898 samples contained 100,034 total variants, 646 non-synonymous SNPs, 3,730 deletions, 148 splice sites, and 31 stop gains. In chromosome 1, our current set of 4,898 samples improves our ability to discover variants compared to a previous dataset of 3,278 samples: we discovered a total of 3. 43 million vs. 2. 86 million SNPs, 383k vs. 350k indels, and rediscovered 95. 6% vs. 94. 6% of variants from HapMap3 in the larger vs. smaller datasets, respectively. Conclusion: We provide a more complete look at the genetics of AMD through whole-genome sequencing. With the increased number of rare variants in our dataset, we will be able to discover rare associated variants that could not be discovered with genotyping array technology. Our data will help us better explore the effects of rare coding and non-coding variation, both in previously associated and novel loci.

746W

Targeted deep sequencing of 28 SLE risk loci reveal regulatory haplotypes that potentiate systemic autoimmunity in Caucasians. *P. Raj[1], E. Rai[1], R. Song[1], BE. Wakeland[1], K. Systemic lupus erythematosus (SLE) is an autoimmune disease caused by loss of humoral immune tolerance leading to the production of autoantibodies to a spectrum of self-antigens. Genetic predisposition is key for SLE susceptibility, however little is known about the nature or functional properties of causal genetic variants. We used targeted population sequencing to comprehensively characterize genetic variability at 28 risk loci for SLE in a panel of 1349 Caucasian SLE cases (773) and controls (576). The HLA-D region contains the strongest risk loci identified for SLE, with multiple alleles of both HLA-DR and -DQ showing strong associations. Sequence analysis of the 380 Kb segment spanning the BTNL2-DR-DQB2 region identified 15,261 common (MAF >0. 05) genetic variants. Analyses of these sequence-defined HLA-D variations identified three independent risk-associated signals reaching genome wide significance. Subsequent analyses demonstrated that these disease-associated variations are imbedded in a series of stable haplotypes formed by multiple, ENCODE and eQTL-defined functional variations impacting the transcription of more than 20 genes that encode components of the antigen processing and presentation (APP) pathways of HLA class I and class II genes. Median neighbor joining analyses identified three HLA-D region regulatory haplotypes forming a risk clade strongly associated with SLE, all of which contained eQTL variants that increased the transcription of HLA-DR, DQ, DP, and other elements of the APP pathway in multiple myeloid and lymphoid cell lineages. This risk clade contains all of the classical HLA-D class II alleles previously associated with SLE, indicating that the systemic upregulation of the APP pathway is a consistent feature of all SLE-associated HLA-D alleles. Similar analyses of non-HLA SLE risk loci identified regulatory haplotypes that were often associated with transcriptional changes in multiple genes within specific pathways. Our analyses demonstrate that such regulatory haplotypes have increased disease-associated odds ratios in comparison to the disease odds for maximal GWAS tagging SNPs in these loci. These findings are consistent with the hypothesis that the functional variations that underlie many common disease alleles form regulatory haplotypes that modulate the transcription of multiple cis and trans genes in immune system pathways and that their functional phenotypes are potent and complex.

747T

Polymorphism of gene *PNPLA3* in Brazilian patients infected with HCV with severe steatosis. *P. Moura[1], M. T. B. Wanderley[1], R. F. Carmo[2], V. C. S. Sousa[1], R. E. Lima[1], E. R. F Siqueira[3], S. C. R. Carvalho[3], L. M. M. B. Pereira[3], M. S. M. Cavalcanti[1], B. M. Carvalho[1], L. R. S. Vasconcelos[3,4].* 1) Biological sciences institute -University of Pernambuco, Recife, Brazil; 2) Federal University of São Francisco Valley- UNIVASF, Brazil; 3) Liver and transplant institute of Pernambuco - IFP, Brazil; 4) Aggeu Magalhães Research Center - FIOCRUZ-PE , Brazil.

Background & Aims: Patatin-like phospholipase domain-containing protein 3(PNPLA3)located on the long arm of Chr. 22 code for a triacylglycerollipasethat mediatestriacylglycerol hydrolysis inadipocytes. GWAS showed the *PNPLA3* I148M (rs738409) variation was associated to steatohepatitis. Patients with chronic infection by hepatitis C virus (HCV) frequently present steatohepatitis, which may contributes to liver disease progression. Our study evaluated the influence of *PNPLA3* gene polymorphism in Brazilian HCV infected patients and steatosis outcome. *Methods:* Four hundred twelve patients infected by HCV with negative serological test for HBV and HIV were enrolled in this study; they were stratified by intensity of steatosis in tree groups based on the liver histopathological exam: G1-no steatosis, G2-mild, G3-moderate/intense and G4- mild/moderate/intense. Genotyping for thers738409 *PNPLA3* gene was performed by real-time PCR using TaqMan Genotyping Assay *Results:* Biochemical analysis showed increase of hepatic enzymes (ALT, GGT and ALP) in groups with steatosis; higher blood glucose and Body Mass Index in the group 3 compared with group 1 (p=0. 004 and p=0. 003, respectively). We showed an association of the G allele with steatosis (G4) *vs.* no steatosis (G1) (p=0. 02, OR 1. 75 CI 1. 08-2. 87) as well as when compared G1 *vs.* G3 (p=0. 002, OR 2. 29 CI 1. 31-4. 01). In recessive model there was association of CG and GG genotypes with increase of moderate/intense steatosis (p=0. 034 OR 2. 23 CI 1. 06-4. 72) and (p=0. 018 OR 6. 88 CI 1. 29-48. 6) respectively. Additionally, for exclude potential confounding variables we perform a multivariate analysis and include in the model the statistically significantly variables in the univariate analysis. We found that genotypes CG/GG was significantly associated for moderate/intense steatosis prediction independently of male gender, BMI, glucose levels and HCV genotype 1, p=0. 010 OR 1. 869 (1. 15-3. 01). *Conclusions:* Thus, the *PNPLA* polymorphism rs738409 seems to influences steatosis severity in Brazilian patients infected with HCV and could be a useful marker for steatosis progression in this population.

748F

Whole Exome Sequence Meta-analysis of 13 White Blood Cell, Red Blood Cell, and Platelet Traits. *L. M. Polfus[1], U. M. Schick[2], P. L. Auer[3], A. P. Reiner[4], S. K. Ganesh[5], the CHARGE and NHLBI GO Exome Sequencing Project Hematology Working Groups.* 1) Human Genetics Center, University of Texas at Houston, Houston, TX. USA; 5) Department of Internal Medicine and Department of Human Genetics, University of Michigan, Ann Arbor, MI. USA.

Blood cell counts and erythrocyte indices are clinically important indicators of a variety of disease states. The ability to detect and include novel rare variants in gene-based tests is best accomplished via sequencing in well-phenotyped samples. In order to identify novel genes influencing hematologic traits, we analyzed whole exome sequencing data in 14,770 participants of 6 population-based cohort studies for 13 traits in European descent (EU) and African Americans (AA), analyzed together and separately, in fixed-effects meta-analyses. All traits underwent rank based inverse normal transformation of the trait residuals to account for outliers influence on rare variants. We analyzed variants individually and aggregated functional and loss-of-function (LOF) variants with MAF<5% within genes using SKAT and T5 burden tests. Discovery phase associations identified 5 novel gene-based results and 3 novel single variants meeting exome-wide Bonferroni corrected thresholds (2. 6x10-6 and 1. 6x10-7). All 5 novel gene-based results were associated with red blood cell traits. In race-combined analyses, rare functional variants in *MYOM2* were associated with mean corpuscular hemoglobin concentration (SKAT PEU+AA=2. 2x10-6). In EUs, rare variants in *MRPL43* were associated with hemoglobin (T5 PEU=1. 2x10-6), and those in *PLAGL1* were associated with mean corpuscular hemoglobin (T5 PEU=1. 5x10-6). LOF Variants in *MMACHC* were associated with hemoglobin (SKAT PEU=1. 3x10-6). *MMACHC* regulates vitamin B12 metabolism and known variants cause a Mendelian syndrome including anemia. In AAs, rare functional variants in *ACTN4* were associated with mean corpuscular volume (SKAT PAA=1. 5x10-6). *ACTN4* variants were previously associated with focal segmental glomerulosclerosis of the kidney. Among the single variant tests, we found low-frequency variant rs9656446 (MAF=0. 03, PEU+AA=1. 5x10-7) in *AGBL3* to be associated with basophil count. A common variant in *CPS1* (rs1047891, MAF=0. 33, PEU+AA=5. 7x10-8) was associated with platelet count. We also identified an association of platelet count with a low-frequency (MAF=0. 009) synonymous variant (rs150813342, PEU=4. 7x10-8) in *GFI1B,* a gene known to cause gray platelet syndrome. *In silico* algorithms predict rs150813342 to affect exon 5 splicing. Replication efforts are currently ongoing. In this exome sequencing study, we identified novel low frequency loci, which may be followed in subsequent functional studies to describe attenuated disease states.

749W

Association of several genes and prostate cancer susceptibility using the Exome-Chip genotyping array. *A. Amin Al Olama[1], S. Benlloch[1], P. D. Pharoah[2], J. Brown[3], K. R. Muir[4,5], A. Lophatananon[5], D. Leongamornlert[6], E. Saunders[6], T. Dadaev[6], K. Govindasami[6], Z. Kote-Jarai[6], D. F. Easton[1], R. A. Eeles[6,7], United Kingdom Genetic Prostate Cancer Study Investigators.* 1) Centre for Cancer Genetic Epidemiology, Department of Public Health & Primary Care, University of Cambridge, Cambridge, UK; 2) Centre for Cancer Genetic Epidemiology, Department of Oncology, University of Cambridge, Cambridge, UK; 3) Centre for Genetic Epidemiology, Department of Public Health and Primary Care, University of Cambridge, Cambridge, UK; 4) Institute of Population Health, University of Manchester, Manchester, UK; 5) Warwick Medical School, University of Warwick, Coventry, UK; 6) Institute of Cancer Research, London, UK; 7) Royal Marsden National Health Service (NHS) Foundation Trust, London and Sutton, UK.

Prostate cancer is the most common non-skin male cancer in the western world and one of the leading causes of cancer related death. Genome-wide association studies have identified over 100 common, low penetrance susceptibility variants. So far only a small number of susceptibility rare variants have been identified. To identify rare coding alterations associated with prostate cancer, we genotyped 8,797 samples from four studies (UKGPCS, SEARCH, SIBS, and UKO) in the UK. After quality control exclusions, we analysed 153,155 SNPs in 3,937 cases and 4,423 controls of European ancestry. We performed single SNP analysis using the Wald, score and likelihood ratio tests. Two gene-based analysis were carried out; a cohort allelic sum test (CAST) and the sequence kernel association test (SKAT). For CAST method we took all variants in a given gene and summed up the minor alleles in cases and controls. Then we used a logistic regression to discover if the difference in these sums is greater than would be expected by chance. SKAT aggregates score test statistics of SNPs in a gene and computes gene level *P*-values. All analyses were adjusted for two principal components. We analysed 16,744 genes and carried out analyses twice; once including all 153,155 SNPs and once including SNPs with MAF ≤ 1%. Single SNP analysis identified 25 SNPs at $P < 5x10\text{-}8$, 5 out of 25 SNPs had MAF less than 1%. For gene-based analysis we used a *P*-value threshold of 2. 8x10-6 after Bonferroni correction for the number of gene tested. We identified 16 genes (*NLGN4X, CD24, USP9Y, PCDH11Y, ZNF673, SSX5, PLCB2, MLNR, OPN1LW, OPN1LW, FRMPD2, TAF1, SLC38A8, MAST4, OR6C3, GAMT*) associated with prostate cancer using both burden tests. These results need to be replicated in larger studies as the study size was limited.

750T

Rare variants in the functional domains of *Complement Factor H* are associated with age-related macular degeneration. *E. D. O Roberson[1,2], M. Triebwasser[1], Y. Yu[3], E. C. Schramm[1], E. Wagner[3,4], S. Raychaudhuri[5,6,7,8], J. M. Seddon[3,4], J. P. Atkinson[1].* 1) Washington University School of Medicine, Department of Internal Medicine, Division of Rheumatology, St. Louis, MO, USA; 2) Washington University School of Medicine, Department of Genetics, St. Louis, MO, USA; 3) Ophthalmic Epidemiology and Genetics Service, New England Eye Center, Tufts Medical Center, Boston, MA, USA; 4) Department of Ophthalmology, Tufts University School of Medicine, Sackler School of Graduate Medical Sciences, Tufts University, Boston, MA, USA; 5) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA, USA; 6) Partners HealthCare Center for Personalized Genetic Medicine, Division of Genetics, Brigham and Women's Hospital, Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Boston, MA, USA; 7) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK; 8) Department of Medicine, Karolinska Institutet, Solna, Sweden.

Age-related macular degeneration (AMD) has a substantial genetic risk component, and several common variants, including Y402H in complement Factor H (*CFH*), have been identified. More recently, rare variants have been discovered to play an independent role in AMD risk. In a previous study, we found association between advanced AMD (A-AMD) risk and the presence of rare variants in the complement component 3 (*C3*), complement factor I (*CFI*), and complement component 9 (*C9*) genes. We hypothesized that rare variants in *CFH* would be a logical contributors to AMD risk. In this study we evaluated whether rare variants in *CFH* contribute to AMD risk independent of two known, common risk alleles. All cases had previously been examined to confirm their A-AMD disease status, and controls had been examined to exclude a diagnosis of AMD. We captured coding regions of approximately 700 candidate genes with hybridization based capture, and sequenced the enriched DNA by Illumina HiSeq. We used the Genome Analysis ToolKit Unified Genotyper tool to genotype the resulting sequencing data after alignment with bwa. We tested 1,665 cases and 752 controls for the effects of rare variants in *CFH* using logistic regression, where the common variants were coded as an additive allele dose and presence of a rare variant was coded as a 0/1 indicator variable. Significance of enrichments was calculated by randomly permuting case/control status and determining how often an equal or larger odds-ratio (OR) was observed. We identified 65 missense, nonsense or splice-site alterations with a control minor allele frequency (MAF) of ≤1%. Rare variants with a MAF ≤1% (OR=1. 5, p=4. 0X10-2) or ≤0. 5% (OR=1. 7, p=2. 4x10-2) and singletons (OR=2. 4, p=2. 6x10-2) were all significantly enriched in A-AMD cases compared to controls. Rare variants in the three major functional domains of *CFH* were also enriched in cases (OR=3. 4, p=9. 8x10-4). Additionally, serum factor H levels in 10 cases that carried rare loss-of-function variants that resulted in a nonsense allele, splice-site alteration or loss of a conserved cysteine were less than the 10th percentile of factor H levels in 60 controls. Like factor I, low serum levels of factor H will be a strong predictor of risk of developing A-AMD. Together, these data further implicate failure of complement cofactor activity in the retina as a central component of AMD pathophysiology, and highlight the importance of both rare and common variants in AMD risk.

751F

Stop gain mutation in the *ZNF528* gene co-segregates with familial early onset spinal-osteoporosis. *S. Skarp[1,2,3], M. Löija[1,2,3], L. Ruddock[2], O. Mäkitie[4], M. Männikkö[1,2,3].* 1) Center for Life Course Epidemiology and Systems Medicine, Faculty of Medicine, University of Oulu, Finland; 2) Faculty of Biochemistry and Molecular Medicine, and Biocenter Oulu, University of Oulu, Finland; 3) Oulu Center for Cell - Matrix Research, University of Oulu, Finland; 4) Division of Pediatric Endocrinology and Metabolic Bone Diseases, Central Hospital and Folkhälsan Institute of Genetics, University of Helsinki, Helsinki, Finland.

Osteoporosis (OP) is the most common bone disorder affecting more than 200 million people around the world. It affects most often the elderly and especially postmenopausal women. As the human population ages cases with OP are increasing making OP a growing socioeconomic challenge. OP is characterized by lowered bone mineral density (BMD) and deterioration of the bone's microarchitecture leading to porous and weakened bones. This in turn leads to increased fracture risk. Osteoporotic fractures (OF) are a severe clinical outcome of osteoporosis. Both OF and BMD are heritable traits with BMD has heritability for BMD ranging from 50-80% and for OF 50-70%. The genetic background of OP is still largely unknown. Studying genes associated with rare OP forms improves the understanding of genetic mechanisms and pathogenesis of this complex disorder. We carried out whole exome sequencing in a Finnish family of five with three male patients suffering from early onset OP of the spine with compression fractures. The exomes of healthy family members and an in-house exome set (N=71) were used to identify variants co-segregating with the disease. We focused on rare (MAF < 0. 01) and private variants with harmful *in silico* estimations. We observed 1236 variants shared by the affected individuals. Out of these variants 239 were exonic or splice site variants. Ten of these were chosen for genotyping based on functional annotation in the five family members and three additional healthy relatives. A stop gain mutation in gene coding zinc finger protein 528 (*ZNF528*) co-segregated with the disease. *ZNF528* encodes a zinc finger protein which is a DNA binding transcription factor. It is expressed in various tissues and cells including osteoblasts. The novel stop gain mutation disrupts the 8th C2H2-type zinc finger of fifteen found in the protein and hence is likely to affect the function of ZNF528. The roles of the gene and the mutation are being studied further in functional studies. This gene is a novel candidate for osteoporosis and bone diseases.

The Helmsley Inflammatory Bowel Disease Exome Sequencing Program (HIESP) – Whole Exome Sequencing of 20,000 Samples. *C. R. Stevens[1], M. A. Rivas[1], R. J. Xavier[1,2,3], M. J. Daly[1,2].* 1) Medical and Population Genetics, The Broad Institute, Cambridge, MA; 2) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Gastrointestinal Unit and Center for the Study of Inflammatory Bowel Disease and Center for Computational and Integrative Biology, Massachusetts General Hospital, Harvard Medical School, Boston, MA.

Crohn's disease (CD) and ulcerative colitis (UC) are debilitating, inflammatory diseases of the gastrointestinal tract, collectively known as the inflammatory bowel diseases (IBD). Among complex diseases, genetics has been particularly successful in the identification of genes for IBD. With support from the Helmsley Charitable Trust, we have launched a transformative program of exome sequencing in IBD for which we continue to engage collaborative partners. The overarching aim of the program, outlined here, is to define the full allelic spectrum of protein-altering variation in genes associated to IBD, assess their role in both CD and UC risk, clinical course and response to therapy, and to determine whether loss-of-function variants confer risk or protection in each IBD gene in order to articulate the most opportune therapeutic targets. Recent technical innovations in DNA sequencing and analysis enable exome sequencing to take place at an unprecedented low cost and high accuracy and have facilitated the launch of this program, which aims to evaluate at least 20,000 exomes. The long-term aim of this program is a complete assessment of the role of rare coding variation to IBD risk and protection. In order to achieve these ultimate goals, we are setting up a collaborative infrastructure for exome sequencing studies to provide sequencing and analysis support for many such studies. As with GWAS, achieving the long term objective of the complete articulation of the contribution of rare variation will ultimately require the analysis of tens of thousands of samples and a worldwide collaborative effort. Here we embark on a series of projects that take advantage of established strategies to increase the power of genetic studies to discover high-impact variants, or which address specific questions of clinical importance over and above IBD risk. In the first year, we specifically have launched exome sequencing of cohorts from the following areas: 1) IBD in Unique Populations, 2) Very Early Onset IBD and Infantile GI, 3) Adverse Drug Response in IBD, and 4) Genetics with Deep Clinical Phenotypes. These categories, focused on specific populations or clinical hypothesis, aim to maximize the impact of HIESP - presenting an unprecedented opportunity to examine the role of rare variants and its contribution to inflammatory bowel disease predisposition.

Identification of Polymorphisms Associated with Extrapulmonary Dissemination of Coccidioidomycosis (Valley Fever). *M. Yourshaw[1], P. Krogstad[1], R. Johnson[2], G. Ameri[2], H. Abukamleh[2], S. Meyer[2], D. Aguirre[2], R. Grewal[2], A. Heidari[2].* 1) Pediatrics, UCLA, Los Angeles, CA; 2) Kern Medical Center, Bakersfield, California.

INTRODUCTION: Valley Fever (coccidioidomycosis) is a fungal infection caused by the inhalation of airborne spores found in the soil. It infects some 150,000 persons each year, most in the central valley of California, and has increased 8-fold in California in the past decade. The disease is found where dry, hot, windy conditions favor dispersion of spores, and has received national attention as climate change increases its range. In some patients the fungus spreads to the skin, bones, and brain, where it may be fatal. There is no cure and treatment can be as debilitating as chemotherapy. The disseminated form of the disease especially affects African- and Filipino-Americans, and thus likely has a genetic component. **METHODS:**We extracted DNA from peripheral blood or archived tissue from a group of 22 ethnically diverse adults with extrapulmonary dissemination of coccidioidomycosis and performed whole exome sequence analysis. We filtered the resulting data for variants in genes known or suspected to be in pathways relating to responses to fungal infections. We sequenced candidate genes in additional samples. **RESULTS:** We identified an enrichment of variants predicted to be damaging in genes associated with resistance to fungal infection, including CHIT1, CLEC7A, and IL17RA. **CONCLUSIONS:** In a pilot study of 22 cases of severe disseminated cocci we found genetic variants in immune system genes that appear to be enriched in susceptible populations.

754F

Mutation in the chromatin-remodeling factor *BAZ1A* is associated with intellectual disability. *A. Zaghlool, J. Halvardson, J. Zhao, M. Etemadikhah, A. Kalushkova, K. Konska, H. Jernberg-Wiklund, A-C. Thuresson, L. Feuk.* Immunology, Genatic & Patholohy, Science For Life Laboratory, Uppsala University, Uppsala, Sweden.

Exome sequencing of trio samples has led to the identification of mutations in several genes involved in chromatin remodeling in syndromic forms of intellectual disability. To date, the majority of these mutations have not been functionally investigated to validate and understand the pathological contribution of these mutations to the disease symptoms. Here, we used exome sequencing to identify a single non-synonymous de novo mutation in *BAZ1A*, encoding the ATP-utilizing chromatin assembly and remodeling factor 1 (ACF1), in a patient with severe intellectual disability, autism, profound speech impairment, seizures, hypotonia, hypoplastic finger-nails and distal phalanges. ACF1 is a member of the ISWI chromatin-remodeling complexes ACF and CHRAC. It has been previously reported to have a function in transcriptional repression of Vitamin D3 receptor (VDR) regulated genes by blocking the accessibility of the transcription factors to VDR in the absence of vitamin D3. Based on RNA sequencing of the family trio, we find that the mutation in *BAZ1A* affects the expression of many genes, mainly involved vitamin D3 metabolism, Wnt signaling, axon guidance and nervous system development. Notably, *CYP24A1,* involved in vitamin D3 metabolism, and *SYNGAP1,* involved in axonal formation and synaptic function and *SMARCA4,* previously linked to Coffin-Siris syndrome, are differentially expressed in the patient. The differential expression of these genes correlates with the clinical diagnosis of the patient. By chromatin immunoprecipitation analysis, we show that the differential expression of *CYP24A1* is caused by reduced binding affinity of the mutated ACF1. Furthermore, RNA interference experiments further supports the role of *BAZ1A* in the regulation of the differentially expressed genes. We therefore propose that *BAZ1A* represents yet another chromatin remodeling gene involved in causing an intellectual disability syndrome. Currently, we are performing RNA sequencing of brain samples from *BAZ1A* knockout mice to further understand the regulatory role of ACF1 in the brain.

Whole exome sequencing in a family with early onset primary angle-closure glaucoma. *B. B. Souza[1,2], J. P. C. Vasconcellos[3], B. S. Carvalho[4], M. G. Borges[4], I. T. Lopes Cendes[4], P. A. O. R. Aguiar Araújo[4], M. B. Melo[1].* 1) Center of Molecular Biology and Genetic Engineering, University of Campinas - Unicamp; Campinas SP, Brazil; 2) Institute of Biology, University of Campinas - Unicamp, Campinas, SP, Brazil; 3) Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas - Unicamp, Campinas SP, Brazil; 4) Department of Medical Genetics, Faculty of Medical Sciences, Unicamp, Campinas, SP, Brazil.

Background: Glaucoma is a degenerative disease of the optic nerve considered the leading cause of irreversible blindness worldwide, which affects about 64. 3 million people between 40 – 80 years old. Primary angle-closure glaucoma (PACG) is a subtype of glaucoma caused by obstruction of the iridocorneal angle with increase in intraocular pressure leading to slow progressive excavation of the optic disc and corresponding visual field loss. Demographic factors like age, ancestry and female sex are still recognized as the main risk factors for PACG, as well as positive family history. PACG is a complex heterogeneous disease with molecular mechanisms poorly understood. Until now, only three genetic markers where associated with susceptibility to PACG, rs11024102 in *PLEKHA7* on chromosome 11, rs3753841 in *COL11A1* on chromosome 1, and rs1015213 located between *PCMTD1* and *ST18* genes on chromosome 8q, all these variants were identified from GWAS studies. **Objective:** To identify genes associated with PACG in an early onset disease family. **Methods:** Whole exome sequencing was performed in a family of four members, being mother and daughter affected by PACG and father and son unaffected. Exome was targeted with Nextera Rapid Capture Expanded Exome kit (Illumina™) and sequenced in a high-performance Hiseq Illumina 2500 DNA Analyzer (Illumina™) to obtain more than 70X average coverage per sample. A bioinformatics analysis was performed using the GATK software package. Sequences were aligned using BWA algorithm. Variant calling and functional prediction were performed through VariantAnnotator and VEP tools. Non-synonymous, frameshift, splicing, and indel variants were prioritized according to novelty, quality score, and degree of pathogenicity. **Results:** We found a total of 376. 742 variants in this family. After bioinformatics processing, we identified 317 functional variants that are shared only by patients and absent in the unaffected individuals. Among them, we observed four genes as potential candidates for PACG in the studied family. **Conclusions:** Putative roles related to cell adhesion, spreading, growth and apoptotic processes make the four candidate genes identified relevant for PACG pathophysiology. **Supported by:** Conselho Nacional de Desenvolvimento Científico e Tecnológico – CNPQ, Brazil, process: 157539/2013-0.

Detection of somatic genetic variation at the *LMNA* locus in non-progeroid individuals. *R. R. Palla[1], N. Viceconte[1], A. Witasp[2], E. Wallén Arzt[1], P. Stenvinkel[2], M. Eriksson[1].* 1) Department of Biosciences and Nutrition, Karolinska Institutet, Huddinge, Sweden; 2) Department of Clinical Science, Intervention and Technology, Division of Renal Medicine, Karolinska Institutet, Stockholm, Sweden.

Several recent studies have investigated structural genetic variation in the context of somatic mosaicism, but so far only few studies have analyzed somatic genetic variation at the single-nucleotide level. Hutchinson-Gilford progeria syndrome (HGPS) is a rare genetic disorder with features reminiscent of premature aging. Previous studies have shown that >90% of affected patients have a mutation in the *LMNA* gene (c. 1824C>T, p. G608G). This mutation and several other mutations have been shown to result in increased activation of a cryptic splice donor site in exon 11, resulting in a truncated lamin A protein, named progerin. Progerin has also been found at low levels in human cells from non-progeroid diseases and its levels were shown to increase during aging. There is no explanation to the expression of progerin in non-progeroid tissue or its contribution to tissue pathology and aging. In this study we aimed to test if occasional progerin expression in human tissues is the result of somatic mutations. We used droplet digital PCR (ddPCR) to analyze single nucleotide variants in a highly mosaic tissue sample. Eight ddPCR assays were developed to test variants in the *LMNA* gene. These variants have previously been identified in children with Progeria and Werner syndrome or recorded in SNP databases. Prediction of alternative splicing was performed using the Alamut Visual mutation analysis software that estimates each mutation effect on splicing. The presence of low-degree somatic single nucleotide variants was analyzed in peripheral blood mononuclear cell (PBMC) DNA samples from 26 patients with end stage kidney disease (ESRD; a group of patients with a prematurely aged phenotype) and controls. The ddPCR allowed detection of low frequency variants in the PBMC DNA, suggesting the presence of low-degree somatic mosaicism. However, the mutation frequency detected in the PBMC from ESRD patients was below, or at similar levels, to that found in unaffected controls. Our results suggest that a more extensive analysis, including a map of progerin expression in several tissues, together with low-degree somatic variation analysis using ddPCR on DNA from the same tissue, is needed to fully explain the significance of these findings. Nevertheless, detection of low frequency genetic variants in non-progeroid patients, previously recorded in premature aging syndromes, might suggest a role for these somatic mutations also in normal aging.

757F

Somatic mutation calling in lung tissue of ex-smokers with different degrees of airway obstruction. *G. -A. Thun[1], S. Derdak[1], F. Castro-Giner[1], L. Ziegler-Heitbrock[2], I. Gut[1], EvA and AirProm Consortium.* 1) Centro Nacional de Análisis Genómico, Parc Cientific de Barcelona, Barcelona, Spain; 2) EvA Study Center, Helmholtz Center Munich, Gauting, Germany.

Chronic obstructive pulmonary disease is a smoking-related disorder characterized by airflow limitations and a high degree of inflammation and tissue remodeling in the lung. As the association with lung cancer can only be partly explained by the duration or amount of smoking, we hypothesized that a higher susceptibility to mutagenesis might be present in the affected lungs. For that purpose, twelve elderly participants of the EvA Study, including both never and former smokers, were selected and whole genome sequencing of lung brush and blood samples (average median coverage 30x) was carried out. The nine ex-smokers all had a history of heavy smoking, but very variable degrees of airflow obstruction. In the absence of a single best protocol for calling somatic mutations, we used several of the existing methods comparing pairwise data of lung brush tissue with blood as the reference. Applying default settings, we observed high heterogeneity with respect to the number of single somatic mutation (SSM) calls (means ranging from ≈600 to 8000). The concordance among the methods was modest (overlapping calls for SSMs between 5 and 48% of those produced by the more restrictive caller in all pairwise method comparisons). Moreover, taking intersects did not appear a fruitful strategy to confine the most promising candidates as we found substantial enrichment of variants present in dbSNP. The results of the selected methods agreed with respect to the frequency of the variant allele peaking close to 0. 25, which suggested some degree of polyclonality or considerable presence of white blood cells in the lung specimen. Independent of the method applied, the number of somatic mutations was neither associated with airflow obstruction nor with smoking history in our small data set. However, we found the proportion of tobacco-related C>A transversions to be associated with former smoking depending on the calling method. Even in the hitherto absence of call verification, the low concordance and the relative high overlap with dbSNP point to low positive predictive values of the applied methods. Careful method-specific post-filtering of the results seems indispensable. Furthermore, ultra-deep sequencing will be necessary to discover if the number of somatic mutations in lung epithelial tissue normalizes years after quitting smoking or if the high polyclonality in brush samples obscured the elevated numbers of somatic mutations in ex-smokers or individuals with airflow obstruction.

Genetics of Obesity and Diabetes Related Quantitative Traits in Omani Arabs. *N. N. Al Kharusi[1], S. A. ALBARWANI[1], M. O. HASSAN[1], R. A. BAYOUMI[1], H. M. HIGHLAND[2,4], M. C. GINGRAS[3], D. M. MUZNY[3], R. A. GIBBS[3], E. A. BOERWINKLE[3,4], L. E. PETTY[4], J. E. BELOW[4], S. A. AL YAHYAEE[1].* 1) Biochemistry and Molecular Biology, Sultan Qaboos University, Muscat, Oman; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC, USA; 3) Human Genome Sequencing Center, Baylor College of Medicine, One Baylor Plaza, Houston, TX 77030, USA; 4) Human Genetics Center, University of Texas Health Science Center, Houston, TX 77225, USA.

Obesity (OB) and type 2 diabetes (T2D) are heterogeneous complex diseases driven by environmental and polygenic effects. Previously identified variants of OB and T2D and their traits account only for a fraction of their expected heritability. Screening for variants in an isolated founder population can reduce the phenotypic heterogeneity explained by environmental effects and focus on enriched segregating genes that explain the genetic risk of the disease. A single large consanguineous family of 227 Arabs from Nizwa village in Oman were genotyped on the Illumina Infinium chip. Heritability estimates of underlying characteristics of OB and T2D, such as body mass index (BMI), waist circumference (WC), fasting glucose (FG) and 2 hour glucose (2hrG) in the village range form 0. 17 (2hr glucose) to 0. 68 (BMI). Quality control of genotyped data was performed with PLINK1. 9 and individuals with excess heterozygosity (F statistic < -0. 1) or missingness of >1%, and SNPs with >10% missingness, and HWE p <0. 001 were removed, leaving 221 individuals with 239,464 genotyped SNPs for analysis. Single variant association analyses of quantitative trait were performed in EPACTS-EMMAX accounting for the pairwise relatedness structures. Both normal residual and inversed normalized residual of the traits were tested. Although no genes were genome wide significant (*p* value < 5 x 10-8), our top associations include variants in *PLD1* (2hrG, rs145015377 (G/A), *p* value 2. 1 x 10-5), *SERPINA6* (BMI, rs2228541 (C/A), *p* value 2. 5 x 10-5), *IRF4* (WC, rs9405666 (A/G), *p* value 1. 93 x 10-5). Gene *PLD1* encodes a phosphatidylcholine-specific phospholipase which was reported to interact with *PED*/*PEA-15* gene and influence insulin-stimulated glucose disposal. *SERPINA6* encodes an alpha-globulin protein, a major transport for glucorticoids and progestins in the blood, which influence body adiposity. Variants in *IRF4* were found to be associated with waist circumference; interferon regulatory factor 4 is required for lipolysis. It is up regulated during fasting, and its absence stimulates lipid synthesis. Although the low sample size in these preliminary analyses did not provide sufficient power to reach genome-wide significance at variants of modest effect, gene function suggests an enrichment of phenotypically relevant pathways in top signals. Formal analyses of functional enrichment and analyses leveraging the unique haplotypic architecture of this cohort will increase power.

759T

Identification of Rare Variants in Schizophrenia Families. *Z. Brkanac, L. F. F. Gelin, M. J. Archer, R. R Nesbitt, A. Patowary, J. Rehker.* Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA.

Schizophrenia is a rare and severe psychiatric disorder affecting approximately 1% of the adult population worldwide. Symptoms can include hallucinations, delusions and catatonic behaviors as well as negative symptoms including a lack of initiative, motivation, affect expression and poverty of thinking. Schizophrenia is a highly heritable and complex disorder with multiple genes contributing to its cause and spectrum of symptoms. In order to identify novel genes responsible for schizophrenia we focused on 16 multiplex families of different ethnicities (two Hispanic, five African-American and nine European-American) from NIMH collection. Using exome sequencing of affected subjects, we identified alleles that are shared among all cases in each family. In order to identify candidate genes, we focused on private (not present in dbSNP 132, 1000 genomes or ESP 6500) and rare (not present in dbSNP 132 and with frequencies lower than 1% in the same databases) protein changing SNPs (nonsense, splicing, frameshift and missense). The exome sequences were analyzed using the BWA-Picard-GATK workflow and annotated using ANNOVAR. Data manipulation and filtering was done using custom python scripts. The number of rare and private variants within families varied from 5 to 45. That data reflects the different family structures with expected genomic sharing among affected individuals ranging from 0. 08% to 1. 25%. Based on the analysis of rare and private SNPs, 256 genes were selected for association analyses. For the association analysis, we used the published Swedish schizophrenia exome data set containing 2,536 cases and 2,543 controls. Gene based and single variant association tests were performed for the 256 genes using PLINK/SEQ. In addition, we performed chi-square analysis for a number of rare and unique variants in cases vs. controls. Using this approach we identified 19 candidate genes that either had either significantly more variant counts in cases than in controls (15 genes, p<0. 01) or had one variant that appeared more often in cases than in controls (4 variants, p<0. 01). To confirm the association from the first sample, multiplex target sequencing is being performed for the 19 candidate genes in 960 independent schizophrenia cases and 960 controls from NIMH collection. The results of the combined analysis will be presented.

760F

Whole-genome sequencing reveals schizophrenia risk mechanisms in humans with 22q11. 2 deletion syndrome. *M. Zarrei[1], D. Merico[1], G. Costain[2,3], L. Ogura[2], B. Alipanahi[4], M. Gazzellone[1], N. Butcher[2], B. Thiruvahindrapuram[1], T. Nalpathamkalam[1], E. Chow[2,5], D. Andrade[6,7], B. Frey[4], C. Marshall[1], S. Scherer[1,8], A. Bassett[2,5,9,10,11].* 1) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Ontario, Canada; 2) Clinical Genetics Research Program, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 3) Medical Genetics Residency Training Program, University of Toronto, Toronto, Ontario, Canada; 4) Department of Electrical and Computer Engineering, University of Toronto, Toronto, Ontario Canada; 5) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 6) Division of Neurology, Department of Medicine, University of Toronto, Toronto, Ontario, Canada; 7) Epilepsy Genetics Program, Toronto Western Hospital, University Health Network and University of Toronto, Toronto, Ontario, Canada; 8) McLaughlin Centre and Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 9) Department of Psychiatry, and Toronto General Research Institute, University Health Network, Toronto, Ontario, Canada; 10) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 11) The Dalglish Family Hearts and Minds Clinic for 22q11. 2 Deletion Syndrome, Toronto General Hospital, University Health Network, Toronto, Ontario, Canada.

Chromosome 22q11. 2 microdeletions impart a high but incomplete risk for schizophrenia. Possible mechanisms include effects of *DGCR8* haploinsufficiency on genome-wide microRNA biogenesis. We obtained high quality whole-genome sequencing data for individuals with 22q11. 2 deletions and extreme phenotypes (schizophrenia or no psychotic disorder at age >50 years). We investigated rare variants in coding and non-coding sequence most likely to have deleterious consequences. The schizophrenia group had a greater burden of damaging coding variants in neurofunctional gene-sets, including genes involved in neuron projection (nominal p=0. 02, joint burden of three variant types). Variants in the intact 22q11. 2 region were not major contributors. Restricting to genes affected by a *DGCR8* mechanism tended to amplify between-group differences and effect sizes. Damaging variants in highly conserved long intergenic non-coding RNA genes were also enriched in the schizophrenia group (nominal p=0. 04). These initial findings support a multiple within-individual rare variant hypothesis for schizophrenia. Here, the 22q11. 2 deletion appears to act as a threshold-lowering first hit to genome-wide deleterious rare variants in coding and non-coding sequence. A functionally and mechanistically-based design using a genetic model of schizophrenia provides a promising approach for using whole-genome sequencing technology to further delineate the genetic architecture of this complex disorder.

A whole exome study identifies novel candidate genes for vertebral bone marrow signal changes (Modic changes). *M. Kraatari[1,2,3], S. Skarp[1,2,4], J. Karppinen[1,3,5], M. Männikkö[1,2,4].* 1) Center for Life Course Epidemiology and Systems Medicine, Faculty of Medicine, University of Oulu, Finland; 2) Center for Cell - Matrix Research, Faculty of Biochemistry and Molecular Medicine, University of Oulu, Finland; 3) Medical Research Center Oulu, Oulu University Hospital and University of Oulu, Finland; 4) Biocenter Oulu, University of Oulu, Finland; 5) Finnish Institute of Occupational Health, Health and Work Ability, and the Disability Prevention Center, Oulu, Finland.

Lumbar disc degeneration (LDD) is one of the contributing factors behind low back pain (LBP). The most prominent change in LDD is the loss of proteoglycans in the lumbar disc. Modic changes (MC) are a specific phenotype of LDD and are visualized as bone marrow signal intensity changes on magnetic resonance imaging (MRI). MC are a heritable trait with a strong association with LBP. The heritability of MC is estimated around 30%. Two families were studied to identify predisposing variants for MC. Nine individuals were chosen for whole exome sequencing. We focused on rare (MAF < 0. 01) and private variants with harmful *in silico* predictions and variants located in regulatory regions. To find variants co-segregating with MC the identified variants were genotyped from additional family members. One rare variant co-segregated with the MC in each family. In the Family I the observed variant was an insertion and deletion mutation in the *HSPG2* gene, resulting in a premature stop codon. *HSPG2* encodes a heparin sulfate proteoglycan called perlecan, which is a structural protein expressed in mammalian cartilage and basement membranes. Rare autosomal recessive disorders with osteochondrodysplasia are caused by mutations in the *HSPG2* gene. In the Family II a single nucleotide polymorphism in the *MAML1* gene was identified in all affected family members. *MAML1* has been reported to affect the activity of RUNX2, a transcription factor essential in the osteoblast differentiation. RUNX2 has been reported to be highly expressed in degenerated discs. MAML1 could affect the disc structure via RUNX2 activity. We identified two promising candidate genes for MC, *HSPG2* and *MAML1*. Our findings are novel in lumbar spine degenerative phenotypes.

762T

Low-frequency germline variants across 6p22. 2-6p21. 33 are associated with non-obstructive azoospermia in Han Chinese men. *Y. Jiang[1], Y. Wen[2].* 1) State Key Laboratory of Reproductive Medicine, Nanjing Medical University, Nanjing; 2) Department of Epidemiology and Biostatistics and Key Laboratory of Modern Toxicology of Ministry of Education, School of Public Health, Nanjing Medical University, Nanjing.

Genome-wide association studies (GWAS) have identified several common loci contributing to non-obstructive azoospermia (NOA); however, a substantial fraction of NOA heritability remains undefined, especially those low-frequency (defined here as having minor allele frequency (MAF) between 0. 5-5%) and rare (MAF below 0. 5%) variants. Here, we performed a 3-stage exome-wide association study in Han Chinese men to evaluate the role of low-frequency or rare germline variants in NOA development. The discovery stage included 962 NOA cases and 1,348 healthy male controls genotyped by exome chips and was followed by a 2-stage replication with additional 2,168 cases and 5,248 controls. We identified three low-frequency variants located at 6p22. 2 (rs2298090 in *HIST1H1E* encoding p. Lys152Arg: OR=0. 30, *P*=2. 40×10-16) and 6p21. 33 (rs200847762 in *FKBPL* encoding p. Pro137Leu: OR=0. 11, *P*=3. 77×10-16; rs11754464 in *MSH5*, OR=1. 78, *P*=3. 71×10-7) associated with NOA risk after Bonferroni correction. In summary, we report an instance of newly identified signals for NOA risk in genes previously undetected through GWAS on 6p22. 2-6p21. 33 in a Chinese population, and highlight the role of low-frequency variants with large effect in the process of spermatogenesis.

763F

Exome sequencing to detect rare variants associated with biliary atresia. *O. Migita[1,2], A. Matsui[2,3], H. Yamamoto[1], Y. Matsubara[2], K. Hata[2].* 1) St. Marianna University School of Medicine, Kawasaki, Kanagawa, Japan; 2) National Research Institute for Child Health and Development, Tokyo, Japan; 3) College of Nursing St. Luke's International University, Tokyo, Japan.

Biliary atresia (BA) is characterized by complete inability to excrete bile from the liver to the duodenum due to sclerosing inflammation of the extra- and intrahepatic bile ducts. It affects 0. 5 (Caucasian), 1. 0 (Japanese) and 2. 9 (French-Polynesian) in 10,000 live-born infants, respectively but is one of the most life-threatening hepatobiliary disorders in childhood. It may start in fetal, in perinatal or early in postnatal life. What causes this inflammation remains unclear in spite of extensive investigation. It is assumed that multiple genetic and environmental factors might affect individuals with BA. Family members, especially siblings, share genetic and environmental backgrounds. Twin studies remain a favorable means to find genetic factors. Identical twins, developed from one single cell, share the same genome and environment. To address genetic factors, we performed whole exome sequencing of BA patients and their family members including identical twins. We collected the DNA from six families with BA which had a non-affected twin sibling in their family. Using exome sequencing to find rare variants which could not or could rarely be found in control data, we made a list of non-synonymous variants in the families. Our exome sequencing identified over 100 candidate genes with biliary atresia. We could not find deleterious variants in previously reported candidate genes such as ADD3, ABCB4, JAG1 and NOTCH2. It is still unknown what affective nucleotide variants are included in the variants list. To our knowledge, this is the first exome sequencing study of families with BA which might suggest new candidate genes for BA.

764W

Rare variants in sporadic Hirschsprung disease patients. *C. Tang[1], M. So[2], S. Cherny[1,3], P. Sham[1,3], P. Tam[2], M. Garcia-Barcelo[2].* 1) Department of Psychiatry, The University of Hong Kong, Pokfulam, Hong Kong; 2) Department of Surgery, The University of Hong Kong, Pokfulam, Hong Kong; 3) Centre for Genomic Sciences, The University of Hong Kong, Pokfulam, Hong Kong.

Sporadic Hirschsprung disease (HSCR), accounting for ~80% of the patients, represents the most common form of the disorder and is believed to be genetically complex. Studies of rare mutations have discovered more than 10 genes associated with HSCR. The major HSCR-susceptibility gene, *RET*, have both rare coding sequence mutations and common regulatory variants contributing to the disease. The differential contributions of rare and common, coding and noncoding variants tend to vary in accordance with gender and length of aganglionosis. In view of this, we performed a whole genome sequencing study of 5 trios of sporadic patients with the rarer subtype (long segment HSCR) to identify rare mutations causal to HSCR. Our data show that de novo as well as inherited variants contribute to the development of ENS and thereby to HSCR. The discovery might give rise to a new insight into the disease pathophysiology.

.

765T

Gene variants associated with spherical equivalent in the Beaver Dam Eye Study. *K. E. Lee[1], F Chen[2], P Duggal[2], B. E. K. Klein[1], R Klein[1], A. P. Klein[2,3,4].* 1) Ophthalmology & Visual Sci, Univ of Wisconsin School of Medicine and Public Health, Madison, Wisconsin; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland; 3) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland; 4) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, Maryland.

Uncorrected refractive errors are the leading cause of visual impairment and blindness worldwide. Refractive errors are associated with a number of ocular disorders, further increasing risk for vision loss later in life. The etiology of refractive errors is complex with both environmental and genetic components reported in many studies worldwide. As the rates of myopia have been increasing worldwide, understanding the underlying causes are important. We conducted an exome array analysis in 1632 individuals from the Beaver Dam Eye Study to identify rare and low frequency variants that influence spherical equivalent. The Beaver Dam Eye Study is a population-based study of eye traits in older Caucasian adults (ages 43-86 years). Genotyping was conducted using the Illumina exome array. We analyzed 35,095 single nucleotide variants and 11,644 autosomal genes across the genome. After adjustment for age, gender and years of education, we identified two novel variants in the TCTE1 gene region at 6p21. 1 (rs2297336, MAF = 14. 2%, b = -0. 67, P = 3. 5 × 10-7; rs324146, MAF = 17. 2%, b = -0. 59, P = 1. 7 × 10-6), and with the *FSCB* gene at 14q21. 1 (P = 2. 1 × 10-8). We successfully replicated the association on rs634990 near *GJD2* at 15q14 (MAF = 47%, b = -0. 34, P = 2. 1 × 10-4), and discovered a novel association with spherical equivalent on rs1550094 (MAF = 31%, b = -0. 27, P = 8. 0 × 10-3), a locus in *PRSS56* at 2q37. 1 that was previously reported for myopia. Novel genetic variants and genes with multiple rare and low frequency variants may play a role in the control of spherical equivalent. Our results contribute to the increasing evidence of *GJD2* and *PRSS56* in the development of refractive errors. The implication of these two genes, as the common genetic factor for both spherical equivalent and myopia may provide new insights to the underlying mechanism leading to myopia and consequent vision loss.

766F

Testing the neuronal carnitine hypothesis for autism using whole exome sequencing in SSC families. *D. Zhang[1,3], J. Ge[1], N. Krumm[2], T. Turner[2], E. Eichler[2], A. L. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX. USA; 2) Dept. Genome Sciences, U. Washington, Seattle, WA, USA; 3) Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China.

Autism is a highly heritable neurodevelopmental disorder with an incidence of 1 in 68 infants in one more recent CDC report. Although there is strong evidence that rare CNV and point mutation variants, often *de novo*, contribute substantially to the causes of autism at the severe end of the spectrum, much less is known about the etiology at the very mild end of the phenotypic spectrum. We have hypothesized that neuronal/synaptic carnitine deficiency may contribute to the etiology of autism especially in males with a normal physical examination and normal structural brain imaging. In this hypothesis, common variants or carrier states in carnitine-related genes could be risk factors for autism. In this study, we investigated the mutation profiles in 29 candidate genes related to carnitine metabolism based on whole exome sequencing data of the Simons Simplex Collection (SSC) families as carried out and made available by the laboratories E. Eichler, M. State, and M. Wigler. We focused on transmission of all variants in these genes among probands, unaffected siblings, and their parents. Although most variants were equally transmitted in probands and unaffected siblings, some candidate variants showed higher frequencies in probands. For instance, the frequency of rs180830030 in *CPT2* in probands was almost 2 folds higher than that in unaffected siblings (p<0. 001). Furthermore, in 6 quad families transmitting this variant, the frequency was higher in probands (6/6) than in siblings (2/6) (p=0. 03, Fisher Exact Test). Next, we explored the variants at gene level. For some genes, pathogenic variant frequencies were higher in SSC families than those in the Exome Aggregation Consortium (ExAC) database. For example, *SLC22A5*, a gene where homozygous or compound heterozygous mutations cause systemic primary carnitine deficiency, had 11 variants, classified as pathogenic but also reported in ExAC database. Over 1% of individuals in SSC families carry pathogenic variants, but at most 0. 5% of individuals in ExAC database have pathogenic variants (p<0. 001). These findings could be compatible with a hypothesis that genotypes which deplete whole body carnitine or impair carnitine metabolism in mitochondria could be a risk factor for autism. We are examining the prediction of our hypothesis that these trends will be stronger in male probands with a normal physical exam and brain imaging and absence of a high penetrance autism mutation compared to all other probands.

767W

Distinct genetic variants in the vitamin D pathway contribute to risk of multiple sclerosis and vary by presence of *HLA-DRB1*15:01*: Results from the Kaiser Permanente MS Research Program. *A. Mok[1,2], X. Shao[2], B. Rhead[2], L. Shen[3], H. Quach[2], A. Bernstein[4], C. Schaefer[3,5], L. F. Barcellos[1,2,3,5].* 1) School of Public Health, Division of Epidemiology, UC Berkeley, Berkeley; 2) Genetic Epidemiology and Genomics Laboratory, UC Berkeley, Berkeley; 3) Kaiser Permanente Division of Research, Oakland, CA; 4) Palm Drive Hospital, Sebastopol, CA; 5) Research Program on Genes, Environment, and Health, Kaiser Permanente, Oakland, CA.

Studies have shown an association between vitamin D serum levels and multiple sclerosis (MS [MIM 126200]). However, the role of genes involved in vitamin D metabolism and of vitamin D response elements (VDREs) in MS has not been extensively examined. We set out to investigate whether genetic variants in 18 vitamin D-related genes and 43 VDREs are associated with MS in non-Hispanic White members of Kaiser Permanente Northern California (1,200 MS cases; 10,000 controls). Gene boundaries were defined as 2 kb upstream/downstream of each gene to capture regulatory regions. VDREs were defined as the vitamin D receptor complex binding sites detected by ChIP-seq in six cellular models (Tuoresmäki, PLoS One 2014). Genotypes were obtained through whole-genome profiling and imputation. Loci failing standard quality control measures and with an imputation info score <0. 8 were removed. Variants in linkage disequilibrium with SNPs identified in MS genome-wide association studies (GWAS) were removed, and SNPinfo was used to select tagging SNPs. In total, we retained 496 SNPs over 17 gene regions and 7 VDREs for analysis. Associations between SNP and case/control status were controlled for sex, year of birth, smoking, body mass index, education, ancestry, and weighted MS genetic risk score for 110 GWAS SNPs order to detect the effect of vitamin D genetics on MS susceptibility independent of well-established risk factors. Analyses were also stratified by *HLA-DRB1*15:01* allele presence/absence, the strongest genetic contributor to MS risk. Preliminary results showed significant disease associations for rs3782905 in *VDR* and rs2892802 in *LRP2* (OR=0. 70 and 0. 61, respectively; FDR q<0. 05) among **15:01* negative subjects, and rs12143452 in *ST6GALNAC3* (OR 0. 36; FDR q<0. 05) among **15:01* positive subjects. These findings further underscore the complex genetic architecture underlying MS susceptibility as effect modification of the association between variants within vitamin D genes and MS risk by the **15:01* allele was observed. A total of 23,409 VDREs have been identified to date, and further analyses are underway to characterize involvement of these VDREs and their downstream targets in MS, and to further understand the biological mechanisms underlying the relationship between vitamin D and MS. This is the first study to examine VDREs outside the *HLA-DRB1* promoter in MS, and the largest study with the most comprehensive multivariable model of vitamin D genetics in MS, to date.

768T

Fine-mapping major histocompatibility complex association in systemic lupus erythematosus identifies a novel association of *HLA-DPB1* in three Asian populations. *JE. Molineros[1], K. Kim[2], C. Sun[1], X. Zhou[3], KH. Chua[4], H. Zhang[3], SC. Bae[2], SK. Nath[1].* 1) Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Rheumatology, Hanyang University Hospital for Rheumatic Diseases, Seoul 133-792, Republic of Korea; 3) Renal Division, Peking University First Hospital, Peking University Institute of Nephrology, Key Laboratory of Renal Disease, Ministry of Health of China, and Key Laboratory of Chronic Kidney Disease Prevention and Treatment (Peking University), Ministry of Education, Beijing, China; 4) Department of Biomedical Science, Faculty of Medicine, University of Malaya, 50603 Kuala Lumpur, Malaysia.

Systemic lupus erythematosus (SLE) is a debilitating heritable autoimmune disease, characterized by a broad spectrum of clinical manifestations including pathogenic autoantibody production and multi-organ damage. *HLA-DRB1* in the major histocompatibility complex (MHC) region is a key genetic factor conferring risk of SLE but residual effects outside of *HLA-DRB1* has not been fully understood. To dissect the MHC association, we imputed classical alleles and amino-acid residues of at 8 HLA genes (*HLA-A, -B, -C, -DPA1, -DPB1, -DQA1, -DQB1, -DRB1*) in 2,496 SLE cases and 7,657 controls from Korean (KR), Han-Chinese (HC) and Malaysian-Chinese (MC) origin using the SNP2HLA software and an ethnicity-matched HLA reference panel. The association was examined by logistic regression for bi-allelic markers and log likelihood ratio test for multi-allelic amino-acid positions, adjusting for principal component and ancestral origin. Consistent with our recent report, the strongest association was localized at *HLA-DRB1* amino-acid position 13 (PKR = 3. 53x10-31; PHC = 7. 86x10-6; PMC = 1. 56x10-9; Pall =1. 41x10-32) and its proxy position 11 across the extended MHC locus, followed by *HLA-DRB1* amino-acid position 26 in a conditional analysis adjusting for the primary-effect positions 11 and 13. We also confirmed the well-established association of *HLA-DRB1**15:01 (Pall=8. 97x10-23, OR=1. 71, 95% CI = [1. 66-1. 76]) along with its tightly correlated *HLA-DQB1**06:02 (Pall=4. 64x10-26, OR=1. 79, 95% CI =[1. 74-1. 85]) in Asian populations. In addition, the second conditional analysis adjusting for the three independent amino-acid positions of *HLA-DRB1* identified a novel association at *HLA-DPB1* amino-acid position 35 (PKR = 9. 85x10-12; PHC = 1. 98x10-1; PMC = 7. 99x10-2; Pall = 2. 50x10-14) in the epitope binding site. In summary, our study keeps emphasizing the strong contribution of MHC class-II molecules as we newly identified a pathogenic role of *HLA-DPB1* in Asians, raising the possibility of additional MHC class-II molecules such as *HLA-DPB1* with complementary or independent roles in the MHC class-II-mediated SLE pathogenesis.

Genetics of sarcoidosis determined by polygenic risk score analysis derived from CD4:CD8 ratio T-lymphocytes genetic variants. *NV. Rivera[1], M. Ronninger[1], M. A. R Ferreira[2], N. G Martin[2], A. Eklund[1], L. Padyukov[3], J. Grunewald[1].* 1) Respiratory Unit, Department of Medicine Solna and, Karolinska Institutet and Karolisnka University Hospital, Stockholm, Stockholm, Sweden; 2) Queensland Institute of Medical Research, Brisbane, Australia; 3) Rheumatology Unit, Department of Medicine Solna and CMM, Karolinska Institutet and Karolinska University Hospital, Stockholm, Sweden.

INTRODUCTIONThe bronchoalveolar lavage (BAL) cell CD4:CD8 ratio has been suggested to be important for diagnosing sarcoidosis. The accumulation of CD4+ T-lymphocytes in BAL fluid extrapolates on the plausibility of a pathogenic role of T-lymphocytes in the disease. Few genetic stuides of sarcoidosis have been performed, and thus a substantial portion its heritability remains unexplained. Herein, we constructed polygenic scores using GWAS results of CD4:CD8 as to evaluate the impact of associated-alleles and predict entities of sarcoidosis. METHODSBased on summary association results from a gene discovery set of 2,538 individuals from the general population whose CD4:CD8 was derived from CD4+/CD8+ T-lymphocytes1, we calculated polygenetic risk scores in a target sample of 518 sarcoidosis patients, of which 205 were diagnosed with Löfgren's syndrome (LS) and 313 were non- Löfgren's syndrome (non-LS). In the target set, bronchoscopy with BAL was performed in all patients with recent disease onset and a median (sd) age of 39 (12) years and BAL T-lymphocytes were measured. The polygenic scores were calculated in the target sample for different cluster sets (by P-value thresholdand by chromosome) using the score function in PLINK software. The significance of the polygenic score was tested in the likelihood ratio test by using it as a predictor in a logistic regression model adjusted by gender. The difference in the explained variance (Nagelkerke R2) between the null and alternative modelwas considered as the variance explained by the genetic score. RESULTSCross-prediction analysis for both LS and non-LS sarcoidosis phenotypes showed distinctive genetic architecture based on CD4:CD8 ratio associated-SNPs. For LS, polygenetic scores explained maximum variations of 7. 55% (*P* = 1. 93 x 10-24) at P-discovery and 7. 71% (P = 7. 5x10-25) by chromosome 6. For non-LS, maximum variations of 0. 42% (P = 2x10-2) at P-discovery and0. 66% (P = 9. 65x10-3) by chromosome 10 were observed. CONCLUSIONSOur study provides significant evidence that genes influencing CD4+ and CD8+ T-lymphocytes are involved in pathogenesis of sarcoidosis phenotypesREFERENCES1. Ferreira, M. A. , Mangino, M. , Brumme, C. J. , Zhao, Z. Z. , Medland, S. E. , Wright, M. J. , Nyholt, D. R. , Gordon, S. , Campbell, M. , McEvoy, B. P. , et al. (2010). Quantitative trait loci for CD4:CD8 lymphocyte ratio are associated with risk of type 1 diabetes and HIV-1 immune control. American journal of human genetics 86, 88-92.

Introduction: The most associated region in idiopathic inflammatory myopathy (IIM) is within the major histocompatibility complex (MHC). Due to the complex linkage disequilibrium/haplotype structure in this region, interpretation of causal associations and independent effects using SNPs may be inadequate. **Methods**: We used SNP2HLA to impute classical human leukocyte antigen (HLA) alleles and amino acids from Immunochip genotyping data. HLA imputation was carried out on Caucasian IIM samples from the MYOGEN consortium. Initial analysis was conducted on clinical myositis subgroups; polymyositis (PM, n=931), adult dermatomyositis (DM, n=879) and juvenile dermatomyositis (JDM, n=481). Analysis was then conducted on common serological subgroups (n>40 individuals). Classical 4-digit HLA alleles are preferentially reported, unless an amino acid association explains more risk than HLA alleles alone. **Results**: In IIM, the strongest associations were with alleles of the 8. 1 ancestral haplotype (8. 1 AH). In PM, there were independent effects of *HLA-DRB1**03:01 (p=3. 2x10-82) and *HLA-B**08:01 (p=3. 3x10-9). Outside of the 8. 1 AH, independent effects were seen with amino acid position 57 of *HLA-DQB1* (p=2. 1x10-14) and *HLA-DQB1**04:02 (p=2. 1x10-6) in DM, and with *HLA-C**02:02 (p=2. 5x10-6) in JDM. Antihistidyl–tRNA-synthetase (anti-Jo-1) autoantibodies (n=331) were associated with *HLA-B**08:01 (3. 1x10-89) and *HLA-DRB1**03:01 (1. 3x10-9). Anti-PMScl (n=127) autoantibodies were associated with *HLA-B**08:01 (p=4. 0x10-41). More modest associations with anti-TIF1 autoantibodies and multiple *HLA-DQB1* alleles may be explained by an association with position 57 of *HLA-DQB1* (p=7. 7x10-10). Associations with rarer autoantibodies were replicated, such as *HLA-DRB1**07:01 (p=1. 6x10-11) with anti-Mi-2 autoantibodies (n=99) and *HLA-DRB1**11 (p=4. 2x10-9) with anti-HMG-CoA-reductase (HMGCR) autoantibodies (n=41). **Conclusions**: The strongest associations were with alleles of the 8. 1 AH. Autoantibody subgroups may have unique HLA associations and there is evidence that specific amino acids within the HLA may be functionally important. Associations of clinical subgroups with the HLA may be explained by the strong associations with prevalent autoantibodies. Although limited statistical power may not allow us to tease out all effects within the MHC, this analysis has shown that stratifying patients by serology is important to expand our knowledge of IIM immunogenetics.

771T

A cross-ethnic survey of *CFB* and *SLC44A4,* novel Indian Ulcerative colitis GWAS hits, identifies allelic heterogeneity and underscores their potential role in disease biology. *B. K. Thelma[1], A. Gupta[1], A. Sood[2], G. Juyal[1], V. Midha[2], K. Yamazaki[3], A. Vich Vila[4], M. Kubo[3], R. K. Weersma[4].* 1) Department of Genetics, University of Delhi, South Campus, New Delhi; 2) Department of Gastroenterology, Dayanand Medical College and Hospital, Ludhiana, Punjab, India; 3) Laboratory for Genotyping Development Center for Integrative Medical Sciences, RIKEN 1-7-22, Suehiro-cho, Tsurumi-ku, Yokohama 230-0045, Japan; 4) Department of Gastroenterology and Hepatology, University of Groningen and University Medical Centre Groningen, Groningen, The Netherlands.

The first ever genome wide association study (GWAS) of Ulcerative colitis (UC) from north India (NI) that we previously carried out showed strong association of complement factor B (*CFB*) and *SLC44A4* with the disease (Juyal et al. , Gut, 2014). Notably, these genes have been previously missed by several GWA studies in different ethnic backgrounds. Such differences could be attributed to allelic/genetic heterogeneity and distinct environmental components across ethnic groups. Considering the biological relevance of *CFB* and *SLC44A4* in UC, this study aimed to investigate allelic heterogeneity in these two genes in UC cohorts from three genetically diverse populations namely NI, Japanese and Dutch. Comparative linkage disequilibrium profiling across each of these two genes and test of allelic/haplotypic association using high density ImmunoChip case-control genotype data (available as part of the IIBDGC project) were performed in this study. Of the 28 SNPs in *CFB* on the ImmunoChip, single SNP analysis showed similar strength of association for rs4151657, the intronic SNP identified in our GWAS, in NI (p=1. 73x10-10) and Japanese (p=2. 02x10-12) UC cohorts but not in the Dutch. Further, a three marker haplotype namely rs17201431-rs2072634-rs4151657 was shared across NI and Japanese (p <10-8), but a different five marker haplotype namely rs4151651-rs4151652-rs17201431-rs512559-rs537160 was significantly associated (p = 2. 07x10-6) in the Dutch population. Of the 22 SNPs in *SLC44A4*, NI UC GWAS index SNP rs2736428 was found significantly associated in NI (p = 4. 94 x 10-10) and Japanese (p = 3. 37 x 10-9) UC cohorts, but not among the Dutch. This study suggests apparent allelic heterogeneity in *CFB* and genetic heterogeneity in *SLC44A4* across the three different ethnic groups. It also highlights that re-exploration of GWAS findings together with high density genotyping/sequencing and trans-ethnic fine mapping approaches may help identify shared as well as population specific risk variants, which holds promise to explain the missing disease heritability.

772F

Epigenetic marks are strongly enriched in IBD fine-mapped variants. *M. UmićevićMirkov[1], H. Huang[2, 3], M. Fang[4], L. Jostins[5], G. Trynka[1], M. Georges[4], M. Daly[2, 3], J. C. Barrett[1] on behalf of International the IBD Genetics Consortium.* 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston MA; 3) Broad Institute of MIT and Harvard, Cambridge MA; 4) Unit of Animal Genomics, Groupe Interdisciplinaire de Génoprotéomique Appliquée (GIGA-R) and Faculty of Veterinary Medicine, University of Liège (B34), Liège, Belgium; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Headington, UK.

Genome wide association studies have been very successful in identifying genetic regions associated with inflammatory bowel disease (IBD) risk, with the most recent GWAS reporting 163 IBD-risk loci. Nevertheless, evidence that the causal variant has been conclusively identified exists for only a small number of these loci. Protein coding variants are the most straightforward to interpret in terms of functional impact, and are responsible for the vast majority of highly penetrant rare disease causing variants identified, yet previous estimates suggest that protein coding variants are causally responsible for less than 20% of GWAS effects. Recent studies have shown that GWAS associated variants are enriched for cell type specific epigenetic marks, offering possible insight into the function of non-coding variants. Here, we integrated predictions of causality for each of the variants in associated regions, generated by a set of Bayesian fine-mapping methods run on Immunochip data in 66,849 individuals, with H3K4me1, H3K4me3 and H3K27ac chromatin mark annotations. We overlaid individual SNP's posterior probabilities of causality from 116 independent associations on chromatin mark annotations in 120 adult and fetal tissues, assayed by the NIH Roadmap Epigenomics Mapping Consortium. We summed posterior probabilities across all chromatin mark peaks in each of the 120 cell types. Expected values and enrichment p-values were calculated by shifting chromatin marks randomly over the fine-mapped regions and calculating sum of posterior probabilities for each permutation. We observed significant enrichment of H3K4me1 marks (p-value<1E-4) in several immune cell types and for H3K27ac in three GI samples (sigmoid colon and colonic and rectal mucosa). Further, we defined a set of "core immune peaks" for H3K4me1 and "core intestinal peaks" for H3K27ac as the intersection of peaks in cells that showed the strongest enrichment. For each of these sets we also created a set of "control" peaks made up of intersecting peaks from fine-mapped region in non-immune and non-intestinal cell types. We observed highly significant enrichment of both "core immune" H3K4me1 and "core intestinal" H3K27ac peaks in comparison to their respective controls. Our results suggest that large portion of IBD risk variants may ultimately be explained by functional variation in cell type-specific regulatory elements.

773W

Dissection of *HLA* class II in Japanese primary biliary cirrhosis: epistasis of protective *HLA-DQ* allele and additional contribution of *HLA-DP* allele. *M. Yasunami[1], H. Nakamura[1,2], K. Tokunaga[3], M. Kawashima[3], N. Nishida[3,4], Y. Hitomi[3], M. Nakamura[2,5,6].* 1) Institute of Tropical Medicine, Nagasaki University, Nagasaki, Japan; 2) Clinical Research Center, National Hospital Organization Nagasaki Medical Center, Omura, Japan; 3) Department of Human Genetics, Graduate School of Medicine, the University of Tokyo, Tokyo, Japan; 4) Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 5) Department of Hepatology, Nagasaki University Graduate School of Biomedical Sciences, Omura, Japan; 6) Headquarters of PBC Research in the NHO Study Group for Liver Disease in Japan (NHOSLJ), Omura, Japan.

Recent genome-wide association studies (GWAS) of primary biliary cirrhosis (PBC) have consistently identified significant association signals with the markers in the *HLA* region on the short arm of chromosome 6 at the highest levels of significance. In the present study, the contribution of chromosomes harboring certain HLA alleles in the GWAS SNP signals was evaluated by the determination of the alleles of seven classical *HLA* loci (*HLA-A*, *-B*, *-DRB1*, *-DQA1*, *-DQB1*, *-DPA1* and *-DPB1*) in 1200 Japanese patients with PBC and 1196 controls who underwent GWAS, for the better understanding of*HLA*-associated genetic risk of PBC. When the dominant model of either predominant or less frequent allele of 4103 SNPs in the *HLA* region was applied, 305 SNPs showed significant signals with p values less than 5 x 10-8, and a SNP (rs9268644) near the *HLA-DRA* locus gave the minimal p value (p = 5. 64 x 10-24). HLA analyses identified four independent *HLA-DR-DQ* alleles satisfying after Bonferroni's correction for multiple comparisons (p < 5. 75×10-4):*DQB1*06:04* (odds ratio: 0. 19, p = 1. 91×10-22), *DQB1*03:01* (odds ratio: 0. 50, p = 6. 76×10-10), *DRB1*08:03* (odds ratio: 1. 75, p = 1. 01×10-7) and *DQB1*04:01* (odds ratio: 1. 50, p = 9. 20×10-6). Association signals of SNPs in the HLA region were mostly attributable to four major *DR-DQ* alleles, which were demonstrated by the stepwise exclusion of *DR-DQ* factors. In the absence of while four *DR-DQ* factors, certain SNPs in the *DP* loci remained significant, which were mostly explained by the protective effect of *DPB1*02:01* (odds ratio: 0. 50, p = 3. 08×10-7 in the absence of four major *DR-DQ* alleles). Further a non-reciprocal "epistatic" interaction of protective *DQB1*06:04* to the risk conferred by *DRB1*08:03* was demonstrated by subpopulation stratification, implicating the presence of active suppression mechanism for pathogenic autoimmune reactions. In conclusion, genetic association of SNPs in *HLA* region with PBC was explained by the effect small number of *HLA* alleles in Japanese, with a special contribution of protective alleles such as *DQB1*06:04, DQB1*03:01* and *DPB1*02:01*.

774T

Identifying autosomal variants that differ in frequency between males and females and implications for sex-based differences in disease. *S. M. Raj[1], A. L. Williams[2], H. Hakonarson[3], A. G. Clark[1].* 1) Dept. Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Dept. Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 3) Center for Applied Genomics, The Children's Hospital of Philadelphia, University of Pennsylvania, Philadelphia, PA.

Many disorders, including common, complex diseases and severe autoimmune and metabolic diseases, have different severity in males and females. Some diseases, including systemic lupus erythematosus and multiple sclerosis, are heavily skewed toward affecting females, while others such as autism and attention deficit/hyperactivity disorder show markedly increased incidence in males. Moreover, the associated symptoms of various diseases often differ between males and females. Many non-disease related, sex-differential traits have been associated with polymorphisms on the X chromosome, but relatively few studies have critically examined sex-based autosomal differences on a genome-wide scale. We hypothesize that some of the differences in disease state and etiology between the sexes may result in sex-specific differential survival at autosomal loci that confer sex-specific effects on disease. If these effects are sufficiently strong, they would manifest as male-female differences in SNP and haplotype frequencies. Using genome-wide genotype data on a diverse collection of 58,000 individuals (primarily European Americans and African Americans) as well as data on 10,000 Europeans from the Wellcome Trust Case-Control Consortium (WTCCC2), we identified SNPs that significantly differed in frequency between males and females ($Z \geq |4|$), even after correction for multiple testing and population structure. We identified regions of the genome enriched for genes involved in immune function, and some evidence that the haplotypes on which these variants are located may have sex-specific fitness consequences. These results suggest that autosomal loci may also have substantial sex-specific phenotypic consequences.

775F

Targeted sequencing of familial idiopathic scoliosis regions of interest on chromosomes 1, 6, 9 and 16. *C. M. Justice[1], E. Baschal[2], C. I. Wethey[2], K. Swindle[2], N. H. Miller[2], A. F. Wilson[1], NIH Intramural Sequencing Center.* 1) Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, MD; 2) Department of Orthopedics, University of Colorado Anschutz Medical Campus, Aurora, CO.

Idiopathic scoliosis (IS) is characterized by a lateral curvature of the spine greater than ten degrees documented by radiographic analysis, which presents in the late prepubertal period in otherwise phenotypically normal individuals. Approximately 2 to 3% of the pediatric population has IS. If an individual with IS has a family history of the disease, it is referred to as Familial Idiopathic Scoliosis (FIS). Targeted Next Generation Sequencing (NGS) methods were used to sequence previously identified linkage regions [Miller et al. 2005] on 1p36, 1q31, 9q33, 16p12 and 16q11 in 174 individuals from 20 families with FIS in order to identify variants responsible for FIS in both coding and noncoding regions. Each family included a minimum of 2 affected individuals with an average family size of 7 individuals. A 2 Mb region on 6q24, encompassing *GPR126,* an IS candidate gene previously identified in a genome-wide association study of a large case/control Japanese population and replicated in a Han Chinese and European-ancestry population [Kou et al. 2013], was also sequenced. Standard QC and filtering methods were used to clean the sequence data. Linkage analysis (MERLIN), and association analysis (PLINK DFAM) were performed on 216,229 single nucleotide variants (SNVs). From the tests of intrafamilial association, 93 SNVs were significant at a level of $p < 1 \times 10\text{-}3$, and 5 SNVs were significant at $p < 1 \times 10\text{-}5$ over all targeted regions. Of the five SNVs significant at a critical value of $1 \times 10\text{-}5$, all were in non-coding regions and four were located within 600 Kb of the *GPR126* locus. Rare variants (MAF < 0. 01) located in exonic regions were prioritized based on: 1) location of the variant in a linkage region and/or in linkage disequilibrium (LD) with associated region, and 2) segregation of the missense variant with the disease phenotype in one or more families. Rare missense variants were identified in several loci. Of note, three SNVs found in our sample cause missense changes in *GPR126*; however, these missense variants were not present in all individuals with IS within a family, and were not significant for association analysis of the whole sample ($p < 0.1$). These results suggest that functional variation in non-coding regulatory regions on chromosomes 1, 6 and 16 may contribute to the FIS phenotype.

776W

CANDIDATE GENE POLYMORPHISMS AS RISK FACTORS FOR PRIMARY KNEE OSTEOARTHRITIS IN ASIAN INDIANS. *s. Poornima[1], p. subramanyam[2], q. hasan[2].* 1) Genetics, Kamineni Hospitals, Hyderabad, india, India; 2) orthopedics, kamineni Hospitals, hyderabad, India.

Primary Osteoarthritis (OA) also know ‘’Degenerative arthritis” is a progressive and irreversible pathology, which is considered as a part of the ageing process. It affects all the joints of the body, predominantly affecting large joints. Symptoms of OR are pain, swelling stiffness and limitations of joint movements. It is estimated that ~10 % of the world’s population ≥60 years have symptomatic OA. At present therapy for OA is only palliative and includes the use of pain relieving medicines, physical, exercise and joint replacement surgery. The increasing incidence of OA in individuals below the age of 60 years and the fact that several members of a single family are affected suggests a genetic predisposition. Current evidence indicates an important role of gene polymorphisms in the aetiology of complex diseases like diabetes, cardiovascular disease and arthritis. Three candidate gene polymorphisms (i)- C1104T (rs143383) of Growth Differentiation Factor 5 (GDF5) (ii) Oligomeric Component of Golgi Complex (COG5) A2236G (rs4730250) and (iii) C242T (rs4673) of Cytochrome B-245 alpha chain (CYBA) have been selected for evaluation in the present study, which were selected based on published results (Kerkhof et al , 2010; Evangelaou et al, 2011 and Liu et al, 2013). Each of these genes are considered to be associated with re-modeling of bones and cartilage. Primary osteoarthritis patients diagnosed clinically and radiologically were included in the study after approval from institutional ethical committee. A total of 900 PCRs were carried out from 300 cases and age, sex matched controls. All individuals belonged to the Asian Indian population. Results demonstrate that the GDF5 1104T (1. 3929 95% CI 0. 9925-1. 9546 p<0. 05), COG5 2236G (2. 0997, 95% CI 1. 5162-2. 9078, p<0. 0001) and CYBA 242T (7. 1005 95% CI 4. 9547-10. 1755 p<0. 0001) were significantly associated with primay OA in our population similar to what was observed in Caucasian patients. Multi -dimensional reduction (MDR) analysis for these three gene polymorphisms showed a strong synergistic interaction between CYBA with GDF(26. 32%) and COG5 (16. 15%) suggesting that the these polymorphisms can be used as biomarkers to assess the risk of knee OA in family members of Asian Indian patients, who can be counseled for a preventative life style.

Identification of genetic variants in Wnt-1-induced secreted protein 1 gene associated with bone mineral density in Old Order Amish. *X. Wang[1, 2], L. Yerges-Armstrong[1], Z. L. Deng[2], J. Perry[1], C. Hong[1], A. Parihar[1], H. Wang[1], Y. B. Zhu[1], Z. Y. Hu[1], E. A. Streeten[1], A. R. Shuldiner[1], B. D. Mitchell[1], M. Fu[1].* 1) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School, baltimore, MD 21201, USA; 2) Department of Orthopaedic Surgery, Second Affiliated Hospital of Chongqing Medical University, Chongqing 400010, China.

Wnt-1-induced secreted protein 1 (WISP1) is a novel target of the Wnt pathway for modulating osteogenesis and improving bone strength. WISP1 is highly expressed in osteoblasts and perichondral mesenchyme and is up-regulated during fracture healing. Compared to wild-type mice, WISP1 knockout mice have lower bone mineral density (BMD) and transgenic mice with overexpressed human WISP1 have increased BMD. The aim of this study was thus to investigate the role of genetic variation in WISP1 as a determinant of BMD and osteoporosis-related traits in 1398 Old Order Amish (OOA) individuals. The OOA are a relatively homogenous population in terms of both genetic ancestry and lifestyle characteristics. We genotyped single nucleotide polymorphisms (SNPs) in the WISP1 gene coding regions using the Illumina Human Exome BeadChip and identified 3 missense SNPs passing quality control thresholds (rs35513885, rs72731540 andrs3739261) and having a minor allele frequency >7% in the OOA. The T allele of rs35513885 (A118S) was significantly associated with higher BMD at the total hip (P=2. 07×10-4, P-value with adjustments for age, age2and gender), and hip subregions including the intertrochanter (P=3. 19×10-4) trochanter (P=3. 96×10-4), and femoral neck (P=3. 93×10-4) as well as lower BMD in the lumbar spine (P=4. 91×10-3). We also found nominally significant association between the A allele of rs72731540 (V184I) and lower lumbar spine BMD (P=0. 043). These 2 SNPs were in high LD (D’=0. 91). In conclusion, we have demonstrated that genetic variants in the WISP1 gene are significantly associated with BMD at multiple skeletal sites in the OOA. These results in humans support a role for the WISP1 gene on influencing variation in BMD. Studies further characterizing variation in this gene and replication of this result in additional cohorts are warranted.

778F

A regulatory variant in the dopamine β-hydroxylase (DBH) gene is associated with nicotine dependence, smoking cessation, and pulmonary function. *D. B. Hancock[1], T. E. Thorgeirsson[2], N. C. Gaddis[1], G. W. Reginsson[2], N. L. Saccone[3], S. M. Lutz[4], M. S. Artigas[5], S. Steinberg[2], C. Glasheen[1], F. Gu[6], M. T. Landi[6], T. B. Baker[7], I. P. Hall[8], M. D. Tobin[5], S. J. London[9], N. E. Caporaso[6], K. Stefansson[2], J. E. Hokanson[4], L. J. Bierut[3], E. O. Johnson[1], CHARGE Consortium Pulmonary Working Group and SpiroMeta Consortium.* 1) RTI International, Research Triangle Park, NC, USA; 2) deCODE Genetics/Amgen, Reykjavik, Iceland; 3) Washington University in St. Louis, St. Louis, Missouri, USA; 4) University of Colorado Anschutz Medical Campus, Aurora, Colorado, USA; 5) University of Leicester, Leicester, United Kingdom; 6) National Cancer Institute, Bethesda, Maryland, USA; 7) University of Wisconsin, Madison, Wisconsin, USA; 8) University of Nottingham, Nottingham, United Kingdom; 9) National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, USA.

Nicotine dependence is a heritable trait that is one of the strongest predictors of smoking cessation. Our study evaluated the association between nicotine dependence and the only genome-wide significant SNP association reported for smoking cessation, rs3025343 near the dopamine β-hydroxylase (DBH) gene (TAG Consortium *Nat Genet* 2010). In a meta-analysis of 20,053 European ancestry participants from 8 independent samples with nicotine dependence defined by the Fagerström Test for Nicotine Dependence, we found that the rs3025343-G allele (frequency=12%) was associated with decreased nicotine dependence risk (*P*=1. 0×10-4, odds ratio [95% confidence interval] = 0. 92 [0. 88-0. 96] for severe vs. mild dependence). Next, using the Brain expression quantitative trait loci (eQTL) Almanac dataset comprised of post-mortem tissue of 10 different brain regions from 134 European ancestry participants, we found that the rs3025343-G allele was associated with reduced *DBH* expression in the dopamine-rich substantia nigra (P=7. 6×10-4), a highly relevant brain region given that DBH functions to catalyze the conversion of dopamine to norepinephrine in the synaptic vesicles of noradrenergic neurons. We next extended the rs3025343 association testing to pulmonary function measures, which are used clinically to diagnose and follow the progression of lung disease and are adversely impacted by cigarette smoking. In meta-analyses of more than 48,000 European ancestry participants from 19 or more samples, the G allele of rs3025343 was positively associated with the ratio of forced expiratory volume in one second to forced vital capacity, accounting for ever smoking history (*P*=2. 5×10-3, Soler Artigas et al. *Nat Genet* 2011) and further accounting for current smoking history, pack-years of smoking, and SNP-by-smoking interaction terms (lowest *P*=2. 1×10-3, Hancock et al. *PLoS Genet* 2012). The observed directions were all consistent with the rs3025343-G allele being associated with (1) reduced *DBH* expression in substantia nigra, (2) decreased risk of nicotine dependence, (3) increased smoking cessation success as previously reported, and (4) higher pulmonary function. Our findings thus highlight rs3025343 as a potential regulatory variant associated with cigarette smoking and an important smoking-related outcome.

779W

Ultra-deep sequencing to identify somatic genetic variations in the brain in Alzheimer disease and during aging. *H. T. Helgadottir[1], L. Lilius[2,3], A. K. Lindström[2,3], C. Graff[2,3], M. Eriksson[1].* 1) Karolinska Institutet, Department of Biosciences and Nutrition, Center for Innovative Medicine, SE-141 57 Huddinge, Sweden; 2) Karolinska Institutet, Department of NVS, Center for Alzheimer Research, Division for Neurogeriatrics, SE-141 57 Huddinge, Sweden; 3) Dept of Geriatric Medicine, Karolinska University Hospital-Huddinge, SE-141 86 Stockholm, Sweden.

The accumulation of mutations in cells over time is predicted to create increased genetic mosaicism in the tissue that may contribute to the declined homeostasis seen with aging. Alzheimer disease (AD; MIM 104300) is a neurological disorder that mainly affects elderly people and causes cognitive dysfunction. The main neuropathological findings are amyloid plaques, neurofibrillary tangles, loss of neurons, and decreased brain volume. However, these findings can also be found in the brains of older unaffected individuals and suggest that neurodegeneration is a more common effect of aging than previously anticipated. AD has been classified into early-onset and late-onset, and although early-onset AD may show autosomal transmission, known mutations account for less than 5% of all AD cases. Genome-wide association studies have revealed several loci conferring risk to AD, with the *APOE* gene (MIM 107741) being the main genetic risk factor. In this study we have used ultra-deep sequencing, aiming for >600X average depth, to investigate somatic mutations in the temporal cortex from AD patients in addition to non-AD controls. Samples included both early-onset AD (45-50 years of age) and late-onset AD (70-90 years of age) as well as brain samples from controls, matched for APOE, gender and age. In addition, DNA samples from blood from all the individuals were included in the study. Custom made arrays from Roche-Nimblegen (SeqCap EZ Choice Library) capturing 2. 85 Mb of the genome was used for sequencing. Our analysis focuses on rare somatic mutations and we hope to identify low-degree somatic mutations that might contribute to aging. We expect the mutations to be more common in older individuals compared to younger and to be able to make an estimate of the prevalence of mosaicism in the brain by comparing different tissues and ages. So far, only few studies have investigated genetic variation in the brain and this will provide an opportunity to detect genetic variation in aging and/or AD, and its contribution to the declined tissue homeostasis.

780T

Genetic Susceptibility for Asthma in Two Resource-Limited Settings in Peru. *W. Checkley[1,2], C. Vergara[5], C. Robinson[1], L. Baumann[1], K. Romero[3], R. Gilman[2], R. Wise[1], K. Barnes[6], N. Hansel[1,4], PURA Study Investigators.* 1) Division of Pulmonary and Critical Care, School of Medicine, Johns Hopkins University, Baltimore, MD; 2) Program in Global Disease Epidemiology and Control, Department of International Health,Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD; 3) Biomedical Research Unit, A. B. PRISMA, Lima, Peru; 4) Department of Environmental Health Sciences, Bloomberg School of Public Health, Johns Hopkins University, Baltimore,MD; 5) Division of Infectious Diseases, School of Medicine, Johns Hopkins University, Baltimore, MD; 6) Division of Allergy and Clinical Immunology, School of Medicine, Johns Hopkins University, Baltimore, MD.

Genetic and environmental exposures related to urbanization are known to be associated with childhood asthma. Peru has the highest rates of asthma in Latin America and one of the highest worldwide. A higher prevalence and severity of asthma is observed in urbanized environments of Peru compared to rural areas. We sought to determine whether genetic susceptibility contributed to asthma and high total IgE (tIgE) levels in two regions of Peru with disparate degrees of urbanization. We analyzed 620 children from Lima (79 asthmatics, 541 non-asthmatics) and 651 children form Tumbes (20 asthmatics, 631 non-asthmatics) with similar age and gender distributions. Total IgE levels were determined in serum by ELISA. 78 SNPs in the genes ADAM33, CD14, GSTM1, GSTP1, IL4, IL13, IL1RL1, TSLP and IL33 were genotyped using the VeraCode technology. The SNPs were previously associated with asthma in GWAS. Population stratification was corrected using 384 ancestry informative markers. Comparisons of allelic frequencies were performed between asthmatics and non-asthmatics in each site and between non-asthmatics from Lima and Tumbes. A P value<0. 05 was considered as significant. We found that SNPs in IL33 were significantly associated with asthma in Lima (rs10975514, rs10975516, rs1332290) and Tumbes (rs16924243, rs12000491). One SNP in GSTM1 (rs2239892) was significantly associated with asthma in Lima and, polymorphisms in ADAM33 (rs598418, rs487377) and ILR1 (rs10204137) showed a significant association in the case-control analysis in Tumbes. Three markers in IL1RL1 (rs2160203, rs10204137, rs10206753) were associated with high tIgE levels in Lima. Rs11905870 (ADAM33) and rs11466750 (TSLP) were associated with tIgE levels in Tumbes. There was a significant difference in the allelic frequency of SNPs in IL13 (rs1295687), IL33 (rs1412420 and rs12000491), ADAM33 (rs3918395, rs487377), IL4 (rs2243252, rs2243253), ILR1 (rs10204137) and TSLP (rs10062929) between non-asthmatics from Lima and Tumbes after correcting with two PCAs. SNPs in candidate genes were identified as risk factors for asthma and high IgE levels within the populations of Lima and Tumbes. Those polymorphisms also showed a significantly different distribution in children without asthma between both sites. Further studies are needed to elucidate if the differences in the genetic component play a role in the observed differences in the prevalence of asthma between an urban and rural environment.

781F

***SLC2A9* sequence variants and serum uric acid concentrations in American Indians: The Strong Heart Family Study.** *G. Chittoor[1], K. Haack[2], S. Laston[3], LG. Best[4], JW. MacCluer[2], JG. Umans[5], SA. Cole[2], VS. Voruganti[1].* 1) Nutrition and Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC; 2) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 3) South Texas Diabetes and Obesity Institute and Regional Academic Center, School of Medicine, University of Texas Health Science Center at San Antonio/University of Texas Rio Grande Valley, Brownsville, TX; 4) Missouri Breaks Industries Research Inc. , Timber Lake, SD; 5) Medstar Health Research Institute, Hyattsville, MD.

Background: Increased serum uric acid (SUA) is a risk factor for gout, renal and cardiovascular disease. The variation in SUA concentrations is under significant genetic influence. Various population studies have shown strong association of SUA concentrations with solute carrier family 2, member 9 (*SLC2A9*), a uric acid transporter gene. Our objective was to identify *SLC2A9* sequence variants and analyze their association with SUA concentrations in a family-based study of American Indians, the Strong Heart Family Study. **Methods:** We sequenced 96 kb of the *SLC2A9* gene using Illumina's TruSeq Custom Amplicon and MiSeq Sequencer in 1118 founders of multigenerational families. Sequence data were aligned to the Human Genome Reference Sequence version 37. 1 (hg19). Variants were called, recalibrated and QC'd using the Genome Analysis Toolkits (GATK v. 3. 3) Haplotype Caller. Of the 427 variants, 233 were single nucleotide polymorphisms (SNPs), 125 were single nucleotide variants (SNVs), 26 were singletons, and 43 were indels/triallelic. Based on comparison with dbSNP database, 117 SNPs were novel. The minor allele frequencies (MAFs) of all variants ranged between 0. 1% and 49%. The association of SNPs with SUA was estimated using a measured genotype analysis accounting for family relationships in SOLAR. The appropriate significance level was determined to be $p < 3 \times 10\text{-}4$ after correcting for multiple tests. **Results:** Strong association was observed between SUA concentrations and *SLC2A9* SNPs ($p < 6 \times 10\text{-}12$). A total of 96 SNPs were associated at the significance level of < 3 x10-4; of which, for example, rs3775946 (A), rs7663032 (C), rs6826764 (G), rs7696983 (A), rs7669090 (C) have not been previously associated with SUA concentrations, and one SNP (chr_pos: 4_10027969) was found to be novel (MAF between 26 and 42%; the effect sizes ranged from 3. 6 to 4. 8%). Our results also showed that the minor alleles of these SNPs were associated with lower SUA concentrations. None of the rare variants were significantly associated with SUA concentrations. **Conclusions:** Our results indicate the importance of common sequence variants in *SLC2A9* in the regulation of SUA concentrations and demonstrate that rare variants of potentially functional effect remain to be discovered in American Indians.

782W

Association of long intergenic non-coding RNA SNP near *MYLIP* (6p23-p22) with Healthy Aging Index: The Long Life Family Study (LLFS). *M. F. Feitosa[1], R. L. Minster[2], M. K. Wojczynski[1], A. M. Matteini[3], R. Mayeux[4], N. Schupf[5], T. T. Perls[6], K. Christensen[7,8], A. B. Newman[9], M. A. Province[1].* 1) Department of Genetics, Washington University School of Medicine, St. Louis, MO; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, PA; 3) Division of Geriatric Medicine and Gerontology, School of Medicine, Johns Hopkins University, Baltimore, MD; 4) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY; 5) Taub Institute, College of Physicians and Surgeons, Columbia University, New York, NY; 6) Section of Geriatrics, Department of Medicine, Boston University, Boston School of Medicine and Boston Medical Center, MA; 7) The Danish Aging Research Center, Epidemiology, University of Southern Denmark; 8) Department of Clinical Genetics and Department of Clinical Biochemistry and Pharmacology, Odense University Hospital, Odense, Denmark; 9) Department of Epidemiology Graduate School of Public Health, University of Pittsburgh, PA.

Elevated level of low-density lipoprotein (LDL) cholesterol is associated with cognitive decline and dementia, and with systolic blood pressure (SBP) in diabetic patients. These diseases may lead to an increased risk of death. We developed a mortality-optimized healthy aging index (HAI-M) that captures these multiple systems and predicts mortality. SBP, pulmonary vital capacity (FVC), modified-mini-mental-status-examination-score (MMSE), creatinine, and glucose were used to generate HAI-M. We hypothesize that SNPs (N = 30 at p < 5E-08) found to be genome-wide associated with LDL in the Global Lipids Genetics Consortium will contribute to HAI-M variability. Association analysis was performed using family mixed model in 3,534 European descent subjects. We found evidence of association between rs3757354 with HAI-M in men (p = 4. 99E-4, beta = -0. 15 ± 0. 04), but not in women (p = 0. 18). Further, we investigated if rs3757354 was associated with each HAI-M component. Rs3757354 was also significantly associated with FVC in men (p = 1. 40E-3) and with MMSE in all data (p = 4. 12E-3). Rs3757354 is in the exon of a lincRNA and is approximately 2kb upstream of *MYLIP*. It encodes the E3 ubiquitin ligase myosin regulatory light chain-interacting protein, which promotes degradation of the LDLR and participates in the inhibition of neurite outgrowth. In neurons, *MYLIP* induces reelin, which down-regulates *VLDLR*, decreasing VLDL levels. Reelin signaling is also associated with neurological disease. Rs3757354 overlaps several potential regulatory markers: (i) DNase hypersensitivity, (ii) binding motifs for transcriptional factors JUND (protects cells from p53-dependent senescence and apoptosis), and EGR1 (involved in neuropathology), and (iii) enhancer (H3K4Me1). Our findings highlight the biological importance of 6p22-p23 to healthy longevous subjects. Further investigations are needed to determine if rs3757354 regulates *MYLIP* and/or other more remote genes with male-specific effects on HAI-M and FVC but in both sexes for cognitive function.

783T

Variation in kidney structure-related genes in African Americans with type 2 diabetes- associated end-stage kidney disease. *M. Guan[1,3], J. Ma[2,4], J. Keaton[3], M. Stromberg[3], P. Mudgal[3], B. I. Freedman[4], D. W. Bowden[3,5,6], M. C. Y Ng[3,5].* 1) Integrative Physiology and Pharmacology Program, Wake Forest School of Medicine, Winston-Salem, NC, USA; 2) Department of Nephrology, Ruijin Hospital, Shanghai Jiaotong University School of Medicine, Shanghai, China; 3) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC, USA; 4) Department of Internal Medicine/Nephrology; Wake Forest School of Medicine, Winston-Salem, NC, USA; 5) Center for Diabetes Research; Wake Forest School of Medicine, Winston-Salem, NC, USA; 6) Department of Biochemistry; Wake Forest School of Medicine, Winston-Salem, NC, USA.

Familial aggregation supports that genetic factors contribute to diabetic and non-diabetic end-stage kidney disease (ESKD) susceptibility in African Americans (AAs). Structural abnormalities in the kidney occur with progression of diabetic kidney disease. The contribution of genetic variants in kidney structure-related genes in AAs with type 2 diabetes (T2D) associated-ESKD has not been systematically evaluated. Therefore, a collection of 49 genes important in kidney structure, including podocyte, glomerular basement membrane (GBM), mesangial cells and matrix, and renal tubule and interstitium was tested. Genotyping of tag SNPs for the selected genes was conducted using an Affymetrix Biobank custom genotyping array. Single variant association analysis was performed for each gene using a linear mixed model based method (MMM) in 2,005 AA T2D-ESKD cases (S1), 1,031 AA non-diabetic non-nephropathy controls (S2), and 630 AA T2D non-nephropathy samples (S3). A total of 19 SNPs from 17 regions demonstrated nominal associations (P<0. 01) with T2D-ESKD (S1 vs. S2) after conditioning on age and gender (Controlling for *APOL1* risk gave similar results). The most significant signal rs201234802 (P<7. 08e-5), a missense variant, was observed at *ATP6V11* (expressed in renal tubules). In addition, 21 SNPs were associated with ESKD (S1 vs. S3) at P<0. 01. Subsequent replication was performed on SNPs with strong evidence of association with T2D-ESKD in an additional 915 AA non-diabetic ESKD cases (S4) and 518 healthy AA controls (S5). 4 SNPs replicated nominal association with ESKD (S4 vs. S5). Meta-analysis combining T2D-ESKD and non-diabetic ESKD (S1+S4 vs. S2+S3+S5) revealed 8 SNPs from 5 loci (*CFH*, *NPHP3*, *ARHGAP24*, *TRPC6*, *COL4A2*) associated with all-cause ESKD (P<0. 05). The top hit was a missense variant rs35485382 (P=0. 0026) located in the *NPHP3* region. Notably, two additional SNPs in the *NPHP3* region (rs78174962, P= 0. 039; rs74504809, P=0. 044) were also associated with all-cause ESKD. These results indicate that variation in genes regulating kidney structure may contribute to the predisposition to T2D-ESKD and non-diabetic ESKD in AAs.

Rs738409 Polymorphism in *PNPLA3* gene is associated with lower insulin resistance in Korean Men. *J. Park.* Family medicine, Seoul National University Hospital, Seoul, Seoul, South Korea.

Background & Aims: The rs738409 polymorphism in adiponutrin is a well-known genetic risk factor for nonalcoholic fatty liver disease (NAFLD) development. When we consider that NAFLD is closely associated with insulin resistance, the association between rs738409 variant and insulin resistance is highly suspected. **Methods**: We screened 1,648 Korean men who visited the Health Promotion Center of Seoul National University in Seoul, South Korea from December 2009 to June 2012 and 1,189 were enrolled in final analysis. Hepatic steatosis was evaluated by abdominal ultrasound and subjects with secondary causes of NAFLD or alcohol consumption of more than 30g/day were excluded from NAFLD classification. Serum glucose and insulin levels were measured using overnight fasting blood sample. The homeostasis model assessment estimated insulin resistance (HOMA-IR) index was calculated by multiplying glucose in mg/dl by insulin in μU/ml/405. The cutoff value of 2. 56 was used for insulin resistance diagnosis as previously reported in Korean men. HOMA-IR index values were natural log-transformed after normality test. Rs738409 genotyping was performed using TaqMan assay on a ViiATM 7 Real-Time PCR System (Life Technologies, California, USA). **Results**: The participants were predominantly middle-aged men (49. 1 ±7. 0 years; range, 30-60 years), and the frequencies of NAFLD and insulin resistance were 43. 7% and 17. 5%. We performed multivariate regression analysis after adjustment for NAFLD status. The rs738409 CG and GG genotype showed lower mean levels of HOMA-IR index compared to the CC genotype (P = 0. 031 and < 0. 001, respectively. Then, we checked the effect of the rs738409 G allele on HOMA-IR index levels in each NAFLD and non-NAFLD subgroup stratified by NAFLD status using one-way ANOVA. In the non-NAFLD group, the CG and GG genotypes compared to the CC genotype showed significantly lower mean levels of HOMA-IR index in an additive manner (Sidak-corrected P = 0. 018 and < . 001, respectively); however, in the NAFLD group, those inverse associations were not shown. **Conclusion**: The adiponutrin polymorphism rs738409 known as a NAFLD genetic risk factor was also associated with decreased levels of insulin resistance assessed by HOMA-IR index, and the inverse association was prominent in subjects without NAFLD.

Genetic Associations between Human Leukocyte Antigen-DQA1 Typing and Gallstone Disease in Han Chinese. *H. Yang[1,2], S. Shih[1,2,3,4], T. Chang[2], H. Wang[1,3], M. Lin[2], Y. Lien[2], Y. Lee[2,4,5,6,7].* 1) Mackay Junior College of Medicine, Nursing and Management, Taipei, Taiwan; 2) Medical Research, Mackay Memorial Hospital, New Taipei City, Taiwan; 3) Division of Gastroenterology, Department of Internal Medicine, Mackay Memorial Hospital, Taipei, Taiwan; 4) Department of Medicine, Mackay Medical College, New Taipei City, Taiwan; 5) Department of Pediatric Endocrinology, Mackay Children's Hospital, Taipei, Taiwan; 6) Department of Pediatrics, School of Medicine, College of Medicine, Taipei Medical University, Taipei, Taiwan; 7) Institute of Biomedical Sciences, Mackay Medical College, New Taipei City, Taiwan.

AbstractBackground and Goal: Biliary crystals in gallbladder induce latent and persist inflammatory responses and affect extra-hepatic bile ducts and multiple symptoms called gallstone disease (GSD). The pathology and environmental risk factors of GSD are well documented. However, lack of immune or inflammatory responses of genetic regulation in GSD development. Major histocompatibility complex (MHC) class II, HLA-DQA1 typing is correlated with many gastrointestinal disorders. In this study, we investigated whether typings of the *HLA-DQA1* gene were associated with GSD susceptibility. **Methods:** Genomic DNA was isolated from whole blood samples of 466 patients with GSD and 385 gallstone-free controls. HLA-DQA1 polymorphisms were genotyped using SBT. **Results:** We did not find any association between HLA-DQA1 polymorphisms and gallstone disease.

Genotyping the Nord-Trøndelag Health Study (HUNT) Cohort Using an Exome+GWAS Array with All Stop-gain Variants in 96 Genes. *W. Zhou[1], O. L. Holmen[2,3], S. Vrieze[4], L. G. Fritsche[5], H. Zhang[6], J. Chen[6], M. Boehnke[5], K. Hveem[2,7], C. J. Willer[1,6,8], G. R. Abecasis[5].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America; 2) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, 7600 Levanger, Norway; 3) St. Olav Hospital, Trondheim University Hospital, Trondheim, Norway; 4) Institute for Behavioral Genetics, University of Colorado, Boulder, CO, 80309, United States of America; 5) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, Michigan, 48109, United States of America; 6) Department of Internal Medicine, Division of Cardiology, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America; 7) Department of Medicine, Levanger Hospital, Nord-Trøndelag Health Trust, 7600 Levanger, Norway; 8) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan, 48109, United States of America.

The Nord-Trøndelag Health Study (HUNT) in Norway is a population-based health study that has lasted more than three decades (www. ntnu. edu/hunt). DNA is currently available for ~70,300 participants. Previous genetic studies have examined targeted subsets of HUNT study participants to discover or replicate disease and complex trait-association signals, demonstrating the value of genetic analyses of HUNT study samples in uncovering novel biological underpinnings and therapeutic targets for a variety of traits. Typically, we see a high correlation of genetic effect sizes estimated in HUNT and other European samples (r2=0. 92 for lipid and cardiovascular disease associated variants, for example), indicating that association findings can be generalized to other European populations. Currently, we are genotyping ~70,300 HUNT participants using an Exome+GWAS array (HumanCoreExome, Illumina), comprised of >500,000 SNPs. We augmented the array with a catalog of potential stop-gain variants in 96 genes that would result in truncated and incomplete gene products because the effect of these variants on phenotypes may be easy to interpret. These 96 genes targeted for this detailed analysis include genes associated with type 2 diabetes, blood lipid levels, Alzheimer's disease, nicotine/alcohol metabolism, and several genes where mutations have been implicated in serious, but treatable, health conditions. In addition to these, we augmented the array with missense and stop-gain variants identified in previous whole genome sequencing of HUNT study participants, associated with any of >900 complex traits in the NHGRI GWAS catalogue, and with ancestry informative markers. The data resource will be used in genetic studies for a wide range of diseases and complex traits. At the meeting, we will describe initial quality control of the genotype data and comparisons with existing whole genome sequence data.

787F

Coding variants in *RREB1* are associated with type 2 diabetes and fasting glucose levels. *H. Kitajima[1], A. Mahajan[1], M. I. McCarthy[1,2] on behalf of GoT2D and T2D-GENES consortia.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, Oxford, United Kingdom.

Non-coding variants in *RREB1/SSR1* region have been shown to be associated with type 2 diabetes (T2D, rs9502570) susceptibility and fasting glucose (FG, rs17762454) levels in previous genome wide association studies (GWAS). We recently reported association of a coding variant in *RREB1* (Ser1554Tyr, MAF=21. 1%, *P*=8. 3x10-9) influencing FG levels among non-diabetic subjects. The biological mechanism driving these associations is not known and the relation between these associations driving FG and T2D signals is still unexplored. We sought to assess the impact of coding variation at this GWAS locus on both T2D susceptibility and FG levels in an attempt to highlight causal transcripts and facilitate identification of molecular mechanisms influencing the traits. We combined exome array data with exome sequencing from 92,794 (28,305 T2D cases, 51,549 controls) for testing association with T2D. We tested single variants for association with T2D using a linear mixed model to account for relatedness and combined association summary statistics by meta-analysis. The FG associated coding variant Ser1554Tyr, was associated with T2D at nominal significance (*P*=4. 9x10-5 in effective sample size 82,784). However, another coding variant in *RREB1*, rs9379084, coding for Asp1171Asn, showed a much stronger association with T2D (MAF=11. 1%, *P*=4. 0x10-9, effective sample size 56,339) despite smaller sample size. The non-coding GWAS variants were not present on the array, therefore, we used imputed GWAS data to explore their relationship. The coding variant association at *RREB1* (Asp1171Asn) was conditionally independent of the original common variant GWAS signal rs9502570 for T2D, indicating multiple risk variants at this locus. In addition, based on European haplotypes from the 1000 Genomes Project, Ser1554Tyr was more strongly correlated (*r2*=0. 59) with the T2D GWAS lead variant rs9502570 as compared to the FG GWAS lead rs17762454 (*r2*=0. 08), which might indicate presence of multiple FG association signals in this region. *RREB1,* encodes Ras-responsive element-binding protein 1, a zinc finger transcription factor that binds RAS-responsive elements of gene promoters. These data point to a likely functional role for *RREB1* at this locus, with separate and possibly multiple association signals for T2D, and for FG in non-diabetic individuals, although further studies are needed to confirm this hypothesis.

788W

Identifying Candidate Genes Associated with Non-syndromic Orofacial Cleft Risk in Puerto Rican Hispanics. *C. J. Buxó-Martínez[1], L. M. López-Del Valle[1], J. F. Cordero[2], N. Debs[1], M. I. Salcedo[1], L. García-Fragoso[3], M. Soto[1], K. K. Ryckman[4], N. Mukhopadhyay[5], M. Govil[5], A. Butali[6], M. L. Marazita[5], J. Murray[7].* 1) Office of the Assistant Dean of Research, School of Dental Medicine, University of Puerto Rico, San Juan, PR; 2) Dept. of Human Development, Graduate School of Public Health, University of Puerto Rico, San Juan, PR; 3) Dept. of Pediatrics, School of Medicine, University of Puerto Rico, San Juan, PR; 4) Dept. of Epidemiology, College of Public Health, University of Iowa, Iowa City, IA; 5) Dept. of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 6) Dept. of Oral Pathology Radiology and Medicine, University of Iowa, Iowa City, IA; 7) Dept. of Pediatrics, University of Iowa, Iowa City, IA.

Non-syndromic orofacial clefts, primarily cleft lip with or without cleft palate (nsCL/P) are among the most common birth defects, with an etiology including both genetic and environmental factors. Because there is limited knowledge about the epidemiology and risk factors for nsCL/P in Puerto Ricans, thus the study objective was to identify maternal exposures and genetic characteristics associated with nsCL/P risk in Puerto Rican children. Children aged 0-14 years with nsCL/P and their parents were recruited as case families (n=150, 98 triads with both parents and 52 dyads with 1 parent). Unaffected controls were selected within the same age range (n=160, 73 triads and 87 dyads). Forty-six single nucleotide polymorphisms were selected for this study from candidate genes/loci previously associated with nsCL/P in recent genome-wide association studies (GWAS). Genotyping was done using Taqman and Fluidigm. Transmission disequilibrium test (triads), logistic regression with/without covariates and gene-environment interaction (offspring) analyses were conducted using PLINK. Significant differences were found for maternal exposure covariates: alcohol consumption (p=0. 04) during pregnancy, and folic acid (p=0. 001) and multivitamin (p=0. 04) use 6 months before pregnancy. The TDT results were significant for *ABCA4* rs560426 (p=0. 02) and *CRISPLD2* rs4783099 (p=0. 02). We observed significant differences (p<0. 05) between cases and controls for *PAX7* rs742071, *ABCA4* rs4147811, *IRF6* rs2235371, *DYSF* rs7568834, but *MTHFR* rs1801131 was the only variant that met the Bonferroni significance level of 10-3. There was no evidence of gene-environment interaction between maternal exposure covariates and variants except for *MTHFR* rs1801131 and the peri-conceptional intake of folic acid before pregnancy (p=0. 04). Our findings may support a role for *MTHFR* rs1801131 variant in nsCL/P and provide specific variant allele frequencies and impact in Puerto Rican/Hispanic populations. Interaction with folic acid and multivitamin use and *MTHFR* should be evaluated in larger GWAS in Puerto Ricans since the strength and direction remains uncertain. Supported by the following grants: 1K99DE024571, 3R37DE008559-23S1, 8U54MD007587, R25RR017580, and U54RR026139.

Rare Variants in Previously Identified Linkage Region on Chromosome 7p Associated With Carotid Bifurcation Intima-Media Thickness in Dominican Families. *N. D. Dueker[1], A. Beecham[1], L. Wang[2], S. Blanton[2], C. Dong[2], S. Guo[1], D. Cabral[3], T. Rundek[3], R. L. Sacco[2,3].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Neurology, Epidemiology and Public Health, Miller School of Medicine, University of Miami, Miami, FL.

Thrombotic disorders including ischemic stroke (IS) and myocardial infarction (MI) are leading causes of death and disability in the US. Though both IS and MI are suggested to be genetically controlled, only a small proportion of the genetic risk for either has been identified. One method to identify genetic variants influencing IS and MI is to study intermediate phenotypes such as carotid intima-media thickness (cIMT), a subclinical measure of atherosclerosis. We have previously shown cIMT measures to be heritable and found evidence for linkage and association of common variants on 7p with carotid bifurcation IMT (BIF). Therefore, we aimed to further characterize the 7p region, hypothesizing that rare variants in this region are associated with BIF. To test this hypothesis, we sequenced the 1 LOD unit down region on 7p in nine extended families from the Dominican Republic with evidence for linkage to BIF in this region (family specific LOD score > 0. 1). Using these data, we performed the family-based sequence kernel association test (famSKAT) on 68 genes within the 7p region to identify those associated with BIF. Analyses were restricted to single nucleotide variants (SNVs) with minor allele frequency (MAF) <5% and a Bonferroni correction was applied to correct for 68 tests (p<0. 00074 considered significant). In our analysis of exonic rare variants, nucleotide-binding oligomerization domain 1 (*NOD1)* was our most significantly associated gene (p=0. 0009; # SNVs=14). This gene showed nominal evidence for replication in an additional sample of twelve extended families from the Dominican Republic with Exome Array data and family specific LOD score >0. 1 for BIF (p=0. 06; # SNVs=9). *NOD1* is an excellent candidate gene as it is expressed in the heart and atherosclerotic lesions have been found to have increased expression of *NOD1*. Furthermore, a study in mice found that administration of a NOD1 agonist led to fibrosis, cardiomyocyte apoptosis and cardiac dysfunction. In addition to *NOD1*, we also identified 15 moderately-associated genes with p<0. 05, including *AQP1* which encodes aquaporin-1, a protein that is present during vascular development and following vascular injury in rats. *AQP1* also showed nominal evidence for replication in our twelve replication families (p=0. 06; # SNVs=5). Taken together, our study provides suggestive evidence for a role of rare variants within our previously identified 7p region in BIF.

790F

Association of *APOE* E3/E4 With A Convex Facial Profile in Individuals diagnosed with Obstructive Sleep Apnea (OSA). *J. K. Hartsfield[1], L. L. Wachs[2], M. Elmahdy[2], J. Roedig[3], L. A. Morford[1], B. Phillips[4], P. Wardrop[5], J. E. Van Sickels[2], G. T. Kluemper[2].* 1) Center for the Biologic Basis of Oral/Systemic Diseases, Univ Kentucky, Lexington, KY; 2) College of Dentistry, Univ Kentucky, Lexington, KY; 3) Private Practice, Nashville, TN; 4) College of Medicine, Univ Kentucky, Lexington, KY; 5) Saint Joseph Sleep & Wellness Center, Lexington, KY.

Objective: Facial profile convexity has been associated with OSA in some but not all studies. *APOE* E4 has also been associated with obstructive sleep apnea (OSA) in some but not all studies. The purpose of this study was to determine the *APOE* alleles in patients with OSA to study potential relationships between the *APOE* alleles, facial profile (skeletal classification), AHI and/or BMI. We hypothesized that there would be an association between a skeletal Class II (convex) facial profile, AHI and/or BMI with certain *APOE* allele(s). Materials and Methods: One-hundred sixty-eight Caucasian OSA subjects (110 males and 58 females) with an AHI > 15 were recruited from two sleep clinics under IRB approval at the University of Kentucky. Subjects underwent an orthodontic clinical exam and lateral photograph-based profile assessment and measurement to determine their facial (Angle) classification (Class I=straight; Class II=-convex; Class III=concave). Exclusion criteria included edentulism, or previous orthodontic treatment. BMI was calculated from clinical chart information. Genomic DNA was isolated from patient saliva and genotyped by Taqman® methodology with the *APOE* allele-defining SNPs, rs429358 and rs7412. Kruskal–Wallis, and chi-squaretests were used to analyze the data using JMP-PRO-10, with significance at 0. 05. Results: No difference (p=0. 3) was observed in AHI amongst the three facial skeletal classifications. Combining the Class I and III groups into a “non-Class II” vs the Class II group was also not significant for AHI (p=0. 3). Class II subjects had significantly lower (p=0. 004) BMI than skeletal Class I or III classified individuals. Both *APOE* genotypic distributions were in Hardy-Weinberg equilibrium (p= 0. 14). While BMI was not associated with any particular combination of inherited *APOE* alleles (p=0. 4), inheriting the E3/E4 alleles together was statistically significant when comparing the Class II versus “non-Class II” group (p=0. 012). Conclusion: This data is suggestive that BMI is lower in the OSA patients with a Class II facial convexity. *APOE* E3/E4 is associated with Class II facial convexity in OSA subjects, but not with BMI. This finding implies a genetic connection between *APOE* and facial growth only, and not between APOE and BMI in OSA patients. Skeletal remodeling variation with *APOE* E4 could be a mechanism to be investigated.

791W

Large-scale integrative fine-mapping over 22 complex traits with over 3. 3 million phenotypic measurements. *G. Kichaev[1], H. Shi[1], M. Roytman[1], B. Pasaniuc[1,2,3].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, Los Angeles, CA, 90095; 2) Dept. of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA. 90095, USA; 3) Dept. of Pathology and Laboratory Medicine,David Geffen School of Medicine University of California Los Angeles, Los Angeles, CA. 90095, USA.

Identification of causal variants underlying GWAS risk loci remains one the main challenges in the post-GWAS era. This is typically accomplished in fine-mapping studies across tens to hundreds of thousands of individuals. Such large-scale analyses are often prohibited by constraints in data sharing of individual-level genetic data. Multiple recent works have proposed to circumvent this by operating directly at the summary statistic level thus not requiring individual genetic data. In addition, the recent completion of the Roadmap Epigenomics Project [Kundaje et al. Nature 2015] has provided a wealth of functional genomic information that can aid fine-mapping endeavors if properly modeled. We have previously described fine-mapping frameworks [Kichaev et al. PloS Gen. 2014] capable integrating functional genomic data that operate directly on summary association statistics and demonstrated its efficacy for a small number of traits and functional marks. Here, we describe a large-scale analysis of over 3. 3 million phenotypic measurements spanning 22 diverse dichotomous and quantitative traits. We conduct integrative fine-mapping on approximately 1,700 genetic loci, leveraging over 4,000 functional genomic marks to build trait-specific models of functional genomic architectures to help uncover causal variants. We report a number of plausible functional variants underlying GWAS risk loci and create a searchable database that we make freely available to the community.

792T

Single nucleotide polymorphisms in the *APCS* gene influence geographic atrophy secondary to VEGF inhibition therapy in neovascular macular degeneration. *G. J. McKay[1], G. Silvestri[2], R. E. Hogg[2], L. Toth[2], P. Earle[2], C. C. Patterson[1], U. Chakravarthy[2].* 1) Centre for Public Health, Queen's University Belfast, Belfast, Northern Ireland, United Kingdom; 2) Centre for Experimental Medicine, Queen's University Belfast, Belfast, Northern Ireland, United Kingdom.

Introduction: Age-related macular degeneration (AMD) is a leading cause of vision loss in the elderly mostly due to the development of neovascular AMD (nAMD) or geographic atrophy (GA). Intravitreal injections of anti-vascular endothelial growth factor (VEGF) agents are an effective therapeutic option for nAMD. Following anti-VEGF treatments, increased atrophy of the retinal pigment epithelium (RPE) and choriocapillaries that resembles GA has been reported. We sought to evaluate the underlying genetic influences that may contribute to this process. **Methods:** We selected 68 single nucleotide polymorphisms (SNPs) from genes previously identified as susceptibility factors in AMD, along with 43 SNPs from genes encoding the VEGF protein and its cognate receptorsas this pathway is targeted by treatment. We enrolled 467 consecutive patients (Feb 2009 to October 2011) with nAMD who received anti-VEGF therapy. The acutely presenting eye was designated as the study eye and retinal tomograms graded for macular atrophy at study exit. Statistical analysis was performed using PLINK to identify SNPs with a P value < 0. 01. Logistic regression models with macular atrophy as dependent variable were fitted with age, gender, smoking status, common genetic risk factors and the identified SNPs as explanatory variables. **Results:** Grading for macular atrophy was available in 304 study eyes and 70% (214) were classified as showing macular atrophy. In the unadjusted analysis we observed significant associations between macular atrophy and two independent SNPs in the *APCS* gene: rs6695377: odds ratio (OR) = 1. 98; 95% confidence intervals (CI): 1. 23, 3. 19; P = 0. 004; rs1446965: OR = 2. 49, CI: 1. 29, 4. 82; P = 0. 006 and these associations remained significant after adjustment for covariates. **Conclusions:** VEGF is a mitogen and growth factor for choroidal blood vessels and the RPE and its inhibition could lead to atrophy of these key tissues. Anti-VEGF treatment can interfere with ocular vascular maintenance and may be associated with RPE and choroidal atrophy. As such, these medications, which block the effects of VEGF, may influence the development of GA. The top associated SNPs are found in the *APCS* gene, a highly conserved glycoprotein that encodes Serum amyloid P (SAP) which opsonizes apoptotic cells. SAP can bind to and activate complement components via binding to C1q, a mechanism by which SAP may remove cellular debris, affecting regulation of the three complement pathways.

793F

Identification of a p. Arg138Trp variant in *TM6SF2* associated with triglyceride and total cholesterol levels in American Indians. *A. Nair, M. Kaur, P. Kumar, P. Piaggi, S. Kobes, W. Knowler, C. Bogardus, R. Hanson, L. Baier.* National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Phoenix, AZ.

Prior genome-wide association studies identified strong association between serum triglyceride (TG) and total cholesterol (TC) levels and variants at the gene rich chr19p13 region. In multiple ethnic groups rs58542926, which predicts a Glutamine to Lysine (p. Glu167Lys) change in *TM6SF2,* was pinpointed as the causal variant, and in functional studies the Lys allele decreased TM6SF2 protein levels and *Tm6sf2* knockdown resulted in reduced TG rich lipoprotein secretion from liver resulting in lower plasma TG and TC levels. Accordingly, strong associations between this variant and myocardial infarction (MI) and non-alcoholic fatty liver disease (NAFLD) have been identified with the Lys allele increasing risk for NAFLD and decreasing risk for MI. In the current study we analyzed coding variation in *TM6SF2* for association with lipid levels in Pima Indians, a population with a high prevalence of type 2 diabetes but a relatively low rate of coronary heart disease (in non-diabetics) and comparatively favorable lipid profiles. Analysis of 335 whole genome sequence data from Pima Indians identified two coding variants, rs142056540 (p. Arg138Trp) and the previously reported Glu167Lys variant which were then genotyped in 5494 Pima Indian subjects informative for lipid levels. The Lys allele at Glu167Lys had a lower frequency in American Indians (2%) compared to Europeans (7%) and had a directionally consistent nominal association with lower TC (by 4% per copy, *P*=0. 005) but not with TG levels (*P*=0. 15). In contrast, the Trp allele at the novel Arg138Trp variant was strongly associated with lower serum TG (by 18%, *P*=1. 0×10-13) and TC levels (by 6%, *P*= 9. 7×10-9). The Arg138Trp variant was further genotyped in 2899 Urban American Indians and a meta-analysis of all 8393 American Indians identified a genome-wide significant association with TG and TC levels such that the TG levels were lower by 18% (*P*= 8. 1×10-14) and TC levels were lower by 6% (*P*= 5. 6×10-10) per copy of the Trp allele. The Trp allele occurs in 10% of full heritage Pima Indians but was not identified in Europeans, Asians or Africans and in only 2/128 subjects of Mexican ancestry in the 1000 genome data. In Pima Indians, Arg138Trp variant is not in LD with either the Glu167Lys variant (r2=0, D'=0) or with any other SNP in *TM6SF2* (*n*=335). The Arg residue is highly conserved across different species and the SNP is predicted to be damaging by SIFT. Functional characterization of the Arg138Trp variant is ongoing.

794W

Mesocorticolimbic Genetic Variants are Associated with Scores on Opioid Risk Screening Tools. *T. Onojighofia, N. Anand, B. Meshkin, M. Hafez, S. Kantorovich, D. Holman, M. Hopkins.* Research & Department, Proove Biosciences, Irvine, CA.

Background

For patients with acute, subacute, or chronic pain, opioids are a common and sometimes effective part of the pain management plan. Before opioids are initiated, a comprehensive evaluation of the risk of misuse and abuse-related behaviors must be conducted. Currently available screening tools that are validated for the assessment of potential opioid addiction such as the Opioid Risk Tool (ORT) and the Screener and Opioid Assessment for Pain Patients (SOAPP®-R) are based on patients' self-reports of behavior; personal and family medical history; and substance abuse-related environmental factors. However, there is evidence that genetic factors may determine pain perception and up to half of substance abuse risk.

Statement of Purpose

The objective of this study was to establish a basis for associating the potential for patient abuse of opioid medications with genetic markers.

Methods

For this retrospective, cross-sectional association study, 2488 subjects were randomly selected from 2 pain centers in the United States. Subjects were treated for primarily chronic non-cancer pain conditions; currently using opioid medications; and had completed either the Opioid Risk Tool (ORT) or the Screener and Opioid Assessment for Pain Patients, Revised (SOAPP-R). Test scores were stratified into low, moderate, and high risk for opioid abuse. All subjects were genotyped using Taqman® SNP Genotyping Assays (Life Technologies, Carlsbad, CA, USA). Analyses were conducted to determine associations between risk scores and a panel of 12 single nucleotide polymorphisms (SNPs), all of which encode for proteins expressed in the mesocorticolimbic reward pathway of the brain.

Results

From our panel of 12 SNPs, analyses showed that ANKK1/DRD2 rs1800497 was significantly associated with ORT results (p=0. 032), while OPRM1 rs1799971 was nominally associated with ORT results (p=0. 067). OPRM1 rs1799971 (p=0. 001), OPRK1 rs1051660 (p=0. 014), DRD1 rs4532 (p=0. 014), and GABRG2 rs211014 (p=0. 044) were all significantly associated with SOAPP-R test results.

ConclusionFive SNPs from a panel of genes associated with opioid abuse and opioid abuse risk factors were found to be associated with 2 widely used opioid risk assessment tools. Thus, identifying opioid abuse risk-related genes in chronic non-cancer pain patients may help to strengthen overall assessments for opioid abuse when opioid therapy is ongoing or being considered.

795T

IBD associated SNP rs4256159 at chromosome 3p24 gene desert is correlated with increased colonic expression of *SATB1*. *A. Onoufriadis[1], R. Sarna[1], S. Twelves[1], L. Demandt[1], F. Gracio[2], A. Amar[1], E. De Rinaldis[2], JD. Sanderson[3], PM. Irving[3], C. Mathew[1], NJ. Prescott[1].* 1) Medical and Molecular Genetics, King's College London, London, United Kingdom; 2) NIHR Biomedical Research Centre, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; 3) Department of Gastroenterology, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom.

Genome-wide association scans (GWAS) have now identified more than 160 genomic regions that influence susceptibility to the two forms of inflammatory bowel disease (IBD), Crohn's disease (CD) and ulcerative colitis (UC). However, GWAS loci only account for a modest proportion of the disease variance in IBD, with genetic variants that underlie protein coding changes playing a relatively minor role. It is therefore hypothesised that the majority of these IBD loci will contain causal variants that exert their effect by altering gene expression levels. In order to assess this, we sequenced the transcriptome of intestinal biopsy samples from 32 IBD patients and controls and focused on transcripts that map to GWAS loci that are devoid of any annotated coding genes, known as "gene-deserts". We observed intestinal transcription of *SATB1-AS1* (special AT rich sequence binding protein 1 antisense 1), a long non-coding RNA that maps to an IBD-associated gene desert at chromosome 3p24 as well as *SATB1* (special AT rich sequence binding protein 1), a protein-coding gene immediately proximal to the gene desert. In order to assess whether the associated SNP in this region (rs4256159) is correlated with altered expression of *SATB1-AS1* or the nearby *SATB1* gene, we performed qPCR in intestinal tissue and whole blood from 85 individuals genotyped for the SNP. eQTL analysis showed a significant upregulation of intestinal *SATB1* expression in individuals carrying the risk allele (p=0. 02098), whereas no significant correlation with *SATB1-AS1* transcription in colon was observed (p=0. 4692). The average expression based on relative quantification (RQ) data was 1. 6 fold greater for the CT genotype and 2. 48 fold greater for the TT genotype, when compared to the non-risk CC. In contrast, eQTL analysis between the risk SNP and expression of *SATB1* and *SATB1-AS1* in whole blood did not show any correlation, suggesting a tissue specific effect. *SATB1* is involved in chromatin remodelling in T-cell differentiation and over-expression of *SATB1* in regulatory T-cells (Treg) has been shown to cause loss of their immunosuppressive function. Taken together, this work suggests the rs4256159 SNP may be confer susceptibility to IBD due to upregulated *SATB1* expression in intestinal mucosa, thus providing insights into the underlying biology of disease associations in gene deserts.

Gender-specific association of *ADIPOQ* gene polymorphisms with adiponectin levels and the influence of genetic ancestry on the association with obesity in the Jackson Heart Study cohort. *P. Riestra[1], SY. Gebrea[1], R. Xu[1], R. Khan[1], A. Bidulescu[2], A. Correa[3], F. Tekola-Ayele[4], SK. Davis[1].* 1) Cardiovascular Section Social Epidemiology Research Unit . National Human Genome Research Institute. 10 Center Drive Bethesda, MD 20892; 2) Indiana University Bloomington School of Public Health. 1025 E. 7th Street, Suite 111 Bloomington, IN 47405; 3) Jackson Heart Study Jackson Medical Mall. 350 West Woodrow Wilson Av. , Suite 701 Jackson, MS, 39217; 4) National Human Genome Research Institute Center for Research on Genomics and Global Health. 12 South Drive Bethesda, MD 20892.

Background: Despite the important role of adiponectin in regulating the general metabolic homeostasis, the analysis of genetic determinants of adiponectin and the related cardio-metabolic traits in African American population has been very limited and inconsistent. Considering the high genetic admixture of African Americans and thus the important population stratification that may be confounding the genetic-trait associations, the objective of this work was to perform a comprehensive analysis of the associations between ADIPOQQ variants and adiponectin levels and obesity phenotypes in a large population of African Americans from the JHS cohort. **Design and Methods**: Genotype data was available for 2968 JHS participants (1131men and 1837women). SNPs were selected by a Tag-SNP Approach and literature review. The genotype imputation was performed using. IMPUTE2 software and reference phased data from the 1000G project. PLINK software was use for the genetic analysis. Plasma specimens were analyzed by ELISA for adiponectin levels. Global European ancestry estimates were calculated using HAPMIX in analyses supported by the CARe consortium. **Results:** We found a gender dependent association of some ADIPOQ variants and adiponectin levels. Only in women four of the studied polymorphisms (rs 6444174, rs 16861205, rs1403697, rs7641507) were associated with adiponectin levels after Bonferroni correction and controlling for the percentage of European ancestry (PEA), age, income and smoking. These results were consistent with the haplotype analysis. The association between the rs12495941 variant and obesity is modulated by the PEA, so that the relationship between the G allele and a higher incidence of obesity was present in those individuals within the lower PEA group. In addition there was an effect modification of obesity on the association between the ADIPOQ rs 6444174 SNP and BMI so that the presence of the T allele was negatively and significantly associated with BMI (p=0. 0003662) only in participants with a normal weight. **Conclusions:** In this big African American cohort, ADIPOQ variants are associated with adiponectin levels in a gender dependent manner and the relationship of some of these variants with obesity and BMI is modulated by the PEA and the obesity status respectively suggesting that the effects of these polymorphisms are subject to a strong interaction with genetic and environmental factors in African American population.

Fine-scale mapping of genomic heritability using summary association statistics. *H. Shi[1], G. Kichaev[1], B. Pasaniuc[1,2,3].* 1) Interdepartmental Program in Bioinformatics, University of California, Los Angeles, Los Angeles, CA 90095; 2) Dept. of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA. 90095; 3) Dept. of Pathology and Laboratory Medicine,David Geffen School of Medicine University of California Los Angeles, Los Angeles, CA. 90095.

Genome-wide association studies (GWAS) have reproducibly identified thousands of associations yet the majority of heritability remains largely unexplained. This is in part caused by the fact that many causal variants with low effect size fail to reach significance level due to limited sample size. Heritability estimation and partitioning provides a way of interrogating the entire genetic architecture of the disease without imposing significance thresholds on the strength of association between individual variants and trait. In this work we provide an estimator for heritability at fine-scale genomic windows (less than 100Kb) from GWAS summary statistics while taking linkage disequilibrium into account. Through extensive simulations, we demonstrate that the estimator is unbiased under various window size, sample size, and reference panel sizes. We apply our new estimator to summary association data of over 3. 3 million phenotypic measurements spanning 22 diverse traits to characterize the genetic architecture of common disease. In a preliminary analysis of BMI and height summary statistics from GIANT Consortium, as expected we observe an enrichment of GWAS hits in genomic regions with high heritability. Interestingly, we also observe a number of genomic regions with high heritability but without any GWAS hit.

798T

Lack of Association Between Leptin T-2549G and Adiponectin C-11377G Genotype in Asthmatic-Obese Children. *H. Verdi[1], O. Ozbek[2], Y. Yalcin[1], FB. Atac[1].* 1) Baskent University School of Medicine, Department of Medical Biology, Ankara, TURKEY; 2) Baskent University School of Medicine, Department of Pediatrics, Ankara, TURKEY.

Asthma the most common pediatric inflammatory disorder is a complex syndrome that encompasses multiple phenotypes. The prevalence, severity and hospitalization index for asthma have increased markedly in the last several decades. Hence, asthma is often diagnosed along with obesity which could be due to the systemic inflammation. Leptin and adiponectin are the two adipokines secreted by active adipose tissue. It is known that different genotypes may enroll in the development of both conditions. The aim of this study was to evaluate the leptin -2549 T/G and adiponectin -11377 C/G genotypes in children with asthma and/or obesity and their relations with leptin and adiponectin levels. 402 children were enrolled in study. Asthma was defined according to GINA criteria and children with a BMI above the 95th percentile for age and sex were defined as obese. Patients were investigated in four groups. Group 1: Obese children with asthma (n=76) Group 2: Lean children with asthma (n=105) Group 3: Obese children without asthma (n=96), Group 4: Lean healthy children (n=125). Serum leptin and adiponectin levels were measured by ELISA and genotyping was performed by PCR-RFLP. Both the frequency of leptin -2549 T/G and adiponectin -11377 C/G genotypes did not show difference between study and control group. No association was found between leptin/adiponectin genotype and leptin/adiponectin levels. Not only in the genotype distribution but serum levels of leptin/adiponectin show difference between study and control groups. Mean leptin levels of obese asthmatics were significantly higher (13. 1±9. 1) than lean asthmatics (3. 7±4. 4) ($p<0.001$). Serum adiponectin levels of lean asthmatics (16±7. 1) were significantly higher than obese asthmatics (12. 1±6. 9) and lean healthy children (13. 2±5. 9) ($p<0.001$ and $p<0.05$, respectively). Although adiponectin level in adiponectin -11377 CC genotype (14. 4±6. 6) was higher than -11377 CG group (9. 3±3. 7) in healthy controls, the difference was statistically insignificant ($p=0.08$). No significant difference was defined in our study. Further investigations are required that could potentially open new scenario in the diagnostic algorithm and in the strategic approach, with a more comprehensive assessment of the disease.

799F

The impact of known type 2 diabetes associated variants on circulating levels of GLP-1, GIP and glucagon during an oral glucose tolerance test. *A. Jonsson[1], S. S. Torekov[1,2], T. Schnurr[1], C. T. Have[1], Y. Mahendran[1,4], N. Grarup[1], N. B. Johansen[3,4], K. Færch[3], D. R. Witte[4,5], T. Lauritzen[5], A. Sandbæk[5], J. J. Holst[1,2], M. E. Jørgensen[3], O. Pedersen[1], T. Hansen[1].* 1) NNF Center for Basic Metabolic Research, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 2) Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 3) Steno Diabetes Center, Gentofte, Denmark; 4) The Danish Diabetes Academy, Odense, Denmark; 5) Department of Public Health, University of Aarhus, Aarhus, Denmark.

Aims/hypothesis: Large-scale genome wide association studies (GWAS) have currently identifiedmultiple genetic determinants of type 2 diabetes. For many of those variants, it is unclear through which mechanisms they exert their effect and little is known whether these genes also affect incretin hormone levels and/or alpha-cell function. Our aim is to examine the impact of known type 2 diabetes associated variants on circulating levels of glucagon-like peptide-1 (GLP-1), glucose-dependent insulinotropic polypeptide (GIP) and glucagon during an oral glucose tolerance test (OGTT). **Methods:** Plasma levels of GLP-1, GIP and glucagon were examined in samples obtained during an OGTT in 1,547 individuals from the ADDITION-PRO cohort. Participants were given a standard 75 g OGTT after an overnight fast of ≥7 hours and blood samples were drawn at 0, 30 and 120 min for assessment of plasma GLP-1, GIP and glucagon levels. The incremental area under the curve (iAUC) of plasma GLP-1, GIP and glucagon were calculated from 0-30 minutes and from 0-120 minutes during the OGTT. Associations between 68 genetic variants and plasma levels of GLP-1, GIP and glucagon were studied using a linear mixed model (EMMAX) implemented in the EPACTS software package by the use of inverse-normalized residuals of the traits adjusted for age, sex and BMI. **Results:** None of the associations of 68 type 2 diabetes risk variants with circulating plasma levels of GLP-1, GIP and glucagon during the OGTT were significant after correction for multiple testing. However, risk alleles in *PPARG* (rs1801282) and *ADCY5* (rs11708067) were associated with increased iAUC of plasma glucagon from 0 to 30 min during the OGTT (Beta [SE]: 0. 171 [0. 054], $P=0.0015$ and 0. 130 [0. 043], $P=0.0025$, respectively), showing reduced repression of glucagonrelease after an oral glucose load. **Conclusion/interpretation:** Known type 2 diabetes risk variants seem not to be strongly associated with alteredpost-OGTT releaseof GLP-1, GIP or glucagon. Large-scale genome-wide association studies of incretin hormone and glucagon release as well as studies of incretin hormone and glucagon action are needed in order to explain the genetic influence on these traits.

Assessing a genetic risk score for type 2 diabetes with abdominal obesity in a Korean population. *J. Lee, Y. Lee, S. Park, M. J. Go, B. J. Kim.* Korea Center for Disease Control and Prevention, Osong, South Korea.

Type 2 diabetes mellitus (T2DM) is a complex disease and metabolic disorder. For few years, genome-wide association studies (GWASs) have found many novel susceptibility loci for T2DM, and have demonstrated that some genetic variants have different effect according to the ethnics. We evaluated single-nucleotide polymorphisms (SNPs) in or near 73 susceptibility loci for T2DM, identified through GWASs of groups with European ancestry and Asian populations using 1,201 cases with T2DM and 328 control individuals aged 40 to 49. We selected 10 significant susceptibility loci and calculated a genetic risk score (GRS) by combining the number of risk alleles. We demonstrated that a GRS based on these 10 susceptibility loci (GRS-10) for T2DM was an important risk factor in the Korean population. Addition of GRS-10 to a clinical model resulted in a small but significant increase in the area under the curve (AUC). Next, we performed abdominal obesity-stratified analyses and assessed the GRS-10 in abdominal obesity and non-abdominal obesity groups.

Genetic Variation in the Maltase-Glucoamylase Gene (*MGAM*) Associates with Measures of Body Mass Index in American Indian Adults and Children. *Y. Muller, P. Piaggi, C. Okani, G. Wiessner, S. Kobes, P. Chen, W. Knowler, R. Hanson, C. Bogardus, L. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institutes of Health, Phoenix, AZ.

Intestinal maltase-glucoamylase (*MGAM*) is an alpha-glucosidase which hydrolyzes linear alpha-1,4-linked oligosaccharide in starch digestion. It plays a crucial role in the production of glucose in the human lumen. The antidiabetic drug Miglitol which is an alpha-glucosidase inhibitor reduces HbA1c and ameliorates obesity in patients with type 2 diabetes (T2D). Therefore, *MGAM* was analyzed as a potential candidate gene for obesity and T2D in Pima Indians. Forty five SNPs tagging 610 common variants (minor allele frequency ≥0. 05; r2≥0. 85) across a ~211 kb genomic region (Chr7:141645679-141856547 which covers ~50kb upstream and downstream of *MGAM*) were genotyped as part of a custom Axiom array (Affymetrix) in a population-based sample of 3494 Pima Indians from a longitudinal study. Genotypes were analyzed for associations with maximum body mass index (BMI) measured in adulthood, maximum BMI z-score in childhood, % body fat and T2D. Conditional analyses demonstrated that two intronic tag SNPs (rs1880924 and rs58864948, D'=0. 07, r2=0) in *MGAM* independently associated with BMI. These two SNPs were further genotyped in a replication sample of 4060 mixed-heritage American Indians. SNP rs1880924 [risk allele frequency (RAF) = 0. 17] associated with adult BMI in both samples (full-heritage Pima Indians: b=2. 6% per copy of T allele, p=8. 2 x 10-4; mixed-heritage American Indians: b=2. 6%, p=8. 6 x 10-4). Combining both samples provided the strongest evidence for association with adult BMI (b=2. 5%, p=6. 3 x 10-6, n=7697). The rs1880924 allele associating with higher BMI in adulthood also associated with a higher childhood BMI z-score (b=0. 08 SD, p=0. 004, n=5350), and a higher % body fat (b=0. 89%, p=0. 05, n=744), but did not associate with T2D [odds ratio=1. 11(0. 99-1. 24) per copy of T allele, p=0. 08, n=7679]. The second SNP rs58864948 (RAF = 0. 23) similarly associated with BMI in adulthood (b=1. 6%, p=0. 001), BMI z-score in childhood (b=0. 049 SD, p=0. 05) and % body fat (b=1. 06%, p=0. 008). When the risk alleles at each of these two SNPs were added together, each additional risk allele increased BMI by 2% in adulthood (p =8. 7x10-8) and BMI z-score by 0. 07 SD in childhood (p=7. 2 x 10-4). Although neither SNP achieved genome-wide significance, both SNPs associated with BMI after accounting for multiple testing (45 tag SNPs require a p≤0. 001 for significance). We conclude that common variation in *MGAM* modestly affects BMI measured throughout lifetime in American Indians.

802F

Analysis of common variants in *SLC19A2* identifies a modest association with type 2 diabetes in Pima Indians. *M. Traurig, A. Moulton, S. Kobes, R. L. Hanson, W. C. Knowler, C. Bogardus, L. Baier.* NIH, Phoenix, AZ.

The *SLC19A2* gene encodes a transporter protein involved in thiamine uptake. *Slc19a2* knockout mice develop diabetes and rare mutations in human *SLC19A2* cause thiamine-responsive megaloblastic anemia (TRMA) syndrome often characterized by early-onset diabetes. In previous linkage studies, the region on chromosome 1 which contains the *SLC19A2* locus was linked to type 2 diabetes in Pima Indians and several other ethnic groups. Whole genome sequencing of 335 Pima Indians identified one rare (mAF=0. 014) missense variant (rs150049339, Thr365Ser) in exon 4, however it was not associated with type 2 diabetes in ≈3500 Pima Indians (P=0. 32). In the current study, we are assessing whether common variants in *SLC19A2* are associated with type 2 diabetes in Pima Indians. We are utilizing genotypic data from a recently designed custom Pima Indian specific Affymetrix Axiom array which captures 92% of all variation with a mAF ≥5% in the Pima Indian genome. Currently, 3,637 full-heritage Pima Indians (Stage 1) have been genotyped with this array which contains 9 tag SNPs in *SLC19A2*; genotyping in an additional 4,060 mixed-heritage American Indians (Stage 2) is ongoing. To date, 2 of the 9 tag SNPs, rs10919175 and rs2056926, across the *SLC19A2* locus have been analyzed in both samples. Rs2056926 was associated with diabetes in both samples and the combined analysis (N=7,697) had a P=2. 1×1 0-6 and OR=1. 28 per copy of the C allele. However, the diabetes association did not replicate in a separate sample of American Indians from the FIND study. Rs2056926 is located in the promoter region 227 bp upstream of the transcription start site; therefore, we examined whether the variant could function as a cis-acting expression quantitative trait locus (eQTL) for *SLC19A2*. Genotypic data for rs2056926 were merged with adipose (N=192) and skeletal muscle (N=204) gene expression data from non-diabetic Pima Indians. A nominal association between rs2056926 and *SLC19A2* expression was observed in adipose (P=0. 03, B=-0. 29, SD per C allele) and the diabetes risk allele was associated with lower *SLC19A2* expression; however, it is unclear whether this weak association is a false positive. Expression levels for *SLC19A2* in the adipose and skeletal muscle samples were very low; therefore, additional functional studies using tissues (e. g. liver) with higher *SLC19A2* expression, which are not available in our study of Pima Indians, are needed to determine whether rs2056926 affects *SLC19A2* transcription.

803W

The genetic and regulatory architecture of the *ERBB3*- type 1 diabetes susceptibility locus. *S. Kaur[1], A. H. Mirza[1,2], T. Floyel[1], C. A. Brorsson[1], H. B. Mortensen[1,2], J. Størling[1], F. Pociot[1,2], The Hvidoere Study Group.* 1) Herlev University Hospital, Herlev, Denmark; 2) University of Copenhagen, Denmark.

Aims- Epidermal growth factor receptor (EGFR) signaling pathway is suggested to play a role in β-cell growth and islet development, and *ERBB3* gene is an important member of this pathway. The genetic and regulatory architecture of the *ERBB3* locus is not well explained with respect to type 1 diabetes. The aim of our study was to explore the role of *ERBB3* locus in type 1 diabetes. **Methods-** We genotyped 984 children with new-onset type 1 diabetes and examined if genetic variation of *ERBB3* (rs2292239) affects residual β-cell function. Furthermore, we systematically explored the regulatory architecture of the *ERBB3* locus, examined the expression of *ERBB3* and its potential regulators in human islets and investigated the effect of *ERBB3* knockdown on apoptosis in INS-1E cells. **Results-** rs2292239 strongly correlated with residual β-cell function and metabolic control in children with type 1 diabetes. We identified evolutionary conserved long non-coding RNAs (lncRNAs) expressed in tissue-specific manner, multiple *CTCF* transcription factor binding sites and *cis*-eQTL signals, suggesting their putative regulatory roles in modulating *ERBB3* expression. Additionally, we found that *ERBB3*, *CTCF*, and antisense lncRNA *NONHSAG011351* are expressed in human islets and that *ERBB3* is down-regulated by pro-inflammatory cytokines. Importantly, knockdown of *ERBB3* in insulin-producing INS-1E cells decreased the expression of CTCF and diminished basal and cytokine-induced apoptosis as shown by reduced Caspase-3 activation. **Conclusions-** Our data suggests an important functional role of *ERBB3* and its regulators in the b-cells and may constitute novel targets to prevent b-cell destruction in type 1 diabetes.

804T

Impact of *APOL1* genetic variation on HIV-1 infection and opportunistic infections in African-American patients with HIV-1. *P. An[1], E. Sezgin[1,2], G. D. Kirk[2], M. L. Van Natta[2], D. A. Jabs[2,3,4], A. Dinh[5], J. B. Kopp[5], C. A. Winkler[1].* 1) Basic Research Laboratory, Center for Cancer Research, National Cancer Institute, Leidos Biomedical Research, Inc, Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Department of Epidemiology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD; 3) Departments of Ophthalmology, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Departments of Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Kidney Disease Section, NIDDK, NIH, Bethesda, MD.

APOL1, encoding apolipoprotein L1, confers resistance to *Trypansoma brucei*, the cause of African trypanosomiasis. *APOL1* G1 (S342G:I384M) and G2 (6 bp deletion) alleles restore resistance to trypanosomes causing acute human trypanosomiasis and are found only in individuals with recent African ancestry. *APOL1* variant alleles are recessively associated with increased risk for HIV-associated nephropathy (OR 27-89); ~12-14% of the AA population carry high-risk genotypes. *In vitro* APOL1 inhibits HIV-1 replication by several mechanisms; the *in vivo* role of *APOL1* variants on HIV-1 infection, progression, and disease outcomes has not been investigated. We determined *APOL1* genotypes for AA enrolled in the ALIVE HIV natural history and LSOCA AIDS cohorts. In the ALIVE cohort (n = 749), 7. 7% of AA HIV+ carried high-risk genotypes compared to 12% of at-risk HIV- individuals (OR 0. 60, 95% CI: 0. 33-1. 08; P = 0. 09). Individuals with the three *APOL1* genotypes showed similar HIV-1 viral load levels (P> 0. 40). *APOL1* genotypes were not associated with the rate of progression from HIV seroconversion to AIDS in survival analyses (P > 0. 70). However, high-risk genotypes were associated with a 71% decrease in the odds of opportunistic infection (OI) (OR 0. 29, 95% CI: 0. 09, 0. 97; P = 0. 04). In the LSOCA cohort (n = 784), *APOL1* genotypes were not associated with baseline CD4+ T-cell counts and HIV-1 viral loads. Carriage of high-risk genotypes was associated with a non-significant decrease in the odds of prevalent OI at enrollment (OR 0. 66, 95% CI: 0. 40, 1. 11; P = 0. 11), which was mainly driven by a protective association with fungal infection (OR 0. 54, 95% CI: 0. 32, 0. 93; P = 0. 02). In summary, *APOL1* G1/G2 variants were not associated with viral load or AIDS progression, but *APOL1* association with resistance to HIV acquisition and OI cannot be excluded. These results, requiring further validation, suggest potential novel anti-pathogen roles for APOL1. Funded by National Cancer Institute Contract HHSN261200800001E; National Institute on Drug Abuse (R01-DA04334, R01-12586); National Eye Institute (U10 EY 08052 to Icahn School of Medicine at Mount Sinai; U10 EY 08057 to Johns Hopkins University Bloomberg School of Public Health; U10 EY 08067 to University of Wisconsin, Madison, School of Medicine).

Immunochip analysis identifies amino acid residues in five separate HLA genes driving the association between the MHC and primary biliary cirrhosis. *R. Darlay[1], K. L. Ayers[1,2], G. F. Mells[3], V. A. Money[4], J. Z. Liu[5,6], M. A. Almarri[5,7], G. J. Alexander[8], D. E. Jones[9], R. N. Sandford[3], C. A. Anderson[5], P. T. Donaldson[9], H. J. Cordell[1], UK-PBC Consortium.* 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, Tyne and Wear, United Kingdom; 2) Icahn Institute for Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, USA; 3) Academic Department of Medical Genetics, Cambridge University, Cambridge, UK; 4) School of Biological and Biomedical Sciences & Department of Chemistry, Biophysical Sciences Institute, Durham University, Durham, UK; 5) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, UK; 6) New York Genome Center, New York, USA; 7) Department of Forensic Science and Criminology, Dubai Police HQ, Dubai, United Arab Emirate; 8) Department of Hepatology, Cambridge University Hospitals National Health Service (NHS) Foundation Trust, Cambridge, UK; 9) Institute of Cellular Medicine, Medical School, Newcastle University, Newcastle upon Tyne, UK.

Primary biliary cirrhosis (PBC) is a classical autoimmune liver disease characterized by progressive auto-immune destruction of intrahepatic bile ducts. The strongest genetic association is seen with *HLA-DQA1*04:01*, with at least three additional independent HLA haplotypes contributing to susceptibility. To identify functional, potentially causal variants within the HLA region, we used dense SNP data in 2861 PBC cases and 8514 controls to impute classical HLA alleles and amino acid polymorphisms using the software packages HIBAG and SNP2HLA. Through stepwise analysis we demonstrate that association in the HLA region is largely driven by variation at five separate amino acid positions: position 11 of HLA-DPb1 (p = 4. 72e-60), position 74 of HLA-DRb1 (p = 2. 95e-40), position 57 of HLA-DQb1 (p = 1. 73e-21), position 156 of HLA-C (p=2. 83e-12) and position -13 in the signal peptide of HLA-DQa1 (p = 7. 64e-12). Three dimensional modelling and calculation of electrostatic potentials was performed to explore the effect of these key residues on these molecules. Two of the associated residues were shown to affect the electrostatic charge of the peptide binding groove. An aspartic acid at residue 57 of HLA-DQb1, which protects against PBC, induces a negative charge in pocket 4 of the peptide binding groove, whereas an arginine at residue 156 of HLA-C, which is associated with an increased risk of PBC, induces a positive charge within the peptide binding groove.

Identification and characterization of functional genetic variants in Dupuytren's disease. *J. Du[1,2], K. Becker[1,2], J. Altmüller[1], H. Thiele[1], S. Tinschert[3], R. Casper[1], P. Nürnberg[1,2], HC. Hennies[1,2,4], The German Dupuytren Study Group.* 1) Cologne Center for Genomics (CCG), University of Cologne, Germany; 2) Cologne Excellence Cluster on Cellular Stress Responses in Aging-associated Diseases (CECAD), University of Cologne, Germany; 3) Institute of Clinical Genetics, Dresden University of Technology, Germany; 4) Center for Dermatogenetics, Div. of Human Genetics, Medical University of Innsbruck, Austria.

Dupuytren's Disease (DD) is a progressive, aging-associated fibromatosis disorder of the palmar aponeurosis, leading to progressive flexion contractures of fingers. DD is the most frequent genetic disorder of connective tissue and current treatment of DD consists largely of surgical or enzymatic removal of the contracted connective tissue, which is, however, associated with risk of neurovascular injury and recurrence. Hence, unraveling the molecular etiology of DD is needed to provide insight into potential therapeutic targets for treatment of DD. Here, we aim to identify causative variants, including both coding and noncoding variants, which directly predispose to DD. In a collaborative study we have previously identified nine disease-associated chromosomal regions using genome-wide association studies (GWAS). We have now further analyzed a 500kb GWAS-identified candidate region on chromosome 7 encompassing the SNP rs16879765 for variants that could explain the strongest disease-association signal by targeted next-generation genomic sequencing of 96 patient samples. The target region was enriched by the SureSelectXT2 kit from Agilent and sequenced on the Illumina HiSeq 2000 platform. Sequencing data was analyzed with the Varbank pipeline (v2. 13). The identified variations were analyzed by SIFT, Polyphen2, Fathmm, GWAVA and Haploregv3. A missense variant was detected in *EPDR1* in four patient samples and predicted to be deleterious. Multiple putative regulatory variants were identified in *EPDR1 and SFRP4* using ENCODE and Roadmap data. We are currently testing the role of these variants on gene expression, functional properties of fibroblasts derived from DD tissue, and regulatory pathways potentially involved in DD pathogenesis. We expect our experiments to pinpoint genetic variants that underlie the manifestation of DD, which peaks at around 60 years of age, and gene networks to unravel pathomechanisms leading to the complex and disfiguring disorder.

807T

Improved methods for multi-trait fine mapping of pleiotropic GWAS risk loci. *M. Roytman[1], G. Kichaev[1], H. Shi[1], R. Tamimi[2,3], S. Lindstrom[3], B. Pasaniuc[1,4,5].* 1) Bioinformatics Interdepartmental Program, University of California Los Angeles; 2) Department of Medicine, Harvard Medical School; 3) Department of Epidemiology, Harvard School of Public Health; 4) Department of Human Genetics, Geffen School of Medicine, University of California Los Angeles; 5) Department of Pathology and Laboratory Medicine, Geffen School of Medicine, University of California Los Angeles.

Genome-wide association studies have identified thousand of variants that alter risk of disease with many loci being implicated in multiple diseases. For example it is widely known that mammographic density and breast cancer share multiple GWAS risk loci [Lindstrom et al Nat Comm 2014]. In this work, we propose methods for the identification of causal variants at loci shown to be at risk for multiple correlated traits. By integrating association data across multiple correlated traits we increase power to find causal variants that impact both traits. Although our proposed methods make an assumption that the same causal variants impact both traits, we allow for heterogeneity in the effects on the two traits. Importantly, our approach only requires summary association statistics thus avoiding the usual restrictions that accompany sharing of individual data. We analyze data on breast cancer and mammographic density, demonstrating that our approach is an improvement on existing methods that only examine one trait. Moreover, recent works have shown that incorporating functional annotations across the genome improves fine mapping performance. Integrating this data into our approach will further enhance our power to detect causal variants.

808F

Devising an imputation reference panel for fine-mapping regulatory variants in autoimmune diseases. *H. Westra[1,2], S. Onengut-Gumuscu[3,4], A. Lee[5], W-M. Chen[3,4], A. R. Quinlan[3,6], P. K. Gregersen[5], S. S. Rich[3,4], S. Raychaudhuri[1,2,7,8].* 1) Brigham and Women's Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Center for Public Health Genomics, University of Virginia, Charlottesville, Virginia, USA; 4) Department of Public Health Sciences, University of Virginia, Charlottesville, Virginia, USA; 5) The Feinstein Institute for Medical Research, North Shore-Long Island Jewish Health System, Manhasset, New York, United States of America; 6) Departments of Human Genetics and Biomedical Informatics, University of Utah, Salt Lake City, Utah, USA; 7) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Smith Building, 1 Jimmy Fund Way, Boston, MA 02115, USA; 8) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

Over the last few years, over 40 loci have been associated with Type 1 Diabetes (T1D) through GWAS, linkage and candidate gene studies. More recently, the associated regions have been analyzed using the ImmunoChip genotyping platform, which has increased the resolution of the associated SNPs at the already identified loci (Onengut-Gumuscu *et al*, Nature Genetics, 2015). Using H3K4me3 ChIP-seq data for 34 cell types from the ENCODE project, we have previously observed significant enrichment for T1D associated variants in CD4+ T-cells (Trynka *et al*, Nature Genetics, 2014). However, variants used in this enrichment experiment were imputed using the 1000 Genomes Project reference panel, which consists mainly of healthy individuals. We reasoned that variants in these regions may have a higher allele frequency in T1D cases, and as such an imputation panel composed of cases would result in a higher imputation quality. We also reasoned that novel variants, such as insertion/deletion polymorphisms, could underlie these functional regions. We fine-mapped the T1D-associated loci by targeted sequencing followed by variant calling using the Genome Analysis Toolkit (GATK) in 160 T1D trios and 384 rheumatoid arthritis (RA) cases. The sequenced individuals were previously genotyped on ImmunoChip. We selected 900 regions of 1 kilobases, which collectively target 54 loci from the T1D and RA ImmunoChip studies that overlap H3K4me3 peaks in CD4+ T-cells. We detected 4,566 novel variants, of which 72 having each allele observed at least 5 times, imputed these variants into 12,097 T1D cases, and 14,342 controls genotyped on ImmunoChip, and performed association analysis using logistic regression. When comparing the association results with 1000 genomes imputation, we observed similar association p-values ($r > 0.99$) and comparable imputation quality scores ($r > 0.63$). We conclude that our sequencing panel can be used to reliably impute variants in regulatory regions in auto-immune diseases.

809W

Genetic modifiers of age at onset of Alzheimer disease in PSEN1 mutation carrier families. *J. H. Lee[1, 5], R. Cheng[1], B. Vardarajan[1, 2], R. Lantigua[1, 4], G. Tosto[1], D. Reyes-Dumeyer[1], A. Piriz[1], M. Medrano[6], I. Z. Jiménez-Velázquez[7], R. Mayeux[1, 2, 3, 5].* 1) Sergievsky Ctr/Taub Inst, Columbia Univ, New York, NY; 2) Departments of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY; 3) Departments of Psychiatry, College of Physicians and Surgeons, Columbia University, New York, NY; 4) Departments of Medicine, College of Physicians and Surgeons, Columbia University, New York, NY; 5) Departments of Epidemiology, School of Public Health, Columbia University, New York, NY; 6) School of Medicine, Pontificia Universidad Catolica Madre y Maestra, Santiago, Dominican Republic; 7) Department of Internal Medicine, University of Puerto Rico School of Medicine, San Juan, Puerto Rico.

We previously reported that three candidate genes – *SORBS2, SNX25, PDLIM3* -- modified age at onset of Alzheimer disease (AD) in families that carry the G206A mutation in *PSEN1*. Moreover, SNPs in these genes were associated with delayed or earlier age at onset in both mutation carriers and non-carriers in Caribbean Hispanics. We postulate that these genetic factors may influence the risk of AD or may influence memory performance. Here we extend our earlier study to examine 4q35 that contains the *SORBS2* gene using a larger set of families. To identify genetic modifiers, we studied 305 family members from 45 carrier families that had at least two mutation carriers. We genotyped the samples using 700k SNPs chips by Illumina. Using the variance component approach as implemented in SOLAR, we performed a genome wide linkage to confirm and refine the previous identified linkage peak at 4q35. For this purpose, we used age at onset for affected family members and age at last examination for unaffected family members. However, environmental risk factors, such as a history of head injury and educational levels, did not explain the variation in age at onset of AD. This study confirms our earlier linkage finding at 4q35 by identifying a SNP located within *SORBS2* (LOD=3. 25) and further nominates an additional candidate gene *CDKN2AIP* (LOD=4. 28). The minor allele for the *SORBS2* gene was associated with delayed age at onset by ~10 years, whereas other SNPs were associated with earlier age at onset by ~10 years. Here, we report candidate genes that are associated with variation in age at onset of AD in *PSEN1* mutation carrier families. This study illustrates the complex nature of genotype-phenotype relations even in a relatively 'simple' form of early onset AD, and provides the possibility of identifying protective genetic variants.

810T

Genotype and phenotype diversity of Indian populations. *A. Mishra, k. Thangaraj.* Medical and Evolutionary Genetic, Centre for Cellular and Molecular Biology, Hyderabad, Telangana, India.

Human skin color varies remarkably both within and between populations. This variation has been mainly depend upon amount, type and distribution of melanin in the melanin producing cells (melanosomes). Middle gangatic belt (middle east geographical region) of India were characterized by the huge phenotype variations (skin colour). Here we study the *SLC24A5*, which has been shown to explain almost one third of the pigmentation variations. This study was conducted in three cohorts of Indian subcontinent. The first cohort (1167 subjects; 27 diverse populations) were selected for phenotype study, second cohort (448 subjects; 25 population) for phenotype-genotype study and third cohort (1825 subjects; 52 populations of India) for phylogeography study. Phenotype study (cohort-1) suggest wide variation in pigmentation with melanin indices (MI) ranging from 23–90. 4. The highest MI was observed among Manjhis (70. 54 ±6. 53); while, it was lowest among Brahmins (MI-47. 37 ± 6. 05). There was no significant difference between the MI of males and females (p value=0. 1036). Genotype study (cohort-2) have identified two polymorphisms rs1426654 (non-synonymous mutation, exon-3; G<A) and rs2470102 (synonymous mutation, intron-8; G>A). Here, LD pattern is varying from strong (r2 = 0. 81) to moderate (r2 = 0. 30). In studied SNPs, the genotype and allele frequencies of the subjects were in Hardy-Weinberg equilibrium (P<0. 05). Association analysis of both SNPs with pigmentation (MI; Cohort-2) using sex and population as covariates suggest a significant association with skin pigmentation; rs1426654 (p = 4. 493x10-7) and rs2470102 (p = 5. 79x10-7) respectively. The effect of sex was found insigificant (p=0. 69) but the effect of population was highly significant (p value<2. 2x10-16). The presence of one copy of derived allele for SNPs rs1426654 and rs2470102 led to decrease in skin pigmentation of approx 2. 3 and 3. 5 melanin units respectively. In silico approaches suggests that rs2470102 might affect pigmentation through micro-RNA binding processes. Phylogeography study (cohort-3) of both the SNPs suggests wide presence of the derived alleles over the Indian subcontinent albeit their frequencies vary across the populations. Our results suggest that both the polymorphisms (rs1426654 and rs2470102) play an important role in skin pigmentation variation among South Asians.

811F

Hypospadias and SRD5A2 gene: Haplotype frequency estimation and mutation in Iranian patients. *M. Rahimi[1], Mir. Omrani[2,3], R. Mirfakhraie[3], B. Emamalizadeh[1], Z. Fazeli[1], M. Rouzrokh[4], S. Omrani[4,5].* 1) Department of Medical Genetics, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2) School of Paramedical Sciences , Faculty of Paramedical sciences, Shahid Beheshti University, Tehran, Iran; 3) Department of Medical Genetics, Faculty of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 4) Department of Pediatric Surgery, Mofid Children's Hospital, school of Medicine, Tehran, Iran; 5) School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Hypospadias is the most common congenital malformation of the male external genitalia affecting 1 in 250 live male births in the Iranian population. However, little is known the causing genes involved in the disease. The aim of the present study was to investigate mutations in steroid 5α-reductase-2 (SRD5A2) gene in Iranian children with hypospadias. In addition, we studied the association between two functional polymorphisms including V89L and A49T in relation to hypospadias. **Subjects and methods***:* A total of 109 boys with hypospadias and 109 healthy controls were enrolled. We used direct sequencing in order to detect mutations in exons of 1, 4 and 5 and the flanking intronic regions of the SRD5A2 gene. Furthermore the PCR-RFLP was used to investigate the association of V89L and A49T Polymorphisms with hypospadias disease. **Results**: The sequencing of exons 1, 4 and 5 of SRD5A2 gene revealed two new mutations including S74T mutation in one patient (0. 91%), and c. 230-231insA in two patients (1. 83%). In addition, the previously identified G196S mutation was detected in one patient. Moreover, strong association were observed between SRD5A2-V89L (OR=5. 8, 95% CI: 3. 94-26. 25; P<0. 001) and SRD5A2-A49T (OR=10. 2, 95% CI: 3. 8-8. 8; P<0. 001) polymorphisms and hypospadias in the patients. Haplotype analysis indicated that the L-A haplotype confers significant risk of hypospadias in Iranian patients (D'= 0. 364; P= 0. 0009). **Conclusion**:In conclusion, the results of the present study suggested that SRD5A2 mutations and polymorphisms may have a critical function on hypospadias in Iranian population.

The association of HLA-DQA1 gene alleles frequencies and Kawasaki Diseases. *H. Chi, NC. Chiu, MR. Chen, FY. Huang, YJ. Lee.* MacKay Children"s Hospital, No 92, 2nd section, Chung-Shan North Rd. , Taipei, Taiwan.

Background:Kawasaki disease (KD) is a systemic vasculitis caused by unknown infectious agents, host immune dysregulation, and genetic susceptibility in children. The human leukocyte antigen (HLA) system plays an important role in regulating immune response because it takes part in the defense against pathogens. Therefore we designed a case-control study to investigate the association between the HLA-DQA1 allele and KD. Material and methods:The diagnosis of KD was according to the diagnostic criteria of the American Heart Association. Treatment consisted of intravenous gamma globulin (IVIG) and aspirin as soon as the diagnosis was made. All patients had two-dimensional echocardiography during the febrile stage and again after discharge from the hospital. A CAL was defined as the inner diameter of a coronary artery being ≥3 mm in KD patients <5 years old and ≥4 mm in those ≥5 years old or a localized caliber of >150% when compared with the adjacent vessel diameter. The controlincluded hospital personnel and individuals who underwent routine health examinations or minor surgery. None had a history of KD or autoimmune diseases. The DQA1 gene was genotyped using sequencing-based typing. The alleles frequencies of HLA-DQA1*0101, *0102, *0103, *0201, *0301, *0401, *0501 and *0601 were analyzed. Results:The patients were 459 unrelated children (264 males, 195 females) with KD. The age at diagnosis was 1. 8±1. 6 (0. 1–10. 2) years. Among them, 140 (96 males, 46 females) had CAL. The controls were 385 subjects (136 males, 249 females). The frequencies of HLA-DQA1*0301 and HLA-DQA1*0501 were 0. 330 and 0. 184 in theKD group, similar to those of the controls (0. 314 and 0. 205 respectively, both $P > 0.05$). There were no significant difference of HLA-DQA1 alleles frequencies betweenKD patients with CALs and control as well as patients with CALs and those without CALs. Conclusion:The alleles frequenciesof HLA-DQA1 gene were not associated with KD and CALsin Han Chinese children.

Fine-mapping analyses to identify additional variants influencing fasting metabolite concentrations. *R. Li-Gao[1], H. G. de Haan[1], R. de Mutsert[1], A. van Hylckama Vlieg[1], K. Willems van Dijk[2,3], F. R. Rosendaal[1], D. O. Mook-Kanamori[1,4,5].* 1) Clinical Epidemiology, Leiden University Medical Center, C-7, Postbus 3600, 2300 RC, Leiden, the Netherlands; 2) Department of Human Genetics, Leiden University Medical Center, S4-P, P. O. Box 9600, 2300 RC, Leiden, the Netherlands; 3) Department of Endocrinology, Leiden University Medical Center, S4-P, PO Box 9600, 2300 RC, Leiden, the Netherlands; 4) Department of Public Health and Primary Care, Leiden University Medical Center, V-7, PO Box 9600, 2300 RC, Leiden, the Netherlands; 5) Epidemiology Section, BESC Department, King Faisal Specialist Hospital and Research Centre, Riyadh, Saudi Arabia.

In previous genome-wide association studies (GWAS) fifteen loci (*FADS1, ACADS, ACADM, ACADL, ELOVL2, CPS1, PLEKHH1, SYNE2, SPTLC3, ETFDH, SLC16A9, ACSL1, SCD, SLC22A4* and *PHGDH*) with strong associations to a panel of fasting metabolite concentrations were identified. To discover independent secondary signals, we performed a high-resolution fine-mapping analysis in each gene region, by conditioning on the previously reported GWAS tag variants in multivariable linear regression models. The analyses were performed with data from the Netherlands Epidemiology of Obesity (NEO) study, a population-based cohort study. Both Illumina HumanCoreExome array genotyping and fasting metabolite concentrations by Absolute*IDQ*TM p150 kit were available for 477 participants (mean (SD) age:(56. 3 (5. 7)) year, BMI: (30. 4 (5. 0)) kg/m2, 56. 4% men). Imputation was carried out by 1000 Genomes Phase one integrated variant release v3 using IMPUTE2. After Bonferroni correction, we observed eight secondary association signals in four gene regions (*FADS1*, *ACADM*, *CPS1*, *PHGDH*). The strongest associations were found at *FADS1* and *CPS1* prior to conditioning. At *FADS1* rs188885524 (MAF=1. 7%, Pbefore= 5. 3×10−15) located in 5' untranslated region showed an, albeit decreased, association with PCaaC36:3-to-PCaaC36:4 ratio after conditioning on the GWAS variant rs174547 (Pconditional=3. 2×10−5 , r2=0. 04). At *CPS1*, three independent association signals with Glycine-to-PCaeC38:2 ratio were observed after conditioning on the tag variant rs2216405: rs186668263 (MAF=0. 5%, Pbefore=7. 3×10−14, Pconditional=3. 4×10−13 , r2=0. 0), rs2371008 (MAF=1. 7%, Pbefore=1. 2×10−7, Pconditional=3. 3×10−6 , r2=0. 0) , rs145922665 (MAF=0. 8%, Pbefore=2. 5×10−12, Pconditional=5. 5×10−12 , r2=0. 01). Furthermore, decomposition of metabolite ratios to individual metabolites resulted in additional independent association signals. More specifically, we identified ten additional association signals in *CPS1* with glycine concentrations, of which two variants (rs2371008 (Pbefore=4. 8×10−23, Pconditional=8. 6×10−19) , rs145922665 (Pbefore=1. 2×10−22, Pconditional=4. 9×10−19)) showed stronger association signals with glycine than with Glycine-to-PCaeC38:2 ratio. In conclusion, high-resolution fine-mapping of previously reported GWAS signals identified eight novel secondary variants associated with fasting metabolite concentrations. Replication of these findings will be sought.

814F

White matter tract laterality indices as endophenotypes to assess genetics of brain asymmetry. *M. S. Naslavsky[1,3], S. A. M. Ezquina[1], C. Malcher[1], G. L. Yamamoto[1], Y. A. O. Duarte[1], M. L. Lebrão[1], M. Thiebaut De Schotten[2], M. Catani[2], E. Amaro Jr. [1,3], M. Zatz[1].* 1) University of Sao Paulo, Sao Paulo, SP, Brazil; 2) Institute of Psychiatry, King's College London, London, UK; 3) Brain Institute, Albert Einstein Hospital, Sao Paulo, SP, Brazil.

Brain laterality is a phenotype common to many animals in which several functions are activated asymmetrically by each hemisphere. In humans, handedness and language are two main examples of lateralized phenotypes in the brain. Dominance for handedness and language is leftward in most humans and it is not fully mirrored in left-handers, but the distribution of this phenotype is more dispersed than in right-handers. The genetic components behind human brain laterality are largely unknown and contribute with medium to small overall effect. Disruption of brain asymmetry patterns is associated with neuropsychological disorders such as dyslexia, schizophrenia and autism. *LRRTM1* is a maternally imprinted gene that was previously associated with lateral hand skill measures in a group of schizophrenic/schizoaffective individuals. The aim of this study was to verify enrichment of variants in *LRRTM1* gene in extreme phenotypes of arcuate fasciculus laterality indices. These indices were derived from white matter fractional anisotropy (FA) values obtained by diffusion tensor imaging in magnetic resonance of a subgroup of a Brazilian population-based sample which were exome-sequenced. The laterality indices based on FA values in four pairs of white matter tracts (arcuate fasciculus: long, anterior and posterior segments; and frontal aslant tracts) were derived and showed a normal skewed distribution. Gene variant enrichment analysis was tested with sequence kernel association test (SKAT) clustering the extremes of the distribution of the arcuate fasciculus long segment and *LRRTM1* variants, with n=30 per extreme ends. Although no significant p-value was obtained, one *LRRTM1* missense polymorphism (rs6733871, p. Asn330Ser) present in two copies in combination with other three rare variants showed a trend of enrichment in leftward lateralization, including non-right-hander individuals. This variant is described with frequency >0. 2 among different populations and exclusive to humans but highly conserved among mammals. Additional analyses with the other language-related white matter tracts laterality indices and *LRRTM1* variation are in progress to provide evidence on *LRRTM1* role in brain asymmetry. Further variant collapsing methods in a genome-wide scale may be useful to identify gene candidates as key components of development and maintenance brain asymmetry.

815W

***TPH2* variants are associated with the Metabolic Syndrome and Obesity.** *V. Causer, S. Reis, I. Halder.* University of Pittsburgh, Pittsburgh, PA.

Tryptophan hydroxylase 2 (*TPH2*) gene encodes a protein that catalyzes the first and rate limiting step in the serotonin pathway and *TPH2* variants have been associated with various psychological outcomes including depression. Studies have shown a bidirectional relationship between depression and metabolic syndrome. We hypothesized that *TPH2* variation may also be associated with Metabolic Syndrome (MS) and/or its components. Study subjects included 771 European Americans recruited in the University of Pittsburgh HeartSCORE study. Subjects were between 45-74 years in age, 64% female, and represented all Framingham risk strata. Information on individual MS components, demographic measures and genotypes for ~49,000 SNPs (as part of an Illumina gene chip) were available for all participants. We analyzed 24 *TPH2* SNPs on the gene chip. Each SNP was in Hardy Weinberg Equilibrium and had minor allele frequency >0. 05. Using Haploview we identified 5 linkage blocks and selected one known tag SNP from each block: rs7963803, rs11179002, rs4760750, rs4760820, and rs12231356 to capture 99% of the variation in *TPH2*. Using PHASE, we estimated five haplotypes in our sample that had frequencies > 0. 05. MS was modeled as a latent variable unifying the individual components of the syndrome. In structural equation models (SEM) adjusted for age and gender (implemented in MPlus) we found two haplotypes CGCCG (Hap1) and CGCGG (Hap2) to be significantly associated with the latent MS variable (p=0. 003, 0. 013). We confirmed the associations with Hap1 and Hap 3 by testing against a continuous metabolic risk score (MRS; defined as mean of standardized MS components) and each MS component (Blood pressure, Waist circumference, Triglycerides, HDL and glucose) after adjusting for appropriate covariates. Hap1 was significantly associated with MRS (p=0. 001) and with waist (p < 0. 001), but not with other MS components. Of the five tag SNPs only rs4760820 was significantly associated with MRS (<0. 001) and waist circumference (p= 1. 62x10-6). In four SNP long moving window haplotypes using all 24 *TPH2* SNPs both MRS and waist circumference remained significantly associated with all four haplotypes containing rs4760820 (MRS: P = 0. 0003, waist: P = 0. 0001). Our results indicate that *TPH2* variations which have previously been associated with depression are also associated with MS primarily through effects on central adiposity.

816T

Metabochip study of body composition measures in black South Africans reveals novel insights into obesity risk loci. *Z. Lombard[1,2], V. Pillay[3], L. M. Hendry[1], A. Choudhury[2], H. Soodyall[3], S. A. Norris[4], N. J. Crowther[5], M. Ramsay[2] for the AWI-Gen Research Group, as members of The H3Africa Consortium.* 1) School of Molecular & Cell Biology, Faculty of Science, University of the Witwatersrand, Johannesburg, South Africa; 2) Sydney Brenner Institute for Molecular Bioscience, University of the Witwatersrand, Johannesburg, South Africa; 3) Division of Human Genetics, School of Pathology, Faculty of Health Sciences, National Health Laboratory Service & University of the Witwatersrand, Johannesburg, South Africa; 4) MRC/Wits Developmental Pathways for Health Research Unit, Department of Paediatrics, School of Clinical Medicine, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa; 5) Department of Chemical Pathology, School of Pathology, Faculty of Health Sciences, National Health Laboratory Service & University of the Witwatersrand, Johannesburg, South Africa.

Obesity is a predisposing factor for many diseases, and results from an interplay between genetic and environmental factors. Strong evidence exists for the role of genetic variation in the etiology of obesity and body composition, and although these findings have been widely replicated, there remains a paucity of data from African populations. Likewise, the heritability of body composition measures has not been comprehensively investigated in Africans. We sought to establish whethergeneticvariants on the Illumina Metabochip array were associated with different body composition measures in black South Africans. Additionally, the heritability of these traits in this population was assessed. Participants from the Birth to Twenty cohort study, a longitudinal birth cohort from South Africa, were the focus of this study, and included 1240 participants (median age = 17. 9 years) and 1033 of their female caregivers (median age = 40 years) (total N=2273). The association between SNPs and a given body composition measure was estimated using linear regression, with adjustment for covariates (sex, age and height) using PLINK 1. 9. Body composition measures investigated included anthropometric measures commonly used to define obesity, such as BMI, waist- and hip circumference and waist-to-hip ratio (WHR). In addition, dual-energy X-ray absorptiometry (DXA)-derived whole body composition measures were evaluated, including fat mass, lean-tissue mass and percentage body fat. Narrow-sense heritability was estimated using genotyped SNP data with GCTA. Strong associations observed in these analyses, are between variants near the *SEC16B* gene with fat mass (P=9. 48 x 10-7; b=1. 79kg) and percentage body fat (P=7. 9 x 10-7; b=1. 35kg). These data suggest the presence of a universal risk locus near *SEC16B* for body fat mass, as it has previously been associated with obesity measures in European, African American and Asian populations. Sex-specific associations are observed in males only near *TRPM7* with both hip- (P=1. 28 x 10-8; b=1. 80cm) and waist (P=6. 19 x 10-8; b=1. 64cm) circumference, and in females only in *FTO* (P=2. 91 x 10-5; b=0. 02) with WHR. Preliminary heritability results are comparable to estimates derived from Europeans. These results provide evidence that the genetic etiology of obesity-related traits may differ by ancestry and sex, and these factors should therefore be considered when assessing the genetic determinants of body composition and related disorders.

817F

Association of rs6967330, a functional variant of *CDHR3*, with asthma exacerbation and rhinovirus infections in African Americans. *M. March[1], P. M. A Sleiman[1], J. McElwee[2], D. Diogo[2], F. Mentch[1], K. Thomas[1], C. Hou[1], C. Kim[1], H. Hakonarson[1].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Merck Research Laboratories, Department of Genetics & Pharmacogenomics (GpGx), Boston, MA.

Asthma is a chronic inflammatory condition of the lungs, characterized by acute episodes of breathing difficulties and hypersensitivity of the lungs to a variety of common environmental stimuli and allergens. Among the most common causes of hospitalization during childhood are acute asthma exacerbations. Considerable effort has been spent examining the genetic underpinnings of the asthma phenotype; very few studies have been conducted investigating the contribution of genetic variation to asthma exacerbations. A recent GWA study (Bønnelykke *et al.* , 2014) associated a coding variant of the *CDHR3* (Cadherin-related family member 3) gene with an asthma exacerbation phenotype defined by hospitalizations in a Danish childhood cohort. It was also shown that cell surface expression of the CDHR3 protein was enhanced in the disease-associated variant, which contains a cysteine-to-tyrosine substitution in the extracellular domain. A recent functional study (Bochkov *et al.* , 2015) showed that the disease associated variant of the CDHR3 protein greatly enhanced infection rates of rhinovirus C in a cell culture model system. This observation provides an excellent model explaining the GWA result, as rhinovirus C infection is a common cause of asthma exacerbation. To further investigate this hypothesis, we chose to investigate the relevant *CDHR3* variant (rs6967330) in the cohort assembled at the Center for Applied Genomics at the Children's Hospital of Philadelphia. We analyzed rs6967330 in our African American cohort (approximately 10,700 subjects) using a phenome-wide association study (PheWAS) based on ICD9 codes. This analysis revealed that rs6967330 is associated with the PheWAS phenotype "Asthma with exacerbation" to a phenome-wide significant level ($p < 9.0 \times 10^{-5}$), a phenotype for which we have 1688 cases and 6285 controls. To follow up the PheWAS result, we compiled a case/control cohort for phenotypes associated with rhinovirus infections based on ICD9 codes associated with diagnoses. Despite the small size of our cohort (178 cases), we found that rhinovirus infection associated to a nominal level ($p < 0.05$) with the genotype at rs6967330 in African American children. The results demonstrate that the indicated variant of CDHR3 is relevant to asthma exacerbations in African Americans, a previously unknown association, and the data provide support for the interaction of this variant with rhinovirus infection in triggering asthma exacerbations.

Tissue and sex-specific gene expression patterns during pubertal development. *H. Hou[1,2], L. Uusküla-Reimand[1], M. Makarem[1,3], C. Corre[1], A. Metcalf[1], C. Bellissimo[1], A. Goldenberg[1,5], M. Palmert[1,4], M. Wilson[1,2].* 1) Department of Genetics and Genome Biology, Hospital for Sick Children, Toronto; 2) Department of Molecular Genetics, University of Toronto; 3) Faculty of Medicine, University of Toronto; 4) Department of Pediatrics, Hospital for Sick Children, Toronto; 5) Department of Computer Science, University of Toronto.

Puberty is a postnatal developmental process achieved by all reproductively competent adults. Age of puberty onset varies among the general population and is associated with adverse health outcomes, including risks for breast cancer, cardiovascular disease and behavioral disorders. Studies of rare mutations in patients with pubertal disorders have revealed a complex regulatory system involving the hypothalamic-pituitary-gonadal (HPG) axis. Recent GWAS studies identified more than 100 loci associated with age at menarche (AAM); however only a few of these loci fall within or near genes implicated in rare pubertal disorders (*MKRN3*, *LEPR*, *TACR3*, *PCSK1*). Little is known about the mechanisms by which these loci affect pubertal timing.

We first asked if genes associated with AAM GWAS loci and disorders of puberty could give us insight into the cell types and tissues that influence pubertal timing. Using transcriptome data from more than 75 normal human tissues/cell types, we found that the expression of these puberty-associated genes was significantly enriched for the pituitary. Interestingly the second most enriched tissue was the pineal gland. For example gene expression levels of *TMEM38B* (the second most statistically significant GWAS hit), *CA10*, *RXRG*, *PLCL1* were most highly expressed in the pineal gland.

We isolated HPG axis tissues, the pineal gland and liver at five developmental time points that span the pubertal transition in male and female mice. Using high-throughput qPCR we then profiled the expression of 183 mouse orthologs of genes known to underlie pubertal disorders and/or are implicated in the regulation of pubertal timing by GWAS. We confirmed previously reported temporal expression profiles such as the decrease in hypothalamic expression of *Mkrn3* prior to puberty. We also found evidence of pineal gland expression for several genes including *Tmem38b*. Overall, the number of significant changes in gene expression between adjacent time points was greatest prior to puberty. Excluding the gonads, pituitary gene expression was found to be the most dynamic between sexes and, interestingly, many of the pituitary sex differences became apparent at the onset of puberty and increased thereafter. Overall our results give new insights into the temporal, tissue and sex specific expression patterns of genes that regulate pubertal timing.

819T

Polymorphisms of genes involved in extracellular matrix homeostasis of tendons and the risk of rotator cuff tears. *M. F Leal[1,2], E. A. Figueiredo[1], P. S. Belangero[1], C. Cohen[1], L. C. Loyola[1,2], M. C. Smith[2], C. V. Andreoli[1], A. C. Pochini[1], B. Ejnisman[1], M. Cohen[1].* 1) Departamento de Ortopedia e Traumatologia, Universidade Federal de São Paulo, 04038-032, São Paulo, SP, Brazil; 2) Disciplina de Genética, Departamento de Morfologia e Genética, Universidade Federal de São Paulo, 04023-900, São Paulo, SP, Brazil.

Rotator cuff tears is common orthopedic disease. The tears occurs in part due to a degenerative process in tendons of the shoulder. The histopathological changes associated with rotator cuff tears include thinning and disorganization of collagen fibers. Several studies, including from our research group, have been demonstrate the deregulated expression of genes involved in the extracellular matrix homeostasis in the ruptured tendon. Recently, two studies showed that genetic variants might have a role in the tears etiology. Therefore, polymorphisms in genes involved in the extracellular matrix homeostasis can contribute to an extended tendon degeneration process, which explains why subsets of patients are more susceptible to rotator cuff tears. In this study, we evaluated if the polymorphisms rs6728999 (*FN1*), rs2104772 (*TNC*), rs1800012 (*COL1A1*), rs3196378 (*COL5A1*), rs11568785 (*TGFBR1*), rs1590 (*TGFBR1*), rs17731 (*KLF6*), rs243865 (*MMP2*), rs243866 (*MMP2*), rs679620 (*MMP3*), rs522616 (*MMP3*), rs17577 (*MMP9*), rs2252070 (*MMP13*), rs4898 (*TIMP1*) and rs2277698 (*TIMP2*) were associated with the risk of rotator cuff tears. We genotyped 210 patients with full-thickness rotator cuff tears and paired 411 controls (individuals without this disease and without any familiar history of rotator cuff tears) using TaqMan inventoried assays in a real-time PCR system. The Chi-square test was used to compare the genotypes differences between groups. Univariate and multivariate logistic regression were performed to investigate whether the studied polymorphisms may contribute to the risk of rotator cuff tears risk. The frequencies of genotypes were in the Hardy-Weinberg equilibrium, except for the polymorphism rs4898. The rare variants of rs17731 (adjusted p = 0. 005) and of rs3196378 (adjusted p = 0. 025) were associated with the risk of rotator cuff tears by multivariate logistic regression (the p-value was adjusted by gender and age). Therefore, these genetic variants of *KLF6* and of *COL5A1* may have a role in the rotator cuff tears etiology.

820F

HLA association analysis and haplotype analysis identify susceptible alleles of HLA class II to tuberculosis. *L. Toyo-oka[1,2], S. Mahasirimongkol[2], H. Yanai[1,3], T. Mushiroda[4], S. Wattanapokayakit[2], N. Wichukchinda[2], N. Yamada[5], S. Nedsuwan[6], P. Kantipong[6], A. Takahashi[7], M. Kubo[8], P. Sawanpanyalert[9], K. Tokunaga[2].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Tokyo, Japan; 2) Department of Medical Science Center, National Institute of Health, Department of Medical Sciences, Ministry of Public Health, Nonthaburi, Thailand; 3) Fukujuji Hospital, Japan Anti-Tuberculosis Association (JATA), Kiyose, Japan; 4) Laboratory for Pharmacogenomics, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 5) Research Institute of Tuberculosis, Japan Association of Tuberculosis, JATA, Kiyose, Japan; 6) Chiangrai Prachanukroh Hospital, Ministry of Public Health, Chiang Rai, Thailand; 7) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 8) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 9) Food and Drug Administration, Ministry of Public Health, Nonthaburi, Thailand.

Tuberculosis (TB) is chronic respiratory infection with high burden to global health especially in Africa and south-east Asia. Genome-wide association study (GWAS) in Thai and Japanese populations identified at-risk locus in 20q12 in young-onset (< 45 years old) TB. Human leukocyte antigen (HLA) class II is considered to play important roles for TB based on its pivotal roles in host interactions with M. tuberculosis and its strong association with leprosy, an infectious disease caused by M. Leprae. However, previous association studies of HLA class II are usually under power due to small number of cases investigated. *HLA-DQB1*05:03* was suggested as strong risk factor for tuberculosis in Cambodia with additional functional confirmation. In Thai population, *HLA-DQB1*05:02*, *HLA -DQB1*06:01* and *HLA -DQB1*03:01* was reported with 82 cases and 160 controls. In GWAS, not all *HLA-DRB1* alleles could be captured by SNP genotyping due to complexity of this genomic region. The purpose of this study is to investigate the associations of HLA class II, *HLA-DRB1* and *HLA-DQB1* with TB. Subjects were recruited through a TB surveillance system in Chiang Rai province in Thailand after obtaining individual informed consent. Diagnosis of TB was by clinical features with microbiological confirmation. HIV seropositive individuals were excluded. In summary, 396 TB patients and 282 controls were selected and their blood samples were drawn for DNA extraction. *HLA-DRB1* and *HLA-DQB1* were determined by PCR-SSO (sequence-specific oligonucleotide probes), WAKFlow. We conducted HLA association analysis and haplotype analysis utilizing alleles and haplotypes with frequencies of >5% and obtained corrected *p*-values (*Pc*) adjusted by Bonferroni correction. In HLA association analysis, *HLA-DRB1*16:02* and *HLA-DRB1*14:01* showed lowest *Pc* of 0. 002 with odds ratio (OR) at 2. 02 (1. 36-3. 06) in dominant model. Moreover, *HLA-DRB1*14:01* was associated with *Pc* of 0. 042 with OR of 0. 58 (0. 39-0. 86) in dominant model while none of *HLA-DQB1* alleles showed association in additive, dominant and recessive model. Haplotype analysis revealed that *DRB1*16:02 - DQB1*05:02* (*Pc*: 0. 002 and OR: 2. 02 (1. 36-3. 06) in dominant model) and *DRB1*14:01 -DQB1*05:02* (*Pc*: 0. 013 and OR: 0. 55 (0. 37-0. 82) in dominant model) were risk and protective haplotypes, respectively. These results suggest that *HLA-DRB1* is more critical than *HLA-DQB1* because *HLA-DQB1*05:02* did not affect the tendency and magnitude of OR of *HLA-DRB1* allele.

821W

Survey of Rare and Common Genetic Variation in Putative Risk Loci for Primary Open-angle Glaucoma. *R. P. Igo[1], J. N. Cooke Bailey[1], W. K. Scott[2], R. J. Sardell[2], M. A. Pericak-Vance[2], L. R. Pasquale[3], M. A. Hauser[4], T. Gaasterland[5], J. L. Wiggs[3], J. L. Haines[1], NEIGHBORHOOD Consortium.* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 3) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 4) Department of Ophthalmology, Duke University Medical Center, Durham, NC; 5) Scripps Genome Center, Scripps Institution of Oceanography, University of California, San Diego, San Diego, CA.

Glaucoma, a progressive degenerative disease of the eye, affects over three million people in the United States and is the second leading cause of blindness. The late-onset form of the disease has a complex mode of inheritance: more than a dozen genetic risk loci for glaucoma have been found to contribute modest effects, but the greater part of the heritability still remains to be explained. To identify new genetic determinants for glaucoma, and to better characterize suspected risk loci, we genotyped 6,044 unrelated primary open-angle glaucoma (POAG) cases and controls of European descent within the NEIGHBORHOOD Consortium for over 240,000 mostly exonic genetic variants on the Illumina HumanExome BeadChip, enriched for variation likely relevant to POAG by the addition of 15,800 custom variants in genomic regions implicated in glaucoma. Here, we report results from single-variant and gene-level tests of association between POAG and 301 diallelic polymorphisms within and near 14 genes in previously reported risk loci, on a sample of 3,208 POAG cases and 2,836 controls. Association analysis for single common variants was conducted by logistic regression, adjusting for age at recruitment, sex, DNA source and three principal components for ancestry, using an additive genetic model (on the log odds ratio scale). For rare variation, gene-based tests using SKAT-O were performed including all variation with minor allele frequency less than 0. 1 or 0. 02, using the default weighting scheme. Association at studywide significance (nominal $p < 0.00017$) was detected for one or more common variants in *AFAP1, ATXN2, CAV1, CDKN2B-AS1, SIX6* and *TMCO1,* including missense variants in *ATXN2* (W262R) and *SIX6* (H141N). Genes *FNDC3B* and *AFAP1* contained multiple rare coding variants enriched in either cases (OR > 2) or controls (OR < 0. 5), and thus had suggestive SKAT-O results ($p = 0.005$ and 0. 008 respectively). Insight into the role of both rare and common variation at POAG risk loci will improve our understanding of the genetic basis of this common eye disease. Grant support: NIH/NEI R0122305; 1X01HG007486-01.

Variants in the HLA-DQB1 region confer susceptibility to Age-Related Macular Degeneration. *E. Jorgenson[1], R. Melles[2], T. Hoffmann[3, 4], X. Jia[5], L. Sakoda[1], M. Kvale[3], Y. Banda[3], C. Schaefer[1], N. Risch[1, 3, 4], L. Shen[1].* 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) Department of Ophthalmology, Kaiser Permanente Northern California Redwood City Medical Center, Redwood City, CA 94063, USA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA, 94143 USA; 4) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA 94143, USA; 5) Department of Neurology, University of California San Francisco, San Francisco, CA 94143, USA.

Age-related Macular Degeneration (AMD) risk variants in the complement system point to the important role of immune response and inflammation in the pathogenesis of AMD. While the Human Leukocyte Antigen (HLA) region plays a central role in regulating immune response, previous studies of genetic variation in HLA genes and AMD have been limited by sample size or incomplete coverage of the HLA region by first generation genotyping arrays and imputation panels. Here, we conducted a large-scale HLA fine-mapping study with 4,841 AMD cases and 23,790 controls of non-Hispanic white ancestry from the Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort. Genotyping was conducted using custom Affymetrix Axiom arrays, with dense coverage of the HLA region. Classic HLA polymorphisms were imputed using SNP2HLA, which utilizes a large reference panel to provide improved imputation accuracy of variants in this region. We examined a total of 6,937 SNPs and 172 serotypes, incorporating established AMD risk variants in a forward-stepwise conditional analysis, which revealed novel associations with two nonsynonymous SNPs, rs9274390 and rs41563814 (OR=1. 21; p=1. 40×10-11) corresponding to amino acid changes at position 66 and 67 in *HLA-DQB1*, respectively, and the DQB1*02 serotype (OR=1. 20; p=3. 9×10-10) with the risk of AMD. Similar effects were observed with non-exudative AMD and CNV AMD subtypes. The effect of rs9274390 was consistent whether it was carried on the DQB1*02 haplotype or not, suggesting that the association of this SNP was primary. These findings support a role of HLA class II alleles on the risk of AMD.

823F

Heterogeneity in expression of HLA class II genes provides evidence for unexpected functions of their products. *E. Hesselberg, M. Houtman, K. Shchetynsky, L. Padyukov.* Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

Introduction. The strongest genetic risk factor for developing rheumatoid arthritis (RA) was described within the *HLA-DRB1* locus. Several genetic variations cumulatively defined as shared epitope (SE) alleles were repeatedly shown to have especially high influence in the development of seropositive RA. However, there is very little knowledge regarding different products from the genes in this locus. We therefore investigated *HLA-DRB1* RNA expression for alternative splicing isoforms. **Methods.** Generic PCR based on flanking exons of HLA-DRB1 was run on cDNA from human PBMCs, osteoclasts, B-cell line, and fibroblasts. Amplicons were sequenced and the most robust product was detected using qPCR on a set of whole-blood cDNA from a cohort of RA patients and healthy controls (n = 95 + 95) for the validation of the isoform. **Results.** We detected a non-canonical 219bp-length isoform lacking premature stop codons across different cell types. The short isoform lacked regions translating Ig domain and antigen-binding domain. This isoform was repeatedly detected in healthy and sick individuals. Interestingly, this isoform was detected in different types of cells, including professional and non-professional antigen presenting cells. **Conclusion.** A short *HLA-DRB1* isoform exists in multiple cell types and its functionality should be further studied. The absence of antigen-binding domain indicates the possibility of unexpected functions of the product from this gene that should be investigated in the context of autoimmune diseases.

Identification and functional analysis of chronic pancreatitis-associated deep intronic variants in the SPINK1 gene. *WB. Zou[1,2,3], A. Boulling[1,2], E. Masson[1,4], Z. Liao[3], ZS. Li[3], JM. Chen[1,2,5], C. Férec[1,2,4,5].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U1078, Brest, France; 2) Etablissement Français du Sang (EFS) - Bretagne, Brest, France; 3) Department of Gastroenterology, Changhai Hospital, the Second Military Medical University, Shanghai, China; 4) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Universitaire (CHU) Brest, Hôpital Morvan, Brest, France; 5) Faculté de Médecine et des Sciences de la Santé, Université de Bretagne Occidentale (UBO), Brest, France.

Over the past two decades, genetic variants have being increasingly reported to be associated with or cause hereditary, familial and idiopathic forms of chronic pancreatitis. However, to date, mutational analyses of the disease-causing or -predisposing genes (e. g. PRSS1, SPINK1, CTRC) have focused on the coding sequences and exon/intron boundaries. Given the certain presence of functional variants in deep intronic sequences, this practice must underlie a fraction of the "missing heritability" of chronic pancreatitis. As a first step to address this issue, we performed Sanger sequencing of the intronic sequences of the SPINK1 gene in a subset of French patients with familial chronic pancreatitis; all of these patients had previously been found not to carry a known disease-predisposing variant. We found deep intronic variants in 13 patients. To determine whether these variants are of pathogenic relevance or not, we sought to perform RT-analysis of each variant in the context of the entire genomic sequence of the SPINK1 gene (i. e. from the translation initiation codon to the termination codon). We have successfully introduced most of the deep intronic variants into the pcDNA3. 1/V5-His-TOPO vector harboring the entire SPINK1 gene by means of directed mutagenesis. The resulting mutant vectors were used to transfect HEK 293 cells; and total RNA were extracted for RT- PCR analysis. One (i. e. c. 87+363A>G) of the so far tested variants was found to cause aberrant splicing. Findings from this analysis will have implications for designing mutation screening strategies in clinical practice as well as for interpreting data that will be obtained from the application of next-generation sequencing.

Modeling Autism by Candidate Gene Editing in Human Induced Pluripotent Stem Cells. *E. Deneault, K. Zaslavsky, R. K. Yuen, T. O. Thompson, J. Ellis, S. W. Scherer.* Sickkids, Toronto, Ontario, Canada.

Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder that is poorly understood at the gene level. As live neurons from human brain are not easily accessible, we generated a series of new iPS cell lines derived from fibroblasts obtained from members of seven different ASD families affected by loss-of-function mutations in ASD-associated genes. The seven candidate genes affected by these mutations are *AGBL4*, *CAPRIN1*, *CNTN5*, *DLGAP2*, *EHMT2*, *KAL1* and *NRXN1*. We used the double-nicking type II CRISPR/Cas9 system to correct mutations in patient-derived iPS cells, hence providing isogenic controls to highlight the role of these genes in autism. Guide RNA (gRNA) sequences were devised in order to minimize the likelihood for off-target binding. In the presence of a single-stranded oligonucleotide (ssODN) template, cellular HDR machinery replaced the disease mutations for the wild-type sequences. Edited alleles were detected using specific DNA probes along with absolute quantification by droplet digital PCR (ddPCR). The frequency of modified alleles was amplified to 100% using sibselection steps in a 96 well format (Miyaoka Y, Nat. Methods, 2014;11[3]). We also adapted this editing system to specifically knock-out 8 additional ASD-associated genes, for which skin fibroblasts were not available to derive iPS cells from ASD patients. These include *AFF2*, *ASTN2*, *ATRX*, *CACNA1C*, *CHD8*, *KCNQ2*, *SCN2A* and *TENM1*. We hypothesized that artificial disruption of a candidate gene in iPS-derived neurons would promote a similar phenotype to that observed in iPS-derived neurons from probands. We preferentially targeted the earliest exon that is common to the different transcripts for each candidate gene. We inserted a 60bp DNA fragment that includes all-frame termination codons, a rare restriction site (*Mre*1) and a V5 epitope tag to possibly reveal truncated forms of proteins. This stop tag is synthesized as ssODN flanked by homology arms that are specific to each candidate gene. All iPS cell lines generated above are currently cultured in vitro under conditions favouring neuronal differentiation. RNAseq, immunostaining and electrophysiology will shed light on the effects of mutated ASD-associated genes on neuronal expression patterns and identity, dendritic complexity and synaptic function.

826F

Prevalence of HLA-DQ alleles, *PTPN22* gene functional variant R620W, and three autoantibodies in Kuwaiti Arab children with Type-1 Diabetes Mellitus. *M. Z. Haider[1], M. A. Rasoul[1,2], S. A. Mathews[1], H. Al-Kandari[3], M. Al-Mahdi[4], J. Sukumaran[1], G. S. Dhaunsi[1,2].* 1) Department of Pediatrics, Faculty of Medicine, Kuwait University, Safat, Kuwait; 2) Department of Pediatrics, Mubarak Al-Kabeer Hospital, Jabriya, Kuwait; 3) Department of Pediatrics, Farwania Hospital, Farwania, Kuwait; 4) Department of Pediatrics, Adan Hoapital, Al-Adan, Kuwait.

A complex interaction between susceptibility genes, immune mediators and environmental factors play a critical role in genetic predisposition to type-1 diabetes mellitus (T1DM). We have determined the prevalence of HLA-DQ alleles, protein tyrosine phosphatase N22 (*PTPN22)* gene C1858T functional variant and three autoantibodies in Kuwaiti children with T1DM. This study included 239 Kuwaiti children with TIDM and 133 controls (healthy and ethnically matched). The diagnosis of T1DM was based on the ISPAD criteria. HLA-DQ alleles were determined by sequence-specific PCR in 178 patients. The genotypes for *PTPN22* gene variant C1858T (R620W) were identified by PCR-RFLP. The presence of autoantibodies (ICA, INS and GAD) were determined by radioimmunoassay. Nine different combinations of HLA-DQ alleles were detected in patients. In 55% patients, the genotype was either homozygous for DQ2 or in combination with a DQ8 allele. In 36% patients, the genotype was homozygous DQ8 or with other alleles. Collectively, 91% of the patients had either DQ2 or DQ8 alleles. The variant genotype of the *PTPN22* gene was detected in homozygous/heterozygous combination in 39% patients compared to 27% in controls. The homozygous TT-genotype was detected in 8% patients compared to 0. 99% in controls (p <0. 001). In patients with TT-genotype of *PTPN22* gene, 93% had at least one DQ2 allele and 60% carried either a DQ2 or a DQ8 allele. In T1DM patients with TT-genotype, GAD autoantibody was detected in 83%, INS-Ab in 67% and ICA-Ab in 54% cases respectively. Our data demonstrate that the HLA-DQ2/DQ8 alleles and the variant T-allele of *PTPN22* gene constitute significant determinants of genetic predisposition to T1DM in Kuwaiti Arabs.

827W

Revealing the functional effect that relates *PTPN2* SNPs to rheumatoid arthritis. *M. Houtman, K. Shchetynsky, L. Padyukov.* Rheumatology Unit, Department of Medicine Solna, Karolinska Institute and University Hospital, Stockholm, Sweden.

Background: Rheumatoid arthritis (RA) is a common chronic autoimmune disorder that has a strong genetic component. Over 100 risk loci have been confirmed in genome-wide association studies and the major risk factor are HLA-DRB1 shared epitope (SE) alleles. Outside the HLA region, one of the recently identified candidate genes for RA is protein tyrosine phosphatase non-receptor type 2 (*PTPN2*), which was previously also shown in association with T1D. However, the functional consequences of genetic variations in the *PTPN2* region remain undefined. We aimed to understand the functional mechanisms that connect variations in the *PTPN2* region with the risk of RA development. **Methods:** We conducted an association study in the RACI cohort (6573 seropositive RA cases and 15870 controls, Eyre *et al.* , 2013), computed gene-gene interactions using attributable proportion for SE alleles with 21 SNPs within *PTPN2*, performed RNA expression analysis for *PTPN2* in blood and analyzed DNA methylation data (689 individuals, Liu *et al.* , 2013). The expression cohorts comprise 69 RA cases and 77 healthy controls (whole blood) and 44 RA cases and 43 healthy controls (peripheral blood mononuclear cells). **Results:** The interaction analysis between SNPs within *PTPN2* and HLA-DRB1 SE alleles identified an additional RA-associated SNP: rs657555 (meta-analysis in RACI cohort, p = 3. 35e-06; OR = 1. 1352; Q = 0. 3993). The expression of total *PTPN2* and *PTPN2* splice variants, *TC45* and *TC48*, did not vary significantly in individuals with different rs657555 genotypes. In addition, the expression of other genes from the locus within 1 Mb from rs657555 were not different in relation to genotypes in our and publicly available data. We identified a significant association independent of disease status between rs657555 genotypes and four CpG sites close to *PTPN2*: cg23544223, cg23598886, cg09945482, and cg24737193 (all p < 5e-9). These CpG sites are located in a CpG island 7 kb downstream of *PTPN2* and provide a potential functionally important link between associated genotypes and RA. **Conclusion:** This study of a complex autoimmune disease integrates genetic association and interaction of HLA SE alleles with the architecture of the *PTPN2* locus, expression and DNA methylation data and could provide a novel insight into disease mechanisms.

828T

Uncommon*PGRN* deletion and FTD responsible for phenotype variability in three familial cases. *E. Vitale[1], S. Napoletano[1], S. Pappata'[2], M. T. Gentile[3], L. Colucci-D'Amato[3], G. Della Rocca[4], A. Maciag[5], A. Puca[5], D. Grossi[6], G. Milan[7], A. Postiglione[8].* 1) Institute of Protein Biochemistry (IBP), CNR-National Research Council, Napoli, Napoli, Italy; 2) Institute of Bioimaging and Biostructures , CNR, Naples-Italy; 3) Department of Environmental, Biological, Pharmaceutical Science and Technology, Second University of Naples, Caserta-Italy; 4) Villa Camaldoli Foundation Clinic, Naples, Italy; 5) Department of Medicine - University of Salerno- Salerno, Italy; 6) Department of Psychology, Second University of Naples, Caserta, Italy; 7) Geriatric Clinic "Frullone" ASL Napoli 1 - Naples, Italy; 8) Department of Clinical Medicine & Surgery, University of Naples "Federico II", Naples-Italy.

Mutations in Progranulin (PGRN) gene have been genetically associated with fronto-temporal dementia (FTD), although the neurobiology of this secreted glycoprotein is still unclear. We identified three familial cases having a rare +5 deletion in exon six of PGRN gene (g. 101349_101355delCTGCTGT) as causative of frameshift mutation. This mutation is not considered frequent and already described in two apparently sporadic case of FTD only, but never associated with familial cases. Our patients showed also heterogeneous clinical phenotypes, such as behavioral variant (bv-FTD) in men and primary progressive aphasia (PPA) in women. Quantitative RT-PCR of *PGRN* gene expression in WBC shows an unusual increasing of expression, while protein analyses of plasma concentration detected a PGRN protein deficiency. Using allele-specific PCR mutation-primers (ARMS), this mutation was searched in three hundreds healthy controls matched by age, sex and geographic regions and no deletion was ever found. The findings provide convincing evidence of the putative role of *PGRN* in the genetic etiology of FTD and show a link between FTD and ex 6-del *PGRN* mutations, which probably are more frequent than previously considered. The described mutation express two different gender linked phenotypes bv-FTD in men and PPA in women. Although we believe that this is the product of a founder effect, we yet cannot prove at this stage. Our findings imply that PGRN is essential for neuronal survival and even partial loss of PGRN eventually leads to neurodegeneration.

Role of endothelial nitric oxide synthase (*eNOS*) G894T polymorphism in ischemic stroke susceptibility: A case-control study in North Indian population. *A. Kaur[1], K. kaur[1], A. Uppal[2].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Uppal Neuro Hospital, Amritsar, Punjab, India.

Introduction: Genetic variations in *eNOS* gene might have some functional implication in pathogenesis of ischemic stroke through reduced basal NO production and may affect individual's susceptibility to ischemic stroke. The only common variation (G894T) in *eNOS* gene leading to an amino acid change in the mature protein is guanine to thymine substitution at exon 7 replacing glutamate by aspartate at position 298. *eNOS* protein containing Asp at position 298 to may be subjected to selective proteolytic cleavage in endothelial cells and vascular tissues, leading to reduced nitric oxide synthase activity. **Objective:** The present study aims to elucidate the association of G894T variant of eNOS gene with ischemic stroke using case-control approach. **Methodology:** The case-control study included total of 239 individuals comprising of 139 patients (74 males and 65 females) with mean age of 62. 84±11. 36, from Uppal Neuro hospital Amritsar, clinically and radiologically diagnosed with ischemic stroke and 100 healthy controls (48 males and 52 females) with mean age of 58. 19±10. 74, validated by Questionnaire for verifying Stroke Free Status. All the subjects were genotyped using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) technique and the data so obtained was statistically analyzed. **Results:** The frequency of *eNOS* 894T allele was slightly higher inpatients as compared to controls (16% vs 8. 55%, p=0. 075). Both the cases and controls were found to be in Hardy Weinberg equilibrium (cases: χ^2=3. 010, p=0. 083; Controls: χ^2=0. 013, p=0. 91). Among the three genetic models, only co-dominant model (TT vs GT / GT vs GG) showed mild increased risk (OR=1. 66, 95% CI, 0. 95-2. 89, p=0. 064) of ischemic stroke susceptibility in patients. Overall, the distribution of *eNOS* G894T genotypes differed insignificantly between patients and controls (χ^2=3. 891, p=0. 143). There was no significant risk of developing disease as revealed by odds ratio (OR) (crude OR; GT: OR=1. 47, 95% CI, 0. 76–2. 83; TT: OR=4. 82, 95% CI, 0. 57–40. 87) in carriers of variant genotype from the reference group (GG). **Conclusion:**Although the co-dominant model showed weak association of *eNOS* G894T variant with ischemic stroke, overall,this polymorphism couldn't predict the risk of ischemic stroke in North Indian population, which can be attributed to small sample size of the study group.

830W

The type 1 diabetes susceptibility gene *CLEC16A* restrains NK cell function by modulating expression of NK receptors via C Vps-HOPS complex, CART and autophagy. *R. Pandey[1], M. Bakay[1], S. Yoeun[1], J. Kushner[2], J. S. Orange[3], H. Hakonarson[1,4].* 1) The Centre for Applied Genomics, Children's Hospital Of Philadelphia, Philadelphia, PA; 2) Section of Pediatric Diabetes and Endocrinology, Department of Pediatric Medicine, Endocrine-Metabolism, Texas Children's Hospital, Houston, TX; 3) Section of Immunology, Allergy, and Rheumatology, Department of Pediatric Medicine, Texas Children's Hospital, Houston, TX; 4) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Type 1 Diabetes is a multi-factorial childhood disease with a strong genetic component. Several GWAS had showed association of CLEC16A with T1D, which encodes a protein of unknown function. We reported previously that protective alleles of CLEC16A [A/A] are associated with higher levels of mRNA. We hypothesize that CLEC16A functions in NK cells to restrain secretory functions including cytokine release and cytotoxicity. Therefore, defining the role of CLEC16A in NK cells will provide insight into the pathogenesis of T1D. To address this, we investigated the expression of CLEC16A in human immune cells and NK cell lines on mRNA level by RT-PCR and on protein level by Western blot. We examined the consequence of knockdown of CLEC16A in NK cell lines and ex-vivo NK cells using siRNA and over-expression of this protein in NK cell line with a GFP expression reporter using a retroviral expression system. Cytotoxicity and INF-γ production were decreased in NK cells over-expressing CLEC16A. siRNAs mediated knockdown resulted in 70% reduction of Clec16A protein levels and 35% increase in cytotoxicity compared to control siRNAs. Clec16a over-expressing NK cells formed smaller number of conjugates for all time points in conjugation assay with no difference in CD107a expression. Sub-cellular localization studies revealed cytosolic localization. Mechanistic studies through reciprocal co-immunoprecipitation experiments reveals that CLEC16A associates with Vps16A, a subunit of class C Vps-HOPS complex and CART: an Hrs/Actinin-4/BERP/Myosin V Protein Complex, and modulates receptor recycling and expression through expansion of autophagosomes by ubiquitin-like conjugation pathways ending with Atg5. Clec16a knockdown in UBC-Cre-Clec16aloxP mice resulted in increase in NK cell cytotoxicity of the YAC-1 targets in comparison to control. Phenotypic analysis of splenocytes from TAM and control littermates revealed up regulation of NKp46, Ly49H and CD226 activating receptors. Splenocytes of Clec16aloxP knockdown TAM mice exhibit decreased mitochondrial membrane potential. Taken together, our results indicate that CLEC16A serves a role in restraining two major functions of NK cells, cytotoxicity and cytokine release. Our mechanistic studies reveal that *CLEC16A* restrains NK cell functions by modulating expression of NK receptors via C Vps-HOPS complex, CART and autophagy**.** Owing to its role in autophagy, Clec16a impacts the function of NK cells and the risk of autoimmunity.

831T

Capture Hi-C reveals a novel causal gene, *IL20RA*, in the pan-autoimmune genetic susceptibility region 6q23. *G. Orozco[1], A. McGovern[1], S. Schoenfelder[2], P. Martin[1], K. Steel[3], J. Massey[1], D. Plant[1], P. Fraser[2], A. Barton[1], J. Worthington[1], S. Eyre[1].* 1) Arthritis Research UK Centre for Genetics and Genomics, University of Manchester, Manchester, United Kingdom; 2) Nuclear Dynamics Programme, The Babraham Institute, Cambridge, United Kingdom; 3) Immunobiology Department. King's College London. New Hunt's House, Guy's London, United Kingdom.

The majority of genetic variants that predispose to complex diseases map to non-coding enhancer regions. There is evidence supporting a role of these non-coding variants in transcriptional regulation through long-range interactions with their target genes. The chromosomal region 6q23 is associated with a number of autoimmune diseases. Associated SNPs lie a large distance from any gene (>180kb). The aim of this work was to identify causal disease genes at the locus by studying long range chromatin interactions. The recently developed Capture Hi-C (CHi-C) method was used to characterize chromatin interactions involving the 6q23 region, in a hypothesis free manner, at high resolution in human T and B cell lines. Both the intergenic region associated with disease and all promoters within 500kb of associated SNPs were targeted. Fragments containing the disease associated intergenic SNPs displayed strong interactions with three distinct regions: the *IL20RA* gene, upstream of *IFNGR1* and a region downstream of the *TNFAIP3* gene containing the lncRNAs RP11-10J5. 1 and RP11-240M16. 1. Additionally, *IL20RA* interacts with these lncRNAs and the promoter of the *TNFAIP3* gene. *TNFAIP3* also demonstrated interactions with the same lncRNAs. A number of interactions were cell type specific, and they were all validated using 3C-qPCR. The most strongly associated SNP in the 6q23 region, rs6920220, is in tight LD (r2<0. 8) with eight other SNPs. Using RegulomeDB, we determined the most plausible causal SNP to be rs6927172, as it maps to an enhancer in both B and T cells, is in a DNase hypersensitivity cluster, shows transcription factor binding and is in a conserved region. To further characterize the functional effect of rs6927172 we used human primary T cell gene expression data to examine expression quantitative trait loci. The risk allele was modestly associated with an increased expression of *IL20RA* mRNA (p=0. 03). Chromatin immunoprecipitation demonstrated binding of chromatin marks of active enhancers (H3K4me1 and H3K27ac) to rs6927172. In conclusion, we have compelling evidence that the autoimmune risk variant, rs6927172, is within a complex gene regulatory region, involving *IL20RA*, *TNFAIP3* and regulatory elements, such as lncRNAs. These results show that CHi-C can help identify GWAS causal genes and suggest novel therapeutic targets; indeed, anti-IL-20 monoclonal antibody therapy has recently been shown to be effective in the treatment of rheumatoid arthritis.

The genetic architecture of human ear morphology. *K. Adhikari, A. Ruiz-Linares, CANDELA Consortium.* Genetics, Evolution and Environment, University College London, London, London, United Kingdom.

The human pinna, consisting primarily of cartilage, is highly variable within and across populations, as anthropological studies trying to characterize pinna shape in major continental populations have provided conflicting findings over the years. The ear lobe, not consisting of cartilage but of areolar and adipose tissue, is a modern human trait not present in other primates. So far the genetic architecture of morphological variation in human pinna is poorly understood. In the Candela project comprising over 5,000 volunteers from five Latin American countries, we scored a set of classical anthropological traits on the outer ear and observed genome-wide significant associations for lobe size, lobe attachment, folding of antihelix, helix rolling, ear protrusion and antitragus size. Seven genomic regions were identified, including a functional variant in the *EctodysplasinA receptor (EDAR)* gene, a key regulator of embryonic skin appendage development, and an evolutionarily conserved binding site for the transcription factor Cartilage paired-class homeoprotein 1 (*CART1*). Varying effect size, direction and prevalence of these variants explain why traditional anthropological studies could not observe consistent continental patterns so far. Associations were followed up with functional studies including replication in mouse models. Human pinna shape is now being used for forensics and user identification in electronic equipment, where these findings can be particularly interesting.

Genetic variants associated with gene expression in the lung and asthma susceptibility. *J. C. Berube[1], E. Lavoie-Charland[1], N. Gaudreault[1], L. Sbarra[1], C. Henry[1], D. S. Postma[2], D. D. Sin[3], K. Hao[4], D. C. Nickle[5], W. Timens[2], P. D. Paré[3], M. Laviolette[1], L. P. Boulet[1], Y. Bossé[1,6].* 1) Institut universitaire de cardiologie et de pneumologie de Québec, Quebec City, Canada; 2) University of Groningen, University Medical Center Groningen, GRIAC Research Institute, Groningen, Netherlands; 3) The University of British Columbia Centre for Heart Lung Innovation, St Paul's Hospital, Vancouver, Canada; 4) Icahn School of Medicine at Mount Sinai, New York, NY, United States; 5) Merck & Co, MRL, Seattle, Washington, United States; 6) Department of Molecular Medicine, Laval University, Quebec City, Canada.

Pathogenic changes occurring in airways of asthma patients generate chronic symptoms such as cough, shortness of breath, chest tightness and wheezing. Studying genetic regulation of lung transcriptome may lead to the identification of new variants associated with asthma susceptibility. The top 160 SNPs associated with gene expression in the lung of 1,111 lung tissue samples patients were selected and genotyped in 965 individuals of the Quebec City Case-Control Asthma Cohort. Allele frequencies were compared between asthma patients and controls. Ten SNPs were found to be significantly associated with asthma (P <0. 05). Rs17138154 on chromosome 7 was the SNP most strongly associated with asthma (P = 1. 26E-03). This protective asthma allele was associated with lower expression of *LOC493754* in the lung (eQTL p value = 1. 87E-45). The lung eQTL-SNP rs3807807 associated with the expression of *ICA1* (eQTL p value = 1. 84E-46) was also associated with asthma (P = 1. 08E-02). In this case, the asthma risk allele showed less expression of *ICA1* in the lung. Rs2249828, regulating the expression of *PIGP* in the lung (eQTL p value =4. 18E-122), was also associated with asthma (P = 1. 71E-02). Two SNPs in linkage disequilibrium with rs2249828 (rs2032088, r2 = 1. 0; rs2835624, r2 = 0. 92), showed an association with asthma in the meta-analysis of the European GABRIEL Consortium (P <0. 05). This project took advantage of a large-scale lung eQTL dataset to identify new functional genetic variants associated with asthma. The identification of lung eQTLs associated with asthma is not only elucidating new susceptibility genes, but also providing vital information about the genetic mechanisms leading to abnormal function of the genes that promote the development of asthma.

Temporal Expression Profiling Identifies Pathways Mediating Effect of Causal Variant on Phenotype. *S. Gupta[1], A. Radhakrishnan[1], P. Raharja-Liu[2], G. Lin[3], L. Steinmetz[3,4,5], J. Gagneur[2], H. Sinha[1].* 1) Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India; 2) Gene Center, Ludwig-Maximilians-Universitét, Munich, Germany; 3) European Molecular Biology Laboratory, Genome Biology Unit, Heidelberg, Germany; 4) Department of Genetics, Stanford University School of Medicine, Stanford, California, United States of America; 5) Stanford Genome Technology Center, Stanford University, Palo Alto, California, United States of America.

Even with identification of multiple causal genetic variants for common human diseases, understanding the molecular processes mediating the causal variants' effect on the disease remains a challenge. This understanding is crucial for the development of therapeutic strategies to prevent and treat disease. While static profiling of gene expression is primarily used to get insights into the biological bases of diseases, it makes differentiating the causative from the correlative effects difficult, as the dynamics of the underlying biological processes are not monitored. Using yeast as a model, we studied genome-wide gene expression dynamics in the presence of a causal variant as the sole genetic determinant, and performed allele-specific functional validation to delineate the causal effects of the genetic variant on the phenotype. Here, we characterized the precise genetic effects of a functional *MKT1* allelic variant in sporulation efficiency variation. A mathematical model describing meiotic landmark events and conditional activation of *MKT1* expression during sporulation specified an early meiotic role of this variant. By analyzing the early meiotic genome-wide transcriptional response, we demonstrate an *MKT1*-dependent role of novel modulators, namely, *RTG1/3*, regulators of mitochondrial retrograde signaling, and *DAL82*, regulator of nitrogen starvation, in additively effecting sporulation efficiency. In the presence of functional *MKT1* allele, better respiration during early sporulation was observed, which was dependent on the mitochondrial retrograde regulator, *RTG3*. Furthermore, our approach showed that *MKT1* contributes to sporulation independent of Puf3, an RNA-binding protein that steady-state transcription profiling studies have suggested to mediate *MKT1*-pleiotropic effects during mitotic growth. These results uncover interesting regulatory links between meiosis and mitochondrial retrograde signaling. In this study, we highlight the advantage of analyzing allele-specific transcriptional dynamics of mediating genes. Applications in higher eukaryotes can be valuable for inferring causal molecular pathways underlying complex dynamic processes, such as development, physiology and disease progression. .

835F

Lung disease-associated SNPs and lung eQTLs in the major histocompatibility complex (MHC). *M. Lamontagne[1], C. Couture[1], DS. Postma[2], DD. Sin[3], K. Hao[4], D. Nickle[4], PD. Pare[3], W. Timens[2], M. Laviolette[1], Y. Bossé[1,5].* 1) Centre de recherche de l'Institut universitaire de cardiologie et de pneumologie de Québec, Québec, Canada; 2) University of Groningen, University Medical Center Groningen, GRIAC research institute, Groningen, The Netherlands; 3) The University of British Columbia Center for Heart Lung Innovation, St. Paul's Hospital, Vancouver, BC, Canada; 4) Merck & Co. Inc. , Rahway, New Jersey, USA; 5) Département de Médecine Moléculaire, Université Laval, Québec, Canada.

The extended Major Histocompatibility Complex (xMHC) is a key locus for the immune system. This region was associated with lung diseases (asthma, cystic fibrosis, interstitial lung disease, lung cancer) and pulmonary function in previous GWAS. As for many GWAS-nominated loci, the causal gene(s) underpinning the genetic association with lung diseases and function in the xMHC locus remain unknown. This study has two goals. First, identify lung expression Quantitative Trait Loci (eQTLs) within the xMHC. Second, identify new lung diseases susceptibility genes by overlaying lung eQTL results in the xMHC with previously reported lung function and respiratory disease SNPs in this region. Non-tumor lung specimens and blood-DNA samples from 1,038 patients recruited at three academic sites were included in this study. The xMHC was delimited by the *HIST1H2AA* and *KIFC1* genes on chromosome 6 including 6,872 genotyped SNPs and 271 probe sets for eQTL analyses. Lung eQTLs were identified in the discovery set (Laval n=409; P-value ≤ 2. 68e-08) and then replicated in two replication sets (UBC n=287; Groningen n=342; P-value ≤ 0. 05). The GWAS Catalog was downloaded and GWAS-SNPs located in the xMHC and associated with lung diseases were selected. A total of 5,790 significant lung eQTLs were detected in the xMHC. These eQTLs consisted of 2,807 SNPs and 66 associated probe sets testing 50 transcripts. The majority of eQTLs were local (n= 5,516), but 274 distant-acting eQTLs were also found. eQTL-SNPs were pruned to 663 independent SNPs (LD with r2 < 0. 8). Among the 28 GWAS SNPs associated with lung diseases in the xMHC, 14 were associated with the expression levels of at least one transcript. Nineteen unique eQTLs were found with SNPs previously associated with asthma (6 SNPs; 8 transcripts), two with interstitial lung disease (1 SNP; 2 transcripts), four with lung cancer (2 SNPs; 4 transcripts) and 13 with pulmonary function (5 SNPs; 10 transcripts). Three genes were associated with GWAS SNPs from two traits/diseases: *AGPAT1* – asthma and interstitial lung disease, *HLA-DQB1* – asthma and interstitial lung disease, *ZFP57* – lung cancer and pulmonary function. This study highlights possible causal genes underlying the genetic association with lung diseases and pulmonary function in the xMHC region.

836W

Impact of common variation at diabetes locus*MTNR1B* on sleep, circadian, and melatonin physiology. *J. M. Lane[1,2,3], AM. Chang[2,3,4,5], D. Aeschbach[2,4,7], SW. Cain[2,4], CA. Czeisler[2,4], EB. Klerman[2,4], SW. Lockley[2,4,8], M. StHilaire[2,4], SA. Shea[2,4], JF. Duffy[2,4], OM. Buxton[2,4,5,6], S. Redline[2,4], FAJL. Scheer[2,4], R. Saxena[1,2,3], Care Consortium.* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Brigham and Women's Hospital, Division of Sleep and Circadian Disorders, Boston, MA; 3) Broad Institute, Program in Medical and Population Genetics, Cambridge, MA; 4) Harvard Medical School, Division of Sleep Medicine, Boston, MA; 5) Pennsylvania State University, Department of Biobehavioral Health, University Park, PA; 6) Harvard School of Public Health, Department of Social and Behavioral Sciences, Boston, MA; 7) German Aerospace Center, Institute of Aerospace Medicine, Cologne, Germany; 8) Monash University, School of Psychological Sciences, Clayton, Victoria, Australia.

Genome-wide association studies of type 2 diabetes suggest a causal link between sleep (*MTNR1B* rs10830963*)* and circadian rhythms (*CRY2* rs11605924*)* and development of diabetes. The causal mechanism of these associations, however, is unknown. In this study, we aimed to determine how both common and rare genetic variation in Melatonin-receptor 1B (*MTNR1B*) predisposes to risk of type 2 diabetes. We undertook three experimental approaches. First, given that prior studies point towards pancreatic islets as the site of action, we tested the effect of the *MTNR1B* ligand, melatonin, on glucose-stimulated insulin secretion in both rat beta cell lines and human islets. Second, we tested for an association between *MTNR1B* rs10830963 and measures of circadian rhythm timing (phase), magnitude (amplitude), length (period) and melatonin physiology using hourly plasma melatonin concentrations and body temperature collected over ≥24 hours in a unique cohort of subjects of European ancestry from intensive in-laboratory sleep studies (n= 193). Third, we tested for an interaction between objectively measured wake time and rs10830963 on glucose metabolism in multi-ethnic subjects from MESA (n=1,501). Our experimental results confirmed previously reported suppression of glucose-stimulated insulin secretion during acute and chronic melatonin administration in an *MTNR1B* dependent fashion in rat pancreatic beta-cells and human islets. Second, the *MTNR1B* variant significantly associated with a delayed timing of melatonin offset (Beta(SE) 1. 37h (0. 55h), p=0. 015) and a longer duration of melatonin secretion (41min (19min), p=0. 032) in our studies, demonstrating that risk allele carriers have altered melatonin physiology. Finally we found nominal evidence of a SNP x wake-time interaction (p=0. 024) effect on risk of type 2 diabetes. Taken together, our results are consistent with a mechanism whereby *MTNR1B* diabetes risk allele carriers have suppressed morning insulin response due to elevated melatonin levels, and food intake concurrent with elevated melatonin levels during this time adversely affects glucose metabolism. This points towards the need for genotype-based intervention trials using light (to suppress melatonin production) or changes in meal timing (to reduce melatonin during glycemic load). Therefore, our work defining mechanisms by which this variant influences melatonin physiology can now be explored for direct translational potential, an important goal for T2D genetics.

837T

The role of conditional genetic effects in determining human longevity. *S. Ukraintseva, K. Arbeev, L. Arbeeva, A. Kulminski, D. Wu, I. Akushevich, E. Stallard, A. Yashin.* Duke University, Durham, NC.

One of the paradoxes in genetics of human longevity is that many clinically relevant variants for major diseases (cancer, CHD, AD, etc.) are often present in genomes of longest-lived people in similar or sometimes even higher frequencies as in individuals with shorter lifespans. Here we discuss several biological mechanisms for the conditional effects of genes on aging and health related phenotypes which together could explain why carrying the genetic "risk factors" may not necessarily compromise longevity. These mechanisms include: (i) trade-off-like effects of genes on two or more health traits; (ii) age-specific influence of genes on vulnerability to death; (iii) gene-gene interaction; and (iv) gene-environment interaction, among other factors. Review of current knowledge suggests that the conditional effects of genes on aging and health related phenotypes are common and may result in situations in which disease "risk allele" can also be a pro-longevity variant.

838F

Integrative *In-Silico* Functional Characterization of Celiac Disease Susceptibility Variants. *N. A. Shaik[1], O. Rashidi[2], B. Babajan[2], J. Al-Aama[1,2], R. Elango[2].* 1) Genetic Medicine, King Abdulaziz University, Jeddah, Saudi Arabia, Select a Country; 2) Princess Al-Jawhara Center of Excellence in Research of Hereditary Disorders, King Abdulaziz University, Jeddah, Saudi Arabia.

Background & Aim: Celiac disease (CD) is a gluten intolerance disorder with an important genetic component. Recent GWAS and fine mapping studies in European CD patients have identified up to 57 non-HLA CD susceptible loci, majority of which lie either in non-coding or intergenic regions. Deciphering their pathogenic relevance to CD, through functional biology assays is a challenging task. Therefore, this study objective was to adopt integrative computational methods to uncover the plausible mechanisms through which CD specific loci contribute to the disease. **Methodology:** In this study, we investigated 1065 LD variants (r2 ≥0. 8) of 57 CD lead susceptible loci using CADD, GWAVA, RegulomeDB and FATHMM tools to rank them from deleterious to benign levels based on integrative scoring system developed. The mRNA levels of corresponding various ranked genes were tested in publicly available gene expression profiles of intestinal tissues and lymphocyte data. Pathway analysis was done to identify the potential pathways that are likely to be influenced by highly deleterious CD loci. **Results:** The integrative prediction analysis of 1065 LD variants revealed 22 SNPs (2% of 1065 LD) lying in 13 genes as highly deleterious (Rank I), followed by 46 SNPs (4. 3% of 1065 LD) of 29 genes which are deleterious (Rank II). Of the six genes with positive immunological function and altered expression levels, only *CCR2, CSK* genes fall under Rank 1 category. These two contribute to pathways which are essential to positively regulate the in vivo activation of leukocytes and T cell lymphocytes, which may further trigger the cascade of immunological events responsible for intestinal gluten intolerance. **Conclusion:** Using *in-silico*functional prediction tools, this study found 2 SNPs ranked in 1st category can contribute to celiac disease through pathways which are not well implicated previously. Although experimental validation is needed, our study shows the effective utility of integrative scoring system in prioritizing non-coding SNPs based on their corresponding gene expression levels, as a useful starting point to screen for putatively celiac causal SNPs from the crowd of GWAS data.

839W

Examining the causal effect of Vitamin D on childhood caries: A Mendelian Randomization study. *T. Dudding[1,2], SJ. Thomas[2], K. Duncan[2], DA. Lawlor[1], NJ. Timpson[1].* 1) MRC Integrative Epidemiology Unit, University of Bristol, Oakfield House, Oakfield Grove, Bristol, Avon, United Kingdom; 2) School of Oral and Dental Science, University of Bristol, Bristol, Avon, United Kingdom.

Dental caries is the localized destruction of susceptible tooth tissues by acidic by-products from bacterial fermentation of dietary products. Although caries in primary teeth is decreasing in the United Kingdom, it is still prevalent with 31% of 5 year olds having obvious decay experience in 2013. Previous studies have reported an inverse association between vitamin D and childhood dental caries, but whether this is causal is unclear. Mendelian randomisation (MR) is an analytical method used to provide evidence for causal associations between potentially modifiable risk factors and health outcomes. We undertook an MR study, using genetic variants known to influence circulating 25-hydroxyvitamin D (25(OH)D) levels, in 5,544 European origin children from the South West of England, to determine the causal effect of circulating 25(OH)D on dental caries. Data on caries and related characteristics were obtained from parental completed questionnaires between 38 and 91 months and clinical assessments in a random 10% sample at 31, 44 and 61 months. In multivariable confounder adjusted analyses we found no strong evidence for an association of 25(OH)D with caries experience, severity or onset, or having a general anesthetic (GA) for dental problems. Known relationships between vitamin D and *CYP2R1, DHCR7* and *GC* were replicated and when combined these SNPs were confirmed as a strong genetic instrument for vitamin D with per allele changes of a clinically relevant magnitude. These variants also showed no associations with factors potentially confounding the vitamin D – dental caries relationship. In MR analysis the odds ratios per 10 nmol/L increase in 25(OH)D were 0. 88 (95% confidence interval (CI): 0. 78, 1. 00; *P*=0. 054) for caries experience and 0. 94 (95% CI: 0. 73, 1. 21; *P*=0. 62) for GA. Our MR study suggests that there might be an inverse causal effect of 25(OH) D on dental caries. However, our estimates are imprecise and a larger study is required to determine a robust effect. With the use of a genetic instrument, a life-course vitamin D exposure model was used to test associations between vitamin D and dental caries in a population that had poorly suited vitamin D measures. In contrast to a recent meta-analysis we found little convincing evidence of an association between vitamin D and caries experience, onset or severity. This study highlights the opportunity to apply genetics based causal methods to dental epidemiology.

840T

Allele-specific enhancers mediate associations between *LCAT* and *ABCA1* polymorphisms and HDL cholesterol levels. *A. D. Howard[1], X. Wang[1], M. Prasad[1], A. D. Sahu[2], R. Aniba[2], S. Hannenhalli[2], Y. C. Chang[1].* 1) University of Maryland School of Medicine, Baltimore, MD 21201, USA; 2) Center for Bioinformatics and Computational Biology, University of Maryland, College park, MD 20742, USA.

For any given trait the majority of associated SNPs identified through genome-wide association studies (GWAS) lie within noncoding regions and are likely to mediate associations via allele-specific enhancer activity. In order to identify likely causal regulatory SNPs underlying the GWAS associations, we developed a bioinformatics pipeline that harnesses epigenetic signatures of enhancers to identify putative enhancers that contain a SNP in linkage disequilibrium (LD) with a GWAS SNP. We applied our approach to GWAS for HDL cholesterol levels. For functional validation, we focused on 8 putative enhancers that contain SNPs associated with HDL cholesterol. Three of the eight putative enhancers demonstrated enhancer activity in liver-derived cell lines HepG2 and Huh7. These enhancers are within introns of the *LCAT* and *ABCA1* genes, which encode lecithin-cholesterol acyltransferase and ATP binding cassette transporter A1, respectively, and play crucial roles in HDL biogenesis. Additionally, two of the eight putative enhancers demonstrated enhancer activity in HEK293 cells. Not only are these putative enhancers cell line-specific and size-specific, more importantly, their *in vitro* enhancer activities are also allele-specific. For example, while the HDL-associated SNPs span over 188 kb, the putative enhancer (743-bp) within *LCAT* containing the rs1109166 T-allele demonstrated 3- and 15-fold higher activity in HepG2 and Huh7, respectively, compared to the same sequence harboring the C-allele. To further elucidate the mechanism of the enhancer-promoter interaction, we sought to determine whether these putative enhancers are in close physical proximity to the promoters of their respective genes, *in vivo*. Using chromosome conformation capture we found that one of the predicted enhancers is in physical proximity to the *ABCA1* promoter. Ongoing efforts are focused on exploring the biological consequences these polymorphic enhancers may have on promoter activity and subsequent perturbation of the HDL biogenesis pathway. Our results demonstrate that through this approach, the regions that contain GWAS signals, often hundreds of kilobases in size with multiple SNPs serving as statistical proxies to the true functional site, can be narrowed down to much smaller regions and, importantly, provide an experimentally testable hypothesis for the underlying mechanism linking genetic variants to complex traits.

841F

A functional regulatory variant associated with type 2 diabetes and fasting glucose levels at the *ADCY5* locus. *T. S. Roman[1], B. Wolford[2], R. Welch[3], M. Morken[2], M. L. Buchkovich[1], Y. Wu[1], S. Khetan[4], A. Uyar[4], R. Kursawe[4], D. Ucar[4], S. C. J. Parker[5], F. S. Collins[2], M. L. Stitzel[4], K. L. Mohlke[1], NISC Comparative Sequencing Program.* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) The Jackson Laboratory for Genomic Medicine, Farmington, CT; 5) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI.

Genome-wide association studies (GWAS) have identified more than 76 loci associated with type 2 diabetes (T2D), however many of the molecular and biological mechanisms are unknown. Many of the variants identified by GWAS are located within noncoding or intergenic regions, suggesting that these variants may influence gene regulation. One association signal for both T2D and fasting glucose levels is located within introns of *ADCY5*. The A allele of rs11708067 has been associated with higher fasting glucose levels and increased risk of T2D ($P<5x10-8$). *ADCY5* encodes adenylate cyclase 5, which catalyzes the production of cyclic AMP (cAMP) from ATP (Vatner 2013). Intracellular cAMP, ATP, and Ca2+ play crucial roles in insulin secretion in pancreatic beta cells (Shibasaki 2004). A previous study established a role for *ADCY5* in glucose metabolism and demonstrated that human islets from individuals homozygous for the rs11708067-A T2D risk allele showed decreased *ADCY5* expression compared to islets from heterozygous donors (P<. 05, Hodson 2014). We sought to identify the functional variants responsible for the association signals. Of the 14 variants in strong linkage disequilibrium (r2> . 8, 1000 Genomes phase 1 CEU) with rs11708067, only rs11708067 overlaps both FAIRE and DNase peaks in human pancreatic islets, suggesting that it could have regulatory function in islets. rs11708067 also overlaps a strong enhancer chromatin state in human islets (Parker and Stitzel 2013). We tested rs11708067 for allelic differences in enhancer activity by cloning a 231-bp candidate regulatory element in both orientations with respect to a minimal promoter luciferase vector and performing transcriptional reporter assays in 832/13 rat insulinoma cells. We observed 1. 3 to 3-fold enhancer activity for rs11708067-G, and lower activity for rs11708067-A, with significant differences between the alleles in both orientations ($P=. 0017$, $P=. 03$). Furthermore, we observed an allelic imbalance in H3K27ac ChIP-seq reads overlapping rs11708067 (26 reads containing rs11708067-G vs. 3 reads containing rs11708067-A, $P=7. 4x10-6$) and evidence of differential protein binding in EMSAs. RNA-seq data from 82 published (Fadista 2014) and 32 new islet samples showed decreased *ADCY5* expression for rs11708067-A ($P=6. 5x10-13$). Taken together, these data suggest that the rs11708067-A risk allele acts to decrease *ADCY5* expression, which may lead to an increase in fasting glucose levels and increased risk of T2D.

ROP a vasoproliferative condition of eye, is a leading cause of blindness among preterm infants with low birth weight (BW) and gestational age (GA). The underlying genetic mechanism contributing to ROP are unclear. The present study aimed to identify gene(s) responsible for ROP by a functional genomics and protein profiling. **Methods:** 384 SNPs spanning 27 candidate genes were screened in a cohort of 400 preterm infants (GA ≤35weeks and BW ≤1700g) including 200 clinically characterized cases of ROP and 200 No-ROP preterm infants by customized genotyping. Allele and genotype frequencies, linkage disequilibrium and haplotype analysis were done to delineate the ROP-associated variants. Global gene expression profiling was performed in 15 preterms infants with different stages of ROP and 9 No-ROP and 3 full term infants with no retinal disease by using Illumina bead chip array having ~47,000 transcripts. The expression profiles were analyzed by the Genome Studio-software and fold change was computed. Meta-analysis of differentially expressed genes were performed by Gene Ontology (GO) and pathway analysis using Panther software. The vitreous humor levels of 27 candidate proteins were assessed in patients with severe ROP (n=30) and congenital cataract (n=30) by multiplex bead arrays. Differentially expressed proteins were further validated by western blotting and zymography. **Results:** Significant differences were noted in the alleles and correponding haplotype frequencies of few SNPs in *TSPAN12, CFH, C2/BF, IHH*, and *MMP9*, between cases and controls that withstood Bonferroni correction for multiple testing (p=1. 3x10-4). Other studied genes did not exhibit any association to ROP. Compared to controls, ROP patients exhibited significant (p<0. 01) increased vitreous levels of MMP9, CFH, C3, C4, Prealbumin, SAP, APO A1 and APOC3. These results were further validated by western blotting and zymography. A total of 142 genes were differentially expressed (115 upregulated and 27 downregulated) between the ROP patients and no-ROP preterm controls. Of these, 19 genes expressed differentially with >2 fold change. Major pathways identified in ROP pathogenesis using differentially expressed genes included inflammation mediated by chemokine and cytokine, endothelin and toll like receptor signaling. **Conclusions:** Significant genetic associations and differential gene expression observed in ROP suggests the possible underlying mechanisms in the development and progression of ROP.

843T

A Lupus-associated variant in purine nucleoside phosphorylase (*PNP*) causes cell cycle abnormalities. *Y. Ghodke-Puranik[1], J. M. Dorschner[1], D. M. Vsetecka[1], S. Amin[2], M. Makol[2], F. Ernste[2], T. Osborn[2], K. Moder[2], V. Chowdhary[2], M. A. Jensen[1], T. B. Niewold[1].* 1) Department of Immunology and Division of Rheumatology, Mayo Clinic, Rochester, MN; 2) Division of Rheumatology, Mayo Clinic, Rochester, MN.

Introduction: Systemic lupus erythematosus (SLE) is a multi-system, autoimmune disease characterized by autoantibodies to nucleic acids and nucleosomal proteins. The type I interferon pathway is dysregulated in SLE and IFN-αlevels are high in patients. We performed a genome-wide association study and found a missense SNP (C297T:gly51ser) in the *PNP* gene that associates with high IFN levels in SLE (rs1049564; P=1. 24 x10-7). PNP is a key enzyme of purine metabolism. PNP deficiency leads to dysregulated deoxynucleotide levels, a block in DNA synthesis, and defective immunity. Previously, the rs1049564 SNP was thought not to impact PNP function. To show a functional link between rs1049564 and SLE, we performed in vitro experiments using HAPMAP cell lines and patient leukocyte samples with and without the PNP variant. **Methods:** To determine if the rs1049564 variant alters PNP function, we exposed 6 HAPMAP cell lines (2 homozygous (CC), 2 heterozygous, and 2 homozygous (TT)) to a dose curve of deoxyguanosine (dGuo; nucleotide precursor and a substrate for PNP). One day later cells were analyzed for cell cycle phase using Click-iT plus EdU chemistry combined with FxCycle violet stain and flow cytometry. Various pharmacological agents were tested for their ability to reverse the cell cycle block caused by the PNP variant. A similar approach was used to study PNP function in SLE patient samples with and without the rs1049564 variant. Colorimetric enzyme and ELISA assays were used to measure the functional activity of the different PNP isoforms. **Results:** We find that the rs1049564 variant causes increased S phase block and cell death in lymphoblastoid cells. Cell lines homozygous for rs1049564 (TT) had 2 fold increases in S phase block compared to cell lines without the PNP variant (CC). The cell cycle block caused by the PNP variant could be reversed pharmacologically and similar findings were observed in SLE patient cells. **Conclusion:** These results suggest that the rs1049564 *PNP* polymorphism is a loss of function variant that leads to altered PNP function and subsequent S-phase block in select cell subsets within the lymphocyte compartment. This may lead to increased frequencies of circulating apoptotic lymphocytes, and higher type I IFN levels in human SLE. These findings have pharmacogenomic implications, as the S-phase block can be rescued in our in vitro experiments, suggesting a potential for personalized therapeutics.

844F

Deciphering the biological role of *C1orf106*, a susceptibility gene in inflammatory bowel disease. *C. Levesque[1, 2], G. Charron[1], A. Alikashani[1], C. Beauchamp[1], L. Villeneuve[1], S. Foisy[1, 2], G. Boucher[1], P. Goyette[1], J. D. Rioux[1, 2].* 1) Montreal Heart Institute, Montreal, Canada; 2) Université de Montréal, Montreal, Canada.

Inflammatory bowel diseases (IBD, [MIM266600]) involve chronic inflammation of the digestive tract and include ulcerative colitis (UC) and Crohn's disease (CD). IBD may reflect a defect in the homeostasis of immune system and intestinal epithelium. The latter forms a physical and biochemical barrier to commensal and pathogenic microorganisms. A dysfunction in the epithelial barrier may lead to a sustained immune response against bacteria of the gut flora. Genome wide association studies have identified 163 susceptibility regions in IBD. Among these, the *1q32* region associated with risk of both CD (p<2x10-11) and UC (p<6x10-7), contains the gene *C1orf106*. Our targeted re-sequencing study has identified a low-frequency variant, Y333F (p=0. 009) in C1orf106, a protein of unknown function and in which tyrosine333 is predicted to be phosphorylated. Its substitution by a phenylalanine could thus have an impact on its biological activity. For this reason, we prioritized C1orf106 for functional analysis to determine its potential causality. Our microarray analysis of human tissues and cell lines demonstrated that *C1orf106* is mostly expressed in small intestine and colon. It is also detectable in monocytic cell lines but more highly expressed in colonic epithelial cells lines. Furthermore, its expression increased by 40% during differentiation of colonic epithelial Caco-2 cells into polarized epithelium. As it is known that intestinal epithelial cells participate in, and are influenced by inflammatory processes, we examined the impact of IL-1b treatment. Specifically, while IL-1b treatment increased mRNA expression of IL-6 and IL-8 in both proliferative and differentiated Caco-2 cells, it had no effect on *C1orf106* expression suggesting that it is not regulated by IL-1b pro-inflammatory cascade. To provide further biological context, we generated HEK293T cells stably overexpressing C1orf106 and demonstrated that it is colocalized with zonula occludens 1 (ZO-1) tight junction (TJ) marker. TJ play an essential role in the establishment of epithelial barrier and require phosphorylation signals for its assembly. C1orf106 localization at these regions suggests its possible implication in epithelial barrier homeostasis. We are now producing stable overexpression of Y333F in colonic epithelial cells to look for possible changes in C1orf106 localization, TJ assembly and stability. Our results suggest that *C1orf106* may be the causal gene in the *1q32* IBD susceptibility region.

845W

Characterising the causal mechanism at the 5q11 susceptibility locus associated with rheumatoid arthritis. *K. McAllister[1], G. Orozco[1], N. Nair[1], J. Massey[1], A. Anderson[2], J. Diboll[2], J. Isaacs[2], A. Pratt[2], J. Worthington[1], S. Eyre[1].* 1) Arthritis Research UK Centre for Genetics and Genomics, University of Manchester, Manchester, United Kingdom; 2) Institute of Cellular Medicine (Musculoskeletal Research Group), Newcastle University, Newcastle upon Tyne, United Kingdom.

The third strongest association to rheumatoid arthritis (RA) is intronic to the *ANKRD55* gene, on chromosome 5q11, with more compelling candidate genes found in the region. Here well-powered genetic data was used to fine-map the region, and through bioinformatic data and functional experiments, we generate robust evidence for the causal variant and causal gene at the 5q11 locus. As part of the ImmunoChip project, 60 SNPs around the lead GWAS marker at the 5q11 locus, rs6859219, were analysed for their association in 11,475 cases and 15,870 controls. Conditional logistic regression and haplotype analysis were conducted in order to fully characterise the genetic architecture of the region. Bioinformatic tools were used in order to examine and prioritise SNPs based on their regulatory potential. Correlation of the putative variants with expression of nearby genes (eQTL) was carried out in whole blood (n=67), CD4+(n=185) and CD8+ T (n=21) cell subsets ; capture Hi-C was used for the first time in RA to look at potential chromatin interactions and chromatin immunoprecipitation (ChIP) experiments for histone markers of enhancers, H3K4me1 and H3K27ac were carried out in both B and T cell lines. Genetic fine-mapping using ImmunoChip data refined the association at the 5q11 locus to a single signal, rs71624119 (p = 5. 59E-20). Bioinformatic prioritisation of SNPs implicated two SNPs, rs10065637 and rs6859219, in high LD (R2>0. 9) with rs71624119, with the strongest evidence of regulatory activity, located within an intronic enhancer element. eQTL evidence was obtained for correlation of these SNPs with expression, showing only *ANKRD55* in whole blood p =3. 85E-05 (n=67); *ANKRD55* (p = 6. 21E-11) and *IL6ST* (p = 6. 54E-04) in CD4+ and no evidence for eQTL in CD8+ T cells. Capture Hi-C data shows that the disease-associated SNPs are brought into close vicinity of both *IL6ST* and *IL31RA,* over 300kb away. ChIP data was suggestive of a greater enrichment for the histone mark of enhancer activity, H3K4me1, with carriage of the risk allele at both rs10065637 and rs6859219. Although the RA associated loci at 5q11 contains multiple candidates for causality, our preliminary findings strongly implicate the associated SNPs being located in an intronic enhancer element regulating expression of *ANKRD55*, a gene of unknown function, with additional weaker evidence for *IL6ST* regulatory activity in CD4+ cells.

846T

To determine the biological role of GPR65, a gene associated to chronic inflammation. *V. Mercier[1,2], G. Charron[1], D. Devost[3], A. Alikashani[1], C. Beauchamp[1], P. Goyette[1], G. Boucher[1], S. Foisy[1,2], L. Villeneuve[1], T. Hébert[3], J. D. Rioux[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Université de Montréal, Montreal, Quebec, Canada; 3) McGill University, Montreal, Quebec, Canada.

Inflammatory bowel diseases(IBD [MIM 266600]), mainly comprising ulcerative colitis (UC) and Crohn's disease (CD), result in the chronic inflammation of the gastrointestinal tract. Genome-wide association studies have associated the *14q31* locus, including the genes *galactosylceramidase (GALC)* and *G protein-coupled receptor 65 (GPR65* [MIM 604620]*)*, to both phenotypes. *GPR65* encodes a pH-sensing G protein-coupled receptor (GPCR). The most associated variant in this region (rs8005161; p=2,35x1014) is correlated (r2=1) to a missense coding variant of *GPR65* (rs3742704: Ile231Leu). We determined that *GPR65* is expressed in lymphoid and mucosal tissues as well as in immune cell lines and human primary immune cells. We also found that its expression is significantly increased in inflamed biopsies from UC patients compared to non-inflamed biopsies and biopsies from healthy controls. Upon activation by low pH, GPR65 stimulates accumulation of cAMP, formation of stress fibers and activation of the RhoA pathway. Thus *GPR65* is a good candidate causal gene. Our objective, therefore, was to define pathways downstream of activation of GPR65 and to evaluate the impact *GPR65**231Leu on these pathways. We used HEK 293 cells stably expressing GPR65 and deficient for either Gas/olf, Gαq/11 or Gα12/13 as it is known that Gαs activates adenylyl cyclase, Gαq/11 leads to the release of intracellular Ca2+, which can also activate certain isoforms of adenylyl cyclase, and that Gα12/13 regulatesactincytoskeletalremodeling. We demonstrated that cAMP accumulation upon activation of GPR65 is, at least partly, due to the Gαs pathway and only slightly or not at all to the Gαq/11 pathway. We have revealed, using bioluminescence resonance energy transfer (BRET)-based biosensors that the Gα12 pathway is also triggered upon acid activation of GPR65. Ongoing analyses of this pathway includes evaluating; (i) stress fiber formation via phalloidin staining, (ii) cellular morphology by microscopy and (iii) activation of small GTPases (RhoA, Cdc42 and Rac1) with G-LISA activation assays using G proteins deficient cells stably expressing *GPR65*. In conclusion, we demonstrate that GPR65 activates both Gαs and Gα12/13 and potentially has a causal role in IBD.

847F

***In vivo* Modeling Implicates *APOL1* in Nephropathy: Evidence for Dominant Negative Effects and Epistasis under Anemic Stress.** *B. R. Anderson[1], D. N. Howell[2], K. Soldano[1], M. E. Garrett[1], N. Katsanis[1], M. J. Telen[3], E. E. Davis[1], A. Ashley-Koch[1].* 1) Center for Human Disease Modeling, Duke University, Durham, NC; 2) Department of Pathology, Division of Pathology Clinical Services, Duke University, Durham, NC; 3) Division of Hematology, Department of Medicine, Duke University Medical Center, Durham, NC.

African Americans have a disproportionate risk for developing nephropathy. This disparity has been primarily attributed to coding variants (G1 and G2) in apolipoprotein L1 (*APOL1*); however, there is little functional evidence supporting the role of this protein in renal function. The G1 allele consists of two nonsynonymous variants in perfect LD, rs73885319 and rs60910145 (encoding S384G and I384M), while the G2 variant consists of a six base pair deletion removing amino acids N388 and Y389 (~21% and ~13% allelic frequency in African Americans for G1 and G2, respectively). Here, we combined genetics and *in vivo* modeling to examine the role of *apol1* in glomerular development and pronephric filtration and to test the pathogenic potential of *APOL1* G1 and G2 variants. Translational suppression or CRISPR/Cas9 genome editing of *apol1* in zebrafish embryos results in podocyte abnormalities and glomerular filtration defects. Complementation of *apol1* morphants with wild-type human *APOL1* mRNA rescues these defects. However, the *APOL1* G1 risk allele does not ameliorate defects caused by *apol1* suppression and the pathogenicity is conferred by the *cis* effect of both individual variants of the G1 risk haplotype (I384M/S342G). *In vivo* complementation studies of the G2 risk allele also indicate that this variant cannot restore normal protein function. Moreover, *APOL1* G2, but not G1, expression alone promotes developmental kidney defects, suggesting a possible dominant-negative effect of the altered protein. In sickle cell disease (SCD) patients, we reported previously a genetic interaction between *APOL1* and *MYH9*. Testing this interaction *in vivo* by co-suppressing both transcripts yielded no additive effects. However, upon genetic or chemical induction of anemia, we observed a significantly exacerbated nephropathy phenotype. Furthermore, concordant with the genetic interaction observed in SCD patients, *APOL1* G2 reduces *myh9* expression *in vivo*, suggesting a possible interaction between the altered APOL1 and *myh9*. Our data indicate a critical role for *APOL1* in renal function that is compromised by nephropathy-risk encoding variants. Moreover, our interaction studies indicate that the *MYH9* locus is also relevant to the phenotype in a stressed microenvironment and suggest that consideration of the context-dependent functions of both proteins will be required to develop therapeutic paradigms.

848W

Association analysis of *TNF*α (-308G>A) polymorphism in Polycystic Ovary Syndrome cases. *R. Kaur[1], S. Pahuja[1], A. Beri[2], A. Kaur[1].* 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India; 2) Beri Maternity Home, Amritsar, Punjab, India.

Introduction: Chronic low grade inflammation is closely related with the incidence of polycystic Ovary Syndrome (PCOS). Tumor necrosis factor alpha (TNFα), which is a pro-inflamatory cytokine is an important mediator of inflammation and is elevated in women with PCOS. TNF-α is secreted by corpus luteum and plays a key role in reproductive physiology, including regulation of ovarian steroidogenesis. -308G>A polymorphism in promoter region of *TNFα* has been shown to be associated with hyperandrogenism, which is a major characteristic in PCOS cases. **Objective:** To analyse the association of *TNFα* (-308G>A) polymorphism in women of 17-40 years of age, suffering from Polycystic Ovary Syndrome and age matched controls. **Methods:** The present case-control study included a total of 91 subjects, including 41 cases and 50 controls. All the cases were recruited from Beri Maternity Home, Amritsar (August 2014 to May 2015). The cases were selected on the basis of detailed ultrasound report and PCOS symptoms as diagnosed by doctor. Age matched healthy controls without any PCOS symptoms were included. Genotyping for *TNFα* (-308G>A) polymorphism in all subjects was performed using polymerase chain reaction based restriction fragment length polymorphism. Statistical analysis was performed using SPSS package (version 17). **Results:** In 41 PCOS cases, the frequency of GG, AG and AA genotype was 73. 17%, 26. 82% and 0% compared to 82%, 18% and 0% in 50 controls. The mutant genotype (AA) was not observed in analysed cases and controls. The major allele (G) and minor allele (A) frequency was 87% and 13% in cases and 91% and 9% in controls. Although minor allele frequency was slightly higher in cases as compared to controls, however the distribution of genotype and allele frequency were not observed to be statistically significant (α^2=0. 571, p=0. 448 and α^2=0. 503,p=0. 478, respectively). The differences in means values between cases and controls were observed to be statistically significant (p=0. 031). **Conclusion:** In the present study *TNFα* (-308G>A) polymorphism has not been observed to be associated with PCOS. This may be attributed to small sample size.

849T

Regulatory variant alters expression of CRISPLD2, a Nonsyndromic Cleft Lip and Palate gene. *L. Mailli[1,2], B. T. Chiquet[2,3], E. C. Swindell[1,2], Q. Yuan[2], A. Letra[3], J. T. Hecht[1,2,3].* 1) Graduate School of Biomedical Sciences, University of Texas Health Science Center, Houston TX; 2) Department of Pediatrics, University of Texas Medical School at Houston, Houston TX; 3) University of Texas School of Dentistry at Houston, Houston TX.

Nonsyndromic cleft lip/palate (NSCLP) is the most common craniofacial birth defect occurring in 1/700 newborns and affecting 4000 babies in the US each year. NSCLP has a multifactorial etiology, wherein genetic variation and environmental factors contribute to causation. Genetic variation in the *CRISPLD2* gene was associated with NSCLP in our nonHispanic white and Hispanic families and confirmed in three other studies. Importantly, *CRISPLD2* is expressed in the mandible, palate and nasopharynx during mouse craniofacial development and knock-down of *CRISPLD2* in zebrafish causes abnormal palate and jaw development. Environmental factors such as retinoic acid, vitamin D and glucocorticoids are known to affect *CRISPLD2* expression. SNP rs1546124, which showed the strongest association in our nonHispanic white families (p = 0. 0006), is located 51 base pairs upstream of the ATG start site, suggesting a potential regulatory function. *In silico* analysis predicted several transcription factors binding differentially to the SNP region depending on the allele present, including a vitamin D receptor-binding site for the ancestral C allele and several retinoic acid binding sites for the alternate G allele. Electrophoretic mobility shift assay revealed allele-specific binding affinities, with the ancestral allele binding more strongly than the alternate allele. Luciferase reporter assays showed that the presence of the C allele was associated with increased promoter activity in COS7 and HEK293 cells (p=0. 000002). Additional *in vivo* and *in vitro* studies are underway to evaluate whether retinoic acid, glucocorticoid or vitamin D treatments influence allele-specific *CRISPLD2* expression. Our results suggest that rs1546124 is a functional SNP that influences *CRISPLD2* expression and may contribute to NSCLP.

850F

Identification of Genotype Driven Gene Expression Changes in Human Kidneys. *Y. Ko[1], H. Yi[1], M. Liang[1], N. Ledo[1], F. Chinga[1], C. Brown[2], K. Susztak[1].* 1) Renal Electrolyte and Hypertension Division, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania.

Introduction: There are more than 5 million sequence variants in humans. Some genetic variations influence transcript levels and therefore have the ability to interfere with cell and organ function. Such genetic variants are called expression quantitative trait loci (eQTL). The goal of our study was identify such functionally important genetic variants at the genome-wide level.

Methods: This analysis requires the collection of large number of human tissue samples with genotype and transcript level data. Here we used 99 human kidney samples of Central European descents. RNAseq and genotype data was normalized and genotype data was imputed using 1,000 Genome reference data. The association between genotype and transcript levels was performed using Matrix eQTL software and was limited to *cis*-eQTLs where the genetic variant and transcript levels were within 2 megabases distance.

Results: We identified 164 significant target genes (we call these eGenes) and 7590 significant SNPs (eSNPs) that passed the threshold for statistical significance after multiple testing correction using adjusted *p*-values<1. 0E-10. Next we compared variants that influence gene expression in the kidney to those that have been published for other organs using the publicly available Genotype-Tissue Expression project (GTEx). Of the 164 eGenes, 103 were common between the kidney and other organs, indicating that there are cell type specific and cell type independent eGenes. Using kidney specific epigenome maps, we found that eSNPs were enriched on kidney specific regulatory elements, including promoters and enhancers. We also found a significantly greater overlap between kidney eGenes and polymorphisms that are associated with CKD development, compared to other traits (digestive, nervous, immune system diseases, hematological measurement, cardiovascular, and metabolic disease).

Conclusion: We identified transcript level changes associated with genotypic variations. These results can highlight kidney specific regulatory elements and may also help to identify target genes for polymorphisms associated with kidney function related traits. .

851W

A polymorphic transposable element regulates *FADS1* expression. *C. Wadelius, M. Bysani, S. Enroth, A. Ameur, H. Nord, M. Cavalli, M. Essand, U. Gyllensten, G. Pan.* Science for Life Lab, Dpt of Immunol, Gen and Path, Uppsala University, Uppsala, Sweden.

Background: The FADS region may be associated to more diseases and phenotypes than any other, except for the HLA. The reported associations include the metabolic syndrome, fasting glucose, inflammatory bowel disease, triglycerides, LDL and HDL cholesterol, brain development and many others. The association was previously mapped to an LD block with 28 known SNPs and we set out to identify the functional one.

Methods and results: Using liver tissue we generated chromatin signals which define regulatory elements and then tested SNPs in them to see if the two variants differed in activity using luciferase assays. We found that all 28 SNPs could be explained by rs174557 which is located in a transposable element in intron 1 in *FADS1*, present in chimpanzee and human but no other species. This SNP showed significant difference between alleles in luciferase assays. PacBio single molecule sequencing detected multiple variants of the polymorphism and luciferase assays verified one main variant with high functional activity and several low activity variants. The regulatory element has three binding sites for the transcription factor (TF) SREBP1, one for SP1, and one at the regulatory rs174557 for the repressor PATZ1. We have verified the binding of each TF in vivo in HepG2 cells using ChIP-qPCR and also mutated all of the binding sites, alone or in combination and thus validated their function using luciferase assays. We have also overexpressed each TF and shown that activation is lost when the TF binding site is mutated. Using mutation and competition experiments it was found that the repressor PATZ1 competes in binding with the activating complex of SREBP1 and SP1 which is due to PATZ1 and SP1 having overlapping binding sites. When SREBP1 and PATZ1 are overexpressed in HepG2 cells there is increased ChIP-signal for each TF. MCF7 cells are heterozygous at rs174557 and after over-expression of PATZ1 allelic bias is shifted towards repression. **Conclusions:** The association of many diseases and traits to the FADS1 region can be explained by a multi-allelic polymorphism in intron 1 of FADS1 bound by the repressor PATZ1 in competition with an activating complex. The results are interesting from evolutionary and genetic perspectives and the gene variants also help explain why we react differently to modern diet as compared to the diet in ancient times.

852T

Novel human DNA Identikit using SNVs in the Fluidigm Nano fluidic Dynamic Arrays. *D. Bercovich[1], Y. Plosky[2], A. Stroler[1,2], Y. Dekel[1], I. Chernovitky[4], R. Gershoni[3].* 1) Human Molecular Genetics, Tel Hai College, Tel Hai, Israel; 2) GGA lab, Kazerin, Israel; 3) Rambam Mdical Center, Hifa, Israel; 4) Afula Medical Center, Israel.

In today's crime scenes, law enforcement authorities use face imaging (or identikit pictures), in order to identify and track down suspects. Usually, face imaging is based on eyewitness's accounts which are notoriously unreliable. occasionally , there is no eyewitness's at all. DNA found at crime scene can be a clincher in prosecuting a suspect when there is a match to the police databases. When there is no match, this important evidence might turn to be useless. In this study, 43 known human SNVs were tested on 251 DNA samples in order to determine a suspect's eye, hair/skin color, hair shape, racial mix (European /African), possible weight/ height, tendency to boldness, blood type (ABO) and left-right hand tendency. In addition, gender identification was performed using X & Y chromosome PCR primers and age determination (decades resolution) using RT-PCR . a correlation of 80-90% was found for SNPs determination of eye colour (Brown and blue respectively) or , dark hair colour , and 87- 90% for European African descent respectively. An average of 83% correlation was found to one of the four ABO blood types (A-77%, B-78%, AB-100%, O-91%) and 99. 99% for Gender determination and age +/- 8. 4 years (R^2 = 0. 7257). The SNV's proposed in this work, proved to be suitable for novel DNA Identikit that can be very helpful for further potential suspect identification. .

Functional characterisation of the osteoarthritis susceptibility locus marked by the polymorphism rs10492367 at chromosome 12p11. 22. *K. Johnson, L. N. Reynard, J. Loughlin.* Newcastle University, Newcastle-upon-Tyne, Tyne and Wear, United Kingdom.

Osteoarthritis (OA) is a polygenic, multifactorial arthritis characterised by the progressive loss of articular cartilage in synovial joints. It is an age-associated disease but has aetiological routes during the life course. The arcOGEN GWAS reported that the rs10492367 G/T SNP marks an intergenic region on chromosome 12p that is associated with hip OA in Europeans, with an odds ratio of 1. 14 and a *p*-value of 1. 48 x 10-8. We hypothesised that the OA association signal acts by regulating the expression of *PTHLH* and/or *KLHL42*, the two most proximal genes. To investigate the functionality of the region we used luciferase reporter assays, showing differential enhancer activity between the alleles of rs10492367 and of several SNPs in high LD (r2 > 0. 8) with it. Through electrophoretic mobility shift assays and chromatin immunoprecipitation, we identified binding of SUB1, RELA and TCF3 to rs10492367. Knock-down of SUB1 in human articular chondrocytes (*n* = 3) revealed a down-regulation of *PTHLH*. We next sought to quantify gene expression in hip cartilage from OA patients who had undergone hip arthroplasties (*n* = 21). We observed decreased *KLHL42* expression (*p* = 0. 03) relative to age-matched non-OA controls (*n* = 18). The association signal did not correlate with expression of either gene. We confirmed this by interrogating the allelic expression imbalance of the genes using pyrosequencing. We used data from an Illumina BeadChip array to identify ten CpG sites from within the association interval that were significantly differentially methylated between OA hip (*n* = 17) and non-OA control cartilage (*n* = 42): six CpG sites had lower levels of methylation and four CpG sites had higher levels of methylation in the OA hip donors. rs10492367 genotype did not correlate with the methylation of any of the CpG sites analysed. We therefore speculated that the effect of the association signal is on *PTHLH* and/or *KLHL42* during joint development. We utilised microarray data and qPCR from mesenchymal stem cells to confirm expression of *PTHLH* and *KLHL42* during chondrogenesis and osteoblastogenesis, highlighting the potential for either of the genes to be regulated during skeletogenesis. Following an extensive interrogation of the OA association locus, our studies have defined a functional role for rs10492367. We have characterised gene expression and regulation, and suggest the region mediates OA susceptibility during joint development rather than in end-stage diseased cartilage.

854W

Long-range modulation of *PAG1* expression by 8q21 allergy risk variants. *C. T. Vicente, S. L. Edwards, K. M. Hillman, S. Kaufmann, H. Mitchell, L. Bain, D. M. Glubb, J. S. Lee, J. D. French, M. A. R. Ferreira.* QIMR Berghofer Medical Research Institute, Brisbane, QLD, Australia.

The gene(s) whose expression is regulated by allergy risk variants is unknown for many loci identified through genome-wide association studies. Addressing this knowledge gap might point to new therapeutic targets for allergic disease. The aim of this study was to identify the target gene(s) and the functional variant(s) underlying the association between rs7009110 on chromosome 8q21 and allergies. Eight genes are located within 1 Mb of rs7009110. Multivariate association analysis of publicly available exon expression levels from lymphoblastoid cell lines (LCLs) identified a significant association between rs7009110 and the expression of a single gene: *PAG1* (*P*=0. 0017), 732 kb away. Analysis of histone modifications and DNase I hypersensitive sites in LCLs identified four putative regulatory elements (PREs) in the region. Chromosome conformation capture confirmed that two PREs interacted with the *PAG1* promoter, one in allele-specific fashion. To determine if these PREs were functional, LCLs were transfected with *PAG1* promoter-driven luciferase reporter constructs. PRE3 acted as a transcriptional enhancer for *PAG1* exclusively when it carried the rs2370615:C allergy predisposing allele, a variant in complete linkage disequilibrium with rs7009110. As such, rs2370615, which overlaps RelA transcription factor (TF) binding in LCLs and was found to disrupt Foxo3a binding to PRE3, represents the putative functional variant in this locus. Our studies suggest that the risk-associated allele of rs2370615 predisposes to allergic disease by increasing *PAG1* expression which may promote B-cell activation and have a pro-inflammatory effect. Inhibition of *PAG1* expression or function may have therapeutic potential for allergic diseases.

On the Prediction of Risk for Autism from Common Variants. *L. Zhu[1], P. Chaste[2, 3], Y. Song[2], K. Roeder[1], B. Devlin[2].* 1) Dept. of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Dept. of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA; 3) FondaMental Foundation, Créteil, France.

Rare and common genetic variations contribute to risk for autism spectrum disorder (ASD). Indeed certain rare variants are so penetrant that their predictive value is beyond doubt. Here we explore prediction from common variation, more challenging because individual variants have small impact. To aid interpretation, we also explore prediction of a related quantitative trait, head circumference, which is often found to be somewhat enlarged in ASD subjects. Two ASD data sets were evaluated, the Simons Simplex Collection (SSC) and the Autism Genome Project (AGP). For head size it was relatively straightforward to develop a significant predictor, although the heritability explained was small, < 1%. One can obtain accurate prediction using parental head size, but common variants do not add to accuracy. It proved much more difficult to predict ASD, consistent with a loss of information for a binary versus continuous outcome. Prediction was only slightly better than a random guess when using pseudo-controls (parental non-transmitted alleles); it gained more predictive power when using unaffected subjects as controls, but was still far from being accurate; and, consistent with theory, its performance was significantly affected by whether ASD individuals carried a highly-penetrant rare variant. Some, although modest traction was garnered by analysis of common variants affecting expression of genes previously implicated in risk based on rare variant studies. Predicting risk from common variants currently is hard, over time it can be refined and in the process it will surely refine our understanding of the genetics of ASD. .

856F

Genomic variation in neuron-specific cell adhesion molecule "bar codes": candidate mechanims for disease and phenotype influences on the brain connectome. *G. R. Uhl[1,2,3], J. Drgonova[2], D. Walther[2].* 1) Research, NMVAHCS, Albuquerque NM , NM; 2) NIDA IRP, NIH; 3) Depts of Neurology, Neuroscience and Mental Health, Johns Hopkins Medical Institutions, Baltimore Md.

Recent reannotation reveals 474 human genes likely to encode cell adhesion molecules (CAMs). Most CAMs are expressed in brain and in neurons. When combined combinatorially, this number of gene products is sufficient to specify the large number of likely brain synapses. Many CAM genes are identified by repeated modest (10-2 < p < 10-8) GWAS signals for brain phenotypes. Eighty three are identified in at least three independent samples for addiction phenotypes. Dopamine neurons, implicated in reward from most addictive substances, express about 20 of these addiction-associated CAM genes (and more than 200 of the 474 human CAM genes in RNA seq datasets). Mice with altered expression of at least four studied addiction-associated CAM genes display altered place preference for stimulants, a reliable index for human abuse liability. Interestingly, several changedose-response relationships for reward. CDH13 and PTPRD, some of the most robstly addiction-related CAM genes, display haplotypes associated with sizable differencs in levels of expression in postmortem brain samples from unrelated individuals. CDH13 alterations produce changes in cerebral cortical dopamine innervation and neurochemistry. These examples undescore the ways in which individual differences in CAM bar codes can change neuronal connectivities, alter the connectome, and underpin substantial genetic influences on complex brain phenotypes.

857W

Genetic interaction analysis of reported longevity-associated epistatic effects in healthy oldest old Super-Seniors. *L. C. Tindale[1,2], S. Leach[1], A. R. Brooks-Wilson[1,2].* 1) Genome Sciences Centre, BC Cancer Agency, Vancouver, Canada; 2) Simon Fraser University, Burnaby, Canada.

Longevity and healthy aging are complex traits for which the genetic contribution is not well understood. Genome-wide association studies (GWAS) of longevity have found few replicable variants, and centenarians do not appear to carry a substantially decreased burden of common disease-associated variants. The existence of rare protective genetic factors has been put forward as a potential explanation for these observations. Protective variants may attenuate the effects of deleterious risk alleles, allowing long-lived individuals to carry disease-associated variants without showing phenotypic effects. A literature search for longevity or health-related epistatic variants produced 18 variants in 15 genes. The variants were genotyped in DNA samples from 466 Super-Seniors, individuals aged 85 or older who had never diagnosed with cancer, cardiovascular disease, major pulmonary disease, diabetes, dementia, as well as in 421 middle-aged controls. Both groups were of European ancestry. GeneMANIA (Warde-Farley et al. , Nucleic Acids Res. 2010;38) was used to explore gene interactions. Entering the 15 genes from the literature search,GeneMANIA produced a network that connected the query genes and incorporated functionally similar genes. Lipid and cholesterol Gene Ontology (GO) terms were significantly over-represented in the network. When each of the 18 variants was tested separately for association with the Super-Senior phenotype, only rs429358 in *APOE* was associated, and only in women, an observation we have made previously (Tindale et al. , Neurobiol. Aging. 2014;35(3)). SNP-SNP interactions were analyzed pairwise in a codominant model using logistic regression analysis. Using Super-Senior status as the outcome variable, one pair of SNPs that had previously been associated with Alzheimer disease (Gusareva et al. , Neurobiol. Aging. 2014;35(11)), rs6455128 in *KHDRBS2* and rs7989332 in *CRYL1*, showed evidence of an interaction after adjusting for sex and *APOE*. Other pairs did not show genetic interactions in our population. GWAS and candidate gene approaches are not sufficient to study healthy aging and longevity. Understanding the genetics of longevity will likely involve further research into complex genetic interactions.

Crispld2 plays a role in neural crest cell migration and cell viability during zebrafish craniofacial development. *Q. Yuan, L. Maili, E. C. Swindell, J. T. Hecht.* Department of Pediatrics, University of Texas Medical School at Houston, Houston, TX.

Variation in the cysteine-rich secretory protein LCCL domain containing 2 gene, *CRISPLD2*, is associated with nonsyndromic cleft lip and palate (NSCLP). Expression of Crispld2 is detected in the craniofacies of developing mice and in the oropharynx of zebrafish during craniofacial development, suggesting that CRISPLD2 may be involved in orofacial morphogenesis. We have previously reported that knockdown of zebrafish *crispld2* by an antisense morpholino (MO3) directed against the start site causes severe craniofacial abnormalities involving both the jaw and palate. MO3 injected embryos showed abnormal expression of several marker genes for neural crest cells (NCCs). We have used a *sox10:egfp* transgenic zebrafish model to examine the NCC migration in live embryos. Knockdown of *crispld2* in zebrafish altered NCC migration pattern at early and late time points during orofacial development. Moreover, we detected an increase in cell death after *crispld2* knockdown as well as an increase in apoptotic marker genes. These preliminary results observed in the morphants suggest that Crispld2 is involved in palate and jaw morphogenesis, and knockdown of *crispld2* specifically affects NCCs. To further confirm these phenotypic changes, *crispld2* mutant lines bearing a deletion in exon1, predicted to abolish the entire gene function, have been generated using CRISPR/Cas9 site-directed nucleases. These mutant lines will serve as a model system for morphant vs mutant phenotype correlation studies. Gene expression analysis will be performed in homozygous mutant lines, which will allow us to identify potential downstream effectors of *crispld2*. Importantly, our results demonstrate that genes involved in complex birth defects, such as NSCLP, can be identified in candidate gene studies and functionally assessed in zebrafish to define the biological processes that are the basis for these complex birth defects.

Integrative analysis for identification of shared markers from various functional cells/tissues for rheumatoid arthritis. *S. Lei[1,2], W. Xia[1,2], J. Wu[3], L. WU[1,2], Y. Guo[3].* 1) Center for Genetic Epidemiolgy and Genomics, Soochow University, Suzhou, Jiangsu, China; 2) Jiangsu Key Laboratory of Preventive and Translational Medicine for Geriatric Diseases, Soochow University, Suzhou, Jiangsu. China; 3) Department of Rheumatology, the First Affiliated Hospital of Soochow University, Suzhou, Jiangsu, China.

Objectives: Rheumatoid arthritis (RA) is a systemic autoimmune disease that may affect many tissues and organs. Gene expression profiling of various cells and tissues has been extensively conducted in RA research. In this study, we conducted a multi-dataset analysis to identify potential shared genes from multiple RA related expression datasets from various cells or tissues, and then a follow-up integrative analysis to test functional relevance of the identified genes on RA. Methods: The selected microarray datasets were downloaded from the publically available National Center for Biotechnology Information (NCBI) Gene Expression Omnibus (GEO). We conducted multi-dataset statistical analysis containing both marginal analysis and joint analysis to identify shared genes. The performed integrative analyses included functional annotation clustering analysis, protein to protein interactions (PPI), gene-based association analysis, and ELISA. Results: Our analysis included 7 datasets, 2 from synovial tissue, 1 from synovial macrophages, 1 from synovial fluid mononuclear cells (SFMCs), 2 from peripheral blood mononuclear cells (PBMCs) and 1 from peripheral blood cells. Multi-dataset statistical analyses identified 18 shared candidate genes, which were mainly involved in the immune response, chemokine signaling pathway and several other related biological processes. PPI analysis indicated that PPBP, PF4, HLA-F, S100A8, RNASEH2A, P2RY6, JAG2 and PCBP1 were connected with the known RA genes and may play crucial roles in the pathogenesis or development of RA. HLA-F and PCBP1 are significant (p=1. 03E-31; p= 0. 013, respectively) in gene-based association analysis. Subsequently, ELISA analysis found that PCBP1 (P=0. 026) has significantly differential expression between RA patients and healthy controls. Conclusions: This study represented the first effort to identify shared genetic RA markers from different functional cells or tissues. The results taken together suggested that PCBP1 and HLA-F are likely to be two shared potential genetic RA biomarkers.

860W

Identification of Novel Metabolic Syndrome Loci by Combining Univariate GWAS Summary Statistics of Multiple Phenotypes. *R. M. Salem[1,2], Z. Liu[1,3], X. Lin[1,3], J. N Hirschhorn[1,2].* 1) Medical and Population Genetics, Broad Institute, Cambridge, MA; 2) Genetics and Endocrinology, Boston Children's Hospital, Boston, MA; 3) Dept of Biostatistics, Harvard School of Public Heath, Boston, MA.

Metabolic Syndrome (MetS) is defined as the clustering of interrelated risk factors for CVD and type 2 diabetes mellitus (T2D). MetS incorporates 5 characteristic phenotypes: raised blood pressure, elevated triglycerides, elevated low -density lipoprotein cholesterol, raised fasting glucose, and obesity (central adiposity). Individuals with abnormal values for 3 out of 5 factors are diagnosed of MetS. MetS increases risk of developing CVD 2-3 fold and risk of developing T2D by over 5 fold. The role of genetic variants, both acting alone and in concert with obesity and lifestyle factors remains largely unknown. Analysis of syndromic phenotypes and multiple phenotypes can be challenging due to issues of phenotype modeling, analysis methods, and pragmatic issues of having complete phenotype traits measured in study samples. To overcome this limitations, we leveraged GWAS summary statistics for the 5 phenotypes (BMI, LDL, Triglycerides, Fasting Glucose, and SBP) used in the MetS definition to identify pleiotropic loci that show an association with combined traits and associate with MetS. Analyses were performed using a recently developed mixed fisher statistical procedure that calculates a joint p-value across the set of phenotypes, while correcting for correlation between the traits (Liu et al. , in preparation). The MetS analysis yielded 422 genome wide significant loci ($p \leq 5e\text{-}8$), of which 267 are novel loci and only observed via the joint analysis, none of the individual traits was genome wide significant alone. DEPICT analysis were performed on the novel and full set loci to prioritize loci and identify enriched pathways and tissues. We show that analysis of a complex multiple phenotype disease (Metabolic Syndrome) can be achieved by leveraging GWAS univariate summary statistics. In conclusion, these results have the potential yield novel insights into the genetic architecture and understanding of Metabolic Syndrome.

861T

Effect of RANK/RANKL/OPG gene polymorphisms on Left ventricular diastolic dysfunction in thalassemia major patients. *M. M. Singh[1], S. Tiwari[2], S. Agarwal[1].* 1) Medical Genetics, Sanjay Gandhi Post Graduate Institute Of Medical Sciences, Lucknow, Uttar Pradesh, India; 2) Department of Cardiology, Sanjay Gandhi Post Graduate Institute Of Medical Sciences, Lucknow, Uttar Pradesh, India.

In thalassemia major most common cardiovascular complication is left ventricular dysfunction, the inability of ventricles to pump blood, which progressively leads to heart failure. RANK (TNFRSF11A)/RANKL (TNFSF11)/OPG (TNFRSF11B) pathway has been shown to play role in the left ventricular dysfunction leading to heart failure. We therefore aimed to analyze their association with left ventricular diastolic dysfunction in thalassemia major patients. 70 asymptomatic patients (mean age 14. 3±5. 5 years) of thalassemia major were recruited, for echocardiography. PCR-RFLP analysis was performed in all to identify five polymorphisms in the RANK/RANKL/OPG pathway system [RANK (rs1805034, rs12458117, +35966insdelC), RANKL (rs2277438) and OPG (rs2073617)]. For echocardiography out of 70 asymptomatic patients of thalassemia major we observed that 25% of these had diastolic dysfunction. The major differences in the LV dimensions both in systole (p-value 0. 002) and diastole (p-value <0. 01), left atrium (p-value 0. 018), isovolumetric relaxation time (IVRT) (p-value 0. 009), left ventricular mass (p-value<. 01) and LV mass index (LVMI) (p-value 0. 005) was observed. RANK and RANKL polymorphisms shows insignificant association (wild type and heterozygous+mutant type) However, for LA diameter and LV mass, association was found with rs1805034, LVESD with rs12458117, IVRT with RANK ins/del, and LVESD with rs2277438. OPG polymorphism (rs2073617) shows significant association in all echocardiography parameter LVESD (p-value 0. 02), LA (p-value 0. 003), IVS (p-value 0. 001), PW(p-value 0. 04), and LVMI (p-value 0. 02). Present study concludes OPG (rs2073617) polymorphism significantly contributes for left ventricular dysfunction in thalassemia major patients thus can be used as cardiac biomarker for assessing left ventricular dysfunctions in Thalassemics.

862F

Whole exome sequencing in families at high risk for Hodgkin lymphoma: identification of a predisposing mutation in the KDR gene. *M. Rotunno[1], M. L. McMaster[1], M. Yeager[1], B. Hicks[1], L. Burdette[1], A. M. Goldstein[1], J. Boland[1], S. Ravichandran[1], B. T. Luke[1], L. Fontaine[2], S. J. Chanock[1], M. Tucker[1], N. C. Caporaso[1], L. R. Goldin[1], NCI DCEG Cancer Sequencing Working Group, NCI DCEG Cancer Genomics Research Laboratory.* 1) NIH, NCI, Rockville, MD; 2) Westat, Rockville, MD.

Hodgkin lymphoma (HL) shows strong familial aggregation but no major susceptibility genes for HL have been identified to date. Studies based on exome sequencing are promising for identifying disease susceptibility rare genetic variants. The goal of this study was to identify high-penetrance variants in HL-prone families. We conducted whole exome sequencing in 17 HL-prone families with three or more affected cases or obligate carriers followed by targeted sequencing in an additional 48 smaller HL families. Reads were aligned using Novoalign and variants were called using GATK software. Possible technical sequencing artifacts were eliminated by filtering out variants found in more than 1% of samples from other studies identically processed and sequenced in our laboratory. The exome called variants were analyzed, annotated and prioritized using ANNOVAR, Ingenuity Variant Analysis, and custom R scripts. Only dominantly segregating, rare ($\leq$ 1% frequency in European populations), coding or potentially functional variants were kept (2,699 variants total) and prioritized based on damage prediction, conservation, literature links to cancer or immune related processes. The top 23 genes were followed up using custom Ampliseq panel targeted sequencing. Only one variant in KDR (kinase insert domain receptor, aka VEGFR2) was replicated in two independent HL families. This variant shows strong evidence as a predisposing mutation for familial HL as it is highly conserved, rare (European population frequency <0. 001), located in the activation loop, and predicted to be damaging. KDR is a type III receptor tyrosine kinase, the main mediator of VEGF-induced endothelial proliferation, survival, migration, and its activity is associated with several diseases including lymphoma. Functional experiments have shown that the identified KDR mutation can promote constitutive autophosphorylation on tyrosine in the absence of VEGF and that the kinase activity was abrogated after exposure to kinase inhibitors. In the largest sequenced cohort of HL families to date, we identified a causal mutation in the KDR gene which could increase downstream tumor cell proliferation activity and be targeted for therapy in HL and NHL patients carrying this mutation.

863W

Sequencing reveals novel, germline variants in *BRIP1*: an analysis of 1300 women diagnosed with breast cancer before age 40. *C. Moyer[1], J. Ivanovich[2], D. C. Koboldt[3], K. L. Kanchi[3], E. R. Mardis[3], P. J. Goodfellow[1].* 1) The James Comprehensive Cancer Center, The Ohio State University, Columbus, OH; 2) Siteman Cancer Center, Washington University School of Medicine, St Louis, MO; 3) McDonnell Genome Institute, Washington University, St Louis, MO.

This year, an estimated 23,000 American women will develop breast cancer before the age of 40. This early-onset is before the recommended age for annual screening, often resulting in late detection, advanced stage, higher medical costs, and decreased survival rate. Many of these young women have a family history of breast cancer consistent with an inherited risk factor. However, nearly 80% of early-onset breast cancer patients lack mutations in known susceptibility genes, indicating there are genetic risk factors that have not yet been discovered. To identify additional breast cancer associated alleles, targeted custom amplicon sequencing of candidate DNA repair genes (*FANCI*, *FANCE*, *ATR*, *BRIP1* and *ERCC2)* was performed on germline DNA of 604 early-onset breast cancer patients negative for mutations in *BRCA1/2.* In combination with whole exome data from 26 additional early-onset patients, 37 women (6. 1% of cohort) were shown to harbor 24 different, rare and or novel missense variants in the BRCA1 interacting protein C-terminal helicase 1 gene (*BRIP1)*. Five previously unreported missense variants identified in our screen cluster within the c-terminal helicase domain of *BRIP1,* all of which are predicted alter protein function. A D791V variant, identified in single patient, was subsequently shown to be shared by a sister with breast cancer. The family pedigrees for several patients with other *BRIP1* variants include multiple members affected with breast and prostate cancers, suggesting the inherited *BRIP1* variants may be associated with cancer risk. To expand and validate our findings, *BRIP1* variant calls from an additional 742 patients in the cohort will be reported. Although a germline, nonsense variant (R798X) has been described as a low-penetrance breast cancer allele, little is known about BRIP1's function in breast cancer. We hypothesize that inherited variants in *BRIP1* account for a small percentage of early-onset breast cancer in individuals who lack mutations in known breast cancer susceptibility genes. Our sequencing studies suggest that novel, missense variants within the helicase domain of *BRIP1* confer risk for breast cancer. Results from functional testing for the effect of mutations on helicase and ATPase activity will be reported.

864T

Novel rare and common genetic variants associated with red blood cell traits identified in > 130,000 individuals genotyped on an exome array. *N. Chami[1,2], M. H Chen[3,4], A. Slater[5,8], N. Pankratz[6], L. Warren[3,4], S. Ganesh[7], G. Lettre[1,2] on behalf of the Blood Cell Consortium.* 1) Faculty of Medicine, Université de Montréal, Montréal, QC, Canada; 2) Montreal Heart Institute, Montréal, QC, Canada; 3) Framingham Heart Study, Population Sciences Branch, Division of Intramural Research National Heart Lung and Blood Institute, National Institutes of Health Framingham, Boston, USA; 4) Department of Neurology, Boston University School of Medicine, Boston, USA; 5) PAREXEL International, Durham, NC; 6) Department of Laboratory Medicine and Pathology, University of Minnesota Medical School, Minneapolis; 7) Cardiovascular Medicine, Department of Internal Medicine and Department of Human Genetics University of Michigan, Ann Arbor; 8) AS previously employed by GlaxoSmithKline (GSK), Research Triangle Park, North Carolina ; work performed on this publication done while employed by GSK.

Introduction: Red blood cell (RBC) traits are important heritable biomarkers used for the diagnosis of hematologic disorders such as chronic anemia and blood cancers. Genome-wide association studies (GWAS) for RBC traits have identified dozens of loci that together explain <10% of the inter-individual variation. **Materials and Methods:** To further explore the genetic factors that influence RBC traits, we meta-analyzed ExomeChip results for 7 RBC-related phenotypes available in up to 130,273 individuals from 29 studies. We used the RareMetalWorker/RVTests/RareMetals software suite to test for genetic associations and to meta-analyze results. For gene-based tests, we applied the SKAT and VT algorithms, considering only coding variants with a minor allele frequency (MAF) <1%. All analyses were performed on each of Europeans, African Americans, and combined ancestry which also comprised East Asians, and Hispanics. **Results:** We replicated many known GWAS SNPs (*e. g*. *HBS1L-MYB*, *TMPRSS6*, and *HFE*) and rare coding variants (*e. g. EPO*, *HBB*). We have additionally performed genome-wide conditional analyses to identify novel independent associations. In European-ancestry individuals, a novel SNP located near *TRIB1* was independently associated with RDW (P=1. 5e-7). The same variant is also associated with total cholesterol levels. Moreover, we found two SNPs in genes involved in lymphoblastic and myeloid leukemia: rs236985 in *AFF1* was independently associated with RBC count (P=4e-8) and HCT (P=4e-10), and similarly rs4911241 in *NOL4L* with RDW (P=6e-8). Further, we identified novel rare variants: a low-frequency missense variant in *HNF4A* (rs1800961, MAF=2. 4%, HCT P=1. 5e-8) previously associated with C-reactive protein and cholesterol levels and a rare missense variant in *ANK1* associated with MCHC (MAF=2. 9% P=1. 6e-16). The *ANK1* rare variant remained significant after conditioning on a GWAS common variant previously associated with MCHC (P=2e-15). Gene-based analysis identified *PKLR* that is associated with HCT in SKAT (P=8e-7). Interestingly, Mendelian mutations in *PKLR* are a cause of a chronic hereditary anemia. **Conclusions:** Our results highlight exciting overlaps between RBC-associated variants and genes implicated in cholesterol metabolism, emphasizing the tight equilibrium between RBC membrane composition and circulating cholesterol levels. We are completing discovery analyses and replicating novel genetic associations in independent studies.

865F

Heritability of Normal Human Facial Shape. *J. B. Cole[1], M. Manyama[2], W. Mio[3], S. A. Santorico[1], B. Hallgrimsson[2], R. A. Spritz[1].* 1) Human Medical Genetics and Genomics Program, University of Colorado Anschutz Medical Campus, Aurora, CO; 2) Department of Cell Biology & Anatomy, University of Calgary, Calgary, AB; 3) Department of Mathematics, Florida State University, Tallahassee, FL.

Facial shape exhibits perhaps the greatest variation of any normal human trait, yet at the same time represents the most recognizable human characteristic. Facial shape comprises multiple complex multifactorial traits with clear genetic components. However, little is known about normal human facial development. Previous GWAS have sought to identify genetic determinants of facial shape with little, if any, reliable replication. Traditional facial shape phenotypes used in GWAS derive from both principal components analysis (PCA) and direct linear distance measurements using sparse morphometric landmarks on a 3D image of the face. Using over 15 million genomewide markers with MAF>. 01 on 3700 normal African Bantu children from Tanzania, we estimated narrow-sense heritability and total heritability explained by the genotyped SNPs of the first 5 PCs from a PCA of 29 landmarks across the face and 24 inter-landmark distances. Taking advantage of close and distant relatedness, we fit a linear mixed model adjusted for age, sex, and centroid size to jointly estimate two variance components corresponding to heritability explained by genotyped and non-genotyped SNPs, the sum representing total narrow sense heritability. Our estimates for narrow sense heritability range from 5% - 64%, with 28/29 being >24%. Our estimates for total heritability explained by the SNPs range from 3% - 56%, with 28/29 being >19%. The most heritable phenotypes include cranial base width (64%); PC4 representing width of the nose and midface and mandible height (55%); outer canthal width (53%); nasal bridge length (51%); and PC5 representing nose shape, displacement of the mouth relative to the nose, and rotation of the eyes (51%). Using 15 million common variants we can explain >90% of heritability for 16/29 phenotypes and at least 45% for all phenotypes. Interestingly, PC1 representing upper face height and midface width has the highest genetic correlation with linear distances representing midface depth (. 82) and labial fissure width (. 60), both distances relating to midface width and not face height. PC2 representing overall and lower face height and mid and lower face prognathism and PC4 representing width of the nose and midface and mandible height have high genetic correlation with nasal bridge length (. 69 and . 78, respectively) and nasal height (. 60 and . 65, respectively). PC4 additionally is highly correlated with labial fissure width (. 77), nasal width (. 69), and subnasal width (. 67).

Autoimmune diseases (AIDs), affecting over 7-10% of the population in the Western Hemisphere, representing a group of common polygenic diseases with few effective therapies. To quantify the contribution of common genomic variations to the risk of pediatric AI diseases (pAIDs), including JIA, SLE, CEL, T1D, UC, CD, PS, AS and CVID, we calculated the heritability attributable to genetic differences (SNP-h2) using genome-wide SNP-genotypes for each pAID and pair of pAIDs. SNP-h2 estimates were significant across multiple pAIDs, including T1D (0. 863 +/- SE 0. 07) and JIA (0. 727 +/- SE 0. 037), but were more modest in UC (0. 386 +/- SE 0. 04) and CD (0. 454 +/- 0. 025). The MHC strongly contributed to SNP-h2 in T1D and JIA, but did not contribute strongly to SNP-h2 in other pAIDs (e. g. UC or CD); the results correlate with how strongly the MHC is associated with pAIDs based on GWAS results, are consistent with population reported h2, and in some cases are greater than SNP-h2 calculated based adult GWAS (i. e. , T1D, UC, JIA/RA). Pairwise genetic correlation (rG) between UC and CD and between JIA and CVID were the highest, consistent with estimated pAID genetic sharing obtained through independent statistical measures. The MHC did not play a significant role in rG. Together, our results partition contributions of shared versus disease-specific genomic variations to pAID heritability, identifying pAIDs with unexpected risk sharing and for which assessments of heritability is highly valuable. Future work utilizing these data may help establish a clinical tool that can be useful in populations that are at high risk for developing pAIDs given family history or to identify patients with a secondary pAID.

Height-specific polygenic score using common alleles predicts extreme height rank. *R. H. Miller, L. M. McKinnon, K. Crofts, M. T. W. Ebbert, J. S. Kauwe.* Biology, Brigham Young University, Provo, UT.

Human height is a complex trait affected by hundreds of contributing genetic loci1 and a significant environmental component2. In documented history, just a small number of individuals have reached a height of 90 inches or more without exhibiting significant pathology related to pituitary function. Here we present evidence that calculating a height-specific polygenic score for such an individual can predict his/her extreme height rank when compared to a score distribution from a population-based control group with the same European-American ancestry. We have collected DNA from an individual who is 90 inches tall with no significant health issues or other physiological abnormalities to test the hypothesis that the subject is exceptionally tall due to a unique and extreme combination of common alleles for increased height. We tested this hypothesis by calculating a height-specific polygenic score3 for the subject and a population-based reference group of 189 individuals, and comparing the subject's score to the population distribution. To calculate the height-specific polygenic score, we extracted 22,539 height-associated SNPs with genome-wide significance ($p < 5e-8$) from a recent meta-analysis of 2. 5 million SNPs1. Data from the meta-analysis include each SNP's effect (b) on height. Of the significant height-associated SNPs, we were able to extract 3696 SNPs for the subject and all individuals within the control group. Using these SNPs, we calculated the height-specific polygenic scores for all individuals. The subject's score is in the 99th percentile (p=0. 005) supporting our initial hypothesis that this subject's height is the result of a unique combination of common alleles of small effect. Ongoing analyses will broaden both the number of alleles evaluated and the number of samples in the reference population. References:1. Wood, A. Novel method to estimate regional genetic associations improves genetic scores performance. *G. Pare[1], S. Mao[1], W. Deng[2].* 1) Pathology and Molecular Medicine, McMaster University, Hamilton, Ontario, Canada; 2) Statistical Sciences, University of Toronto, Toronto, Canada.

Despite considerable efforts, known genetic associations only explain a small fraction of predicted heritability. We have previously shown that large regions joint associations, where multiple contiguous genetic variants are included in regression models, can improve the variance explained by established association loci as compared to genome-wide significant SNPs alone (Pare et al. PLoS Gen 2015). However, such regional joint associations are not easily amenable to estimation using summary data because of sensitivity to linkage disequilibrium (LD). Since only large genetic meta-analyses are likely to be powered to identify weak associations, we propose a novel method to estimate regional variance explained using summary GWAS data, accounting for LD while remaining robust to misspecification. **Methods:** We first divided the genome into SNP blocks of approximately 1 Mb minimizing inter-block LD. We then derived a method to estimate regional genetic effects using summary data, and showed it is asymptotically equivalent to multiple regression models when genetic effects are strictly additive (i. e. no interaction nor haplotype effect). We next extended our method to provide corresponding gene scores (GS) incorporating all genotypes within a given region. **Results:** We first compared our method to multiple regression on height and BMI using individual-level (N=7,776) data from the Health Retirement Study (HRS). While strong correlations were noted ($R2 \sim 0.25$), we estimated the loss of variance explained due to the additivity assumption at 0. 15 and 0. 26, respectively. Using summary GWAS statistics from GIANT for height (N=253,288) and BMI (N=236,231), we estimated variance explained by each SNP block and derived corresponding GS. We found that only the top 20% of blocks contributed to height variance in HRS, with GS prediction R2 of 0. 055 and 0. 021 before and after adjustment for genome-wide SNPs. Indeed, polygenic contribution of the 20% top blocks by REML (using GCTA) was 0. 63 (SD=0. 03) in HRS, while it was 0. 00 (SD=0. 04) in the remaining 80%. In contrast, all blocks contributed to BMI variance, with GS prediction R2 of 0. 050 and 0. 044 before and after adjustment for genome-wide SNPs. In summary, our results show that 1) strictly additive models do not fully capture complex traits associations, 2) traits differ in terms of the presence and distribution of regional associations, and 3) GS derived from regional associations can improve trait prediction.

Dissecting genetic and environmental contributors to asthma and allergy in two founder populations. *M. Stein[1], C. L. Hrusch[2], C. Igartua[1], R. Anderson[1], N. Metwali[3], M. Holbreich[4], P. S. Thorne[3], E. von Mutius[5], D. Vercelli[6,7], A. I. Sperling[2], C. Ober[1].* 1) Human Genetics, University of Chicago, Chicago, IL. 60637, USA; 2) Department of Medicine, Section of Pulmonary and Critical Care Medicine, and the Committee on Immunology, University of Chicago, Chicago, IL 60637, USA; 3) Department of Occupational and Environmental Health, University of Iowa, Iowa City, IA 52242, USA; 4) Allergy and Asthma Consultants, Indianapolis, IN, USA; 5) Dr. von Hauner Children's Hospital, Ludwig Maximilians University Munich, Munich, Germany; 6) Arizona Respiratory Center and Bio5 Institute, Tucson, AZ 85721, USA; 7) Department of Cellular and Molecular Medicine, University of Arizona, Tucson, AZ 85724, USA.

Although asthma and allergic diseases are heritable, studies in central Europe have shown protection from these diseases in children raised on farms compared to their non-farming neighbors. This observation is recapitulated in two U. S. farming populations: the Indiana Amish, of Swiss-German descent, and the South Dakota Hutterites, who originated in the South Tyrol. These populations share similar lifestyles, although Amish live on single-family traditional dairy farms and use horses for field work and transportation whereas the Hutterites live on large, communal farms that are highly industrialized. Remarkably, the reported prevalence of asthma and allergic disease is 3- and 5-fold higher, respectively, in Hutterite compared to Amish children. To begin to unravel the factors accounting for these differences in disease prevalence, we studied 30 Amish and 30 Hutterite schoolchildren (ages 6-14). None of the Amish and 6 Hutterite children had asthma, and 2 Amish and 9 Hutterite children had high levels of specific IgE against common allergens (p=0. 04). There were similar and low levels of airborne allergens (dog, cat, house dust mite, cockroach) in dust collected in 10 Amish and 10 Hutterite homes, but dust from Amish homes had significantly higher levels of endotoxin (median 4399 vs 648 EU/m2; p=3. 3x10-6), reflecting higher levels of microbial exposure in Amish homes. Principal component analysis of ~72,000 genome-wide SNPs showed overlapping Amish and Hutterite clusters that were distinct from other European populations, reflecting similar ancestry and making it unlikely that the striking differences in disease prevalence are due to genetic differences between these populations. In contrast, gene expression levels in peripheral blood leukocytes were markedly different between the two groups, with 2,809 differentially expressed genes (FDR of 1%) between Hutterite and Amish school children. These differences in gene expression were entirely explained by differences in cell composition: after regressing out proportions of T cells, B cells, monocytes, eosinophils, and neutrophils, no genes were differentially expressed at a FDR of 1%. Moreover, neutorphils, monocytes, and T regs were phenotypically different between Hutterites and Amish. Overall, our study provides a first step toward identifying environmental correlates of asthma protection, and suggest the specific immune cells involved in risk or protection from asthma and allergic disease. (R01 HL085197).

Maternal filaggrin mutations increase the risk of atopic dermatitis in children: an effect independent of mutation inheritance. *J. Esparza Gordillo[1,2], A. Matanovic[1,2], I. Marenholz[1,2], A. Bauerfeind[2], K. Rohde[2], K. Nemat[3], M. A. Lee-Kirsch[3], M. Nordenskjöld[4], M. C. G. Winge[4], T. Keil[5], R. Krüger[6], S. Lau[6], K. Beyer[6], B. Kalb[6], V. Niggemann[6], N. Hübner[2], H. J. Cordell[7], M. Bradley[4,8], Y. A. Lee[1,2].* 1) Experimental and Clinical Research Center, Charite Univ Med, Berlin, Germany; 2) Max-Delbrück-Centrum (MDC) for Molecular Medicine, Berlin, Germany; 3) Klinik fur Kinder- und Jugendmedizin, Technical University Dresden, Dresden, Germany; 4) Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 5) Institute for Social Medicine, Epidemiology and Health Economics, Charité Universitàtsmedizin Berlin, Berlin, Germany; 6) Pediatric Pneumology and Immunology, Charité Universitàtsmedizin Berlin, Berlin, Germany; 7) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, United Kingdom; 8) Dermatology Unit, Department of Medicine, Solna Karolinska University Hospital, Stockholm, Solna, Sweden.

Epidemiological studies indicate that maternal allergy is a stronger risk factor for the offspring than paternal allergy, suggesting a preferential maternal transmission of disease risk. However, the molecular mechanism underlying this parent of origin effect is currently unknown. Common loss-of-function mutations in the filaggrin gene (*FLG*) cause skin barrier deficiency and strongly predispose to atopic dermatitis (AD). We analyzed the 4 most prevalent European *FLG* mutations (c. 2282del4, p. R501X, p. R2447X,and p. S3247X) in two family-based samples (759 and 450 AD families) and applied the PREMIM/EMIM tool to test for parent-of-origin effects. As expected, children carrying a *FLG* mutation had a 2. 4 fold increased disease risk (R1meta-analysis = 2. 4, P = 1. 0 x 10–36). Strikingly, we also observed a strong maternal *FLG* genotype effect indicating that children of *FLG*-carrier mothers had a 1. 5-fold increased AD risk (S1meta-analysis = 1. 50, P= 8. 4 x 10–8). This maternal effect was consistent in both sets of families and for all 4 mutations analyzed. Our results point to two independent scenarios where *FLG* mutations increase AD risk: i) carrying a mutation and ii) having a mutation carrier mother. This maternal effect is independent of mutation inheritance and can be seen as a non-genetic transmission of a genetic effect. Interestingly, the *FLG* maternal effect was observed only when mothers had IgE antibodies against environmental allergens, suggesting that *FLG*-induced changes in the maternal immunity shape the child's immune system through feto-maternal cross-talk and increase the child's risk for AD. Our study supports the concept of "developmental origins of disease" and indicates that maternal *FLG* mutations act as strong environmental risk factors for the child. Additionally, it highlights the potential of family-based studies in uncovering novel disease mechanisms in the field of complex disease.

A meta-analysis of atopic dermatitis reveals novel loci. *L. Vazquez[1], B. Almoguera[1], J. Connolly[1], P. Sleiman[1], F. Mentch[1], J. Linneman[2], M. Brilliant[2], M. Williams[3], K. Borthwick[3], A. Sundaresan[3], H. Hakonarson[1,4].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Marshfield Clinic, Marshfield, WI; 3) Geisinger Health System, Danville, PA; 4) Department of Pediatrics, The Perelman Schoolof Medicine, University of Pennsylvania, Philadelphia, PA.

Introduction: Atopic Dermatitis is a chronic inflammatory skin disease with a prevalence rate up to 20% in children and 3% in adults. The condition is characterized by intense pruritus and a course marked by exacerbations and remissions. There are 19 GWA loci reported to date. **Methods:** All cases and controls were defined by an electronic health record (EHR)-based algorithm, which mines health EHRs for pertinent diagnostic (i. e. ICD9 codes) and medication information. The algorithm was run and validated internally at the Children's Hospital of Philadelphia, with external validation at an independent site revealing positive predictive values of 92%-96%. A total of 6,100 children and 5,421 adults of European ancestry were included in the analysis. Imputation of non-observed genotypes was carried out using SHAPEIT and IMPUTE2. Population ancestry was determined by principal component (PC) analysis using Eigenstrat 3. 0 and 10 PCs were generated and used as covariates in each individual association analysis, which was conducted using SNPtest. Metal was used for the meta-analysis of the two cohorts. **Results:** Three loci reached genome-wide significance in the meta-analysis of all 11,521 subjects: a novel locus on 17q21. 33 (p=8. 61e-09), where the carbonic anhydrase 10 gene (*CA10)* is located; *SLC22A8* in 3q21, which is known psoriasis susceptibility gene; and *CDH26* at 20q13. 33, a known susceptibility locus for atopic dermatitis. **Conclusion:** We have identified two novel loci that help contribute to our understanding of the missing heritability of atopic dermatitis.

Chromatin regulatory circuitry defines inherited disease risk. *O. Corradin[1], A. J. Cohen[1], J. M. Lupinno[1], I. M. Bayles[1], P. C. Scacheri[1,2].* 1) Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH; 2) Case Comprehensive Cancer Center, Case Western Reserve University, Cleveland, OH.

SNPs associated with susceptibility to common diseases through Genome Wide Association Studies (GWAS) often lie in clusters of active gene enhancer elements including super or stretch enhancers. At these loci, the individual constituents of the enhancer clusters interact and cooperate to regulate target gene levels, and these constituents are distributed both within and beyond the boundaries of the linkage disequilibrium blocks containing the lead risk SNPs. These observations led us to hypothesize that SNPs surrounding, but not in LD with lead SNPs can target elements of a gene's regulatory circuitry and impact not only the effect of the risk SNP on gene expression, but also the clinical risk to disease. We tested this hypothesis using a novel strategy to integrate GWAS SNPs associated with six autoimmune diseases with haplotype maps, epigenomic landscapes, Hi-C chromatin interaction maps, and transcriptomic and proteomic datasets. We identified thousands of novel variants that are inherited independently of the risk locus (r2 < 0. 5, D' < 0. 9, LOD < 2), but nonetheless interact with the risk SNPs as part of the target gene's regulatory circuitry. These interacting SNPs, which we call "outside variants," were found to functionally modify the effects of the risk SNP on target transcript levels for over one-third of all evaluated GWAS loci (n = 64/186). A subset of these outside variants were functionally validated at the protein level, and using luciferase reporter assays. To determine if these effects contribute to disease pathogenesis, we evaluated their impact on clinical risk. Outside variants were found to alter the clinical risk to disease for over two-thirds of all evaluated GWAS loci (n = 23/33, P < 0. 05). Our findings indicate that the DNA sequence underlying all of a gene's regulatory elements, regardless of linkage disequilibrium with the GWAS SNPs, need to be taken into account when quantifying the effects of GWAS risk SNPs on target gene levels and calculating the true clinical risk of the associated locus. The findings also suggest that interactions defined by 3D chromatin architecture can be used to uncover novel variants that can explain additional heritability of common disease.

873T

The Inheritance of human lifespan in 20th Century Scotland. *P. K. Joshi[1], H. Tochet[1,2,3], P. Navarro[2], C. S. Haley[2], J. F. Wilson[1,2].* 1) Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, United Kingdom; 2) MRC Human Genetics Unit, University of Edinburgh, Western General Hospital, UK; 3) Wellcome Trust Centre for Human Genetics, Roosevelt Dr. Oxford, OX3 7BN.

Longevity is the ultimate phenotype and is a consequence of many intermediate complex disease phenotypes and other genetic and environmental factors. The genetic basis of human longevity is thus even less straightforward than complex trait diseases. Furthermore, the phenotype takes a lifetime to emerge and large sample sizes are needed for useful analysis. Whilst, a number of frequently cited studies have estimated the heritability of human longevity, for the populations concerned, in the range of 0. 20-0. 33, many of these studies have been twin based, or used isolated or otherwise unusual populations. It is therefore of interest to establish further estimates of the heritability of longevity with narrow confidence intervals in social settings more typical of Western European life today. Our study estimated the narrow-sense heritability (h) of human longevity conditioned on living beyond the age (42), prior to which accident or war was likely to be a greater factor. Our data was drawn from two sources. Firstly, we gathered records for offspring born in Eastern Scotland around 1900 and their parents, from Scottish public records using rare family names to facilitate efficient searches. Variables available for analysis were thus defined by the contents of death certificates. We examined the regression of child age at death on parental age at death using covariates reflecting social class, industry and location as well as year of birth and parental age at birth effects. Secondly we extracted parent-offspring trio data for offspring born around 1900, from a pedigree already gathered for the ORCADES complex disease study. Using the correlation between parent and offspring, we estimated h2 for human longevity (+/- 1 SE) as 0. 15 (+/- . 025) and found suggestions of differences between the sexes. At the same time, we found similar correlations between spouses and between a single parent and offspring, raising questions as to whether common environment has resulted in an overestimate of the heritability of lifespan by ourselves and others. Thus our results suggest the heritability of longevity may be somewhat lower in regular Western European settings than suggested by other studies but also raise tantalizing questions about the differences in the genetic basis of lifespan and the confounding effect of common environment, in particular mothering environmental influences on longevity outcomes.

874F

Genome-wide heritability estimates of sporadic brain arteriovenous malformations. *H. Kim[1, 2, 3], J. Nelson[1], S. M. Weinsheimer[4], N. Bendjilali[5], C. E. McCulloch[2], L. Pawlikowska[1, 3].* 1) Dept. of Anesthesia, University of California San Francisco, San Francisco, CA; 2) Dept. of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA; 3) Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 4) Institute of Biological Psychiatry, Copenhagen, Denmark; 5) Dept. of Mathematics, Rowan University, Glassboro, NJ.

Introduction. Brain arteriovenous malformations (BAVM) are abnormal tangles of blood vessels that can lead to hemorrhagic strokes, seizures, headaches, and other neurological deficits. Most BAVMs are "sporadic" lesions of unknown genetic etiology. The prevalence of sporadic BAVM is typically estimated as 1d1. 8 in 10,000, but may be as high as 5 in 10,000 based on a recent meta-analysis of incidental findings on MRI. The heritability of sporadic BAVM has never been formally estimated. Thus, we calculated and tested whether sporadic BAVM was a heritable trait using genome-wide complex trait analysis. **Methods**. The study included 371 BAVM cases and 563 healthy controls, all Caucasian, and genotyped on the Affymetrix Genome-Wide Human SNP Array 6. 0 in the same laboratory. We applied stringent QC filters as described by de Candia et al (Am J Hum Genet. 2013;93(3):463-70), and estimated the heritability of sporadic BAVM after adjusting for age and sex with an expectation maximization algorithm implemented in GCTA software. We varied the disease prevalence and evaluated statistical significance by permutation test. **Results**. After QC filters, our sample comprised 297 cases and 468 controls, and 484,737 common SNPs. Age and sex adjusted heritability of BAVM was 17. 6% (SE=8. 9%) for a prevalence of 1 in 10,000, and 26. 9% (SE=13. 6%) for a prevalence of 5 in 10,000. The permutation p-value was 0. 015, suggesting that heritability is significantly greater than zero. **Conclusions**. Genomewide estimates of heritability suggest that sporadic BAVM has a significant, albeit modest, additive genetic contribution. However, our heritability estimates should be viewed with caution since the true prevalence of BAVM is unknown, disease prevalence strongly affects heritability estimates, and simulations have shown that traits with both low heritability and low prevalence can have upwardly biased estimates.

875W

Defining endophenotypes of Age-related Macular Degeneration in the Amish. *R. J. Sardell[1], L. D. Adams[1], R. Laux[2], D. Fuzzell[2], L. Reinhart-Mercer[1], L. Caywood[1], D. Dana[3], A. Bowman[3], M. G. Nittala[4], S. R. Sadda[4], W. K. Scott[1], D. Stambolian[3], J. L. Haines[2], M. A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 3) Departments of Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA; 4) Doheny Eye Institute, Los Angeles, CA.

Known common and rare genetic variants explain up to 60% of the heritability of AMD. Unexplained heritability may partly reflect challenges defining the complex phenotype; the current classification system uses broad-scale grades that may not adequately represent the underlying biological basis of the disease. Furthermore, most studies compare advanced cases with controls. We hypothesized that parsing the AMD phenotype into heritable sub-phenotypes, each with a distinct genetic basis ("endophenotypes"), will improve prediction of risk and increase our understanding of the genetic architecture of AMD. We used Ocular Coherence Tomography (OCT) imaging to quantify fine-scale retinal features, compare these traits to the traditional Age-Related Eye Disease Study (AREDS) scale and assessed their potential as endophenotypes. We sampled 566 related individuals from Amish families with early/intermediate AMD cases in Pennsylvania, Ohio and Indiana. The Amish provide an excellent opportunity to analyze the heritability of complex traits given their large nuclear families and relatively homogeneous environmental and genetic backgrounds. Approximately 69% of individuals were controls (grade 0/1), 11% had early AMD (grade 2), 12% had intermediate AMD (grade 3) and 8% advanced AMD (grades 4/5). AREDS grade (rs=0. 86) and choroidal thickness (r=0. 84) were highly correlated between left and right eyes. Choroidal thickness was moderately correlated with AREDS grade in both eyes (rs=-0. 31). A generalized linear mixed model, accounting for age, gender, clinic and repeated measures (left and right eyes) confirmed that choroidal thickness was highly repeatable within individuals (0. 78) and moderately heritable (additive genetic variance h2=0. 30, 95% CI=0. 13-0. 50). Choroidal thickness was also negatively correlated with age (r=-0. 48), but not gender. This study is the first reported estimate of the heritability of choroidal thickness, highlighting a heritable, quantitative OCT trait that is both measurable in all individuals and correlated with AMD status. Choroidal thickness may therefore be an informative biomarker of AMD risk. Moderate correlation between choroidal thickness and AREDS grade suggested that this OCT trait may capture phenotypic variation not captured by the traditional AREDS system. Choroidal thickness will therefore be tested for association with genetic variants to determine whether this trait has a distinct genetic etiology and defines an AMD endophenotype.

876T

Missing heritability may be explained by the common household environment and its interaction with genetic variation. *N. Wang[1,2,3], R. M. Watanabe[1,2,3].* 1) Department of Preventive Medicine, Keck School of Medicine of USC, Los Angeles, CA; 2) Physiology and Biophysics, Keck School of Medicine of USC, Los Angeles, CA; 3) Diabetes and Obesity Research Institute, Keck School of Medicine of USC, Los Angeles, CA.

Genome-wide association studies have identified thousands of common genetic variants associated with complex diseases and disease-related quantitative traits (QTs). However, the majority of the heritable variance (narrow-sense,*h2*) remains unexplained. Although numerous plausible explanations for the inability to fully account for*h2*have been put forth,*e. g.* , undetected rare variants, structural variation, gene-gene and gene-environment interactions, none fully explains this phenomenon. We formulated an alternative explanation that*h2*estimates may be upwardly biased due to model misspecification. In particular, we hypothesize that*h2*estimates have not accounted for the common household environment (CHE) and/or its interaction with genetic variation. We tested our hypothesis by simulating trios with a QT as the sum of 4 components: (1) additive effect of*m*common SNPs with joint variancea2, (2) CHE distributed as*N*(0,dH2), (3) a multiplicative interaction between CHE and one SNP (xint) with effect sizebint, and (4) the residual error distributed as*N*(0,e2). Genotypes were simulated assuming linkage and Hardy-Weinberg equilibria. Trio members were individually assigned the same sampled CHE. Simulated data were analyzed by variance components with maximum likelihood to estimate*h2*. Different parameter combinations were tested with 1000 sets of 200 trios analyzed for each setting. We first examined the case where no interaction was in the true model, and onlya2ande2were in the estimation model. We theoretically derived equations based on Huber (1967) and showed the estimateda2was inflated and the degree of inflation increased with an increasing CHEdH2, consistent with simulation studies. For example, whena2=dH2=e2=100, estimateda2is 228; a 2. 3 folds inflation. We then examined the case where all 4 components were in the true model, and onlya2ande2were in the estimation model with or without specifying CHE. Simulation studies showed the estimateda2was inflated, even with specifying CHE, and the degree of inflation increased with an increasingbint. For example, whena2=dH2=e2=100and the effect allele frequency of the SNP xintbeing 0. 2, the inflation of a2 ranges from 1. 3 to 8. 7 folds with |bint| in the range of 1 to 5. In conclusion,*h2*estimates may be greatly biased upward due to model misspecification. This inflation can be caused by not taking into account CHE and its interaction with genetic variation.

877F

Bayesian analysis of polygenic effects on BMI. *J. H. Zhao, J. A. Luan, S. J. Sharp, C. Langenberg, R. Scott, N. J. Wareham.* MRC Epidemiology Unit, University of Cambridge School of Clinical Medicine, Cambridge Biomedical Campus, Cambridge, CB2 0QQ, United Kingdom.

Background: In study of obesity-related traits, there has been considerable interest in polygenic effects on body mass index (BMI) which usually involves maximum likelihood methods with uncertainty in parameter estimation. We investigated this through Bayesian analysis of whole genome data in population-based studies. **Methods:** We analysed data from two population-based studies of European origin: EPIC-Norfolk (N=21,044) and Fenland (N=8,994), genotyped with Axiom BioBank genotyping arrays, and compared with results from earlier data from the same cohorts using Affymetrix 500K (N=2,514) and Affymetrix 6. 0 (N=1,357) genechips. We conducted our analyses using Bayesian linear regression implemented in R instead of the computer program GCTA. **Results:** Using scaled inverse chi-square priors on the polygenic and residual variance components and MCMC procedures involving with 15,000 burn-ins and 50,000 iterations, the point estimates (95% HPD interval) for heritability, the total additive genetic variance as proportion of the total phenoyptic variance, were 0. 33 (0. 28-0. 38) and 0. 45 (0. 36-0. 54) for EPIC-Norfolk and Fenland data compared to heritability estimates (95%CI) of 0. 13 (0-0. 35) and 0. 35 (0-0. 76), respectively using earlier data on the two cohorts. In particular, the Fenland estimate agrees with those reported from family studies such as the Framingham study and is slightly higher than EPIC-Norfolk possibly due to younger age of the participants (mean (SD) age 48. 9 (7. 4) and 59. 2 (9. 3), respectively). In addition, we obtained the posterior distribution of polygenic effects. **Conclusion:** Our work corroborates earlier evidence on polygenic effects on BMI from family studies and shows that Bayesian approach applied to large sample and whole genome data can give better account of the sampling variations in polygenic effects. We are examining performance of prediction with single nucleotide polymorphisms (SNPs) across the genome with the same framework.

878W

Comparison of Predictive Value of Genetic and Transcriptional Risk Scores. *U. Marigorta, G. Gibson.* School of Biology, Georgia Institute of Technology, Atlanta, GA.

Most variants discovered by genome-wide association studies (GWAS) lie in regulatory regions, and a sizable fraction act as alleles that alter gene expression (eQTL). These observations suggest that a large proportion of susceptibility to complex disease may be due to detrimental changes in gene regulation. Consequently, transcript abundance levels could be used as biomarkers for prediction of individual risk of disease. Since these presumably integrate both the genetic and environmental influences, it might be expected that transcript abundance is a better predictor of disease than genotypes alone. Given this expectation, we propose that the average relative abundance of transcripts influenced by disease-associated eQTL could be used to calculate transcriptional risk scores (TRS). We here report results of simulations designed to evaluate the relative performance of GRS and TRS as predictors of disease risk. For a wide range of parameter space consistent with current knowledge of the genetic architecture of disease, we observe that transcriptional risk scores are indeed likely to be more sensitive markers of susceptibility to disease. Moreover, we develop a number of alternative scores that make different assumptions about the weights of extreme values of gene expression, or the role of the gene embedded in a pathway. We argue that this parameterization might be used to constrain models of the relationship between eQTL, GWAS signals, and actual disease etiology. For example, if it is assumed that only extreme gene expression is causal in disease, common variant genetic effects should not be seen as average effects, but rather as markers of heterogeneous common variants of rare effect. Testing of these concepts requires development of more datasets where gene expression is measured in relevant tissues from patients with disease, in addition to healthy people samples that currently dominate the gene expression studies.

879T

Identifying genes associated with maternal nondisjunction of chromosome 21. *J. M. Chernus[1], E. G. Allen[2], Z. Zeng[3], C. Trevino[2], E. Feingold[1,3], S. L. Sherman[2].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Human Genetics, Emory University, Atlanta . GA; 3) Department of Biostatistics, University of Pittsburgh, Pittsburgh PA.

We have conducted the first GWAS to identify genes associated with nondisjunction of chromosome 21 in oocytes. A total of 2,186 study subjects were genotyped on the HumanOmniExpressExome-8v1-2 array. These subjects included over 700 live birth offspring with standard trisomy 21 derived from an error in the oocyte and over 1400 parents. Genotypes for chromosome 21 in children were called using methods we previously developed. Genotypes for parents and child were then used to establish parent of origin, stage (meiosis I or meiosis II) and meiotic recombination patterns for each child. We used two different designs for conducting the GWAS. In the first, we take advantage of the fact that the etiologies of meiosis I trisomy 21 and meiosis II trisomy 21 appear to be quite different, and perform a GWAS of mothers of meiosis I cases vs. mothers of meiosis II cases. This approach cannot find variants that are common risk factors for both meiosis I and meiosis II errors, but is a well-controlled design for finding variants that are unique to one or the other. The second approach uses the fathers as controls. In that approach, we may also discover genes that affect the likelihood of a fetus with trisomy 21 surviving to term.

Genome-wide association study of 41 circulating cytokines. *A. V. Ahola-Olli[1], J. Kettunen[2], P. Würtz[2], N. Pitkänen[3], K. Aalto[1], M. Salmi[1], A. Havulinna[1], V. Salomaa[4], T. Lehtimäki[5], S. Jalkanen[1], O. T. Raitakari[1].* 1) University of Turku, Turku, Finland; 2) University of Oulu, Oulu, Finland; 3) University of Eastern Finland, Kuopio, Finland; 4) Finland National Institute of Health and Welfare, Helsinki, Finland; 5) University of Tampere, Tampere, Finland.

Introduction: Cytokines have essential roles in regulation of immune response. Dysregulation of immune system have been linked to various autoimmune diseases such as inflammatory bowel diseases and rheumatoid arthritis. The purpose of this study is to shed light to yet unknown biology behind immune system regulation and pathogenetic mechanisms behind autoimmune diseases. To achieve this, we performed genome-wide association study of healthy Finnish subjects randomly chosen from national registers. To dissect biological mechanisms behind the associated loci, we performed expression quantitative trait loci analyses for lead SNPs in whole blood and searched existing databases for additional information from the loci. Materials and Methods: Both the genotype and cytokine data were available from three Finnish population based cohorts: The Cardiovascular Risk in Young Finns Study, Finrisk97 and Finrisk02. Total of 8153 subjects were included in this study. Cytokine measurements have been performed with Bio-Rad's premixed Bio-Plex Pro Human Cytokine 27-plex Assay and 21-plex Assay. The amount of bound cytokine was detected using streptavidin-phycoerythrin conjugate. 1000 genomes imputation panel was used to impute genotypes. Snptest software was used to conduct genome-wide scans. Meta-analyses were performed with METAL software. Following filters were applied to data: info > 0. 7, minor allele count > 10 and association test info > 0. 7. Cis eQTL analyses were performed for lead SNPs. Results: We identified 14 new loci previously not associated with cytokines, hsCRP or white blood cell count. Six of these loci are located near a SNP previously associated with an autoimmune disease. Total of 27 loci had genome-wide significant association with the concentration of at least one cytokine. Conclusions: This study have provided important insights to development of autoimmune diseases and identified cytokines that probably have important role in development of these diseases.

Analysis of pathways associated with Body Mass Index in individuals with multiple sclerosis. *M. G. Durrant[1], J. C. Denny[2], M. F. Davis[1].* 1) Department of Microbiology and Molecular Biology,, Brigham Young University, Orem, UT; 2) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Current evidence suggests that a high body mass index (BMI) earlier in life is associated with multiple sclerosis (MS) later in life. The nature of this association is not fully understood. Previous research indicates that MS patients may also experience weight gain through the course of their disease, with the hypothesized cause being a combination of pain, fatigue, and medications such as glatiramer acetate.

The electronic medical records of 1,809 MS cases and 34,997 controls were analyzed to determine significant differences in BMI between the first recorded clinic visit and the most recent clinic visit. Results indicate that MS patients have a significantly higher BMI at the first and last clinic visits. Then, three linear regression and pathway-based association studies were conducted for 1,003 MS patients' BMI phenotype data from the first and last clinic visits, as well as the slope of BMI change between the first and last visits. Pathway analyses were conducted using the PARIS algorithm. The resulting significant KEGG pathways were compared to other BMI pathway analysis studies to identify unique pathways associated with MS patients.

No individual SNPs met genome-wide significance in any of the linear regression analyses. Among the top 20 most significant SNPs in each analysis, several SNPs occurred in groups around specific genes, including BANK1, RNLS, SLC14A2, TDH and C8orf12. After removing pathways already known to be associated with BMI, PARIS results indicated an association between a high BMI at first clinic visit and cerebellar long-term depression ($p = 0.014$), as well as an association between the overall BMI slope-change between visits and the systemic lupus erythematosus (SLE; $p = 0.001$) and RIG-I-like receptor signaling ($p < 0.001$) pathways.

We found that BMI was significantly elevated in MS patients both at the first and last clinic visit when compared to controls, providing some evidence for a link between MS and elevated BMI. The BANK1 gene has previously been linked to other autoimmune diseases such as type 1 diabetes (T1D) and SLE, but not directly with MS. RNLS has also been previously linked to T1D. Additionally, the relationship between the slope of BMI change between visits and other autoimmune disease pathways suggests that the nature of the MS itself and susceptibility to other autoimmune diseases such as SLE and T1D may contribute to high BMI in MS patients.

A comprehensive framework for fine-mapping disease loci across autoimmune diseases. *A. Hadjixenofontos[1], M. Mitrovic[1], C. Cotsapas[1,2].* 1) Department of Neurology and Immunobiology, Yale University, New Haven, CT; 2) Broad Institute of MIT and Harvard, Boston, MA.

Epidemiological, genetic and clinical evidence suggests the co-morbidity between autoimmune diseases (AID) is due to shared pathogenic mechanisms. Understanding if risk is driven by the same alterations would allow treatment re-purposing across diseases and the emergence of a molecular nosology to guide both therapeutic intervention and development. Genome-wide association studies have identified tens of loci mediating risk to multiple AID; however, inferring a shared pathogenic mechanism requires demonstrating that the same genetic effect mediates risk to multiple diseases. To address this challenge, we have collated genotype-level data from 79,638 cases with inflammatory bowel disease, multiple sclerosis, systemic lupus erythematosus, type I diabetes, or celiac disease and ~85,000 matched healthy controls. We have created a robust analysis framework for cross-disease analysis where we can distinguish between heterogeneous but co-localizing effects and those that are truly shared across traits. After applying a unified quality control pipeline, we use a flexible population-matching scaffold that we have developed based on principal component projection. This scaffold allows us to select optimal sets of samples for analysis of each locus harboring risk variants for any subset of diseases. We have developed methods for assessing if associations in a genomic locus are driven by the same risk variant across independent phenotypes. We then use these methods in all case samples, identify cases in which the effect appears to be shared thereby increasing effective sample size in the region and thus increasing the resolution of fine-mapping. In simulations of the NFKB1/MANBA locus on chromosome 4, where an extended haplotype of 102 markers shows strong association to risk of multiple sclerosis, we find that we are able to reduce the size of the credible interval by 37% by increasing sample size in our framework. In addition, the simulated causal variant is included in the credible interval 96% of the time, compared to 71% of the time using only multiple sclerosis samples. We are currently fine-mapping 185 loci robustly associated to at least one AID in this fashion, including deriving expectations through simulation.

Genome-wide Study of Late-Onset Myasthenia Gravis: Confirmation of *TNFRSF11A*, and Identification of *ZBTB10* and Three Distinct HLA Associations. *M. F. Seldin[1], O. K. Alkhairy[2], A. T. Lee[3], J. A. Lamb[4], J. Sussman[5], R. Pirskanen-Matell[6], F. Piehl[6], J. J. G. M. Verschuuren[7], A. Kostera-Pruszczyk[8], P. Szczudlik[8], A. Maniaol[9], H. F. Harbo[10], B. A. Lie[11], A. Melms[12], H-J. Garchon[13], N. Willcox[14], P. K. Gregersen[3], L. Hammarstrom[2].* 1) Biochemistry and Molecular Medicine, Sch Med, Univ California, Davis, Davis, CA; 2) Division of Clinical Immunology, Karolinska Institutet at Karolinska University Hospital Huddinge, Stockholm, Sweden; 3) The Robert S. Boas Center for Genomics and Human Genetics, Feinstein Institute for Medical Research, North Shore LIJ Health System, Manhasset, NY; 4) Centre for Integrated Genomic Medical Research, Manchester Academic Health Science Centre, University of Manchester, Manchester, UK; 5) Department of Neurology, Greater Manchester Neuroscience Centre, Manchester UK; 6) Department of Neurology, Karolinska University Hospital Solna, Stockholm, Sweden; 7) Department of Neurology, Leiden University Medical Center, Leiden, The Netherlands; 8) Department of Neurology, Medical University of Warsaw, Warsaw, Poland; 9) Department of Neurology, Oslo University Hospital, Ullevål, Oslo, Norway; 10) Department of Neurology, Oslo University Hospital and University of Oslo, Oslo, Norway; 11) Department of Medical Genetics, University of Oslo and Oslo University Hospital, Oslo, Norway; 12) Department of Neurology, Tübingen University Medical Center, Tübingen, Germany and Neurologische Klinik, Universitétsklinikum Erlangen, Erlangen, Germany; 13) Inserm U1173, University of Versailles,Campus, Paris-Saclay, France; 14) Department of Clinical Neurology, Weatherall Institute for Molecular Medicine, University of Oxford, Oxford, United Kingdom.

To define the genetics of late-onset myasthenia gravis (LOMG), we conducted a genome-wide association study including imputation of >6 million SNPs in 532 LOMG cases (anti-cholinesterase receptor antibody positive, onset age >50 years) and 2128 controls matched for sex and population substructure. The data confirm reported *TNFRSF11A* associations [rs4574025, p = 3. 9x10-07, odds ratio (OR) = 1. 42] and identify a novel candidate gene, *ZBTB10*, achieving genome-wide significance (rs6998967, p = 8. 9x10-10, OR = 0. 53). Several other SNPs show suggestive significance including rs2476601 (p = 6. 5x10-06, OR =1. 62) encoding the *PTPN22* R620W variant associated with early-onset MG (EOMG) and other autoimmune diseases. In contrast, *TNIP1* SNPs associated with EOMG show no association with LOMG, nor did other loci suggested for EOMG. SNPs within HLA show strong associations in LOMG, but with smaller effect sizes than in EOMG (highest OR ~2 vs. ~6). Moreover, the specific LOMG associated determinants show a different pattern from EOMG. Indeed, the strongest LOMG HLA determinant is *DQA1*0501* (p = 5. 9x10-12, OR = 0. 54). Association and conditioning studies for the HLA region show three distinct and largely independent association peaks for LOMG corresponding to i) HLA class II (highest attenuation when conditioning on DQA1), ii) HLA-A and iii) HLA class III (equivalent results with SNPs within *DDX39B-ATP6V1G2*, *NFKBIL1*, and *LST1*). Conditioning studies of HLA amino acid residues also suggest potential functional correlates. Together these data emphasize the need to subgroup MG for clinical and basic investigative studies, and imply distinct predisposing mechanisms in LOMG.

Multi-level Genome-wide Association Study on Bone Geometry and Microstructures. *X. Fu, H. Shen, LJ. Zhao, Q. Tian, HW. Deng.* Biostatistics and Bioinformatics, Tulane University, New Orleans, LA.

Osteoporosis isan increasingly prevalent public health problem worldwide. Previousgenetic studiesfor osteoporosis were mainly focused on areal bone mineral density(aBMD). However,bone geometry and microstructuresare alsoplaying critical roles inindetermining bonestrength and risk of fracture. To identify novel osteoporosis susceptibility genes, weperformedamulti-level genome-wide association study (GWAS)onbone geometry and microstructuralcharacteristics. A total of3,209subjects from theFramingham Studywereincluded in the analysis. Eachof subjectswas measured for trabecular volumetricBMD(TBMD), integral vertebral body volumetricBMD(IBMD) and cross-sectional-areal (CSA) byquantitative computed tomography (QCT),as well asaBMD,at lumbar spine. Genotypesfor ~9. 9millionSNPswereimputedand passedquality control. Genome-wide Efficient Mixed Model Association(GEMMA)approach, which takesadvantageofuni-andmulti-variate linear mixed model, was used for the multi-level GWASanalyses. By univariate analyses, we identifiednovel significant associations for SNPs(rs143042601,p=2. 4e-09)in an intergenic region of2q23. 3withTBMD, andSNPs(rs114032442,p=4. 0e-08)proximal tothespalt-like transcription factor 1 (*SALL1*)genewith CSA. Through bi- and multi-variate analyses, we further identified a number of loci that are significantly associated with multipletraits. For instance,severalSNPs mapped tothelatecornifiedenvelope(*LCE*)gene familyon 1q21. 3showed significant association(p= 2. 6e-10~8. 8e-09)withTBMD and IBMD, and SNPs ingene*ZNF678*(rs149363602,p=1. 3e-08)weresignificantlyassociated withall fourphenotypes. In summary,we conducted a multi-level GWAS forbone geometry and microstructuresof lumbar spine and identified a number of novel osteoporosis susceptibility genes. Particularly, some of the identified loci were previously implicatedinregulating bone strength in animal models, but werefor this timeassociated with human bone phenotypes, highlighting the power of bi-/multi-variant analyses for human complex disorders/traits.

885T

Identification of 10 novel uterine leiomyomata susceptibility loci by genome-wide association analysis in population-based conventional and direct-to-consumer cohorts. *C. S. Gallagher[1,2], D. Uterine leiomyomata (UL), also known as fibroids, are the most common tumor of the female reproductive tract and have been shown to have heritable risk. Within FibroGENE, a consortium for genome-wide association study (GWAS) of UL, we report a two-stage, large-scale GWAS combining data from a population-based research cohort (Women's Genome Health Study, WGHS) and a direct-to-consumer genotyping service (23andMe) with the goal of discovering novel UL susceptibility loci in women of European ancestry. We first investigated 3,375 self-reported cases and 9,465 controls from WGHS along with subgroup analyses among 2,717 severe cases and 6,359 controls. Two loci, in *WNT4* at 1p36. 12 (rs7412010; *P* = 4. 0x10-8; OR [95% CI] = 1. 24 [1. 15-1. 33]) and *FSHB* at 11p14. 1 (rs74485684; *P* = 6. 1x10-8; OR [95%CI] = 1. 29 [1. 18-1. 42]), revealed strong candidate associations with UL predisposition in the broad and subgroup analyses, respectively. In an independent cohort of 15,068 self-reported cases and 43,587 controls from the 23andMe research participant database, both candidate loci have genome-wide significance: 1p36. 12 (rs7412010; P = 9. 0x10-11; OR [95% CI] = 1. 13 [1. 09-1. 17]) and 11p14. 1 (rs74485684; *P* = 5. 9x10-8; OR [95%CI] = 1. 11 [1. 07-1. 15]). In a genome-wide meta-analysis of the two cohorts, associations at the initial loci were reinforced (rs7412010, *P*=1. 4x10-16; rs74485684, *P*=3. 4x10-10) and we observed additional genome-wide significant associations for 546 SNPs at 11 separate regions, including a region previously reported for UL in a cohort of Japanese women: rs1265164 on 10q24. 33 (*P* = 4. 3x10-10; OR [95%CI] = 1. 12 [1. 09-1. 16]). Strong candidate associations were also observed in a second region reported in the Japanese cohort: rs143521471 (P = 4. 1x10-7; OR [95%CI] = 1. 09 [1. 05-1. 12]). Candidate genes at the 10 novel UL susceptibility regions were previously associated with endometriosis (*GREB1*, *WNT4*) and biological processes relevant to UL: estrogen receptor signaling (*ESR1*), metabolism (*CYP17, SLC38A*), cancer susceptibility, cell growth, or development (*ESR1, TP53, GREB1, PDCD6, FRMD7*), and regulation of sex hormones (*ESR1, WNT4, FSHB*). Our findings provide novel insights into the pathogenesis of UL and suggest a number of potential therapeutic avenues.

886F

Polymorphisms in SLC6A3 and DBH genes of the dopaminergic pathway associated with resistance to M. tuberculosis infection. *K. R. Fluegge[1], R. P. Igo[1], N. B. Hall[1], L. L. Malone[3], H. Mayanja-Kizza[4], W. Henry Boom[2, 3], C. M. Stein[1, 3].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Medicine, Case Western Reserve University, Cleveland, OH; 3) Case Western Reserve University and Makerere University Research Collaboration, Cleveland, OH; 4) Makerere University School of Medicine and Mulago Hospital, Kampala, Uganda.

Tuberculosis (TB), caused by Mycobacterium tuberculosis (Mtb), is a major public health threat globally, with a high burden in sub-Saharan Africa. According to the World Health Organization in 2013, Uganda's TB incidence rate was 166 per 100,000 people. Human host genetic factors have been demonstrated to be involved in the pathogenesis of TB. Furthermore, the immunology literature also hints that allelic variations within genes relevant to the dopaminergic system may impact susceptibility to infections, including TB. Exposure to Mtb is a necessary but insufficient condition for infection to occur. Of those ultimately infected, only about 10% of individuals develop active TB disease. The two main phenotypes of interest in TB pathogenesis are active TB disease and remaining persistently TST negative (PTST-) despite close and prolonged exposure to Mtb. In this analysis, we used data collected through a large ongoing household contact study in Kampala, Uganda, to examine genetic association with these phenotypes. We focused on seven genes within the dopaminergic system, analyzing 2266 single nucleotide polymorphisms (SNPs) within these genes and within 100 kilobasepairs of these genes that were genotyped on the Illumina Omni5 chip. The 483 subjects from 299 households included in this analysis were enrolled between 2002-2010. Analysis was conducted using generalized estimating equations, clustering the data by family. For each outcome, TB (42%) and PTST- (7%), both the dominant and the additive models were run. We found 11 SNPs in the solute carrier family 6 (neurotransmitter transporter), member 3 (SLC6A3, or dopamine transporter (DAT) gene) gene, 3 SNPs in the dopamine beta-hydroxylase (DBH) gene and 6 SNPs in the DOPA decarboxylase (DDC) gene which were associated with PTST-phenotype ($p < 0.05$). Among the most significant SNPs associated with PTST- were SLC6A3 rs11564771 (6. 96E-05) and DBH rs3025373 (1. 29E-05). However, only the SNP in the DBH gene was significant after multiple testing correction. This particular finding extends previous work on the role of the DBH gene in susceptibility to TB infection in a murine model. We found 9 SNPs in the SLC6A3 gene, 6 SNPs in the DBH gene and 3 SNPs in the DDC gene which were associated with the TB phenotype ($0.01 < p < 0.05$), none of which were significant after multiple testing correction. These findings suggest that the dopaminergic system may play a role in resistance to Mtb infection.

Airflow obstruction occurs in chronic obstructive pulmonary disease (COPD) which is the 3rd leading cause of death globally. Forced Expiratory Volume (FEV1) is reduced in airflow obstruction. In the UK BiLEVE (UK Biobank Exome Lung Evaluation) study we aimed to investigate the genetic architecture of FEV1 extremes using a nested case-control design. A total of 50,008 individuals of European ancestry with high quality spirometry measures were sampled from the 502,682 individuals in UK Biobank. Among never smokers we sampled 10,000 individuals with the lowest percentage predicted FEV1, 10,000 from the middle of the percent predicted FEV1 distribution and the 5,000 with the highest percentage predicted FEV1. The same sampling method was used in heavy smokers. Using a custom design array (that included 130,000 rare missense and loss of function variants) a case-control analysis of high versus low percentage predicted FEV1 was performed separately in never and heavy smokers. Shared polygenic aetiology of phenotypes defined by FEV1 extremes was analysed using polygenic risk scores, gene expression levels were investigated and a genome-wide pathways analysis was performed. This study identified six novel variants that were genome-wide significant when comparing high versus low percentage predicted FEV1. Loci identified as significant in either heavy or never smokers were at 4q24 on the gene *NPNT* (p=9. 62x10-16), another independent signal at 4q24 in *TET2* (p=1. 31x10-8), at 17q21. 31 covering the *KANSL1*, *MAPT* and *CRHR1* genes (p=1. 66x10-10), on chromosome 6 within the HLA region (p=1. 26x10-10), at 17q25. 1 within *TSEN54* (p=1. 18x10-8) and an intergenic signal near *RBM19* and *TBX5* on chromosome 12 (p=1. 16x10-8). *TET2*, *TBX5* and 10 genes at 17q21. 31 showed differential expression during foetal lung development. The SNP rs2532349 in 17q21. 31 was also found to be associated with mRNA expression levels of 15 genes in the lungs and blood. There was evidence of shared genetic aetiology between low FEV1 and high FEV1 (p=1. 64x10-22). We also showed there is shared genetic aetiology for low FEV1 between heavy and never smokers (p=2. 29x10-16) and for low FEV1 between those with and without doctor-diagnosed asthma (p=6. 06x10-11). Genome-wide pathway analysis identified the histone subset of the chromatin packaging and remodelling process gene set, implicating a role for epigenetic regulation in lung health. This research has been conducted using the UK Biobank Resource.

The International Psoriasis Council Exome Chip Project: Exome arrays reveal known and novel coding variant associations. *N. Dand[1], S. Mucha[2], L. C. Tsoi[3], J. T. Elder[4,5], A. Franke[2], M. A. Simpson[1] on behalf of the International Psoriasis Council Exome Chip Consortium.* 1) Division of Genetics and Molecular Medicine, King's College London, London, UK; 2) Institute of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Germany; 3) Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 4) Department of Dermatology, University of Michigan Medical School, Ann Arbor, MI; 5) Ann Arbor Veterans Affairs Hospital, Ann Arbor, MI.

Genetic association studies, including genome-wide association studies and the recent international immunochip collaboration, have identified more than 50 common loci associated with psoriasis susceptibility in European populations. However, a substantial fraction of the genetic contribution to psoriasis risk remains undefined. Direct investigation of functional genetic variation has the potential to further elucidate the molecular genetic contributants to the heritability of psoriasis. Focus on protein-altering variation, and particularly low-frequency and rare coding variants, will inform the fine mapping of established common susceptibility loci and has the potential to identify low-frequency and rare susceptibility alleles overlooked by previous studies of common variation. We examined the role of functional protein coding variation in psoriasis susceptibility in a large case-control study incorporating 11,456 cases and 21,355 controls. Genotyping was performed at three centres (Michigan, USA; Kiel, Germany; and London, UK) using Illumina and Affymetrix Exome arrays that are designed to interrogate variants predicted to alter protein sequence. The two platforms share 231,130 variants including 28,181 common (minor allele frequency 5-50%), 21,578 low-frequency (0. 5-5%) and 184,371 rare (< 0. 5%) variants. We undertook a standard error weighted meta-analysis of 72,260 SNPs, outside of the MHC region, which are polymorphic in each of the three datasets. We observed genome-wide association (p < 5x10-8) of common missense alleles within established psoriasis susceptibility loci, including those in *IL13*, *STAT2*, *TRAF3IP2*, *TYK2*, and *ERAP1*. Aggregation tests for low-frequency and rare variation also revealed exome-wide association (p < 2. 5x10-6) for several genes, including *IFIH1*. These observations provide a basis for a more detailed analysis to determine the functional alleles responsible for these association signals.

889F

A genome-wide association study of uterine fibroids confirmed by imaging in eMERGE. *T. L. Edwards[1], M. J. Bray[10], K. S. Tsosie[1], K. E. Hartmann[2], J. C. Denny[3], J. Jeff[4], E. Kenny[4], P. L. Peissig[5], C. A. McCarty[5], M. S. Williams[6], R. P. Gogoi[6], H. S. Kuivaniemi[6], G. C. Tromp[6], A. Kho[7], J. A. Pacheco[7], K. L. Jackson[7], I. J. Kullo[8], J. Pathak[8], E. A. Stewart[8], D. M. Roden[9], D. R. Velez Edwards[10].* 1) Vanderbilt Epidemiology Center, Division of Epidemiology, Department of Medicine, Vanderbilt Genetics Institute, Vanderbilt University; 2) Department of Obstetrics and Gynecology, Institute for Medicine and Public Health, Vanderbilt University; 3) Department of Biomedical Informatics, Department of Medicine, Vanderbilt University; 4) Mount Sinai School of Medicine; 5) Marshfield Clinic; 6) Geisinger Health System; 7) Northwestern University; 8) Mayo Clinic; 9) Division of Cardiology, Department of Medicine, Department of Pharmacology, Vanderbilt University; 10) Department of Obstetrics and Gynecology, Vanderbilt Genetics Institute, Vanderbilt University.

Up to 77% of women have a uterine fibroid (UF) by menopause. UF are the leading indication for hysterectomy and account for $9B to $39B in annual healthcare costs. Risk of UFs is heritable with large disparities in UF risk, symptoms, and severity among ancestral groups. Recent African ancestry (AA) populations have a high burden of UF, with 2-3 fold higher prevalence, more severe symptoms, and earlier onset than Europeans (EA). Because up to 51% of UF cases are unaware of fibroid status and are misclassified as controls in surveys, association studies of UF risk without UF status confirmed by imaging suffer from significant information bias. We conducted an association study of rare and common genetic determinants of UF risk confirmed by pelvic imaging from electronic medical records (EMR) from 6 eMERGE Network sites (N=10,227; AA:1,354 cases and 1,419 controls; EA:2,843 cases and 4,611 controls). All subjects were classified using a validated EMR algorithm (PPV 98%, NPV 96%). All samples were genotyped by GWAS arrays and a subset was also genotyped by exome arrays (AA: 580 cases, 804 controls; EA: 1195 cases, 1164 controls). Genotypes were imputed using the 1KG reference and UF risk was modeled as a function of PCs of ancestry and genotype by logistic regression, followed by fixed effects meta-analysis of results (meta-analysis λGC=1. 02). The most statistically significant associations from transethnic analyses with meta-data from all cohorts were the intergenic SNPs rs2983218 at chr6q27 (OR=1. 23, p=8x10-10) and rs13103279 at chr4q34. 3 (OR=0. 81, p=2x10-9) near genes involved in angiogenic pathways, with consistent effects across samples (Cochran's Q p>0. 5). Statistically significant associations were observed in the subset of African ancestry cohorts for the rare (MAF<0. 01) variants rs190615976 at chr17 near *IGF2BP1* (OR=3. 82, p=2x10-10), chr2 at rs77950674 near *RUFY4* (OR=4. 15, p=7x10-10) and rs116003406 in the 3'UTR of *SLC9A4* (OR=3. 57, p=3x10-9), and chr4 at rs115077882 in *ARFIP1* (OR=1. 98, p=5x10-9). In the European subset the rare variant rs148308239 near *NEBL* on chr10 was significantly associated with UF risk (OR=0. 44, p=5x10-8). Ongoing genotyping experiments and additional cohorts will provide 4,864 imaging-confirmed samples for multistage replications of these associations. These results suggest UF risk is influenced by common and rare variants, and ancestral genetic heterogeneity in UF risk is likely.

Clinical and genetic characteristics of novel emphysema distribution subtypes identified by unsupervised learning analysis. *A. El Boueiz[1,2], M. H. Cho[1,2], G. R. Washko[2], R. San José Estépar[3], D. A. Lynch[4], E. K. Silverman[1,2], D. L. DeMeo[1,2], P. J. Castaldi[1,5].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States; 2) Pulmonary and Critical Care Division, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States; 3) Surgical Planning Laboratory, Laboratory of Mathematics in Imaging, Department of Radiology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States; 4) Division of Radiology, National Jewish Health, Denver, Colorado, United States; 5) Division of General Medicine and Primary Care, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, United States.

Background: Emphysema, irreversible destruction of lung parenchyma, is an important component of chronic obstructive pulmonary disease (COPD) with considerable variability in distribution and severity. Recent evidence suggests that a significant amount of this variability is due to genetic factors. To assess the clinical impact and determine the genetic influences of emphysema distribution, we examined lobar emphysema in the COPDGene cohort. **Methods**: 9213 NHW and AA smokers were included. Genotyping was performed on the Illumina Omni Express platform with additional markers imputed using the 1000 Genomes reference. Emphysema percentage (i. e. CT densitometry low-attenuation area less than -950 Hounsfield units) was measured in each lung lobe. Lobar emphysema variables were regressed on total emphysema and lobe-specific residuals were extracted. Unsupervised learning with random forest predictors was then used to cluster these residuals. GWASs were performed in the identified clusters per racial group to look for emphysema distribution risk loci. These clusters were also tested for associations with clinical outcomes and genetic variants previously associated with COPD. **Results**: We identified one "unclustered" group (n=6197) and three clusters that can be characterized as 1) Controls with no or minimal emphysema (n=1312), 2) Upper lobe predominant emphysema (n=905), and 3) Lower lobe predominant emphysema (n=799). GWASs, conducted in each lobar predominant cluster compared to the control cluster, identified a novel genome wide significant locus (9q31 near *ZNF462*; *P=E-8*) in the NHW upper lobe group. The other top hits were 14q21 near *DLGAP5* (AA upper lobe; *P=3E-7*), 3p14 near *FHIT* (NHW lower lobe; *P=6E-7*), and 8p12 near *TTC23* (AA lower lobe; *P=2E-7*). In the candidate analyses, strong associations were seen with rs13141641 near *HHIP (P=3E-6)* and rs2070600 near *AGER (P=E-5) respectively* in NHW upper and lower lobe groups vs control. Clinically, upper lobe predominant subjects had a more rapid disease progression over 5-year follow up. **Conclusion**: This clustering of densitometric lobar emphysema identifies subgroups of smokers with different emphysema distribution patterns, clinical features, and genetic signatures. These findings suggest that emphysema distribution is a clinically and biologically important COPD phenotype that can be used fordisease subtyping to ultimately improve and personalize therapy. **Grant support:** NIH R01s HL089897, HL089856, HL124233.

Y chromosome variation and complex traits: the Ygen consortium. *I. Gandin[1,2], P. K. Joshi[2], P. Gasparini[1,3,4], T. Esko[5,6,7,8], J. F. Wilson[2,9], The Ygen consortium.* 1) Department of Medical Sciences, University of Trieste, Strada di Fiume 447 - Osp. di Cattinara, Trieste, 34149, Italy; 2) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, EH8 9AG, Scotland; 3) Sidra Medical and Research Center, Doha, Qatar; 4) Institute for Maternal and Child Health - IRCCS "Burlo Garofolo", via dell'Istria 65, Trieste, 34137, Italy; 5) Estonian Genome Center, University of Tartu, Riia 23b, 51010, Tartu, Estonia; 6) Division of Endocrinology and Center for Basic and Translational Obesity Research, Boston Children's Hospital, Cambridge, 02141, MA, USA; 7) Program in Medical and Population Genetics, Broad Institute, Cambridge Center 7, Cambridge, 02242, MA, USA; 8) Department of Genetics, Harvard Medical School, 25 Shattuck St, Boston, 02115, MA, USA; 9) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, Scotland.

The genetics of complex traits have been studied in great detail using Genome-Wide Association Studies (GWAS), leading to substantive insights regarding the genetic determinants of quantitative traits and disease mechanisms. However, there remain significant parts of the genome which are not routinely assayed in GWA studies, the largest of which is the Y Chromosome. Only carried by men and constitutively haploid, the Y Chromosome totals about 25 Mb of sequenceable DNA containing 27 genes or gene families, including genes known to be implicated in Mendelian conditions such as infertility and deafness. Nevertheless, the Y Chromosome has been almost completed neglected in the context of complex traits and diseases, until a recent study that associated Y Chromosome variants and risk of coronary artery disease. Here we present Ygen, an international consortium that gathers together a large number of collaborating population-based cohorts. Ygen allows us to investigate the role of the Y chromosome in complex traits for the first time in an adequately powered setting. In the project more than 30 diverse traits of public health or evolutionary interest are considered, including anthropometric measures, haematological counts, cardiovascular risk factors, metabolic markers, inflammatory response and fertility. The study uses 70 SNPs included in the Illumina HumanExome Beadchip that were specifically designed to represent Y Chromosome diversity across the world. Genotypes are used to define haplogroups which in turn provide information on Y Chromosome lineages, thus increasing the number of SNPs tested. These are analysed using a single-SNP association approach and results combined in a meta-analysis. We will present results of the ongoing study which already includes more than 10,000 men. This will include an overview of quality control, focusing on genealogical consistency and SNP performance in haplogroup estimation, and the results of the association study.

Electronic health records empower the first genome wide association study of developmental dysplasia of the hip. *K. Hatzikotoulas[1], M. J. Clark[2], D. M. Eastwood[3], J. M. Wilkinson[2], E. Zeggini[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom; 2) Academic Unit of Bone Metabolism, Northern General Hospital, University of Sheffield, Sheffield, United Kingdom; 3) Consultant Paediatric Orthopaedic Surgeon The Catterall Unit, Royal National Orthopaedic Hospital, Stanmore Middlesex HA7 4LP.

Developmental dysplasia of hip (DDH) is a disorder characterised by incomplete development of hip joint. Although DDH is one of the most common skeletal dysplasias, the incidence of DDH is approximately 1. 5 cases per 1. 000 births, and it remains slow and costly to recruit large-scale patient cohorts for powerful genetic association studies. The UK has an established and expanding e-health record (EHR) infrastructure that provides a comprehensive platform upon which to develop genomic research of clinical relevance and impact. The National Joint Registry for England, Wales, and Northern Ireland (NJR) is the largest registry of joint replacement in the world, with 1. 9 million recorded procedures, adding new procedures at a rate of 200. 000 each year. In this work we have successfully used the NJR as a platform to generate a DDH biobank of 903 individuals. Following genotyping on the Illumina CoreExome platform, we carried out the first ever genome-wide association study (GWAS) for DDH in 840 patients and 3364 controls. Following stringent quality control, ~450. 000 variants were tested for association with DDH. We identified 34 independent variants with p<1x10-5 (binomial p<2. 2x10-16). Among these, rs143384 reached genome-wide significance (allele A, allele frequency 0. 60, OR[95% CI] 1. 58[1. 41-1. 77], p=8. 5x10-16). Rs143384 is a 5' UTR variant in *GDF5*, which plays a central role in cell growth and differentiation in both embryonic and adult tissues. Rs143384 has previously been associated with height, chondrodysplasia and osteoarthritis, and has also been associated with DDH in a candidate gene study with p=0. 002. We are currently following up further GWAS signals in replication cohorts. Here, we establish the first genome-wide significant locus for DDH, discovered through linking EHRs with genomics as a proof of principle in enabling powerful genetic association studies of relatively rare but complex diseases.

Assessing the Shared Genetic Basis of Benign Prostate Hyperplasia and Prostate Cancer; The Kaiser Permanente Genetic Epidemiology Research on Adult Health and Aging (GERA) Cohort. *J. D. Hoffman[1], C. G. Tai[1], T. J. Hoffmann[1,2], E. Jorgenson[4], C. P. Quesenberry[4], J. Shan[4], D. Aaronson[4], J. Presti[4], L. A. Habel[4], C. R. Chao[4], N. R. Ghai[4], D. K. Ranatunga[4], C. Schaefer[4], N. J. Risch[1,2], J. S. Witte[1,2,3], S. K. Van Den Eeden[3,4].* 1) Department of Epidemiology and Biostatistics, UC San Francisco, San Francisco, CA; 2) Institute for Human Genetics, UC San Francisco, San Francisco, CA; 3) Department of Urology, UC San Francisco, San Francisco, CA; 4) Kaiser Permanente, Division of Research, Oakland CA.

Benign prostatic hyperplasia (BPH) is a non-cancerous highly prevalent form of prostate enlargement observed within aging males; prostate cancer is one of the most common forms of cancer in the elderly male population. Although these two diseases frequently co-occur, little is known on whether they have a shared genetic basis. Using the Kaiser Permanente GERA cohort, we set out to examine whether known risk SNPs for prostate cancer were predictive of BPH. Our analysis included published results from the literature for prostate cancer and 11,090 men with BPH and 20,371 men without this condition, all of European descent. A genetic risk score incorporated 105 known prostate cancer variants, weighting each variant observed among BPH cases and controls by their respective log-odds ratios for prostate cancer as reported in the literature. Risk scores were adjusted for the first ten principal components and age at exam within a multivariate logistic regression model. Our results show that the genetic risk score was not significant in predicting BPH risk (p = 0. 67). When the 105 prostate cancer risk variants were analyzed individually, we observed a significant genetic association with rs1270884 and BPH (p = 1. 98*10-4). This variant is an intergenic SNP located at 12q24. An additional ten variants out of the 105 were nominally associated with BPH (p < 0. 05). In summary, although previous applications of the same risk score in the GERA cohort have shown highly significant associations with prostate cancer and PSA levels, we do not observe that known prostate cancer variants are predictive of BPH risk. Further analyses exploring co-heritability of BPH and prostate cancer, as well as the genetics of BPH independently, at the genome-wide level are warranted.

894T

GWAS of Urinary Metabolites within the Framingham Heart Study. *J. E. Huffman[1], S. -J. Hwang[1], G. M. McMahon[1,2], C. B. Clish[3], R. E. Gerszten[3,4], C. S. Fox[1,5].* 1) The Framingham Heart Study, NHLBI Population Sciences Branch, Framingham, MA; 2) Division of Nephrology, Brigham and Women's Hospital, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) Cardiology Division, Massachusetts General Hospital, Boston, MA; 5) Division of Endocrinology and Metabolism, Brigham and Women's Hospital, Boston, MA.

The field of metabolomics provides a platform for the rapid analysis of many metabolites within a biological sample and is a rich source of potential biomarkers. Urinary metabolites allow insight into the health and function of the kidney and may serve as biomarkers for dysregulation and disease. In order to investigate the biological mechanisms associated with these urinary metabolites, we examined their associations with common genetic variation within the Framingham Offspring Cohort. Urinary metabolites (n=154) were measured among 384 exam 6 participants using liquid chromatography mass spectrometry. Each metabolite was natural log-transformed, adjusted for age and sex, then the genetic association tested with HapMap2 imputed genetic dosages (n=371 participants) after accounting for relatedness. SNPs were filtered to remove those which were poorly imputed or rare and deemed significant at a p-value < 5E-08. This was followed by a look-up of significant results in published findings from complementary studies and in GWASs of kidney function traits from the CKDGen consortium. Significant associations were found at 21 loci across 19 metabolites. SNPs within *AGXT2* were associated with levels of aminoisobutyric acid (rs37370, beta=1. 13, p=1. 92E-23) which replicates previous associations of this loci with both urine and serum concentrations. The *SLC7A9* region was associated with lysine levels (rs12460876, beta=0. 41, p=1. 05E-12) and has been associated with eGFRcrea levels (beta=+, p=5. 50E-09) and with urinary lysine and lysine-containing ratios. rs2286963 in *ACAD* was associated with concentrations of nonanoylcarnitine (beta=0. 36, p=1. 15E-11) and this locus was associated in a previous GWAS of urinary metabolites with an unidentified metabolite. The top SNP in all other significant regions had p-values > 7E-03 with kidney-related traits in the CKDGen consortium. They were also not reported to be associated with the corresponding urinary metabolite in previous studies but only the significant results are publically available and the metabolite in question may not have been measured. The protein products for several of the associated genes are involved in the metabolic reaction containing the associated metabolite. In this study we identified both known and novel loci associated with various urinary metabolites. Despite our small sample size, we achieved highly significant p-values which shows how amenable metabolomic data is to GWAS.

895F

Genome-wide association studies of upper airway microbial composition in a founder population. *C. Igartua[1], E. R. Davenport[1], Y. Gilad[1], C. Ober[1], J. M. Pinto[2].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Section of Otolaryngology-Head and Neck Surgery, Department of Surgery, University of Chicago, Chicago, IL.

Whether host genetic variation can shape the airway microbiome remains an open question that is relevant for a number of respiratory diseases. In this study, we mapped the relative abundance (RA) of bacterial taxa from the upper airway in the Hutterites, a founder population of European decent. As a result of their communal, farming lifestyle, individuals are exposed to remarkably similar environmental exposures. For these studies, we selected ~170k variants (MAF>10%, CR>90%, LD-r2<0. 5) from among all variants discovered in Hutterite genome sequences and examined associations with the RA of bacterial genera from adult Hutterites at two accessible sites, the nasopharynx (NP) and the nasal vestibule (NV), in two seasons, summer (NP N=88, NV N=87) and winter (NP N=77, NV=80). RAs of the 16S rRNA gene (V4) were calculated at the genus level after subsampling 250k sequence reads per individual. To identify variants associated with normalized bacterial abundance in genera present in at least 75% of individuals (summer NP=91 and VP=79, winter NP=59 and VP=52), we used a linear mixed model that included sex, age, and date of collection as fixed effects and kinship as a random effect to adjust for relatedness (GEMMA). In the summer samples, the RA of four bacterial taxa in the vestibule and three in the nasopharynx were associated with host genotypes at a FDR <5%. The strongest association in this season was between the genus *Dermacoccus* in the NV and an intergenic variant 8kb upstream of *TINCR* (rs62105955; *P*= 1. 52x10-8; FDR= 0. 006%), a long non-coding RNA gene that directly binds to PGLYRP3,a protein that binds to peptidoglycans of gram-positive bacteria. In the winter samples, we identified 2 bacterial genera in each of the two anatomic sites that were associated with host genotypes (FDR< 5%). For example, 6 SNPs were associated with the RA of genus *Aerococcus* in the NP, one of which is an exonic variant in *PGLYRP4* (rs3006448; *P*=1. 28x10-6; FDR=0. 03), another peptidoglycan recognition protein known to have bactericidal activity towards gram-positive bacteria. Our findings support the concept that host genetic variation can influence airway microbial composition and suggests that innate immunity genes may mediate such relationships. Studies of the interaction between host genetics, alterations in the microbiome, and airway biology may provide insights into design of novel therapies across a range of respiratory diseases. This work is supported by R01 HL085197.

Identifying genetic associations with waist-to-hip ratio in Hispanic/Latino ancestral background groups: the HCHS/SOL Study. *A. Justice[1], K. Young[1,2], S. M. Gogarten[3], M. Graff[1,2], L. Sánchez-Johnsen[4], C. A. Laurie[3], C. R. Isasi[5], C. C. Laurie[3], K. E. North[1,2].* 1) Epidemiology, University of North Carolina, Chapel Hill, NC; 2) Carolina Population Center, University of North Carolina, Chapel Hill, NC; 3) Biostatistics, University of Washington, Seattle, WA; 4) Psychiatry, University of Illinois at Chicago, Chicago, IL; 5) Epidemiology & Population Health, Department of Pediatrics, Albert Einstein College of Medicine, Bronx, NY.

Central obesity is a leading public health concern and its prevalence has more than doubled since the 1980s, with the greatest burden carried by ethnic minority populations, and in particular Hispanics/Latinos. Emerging evidence suggests that genetic factors contribute to the obesity burden overall and to population-specific differences. We aim to 1) identify novel loci associated with waist-to-hip ratio adjusted for BMI (WHR), a relative comparison of central adiposity after accounting for overall body size, using the Hispanic Community Health Study/Study of Latinos (HCHS/SOL); 2) determine if differences in genetic associations differ by ancestral background (Caribbean versus mainland populations). Our analyses included 7,472 women and 5,200 men of mainland (Mexican, Central and South American) and Caribbean (Puerto Rican, Cuban, and Dominican) ancestry residing in the US, genotyped on the Illumina SOL custom Omni2. 5M array, imputed to the 1000 genomes Phase I reference panel. Due to known differences in genetic effects on WHR between males and females, we analyzed associations stratified by sex for WHR in addition to combined sexes using a linear mixed model regression, assuming an additive genetic model, adjusted for age, age2, study center, sample weights, population structure, relatedness, and sex in the combined analysis. For men, we identified one novel genome-wide significant (GWS) SNP near *PLEKHG4B* (P=2. 01E-8). No SNPs reached GWS for women-only or combined sexes in the primary analyses. However, one novel SNP near *NTM* reached GWS in the women-only mainland background group (P=5. 47E-8 in all women, P=1. 63E-8 in mainland women, I2=73). Many of the other loci also exhibit background-specific associations, possibly due to population history and especially admixture. We found notable differences in linkage disequilibrium and allele frequencies around our tag SNPs. For example, variants that exhibited association in Caribbean populations and not in mainland groups tended to be African-specific alleles or have higher frequencies in African descent populations. While differences in allele frequencies were not statistically significant, the differences in allele frequencies by background group were large enough to effect power in one group. These observations highlight the importance of large-scale genomic studies in ancestrally diverse Hispanic/Latino populations for identifying obesity-susceptibility that are ancestry or background-specific.

897T

Genome-wide association meta-analysis identifies novel variants associated with fasting plasma glucose in East Asians. *B. Kim, J. Hwang, B. Han.* Div. of structural and functional genomics, Korea National Institute of Health, Cheongju-si, Chungcheongbuk-do, South Korea.

Fasting plasma glucose (FPG) levels are tightly regulated as a part of metabolic homeostasis. Failure in blood glucose regulation can lead to elevated FPG levels, representing an independent risk factor for T2D and a predictor of cardiovascular disease. The fasting glucose level is a moderately heritable trait with the heritability around 30%. A considerable number of genetic determinants influencingfasting glucose levels have been identified from numerous genetic studies in the last few years. The total heritability of fasting glucose levels, however, is yet to be fully explained. To date, 39genetic loci harbouring variants associated with FPG have been identified from genome-wide association (GWA) studies and GWA meta-analyses that were conducted in populations of European ancestry. The genetic basis of glycemic regulation has not been fully explored in non-European populations with only one study in East Asians which identified a single locus associated with FPG (rs895636 at the *SIX2-SIX3* loci. Consideringdifferences in the allele frequencies and linkage disequilibrium structuresamong ethnic groups, large scale genetic studies in populations of non-European ancestries may increase the chance to detect additionalnovel genetic loci for FPG. Genome-wide association meta-analysis has an advantage to identify geneticvariantswith small effect size and low allele frequency that were hardly detected in a single GWA study. Therefore, in this study, we aimed to identify novel loci influencing fasting glucose variation by conducting GWA meta-analysis in East Asian populations. We conducteda two-stage association study, comprisinga discovery set (stage1) of 24,740 individualsfrom the Asian Genetic Epidemiology Network (AGEN) and follow-up*de novo*genotyping replication set (stage 2) of 21,345 individuals from independent East Asian populations. Three new FPG loci reach genome-wide significance in or near *PDK1-RAPGEF4, KANK1* and *IGF1R*. Our results could provide additional insight into the genetic variation implicated in fasting glucose regulation.

898F

Identification of four novel risk loci and functional causative elements in nonsyndromic cleft lip with or without cleft palate. *K. U. Ludwig[1,2], A. C. Boehmer[1,2], B. Nagarajan[3], H. Schuenke[1,2], J. Klamt[1,2], J. Hecker[4], K. Aldhorae[5], A. Rojas-Martinez[6], L. Goelz[7], A. Rada-Iglesias[8], H. Fier[4], J. L. Cotney[9], M. M. Noethen[1,2], M. Knapp[10], B. Odermatt[3], E. Mangold[1].* 1) Institute of Human Genetics, University of Bonn, Bonn, Germany; 2) Department of Genomics, Life&Brain Center, Bonn, Germany; 3) Institute of Anatomy, University of Bonn, Bonn, Germany; 4) Institute for Genomic Mathematics, Bonn, Germany; 5) Department of Orthodontics, College of Dentistry, Thamar University, Thamar, Yemen; 6) Department of Biochemistry and Molecular Medicine, School of Medicine, Universidad Autonoma de Nuevo Leon, Monterrey, Mexico; 7) Department of Orthodontics, University of Bonn, Bonn, Germany; 8) Center for Molecular Medicine, University of Cologne, Cologne, Germany; 9) Deptartment of Genetics and Genome Sciences, University of Connecticut School of Medicine, Farmington, CT 06030, USA; 10) Institute of Medical Biometry and Informatics and Epidemiology, University of Bonn, Bonn, Germany.

Nonsyndromic cleft lip with or without cleft palate (nsCL/P) is a common congenital malformation with multifactorial etiology. Here, we imputed genotype data from a recent meta-analysis (Ludwig et al. 2012, Nat. Genet.) in order to identify novel risk loci. These data were then also used to delineate causative elements at known risk loci. Genome-wide imputation was performed for 399 cases, 1,318 controls, and 666 trios of Central European descent. One previously unreported variant showed genome-wide significance (rs6740960 at 2p21, P=1. 6x10-08). This variant maps 5bp adjacent to a predicted Myc binding site, which is located upstream of the *PKDCC* gene. In a previous report, this gene was downregulated in mice carrying a deletion of the region homologous to the major nsCL/P risk locus at 8q24 (Uslu et al. 2014). Genotyping of 35 selected SNPs with P<10-03 in an independent nsCL/P sample (609 cases, 1,745 controls) revealed three additional genome-wide significant loci in the combined sample (2p24. 2, 14q22. 1, 15q13. 3). Notably, a significant positional overlap of association signals was observed in functional datasets of relevance to craniofacial development. Also we discovered that 30% of the genetic heritability could be attributed to common variants within this dataset, with around 24% being attributable to the 20 established risk loci identified through the present study and previous research. This novel data set was then used to finemap known susceptibility regions and identify candidate variants for functional follow-up. For example, the top-associated genotyped variant rs8001641 at 13q31 maps to a non-coding region upstream of *SPRY2*. In the imputation data, rs1854110 showed a larger odds ratio than rs8001641, and this result was supported by independent replication. Notably, rs1854110 was located in a putative regulatory enhancer element identified in craniofacial tissue. After cloning this element into a reporter vector based on Tol2/E1b-mediated transgenesis, GFP expression was observed in cephalic regions in zebrafish embryos injected with the plasmid, thus demonstrating the functional effect of the regulatory element. In summary, investigation of a high-density dataset identified four novel risk loci for nsCL/P, and provided evidence for causality of regulatory effects. The present study demonstrates that the integration of genomic and functional datasets is a powerful approach to the investigation of craniofacial development and nsCL/P etiology.

899W

Copy number variation in *FCGBP* gene is associated with endometriosis development. *F. A. Mafra[1,2], D. M. Christofolini[2], B. Bianco[2], C. P. Barbosa[2], R. Pellegrino[1], H. Hakonarson[1].* 1) Center for Applied Genomics. The Children's Hospital of Philadelphia. 3615 Civic Center Boulevard, Abramson Research Center, Suite 1014. Philadelphia, PA, USA; 2) Center of Human Reproduction and Genetics. Faculdade de Medicina do ABC. Av. Principe de Gales, 821, CEPES Lab 101. Santo Andre, SP, Brazil.

Introduction:Endometriosis is a steroid-dependent condition in which a tissue that is histologically similar to the endometrium with glands and stroma grows outside the uterine cavity. This condition play an important role in infertility, a very common gynecologic problem that affects approximately 15-20% of couples who attempt pregnancy. Gene interactions, pointing to associations between the development of endometriosis and genetic polymorphisms have been described. The Copy Number Variation (CNVs) investigation approach can be an important step in discerning a possible pathophysiology of endometriosis. **Objective**: Identification of genomic regions that might contribute to the development of endometriosis by identifying CNVs (primary identified by microarrays) that differentiate cases from healthy controls. **Material and Methods:** Case-control study comprising 564 infertile women with endometriosis and 652 fertile woman of the control group. A total of 150 samples were selected and analyzed according to DNA pooling methodology. Experiments were performed using Beadchip HumanOmni2. 5 (Illumina). Real-time qPCR was performed in all subjects to validate the candidate CNVs in the *FCGBP*, *NR5A1*, *PTGES2*, *SLC25A25* and *CXXC5* gene regions. Approval Research Ethics Committee (CEP FMABC n. 310. 094). **Results:** We found 49 CNVs loci present in patients with endometriosis and absent in the control group. Of these, 33 were kept and 16 were excluded from the study; six due to size smaller than 1 kb and 10 for not present the minimum number of probes required to be considered as a reliable CNV. 48% (16/33) of the CNVs were located at subtelomeric regions, while 17 (52%) were intrachromosomal. Four loci were selected for validation based on the gene functions present in each locus, and its possible correlation with the development and progression of endometriosis. The 4,678 bp duplication involving *FCGBP* gene was observed in 8 patients and was absent in controls, thus conferring significantly increased endometriosis risk. **Conclusion:** This is the first report (to date) of CNV data in a Brazilian population with endometriosis. We have identified one locus involving the *FCGBP* gene on chromosome 19q13. 1 possibly associated with disease risk. The discovery of how these CNVs act can be an important step in discovering the pathophysiology of endometriosis. **Support:** This work was supported by FAPESP #2011/01363-7 #2012/22394-8 #2014/07136-8.

Exome array-based genome-wide association study of fasting glucose level in Korean population. *s. Moon, M. Hwang, B. Kim.* Div. of structural and functional genomics, Korea National Intsitute of Health, Cheongju-si, Chungcheongbuk-do, South Korea.

Elevated blood glucose is associated with increased risk of type 2 diabetes (T2D). Until now, more than 50 loci associated with fasting glucose (FG) and fasting insulin (FI) level have been identified by genome-wide association studies (GWAS). However, a substantial proportion of the genetic contribution remains unclear. Here, we explore the role of coding variants on FG by exome array-based genome-wide association study in Korean population. A total of 14,952 samples as a part of the Korean Genome Epidemilogy Study (KOGES) were genotyped using Illumina HumanExomeBeadChip. Subsequenctly, through quality control processes such as exclusion of relatives, samples with sex inconstant, variants with missing, and low call rate, 14,032 samples remained. The we performed GWAS of FG using EPACTS software. From the results, a SNP nearby MTNR1B satisfied genome-wide significance (6. 5x10-7) in the discovery stage. After the replication study, we discovered 15 additional variants which have suggestive combined P-values. Most of significant variants were overlapped with previously known SNPs on several genes such as HECTD4, MYL2, KCNQ1, SLC30A8 and GCKR. Particularly, several loci were enriched on 12q24. Moreover, we newly identified an intron SNP on ACAD10 and two nonsynonymous SNPs on ALDH2 and BRAP, respectively. These findings provide evidences of genetic influence related to FG.

901F

Replication study of whole genome association for caries in a Guatemalan population. *N. Mukhopadhyay[1], M. Govil[1], C. A. Sanchez[1], F. W. -B. Deleyiannis[2], K. Neiswanger[1], J. M. Resick[1], A. R. Vieira[1], R. M. Silva[3], A. M. Letra[3], M. L. Marazita[1].* 1) Oral Biology, Univ Pittsburgh/Sch Dental Med, Pittsburgh, PA; 2) Department of Surgery, Plastic and Reconstructive Surgery, University of Colorado School of Medicine, Denver, Colorado; 3) Department of Endodontics and Craniofacial Research Center, The University of Texas Health Science Center School of Dentistry at Houston, Houston, Texas.

Dental caries is one the most common chronic diseases world wide, posing a high health burden. Both genetic and environmental factors affect the severity of caries, and several studies have been conducted to identify these factors in Caucasian and African-American cohorts from rural Appalachia, Pittsburgh and Iowa, and in the Philippines and Turkey. Findings have implicated genes for enamel formation, taste preferences, and host immune response. In this study we attempted to replicate prior association findings in a Guatemalan cohort ascertained for non-syndromic oral clefts. Genome-wide association (GWA) analysis was carried out using the PLINK program for a novel age-adjusted quantitative caries phenotype based on counts of decayed primary and permanent teeth excluding precavitated lesions, and missing or filled teeth. We used 379 subjects aged 2-60 years with phenotype information, including 52 individuals with no caries and 327 affected individuals whose caries indices ranged from 1 to 28 (mean=7. 32, SD=6. 36). Caries indices of the 379 phenotyped subjects were adjusted for age using LOESS fitting with a second-degree polynomial. Genotyping was performed with the Illumina HumanHap 550 SNP panel. Guatemalans have a mixed Caucasian/Native American ancestry; therefore, we corrected for population substructure using ancestry principal components derived from a larger set of 1,559 genotyped individuals. A genome-wide significant association was observed on chromosome 21 (p-value 8. 2E-8) near DSCAM. Suggestive associations (7. 9E-5 ≥ p-value ≥ 3. 4E-6) was observed on chromosomes 1 (HCRTR1, CSRP1, KMO), 6 (SMAP1), 12 (CAPS2) and 19 (DUXA). DSCAM is a candidate for Down syndrome, HCRTR1 regulates feeding behavior and glucose uptake, CAPS2 encodes a calcium-binding protein, and DUXA is involved in early embryonic development. These genes have not been reported in previous GWA studies, possibly due to the fact that Guatemala samples come from a different ancestral background, and/or our use of a novel quantitative phenotype. Work is underway to leverage existing familial relationships in a quantitative association framework. This work was supported by NIH-NIDCR R00-DE018085, U01-DE018903, R21-DE016930, R01-DE016148. Visits to Guatemala were conducted in collaboration with Children of the Americas. All analyses were carried out on a Centos 276-node cluster, Indy, supported by the School of Dental Medicine at the University of Pittsburgh.

Identification of three additional susceptibility loci for ulcerative colitis through an Immunochip analysis in Koreans. *H. Oh[1], M. Hong[1], H. Choi[1], J. Baek[1], T. Haritunians[2], B. D. Ye[3], S. H. Park[3], J. Liu[4], D. P. B. McGovern[2], S. Yang[3], K. Song[1].* 1) Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, South Korea; 2) Cedars-Sinai Medical Center, Los Angeles, USA; 3) Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 4) Genome Institute of Singapore, Singapore.

We have performed an immunochip study in 1,685 Korean patients with ulcerative colitis and 3,872 controls. We confirmed 3 reported loci at genome-wide significance: *IL23R* at 1p31 (rs76418789; OR = 1. 75, *P* = 1. 25 x 10-8), *IRF5* at 7q32 (rs4728142; OR = 1. 40, *P* = 3. 17 x 10-8), *JAK2* at 9p24 (rs1830610; OR = 1. 35, *P* = 2. 28 x 10-9). Additionally, eight European IBD loci showed significant associations with UC, increasing the number of known UC risk loci to 11 in Koreans. The percentage of phenotype variance explained by the 11 risk loci was 5. 26 % in Koreans (on the liability scale, population prevalence = 0. 0308%). Our finding of overlapping UC susceptibility loci between Korean and European populations strengthen the hypothesis that genetic associations for UC tend to overlap more among different ethnic groups than for CD.

Investigation of genetic risk factors of very low birth weight infants within the German Neonatal Network. *M. Preuss[1], A. Ziegler[1], E. Herting[2], W. Göpel[2].* 1) Institute of Medical Biometry and Statistics, University of Luebeck, Luebeck, Schleswig-Holstein, Germany; 2) Universitätsklinikum Schleswig-Holstein, Campus Lübeck, Lübeck, Germany.

Very Low Birth Weight (VLBW) infants have substantially increased mortality and morbidity rates, but the factors influencing long-term development are not well understood. The German Neonatal Network (GNN) was founded in 2009 to identify genetic, clinical and social factors influencing etiology and long-term development of VLBW. Clinical information includes oxygen demand, administration of surfactant, catecholamine, steroid hormones and bronchopulmonary dysplasia (BPD), brain haemorrhage (IVH), sepsis and death among others. The cohort size is 20,000, and the recruitment includes more than one quarter of all German VLBW per year. DNA samples from more than 9000 VLBW as well as buccal swabs from mothers have been collected from a total of 54 participating German hospitals. Approximately 2600 VLBW from GNN were genotyped on the Axiom™ Genome-Wide CEU 1 Array, and replication was performed in another 4400 GNN VLBW. Results of the initial genome-wide association study revealed genome-wide significance (p <5E-08) for several traits. An interesting finding is for the use of surfactant during hospital stay with an association to *LINGO2* (lead SNP rs4878404, initial p=5E-06, replication one-sided p=2. 3E-03). These results demonstrate that GNN is a unique resource for genetic and pharmacogenetic studies in VLBW.

Novel genetic loci and Alzheimer's disease genes influence retinal nerve fibre layer thinning: an European ancestry meta-analysis of 10,502 individuals. *C. Venturini[1,2], H. Springelkamp[3], J. Lamparter[4], R. Höhn[4,5], A. Nag[2], E. Yonova-Doing[2], K. M. Williams[2], A. I. Iglesias[3], T. Zeller[6,7], A. Mirshahi[4,8], S. Nickels[4], P. Hysi[2], C. W. Klaver[3], C. J. Hammond[2], N. Pfeiffer[4], C. M. van Duijn[3], A. C. Viswanathan[1,9].* 1) Department of Genetics, Institute of Ophthalmology, UCL, London, United Kingdom; 2) Twins Research & Genetic Epidemiology, King's College London, London, United Kingdom; 3) Department of Epidemiology and Clinical Genetics, Erasmus University Medical Centre, Rotterdam, Netherlands; 4) Department of Ophthalmology, University Medical Center Mainz, Germany; 5) Department of Ophthalmology, Inselspital, Bern, Switzerland; 6) Clinic of General and Interventional Cardiology, University Heart Center Hamburg, Germany; 7) German Center for Cardiovascular Research (DZHK), Partner Site Hamburg/Kiel/Lübeck, Germany; 8) Dardenne Eye Hospital, Bonn-Bad Godesberg, Germany; 9) NIHR Biomedical Research Centre for Ophthalmology at Moorfields Eye Hospital NHS Foundation Trust, London, United Kingdom.

The retinal nerve fibre layer (RNFL) thickness is a complex trait used in the diagnosis of glaucoma and the assessment of its progression and stability. It has also been suggested as a possible biomarker for neurodegenerative conditions such as Alzheimer's disease (AD). Despite the known high heritability of RNFL thickness, the genes affecting its variation have not been extensively investigated. The purpose of this study was to investigate genetic factors underlying RNFL thickness and whether genes for AD also play a role in RNFL thinning in the general population. We conducted a meta-analysis of genome-wide association studies imputed to HapMap2 in 10,502 individuals of European ancestry to identify genes associated with RNFL thickness variation. We identified 5 novel genetic regions associated with RNFL thickness: on chromosome 1 nearby *C1orf100* and *ZBTB18/ZNF238* genes (rs7554059 p=1. 17E-08 and rs6429459 p=1. 35E-08) and *BRINP3* (rs12087686 p=1. 92E-08), on chromosome 14 near to *DLK1* transcript (rs11625568 p= 4. 72E-08), on chromosome 10 within *CACNB2* gene (rs1277751 p= 5. 04E-08 and rs1277752 p=5. 54E-08) and on chromosome 17 within *PITPNM3* gene (rs1966778 p=6. 63E-08). We next created a multi-SNP genotypic risk score to test the association of AD risk alleles on RNFL thickness using meta-analysis data. We used 16 independent SNPs from ADGC meta-analysis for AD that also showed nominal significance in the RNFL meta-analysis. This risk score was associated with the decrease of RNFL thickness (beta=-0. 0047, se=0. 001, p=0. 005). To the best of our knowledge this is the most extensive study investigating RNFL thickness genetics in an European-ancestry population. These findings suggest that the genetic factors underlying RNFL thickness are mainly involved in neuronal development (*ZBTB18/ZNF238* and *BRINP3*) and calcium channels and cell adhesion (*CACNAB2* and *PITPNM3*). The study also shows that known Alzheimer's genes, such as *APOE*, *PVRL2*, *PICALM* and *CLU*, might also play a role in RNFL thinning. Our findings suggest common genetic background of RNFL thickness and AD and thus supporting its role as a potential biomarker for neurodegenerative diseases.

905W

Discovery of genetic associations underlying metabolically healthy obesity (MHO) and metabolically obese normal-weight (MONW). *N. Y. Yang[1,2], U. M. Schick[1,2], C. Schurmann[1,2], T. O. Kilpeläinen[3], R. J. F. Loos[1,2,4].* 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 2) The Genetics of Obesity and Related Metabolic Traits Program, The Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA; 3) The Novo Nordisk Foundation Center for Basic Metabolic Research, Section of Metabolic Genetics, Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 4) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, New York 10029, USA.

Background: Obesity is associated with increased risk of metabolic complications including cardiovascular disease and type 2 diabetes. However, 17-45% of obese individuals remain metabolically healthy, also called the metabolically healthy obese (MHO). Furthermore 7-30% of normal weight individuals demonstrate metabolic complications typically seen in the obese, also called the metabolically obese normal weight (MONW). The physiological mechanisms that underlie MHO and MONW are poorly understood. While many known adiposity loci show cross-phenotype (CP) associations with metabolic complications that are concordant with the phenotypic correlations, some loci display discordant associations (i. e. adiposity increasing alleles associate with reduced risk of complication). In this study, we performed a genome-wide search to systematically identify loci with discordant CP associations between adiposity and cardiometabolic traits, which may underlie MHO and MONW. **Methods:** We analyzed summary statistics from nine publicly available genome-wide datasets with ~2,000,000 SNPs using CPASSOC, a CP association method that integrates summary statistics from multiple correlated traits. We evaluated all pairwise combinations of adiposity measures (BF%, BMI, WHRadjBMI) and cardiometabolic phenotypes (fasting glucose, insulin, HDL- and LDL-cholesterol, triglycerides, systolic blood pressure) to identify discordant CP associations between traits. **Results:** We identified 239 SNPs that clustered in 65 loci showing significant (P<5E-8) discordant CP associations for pairs of adiposity and cardiometabolic phenotypes. We identified known (e. g. *IRS1*, *PPARG, GCKR*) and novel (e. g. *TRIB1, SLC22A2, CCDC92)* loci that showed association with a wide range of phenotypes, whereas others demonstrated very specific association signatures (e. g. *ABO* with LDL-cholesterol/WHRadjBMI). SNPs from 38 of the loci are *cis*-eQTLs for a proximal gene (FDR<0. 05) in whole blood, adipose, or muscle. Prioritization with DEPICT identified enrichment of gene sets related to lipid localization (GO:0010876, P=4. 6E-7) and gluconeogenesis (GO:006094, p=3. 28E-6), among other metabolic pathways. **Conclusion:** By integrating data across multiple traits, we identified novel loci with distinct CP association signatures that provide more refined insights into biological pathways that may underlie MHO and MONW. These signatures may help pinpoint the causal gene within each locus to prioritize for further functional follow-up.

906T

Reanalysis of 15 Genome-wide Association Data Sets Revealed Novel Inflammatory Bowel Disease Loci. *Y. Zhang[1], L. Tian[2], P. Sleiman[3], H. Hakonarson[2,3,4].* 1) Department of Statistics, Pennsylvania State Univ, State College, PA; 2) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Crohn's disease and Ulcerative Colitis are the two principal types of Inflammatory Bowel Disease (IBD) that are common in people of European origins. Genome-wide association studies and more recently imputation and meta-analyses have achieved multiple milestones in identifying the genetic architecture of IBD. The massive collaborative efforts of the International IBD Genetics Consortium (IIBDGC) has combined more than 75000 cases and controls from 15 genome-wide association studies (GWAS) and identified 71 new IBD loci, making a total of 163 IBD susceptibility loci reported to date. Here, we reanalyzed the Immunochip IBD data sets from IIBDGC using a novel Bayesian method, called BEAM3, that combines single and group based SNP testing into an unified framework. Our BEAM3 method removes indirect associations caused by the linkage disequilibrium among genetic variants, thereby producing much increased resolution at the disease loci. We identified 35 novel IBD loci reaching genome-wide significance that were not included in the current list of 163 IBD loci (permutation p-value <2e-7, corresponding to Bonferroni adjusted p-value <0. 025). Using two validation data sets independent of the Immunochip samples, we were able to replicate 8 new loci in both validation data sets and an additional 8 new loci in one validation data set. Many of the replicated new IBD loci implicated functionally interesting candidate genes, including *DNMT3A, THADA, UBE2E3*, *CCR2*/*CCR5*, *OSMR*, *CIT* and *CCL20* (locus-wise replication p-values are between 1e-4 and 1e-2). Our reanalysis of the currently largest IBD data sets added new insights into the IBD genetics and also highlighted the importance of advanced computational methods in disease association studies.

907F

Copy Number Variations in *CTNNA3* and *RBFOX1* Associate with Pediatric Food Allergy. *M. Bakay[1], J. Li[1], I. Fung[2], J. T. Glessner[1], R. Pandey[1], Z. Wei[5], F. D. Mentch[1], R. Pellegrino[1], T. Wang[1], C. Kim[1], C. Hou[1], F. Wang[1], R. M. Chiavacci[1], K. A. Thomas[2], J. M. Spergel[2,4,6], H. Hakonarson[1,3,4], P. Sleiman[1,3,4].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Allergy and Immunology, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 3) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA; 4) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA; 5) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ 08540, USA; 6) Center for Pediatric Eosinophilic Disorders, The Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA.

Food allergy has become a significant public health concern, which is estimated to have a prevalence of 8% among children in the United States. Several susceptibility loci for food allergy have been examined through candidate gene studies, but there have been no studies systematically investigating copy number variations (CNV) which may contribute to the etiology of food allergy. To identify novel genetic factors for food allergy, we performed genome-wide SNP genotyping of pediatric food allergy cohorts and conducted CNV calling based on SNP intensity data. We then conducted CNV association analysis for a discovery cohort of 357 cases and 3,980 controls, and did a replication study on 167 cases and 1,573 controls. We found significant association between CNVs in gene αt-catenin (*CTNNA3*) and food allergy in both the discovery cohort and the replication cohort. CNVs in another gene RNA Binding Protein, Fox-1 Homolog1 (*RBFOX1*) showed significant association specifically in the Caucasian cohorts. We also validated these CNVs by quantitative polymerase chain reaction. In addition, we showed that knockdown of *CTNNA3* led to increased degranulation in mononuclear cells, comparing to control. In summary, we have identified two CNV loci that are significantly associated with food allergy among children and further functional study suggests that CTNNA3 may be involved in sensitization to allergen.

908W

Burden Analysis of Copy Number Variation in Gallstone Disease. *E. E. Perez-Palma[1,2], B. I. Bustos[1], D. Lal[2], L. Azócar[3], C. Moraga[4], J. Hampe[5], P. Nürnberg[2], R. A. Gutiérrez[4,6], J. F. Miquel[3,6], G. V. De Ferrari[1,6].* 1) Centro de Investigaciones Biomédicas, Facultad de Ciencias Biológicas, Universidad Andres Bello, Chile; 2) Cologne Center for Genomics, University of Cologne, Germany; 3) Depto. de Gastroenterología, Facultad de Medicina, Pontificia Universidad Católica de Chile; 4) Depto. de Genética Molecular y Microbiología, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile; 5) Medical Department I, University Hospital Dresden, TU Dresden, Germany; 6) FONDAP Center for Genome Regulation (CGR), Chile.

Cholesterol gallstones disease (GSD) constitutes a major burden to public health systems due to its high prevalence among occidental countries. Current evidence supports the hypothesis that GSD has a significant genetic component. However, to date the only common genetic risk factors found to be associated are two SNVs, one in *ABCG8* and the other in *UGT1A1* (only in men), discovered through genome-wide association studies performed in Germany and replicated consistently in a Chilean and other cohorts. Together these two variants explain only a minor part of the estimated heritability of GSD, suggesting the existence of additional genetic variants that remain to be discovered. In the present study we explored the contribution to GSD susceptibility that copy number variants (CNVs) might have by examining large case control cohorts composed of 1,076 Chilean and 1,957 German samples, in total 1,574 cases and 1,459 controls, genotyped on the Affymetrix GeneTitan platform using the Axiom LAT 1 and GW Hu SNP World arrays, respectively. The Affymetrix Axiom CNV tool was used to calculate allele intensity ratios and B allele frequencies. These data were then put into the Nexus Copy Number Software to call CNVs using the SNP-FASST2 Segmentation algorithm. We considered CNV calls with at least 50 probes involved and larger than 100kb. Further, we avoided calls overlapping telomeric and centromeric regions. A total of 1,414 events was detected (633 in Chileans; 781 in Germans). Burden analyses revealed enrichment of patients carrying at least one duplication covering genes expressed in disease related tissues, particularly in small intestine: suggestive for the Chilean cohort (p=4. 91x10-2) and statistically significant in the German dataset (p=4. 91x10-4). Analyzing the whole dataset together confirmed the finding (p=2. 10x10-4). Breaking the dataset down for gender effects revealed that the observation was almost exclusively male-specific. At this level the overall amount of CNVs detected was higher in patients than in controls (p=2. 34x10-4) and primarily affected genes expressed in the small intestine (7. 96x10-5) with significant participation of genes involved in lipid metabolism according to gene ontology (GO:0006629, p=1. 6x10-3). Our preliminary results provide novel insights in the genetic architecture of GSD and suggest that CNVs may explain a part of the missing heritability in GSD. **Funding:** FONDECYT #1130303-JFM, #1140353-GVD, FONDAP #1509000.

The Contribution of Glycemic and Non-Glycemic Genetic Variants Identified Through a Trans-Ethnic Discovery Meta-Analysis of A1c to Type 2 Diabetes Prediction and Reclassification. *E. Wheeler on behalf of MAGIC, AAGILE, AGEN and TAICHI.* Wellcome Trust Sanger Institute, Cambridge, United Kingdom.

Glycated hemoglobin (A1c) is currently used as a diagnostic test for type 2 diabetes (T2D). Ethnic-specific meta-analyses in European and East Asian populations have identified 17 loci associated with A1c thought to act on A1c through glycemic or erythrocyte biology. We investigated the genetic determinants of A1c in up to 159,940 non-diabetic participants from cohorts of European, African American, East Asian, and South Asian ancestry with genome-wide or Metabochip data. Trans-ethnic meta-analysis in MANTRA and ethnic specific meta-analyses in METAL identified 37 novel loci associated with A1c: 35 loci in our trans-ethnic MANTRA analysis and 2 in the European-only meta-analysis. We also confirmed the 17 known loci and found independent secondary signals at 5 of these loci. Conditional analyses and cross trait look-ups classified the 60 A1c loci as glycemic (eg. *CDKAL1*, log10BF = 16. 52), erythrocytic (*G6PD*, log10BF = 50. 60), or unknown (eg. *ATAD2B*, log10BF=13. 30). We tested the hypothesis that glycemic A1c single nucleotide polymorphisms (SNPs) predicted incident T2D differently from erythrocytic SNPs in both the Framingham Offspring Study (N=1,705) and InterAct (N=16,687). T2D risk was modeled using 2 separate genetic scores calculated from the weighted sum of A1c -raising alleles at 19 glycemic SNPs (GS-G) and at 21 erythrocytic SNPs (GS-E). In age and sex adjusted models, higher GS-G was associated with increased risk of incident T2D (HR=1. 05 [1. 04-1. 06], P=5. 45x10-22 in InterAct). In contrast, higher GS-E was not associated with increased risk of incident T2D (P > 0. 1). However, higher GS-E decreased risk of incident T2D after adjustment for baseline A1c (binary: <5. 7 vs. ≥5. 7%) (HR=0. 96 [0. 94-0. 98], P = 4x10-7 in InterAct). Similarly, in a Net Reclassification Improvement (NRI) analysis we found that adjustment for GS-E over baseline A1c (binary: <5. 7 vs. ≥5. 7%) reduced the number of false positive cases of T2D in InterAct by 13% (P < 0. 0001), consistent with the idea that nonglycemic genetic factors contribute to the misclassification of T2D risk based on A1c in some individuals. In conclusion, the novel loci identified expand our understanding of genetic and biologic determinants of A1c variation. Examining whether non-glycemic variants partly explain inter-ethnic differences in A1c levels or their ability to accurately predict and or diagnose T2D in multi-ethnic populations may have relevance in clinical practice.

910F

Genome-wide association study for Gallstone disease in Latin Chilean population. *B. I. Bustos[1], E. Pérez-Palma[1], S. Buch[2], L. Azócar[3], C. Moraga[4], M. Toilat[5], J. Hampe[2], P. Nürnberg[5], R. A. Gutiérrez[4,6], G. V. De Ferrari[1,6], J. F. Miquel[3,6].* 1) Centro de Investigaciones Biomédicas, Facultad de Ciencias Biológicas, Universidad Andrés Bello, Santiago, Chile; 2) Medical Department I, University Hospital Dresden, TU Dresden, Dresden, Germany; 3) Cologne Center for Genomics, University of Cologne, Köln, Germany; 4) Depto. de Gastroenterología, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile; 5) Depto. Genética Molecular y Microbiología, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile; 6) FONDAP Center for Genome Regulation (CGR).

Cholesterol gallstones disease (GSD) is one of the most prevalent gastrointestinal disorders in western countries with a high genetic susceptibility. Only one genome-wide association study (GWAS) on GSD has been published in the past, reporting a lithogenic variant on the sterolin transporter ABCG8 (p. D19H). This signal was replicated in different populations worldwide, including Latin Chileans. However, it only explains a small portion of the population attributable risk. The Chilean population, with one of the highest prevalence of GSD in the world (36% and 17% in adult women and men, respectively), has been the target of only a few genetic studies. Here, we present results from the first GWAS performed on the Chilean population comprising 1,095 individuals (529 cases, 566 controls), aiming to uncover novel susceptibility risk factors for GSD. Subjects were recruited from Community medical Centers in Santiago city. Status of GSD (cases or controls) was diagnosed by abdominal ultrasonography. Genotyping was done using Affymetrix Axiom LAT 1 World array Plates. Genome-wide Imputation was performed with IMPUTE2 using the 1000 Genomes Project Phase 3 reference panel. Association analyses were done using SNPTEST. After QC and imputation, we analyzed ~9. 5 Million SNVs observing a number of clear signals surpassing the suggestive genome-wide significance threshold (<1x10-5). We confirm a signal in chromosome 2 inside the previously known ABCG5/8 locus (p= 7. 04x10-6). Novel signals were found on chromosome 7 (p= 5. 93 x10-7) and 14 (p= 5. 31x10-6), in regions that encompasses ELMO1 (gene involved in cell motility) and TRAF3 (involved in immune/inflammatory response), respectively. Since women compared with men are 3 times more likely to develop GSD, we performed a women specific analysis (489 cases and 525 controls). Results show an additional signal in chromosome 7 inside the GPR30 gene (p= 5. 78x10-6), a G-protein coupled estrogen receptor. Interestingly, knock-down mice for this gene have shown increased GSD susceptibility under a lithogenic diet. Our results show suggestive evidence of novel genetic variants associated with GSD providing new insights into the genetic susceptibility of this prevalent disease in high a risk Latin population. Replication and meta-analysis efforts with other independent cohorts are currently underway in order to have a more comprehensive view of the current results. **Funding:** FONDECYT #1130303-JFM, #1140353-GVD, FONDAP #1509000.

Inorganic arsenic (iAs) is a naturally occurring toxicant and carcinogen in groundwater and food. Some rural and tribal U. S. communities are disproportionately exposed to iAs in drinking water. Inter-individual variability in iAs metabolism influences arsenic (As) toxicity. The genetic determinants of As metabolism are not well understood, especially among American Indians. Our objective was to evaluate genetic determinants of As metabolism in the Strong Heart Family Study, a large family-based study in American Indian communities from Arizona, Oklahoma and North/South Dakota. We evaluated 2,431 individuals from extended pedigrees with As and genotype data. Percent dimethylarsinate (DMA%), percent methylarsonate (MMA%), and iAs% in urine were calculated as the relative proportion of each As species to their sum. Percent As species were logit transformed. We created principal components (PC) of As species. PC1 reflected higher iAs%/MMA% and lower DMA%. PC2 reflected higher iAs% and lower MMA% at similar DMA%. Genotyping used the Illumina MetaboChip and single nucleotide polymorphism (SNPs) from candidate cardiometabolic genes. The alpha threshold was corrected for multiple testing using Bonferroni (MetaboChip 3. 07e-7; candidate SNPs 9. 33e-5). Additive SNP effect and minor allele frequency (MAF) cutoff of 0. 01 was used. Models were adjusted for age, sex, total As levels, and principal components for population stratification. Models were analyzed by study region using SOLAR and meta-analyzed using METAL. We also conducted conditional analysis and Bayesian quantitative trait nucleotide analysis with index SNPs. The index SNP for percent As species (rs12768205, MAF 0. 27) was in AS3MT at 10q24 (logit DMA% Z-score 10. 07, logit MMA% -7. 99, logit iAs% -5. 92). Index SNPs rs3740394 for PC1 and rs7098825 for PC2 were located at 10q24 in a region of strong LD (r2 > 0. 8). Among the candidate SNPs, a non-synonymous coding SNP in AS3MT (rs11191439, MAF 0. 18) was significantly associated with PC1 (1. 12e-36), PC2 (3. 96e-8), logit DMA% (2. 89e-19) and logit MMA% (2. 60e-7). A SNP upstream of USMG5 at 10q24 (rs7911488, MAF 0. 25) was significantly associated with PC1 (3. 57e-31), logit DMA% (7. 04e-18), logit MMA% (6. 54e-8) and logit iAs% (1. 04e-6). Our results suggest the importance of AS3MT in As metabolism and potentially in As toxicity. Significant associations among other cardiometabolic genes in 10q24 may also be involved in As metabolism, especially between iAs% and MMA%.

912T

Mega-analysis versus Meta-Analysis: On the gain of jointly imputing and analyzing 33,976 subjects compared to meta-analyzing study-specific aggregated genome-wide association statistics on the example of Age-related Macular Degeneration. *M. M. Gorski for the International AMD Genomics Consortium (IAMDGC).* Mathias M. Gorski, Department of Genetic Epidemiology, Institute of Epidemiology and Preventive Medicine, University of Regensburg, D-93053 Regensburg, Germany.

Background: Current meta-analyses of genome-wide association studies impute and analyze data study-specifically and combine study-specific statistics. We have evaluated the gain in substituting this common practice with imputing and analyzing all subjects jointly (mega-analysis) by examining effect sizes, p-values and imputation quality. We use age-related macular degeneration (AMD), a leading cause of blindness, as model disease as it exhibits a broad range of effect sizes for common and rare variants. **Methods:** For our methodological evaluation, we use a real data set that allows us to conduct a mega-analysis and mimic a meta-analysis to avoid artificial data sets from simulations. We used quality controlled genotypes from a custom-modified chip array of 33,976 subjects from 26 study centers from the International AMD Genomics Consortium. The genotypes were phased (shapeit. v2. r727. linux. x64) and imputed (minimac-omp_2013_7_17) with the Giant All Phase I v3 reference panel jointly (mega-imputation) and per study (meta-imputation). We then analyzed both data sets by the Firth-corrected logistic (epacts v3. 2. 6) regression jointly (mega-analysis) and per study (meta-analysis). Results are exemplified on chromosome 22, including the known genetic AMD loci *SYN3/TIMP3* and *SLC16A8.* **Results:** The imputation quality in the mega-imputation was higher compared to the meta-imputation in all and well imputed (RSQ>0. 4) variants (median difference of RSQ = 0. 035 and 0. 0016, respectively). We were also interested in the impact of these differences on association analysis results conducting a mega-analysis (with mega-imputed genotypes) compared to a meta-analysis (by study, with meta-imputed genotypes). We found, that the p-values in the meta-analysis were approximately two magnitudes higher in *SNY3/ TIMP3* (1. 17x10-22 vs. 9. 77x10-25) and one magnitude higher in *SLC16A8* (6. 86x10-10 vs. 6. 04x10-11). **Conclusion:** Our evaluation shows that imputation quality can be slightly, but not substantially improved by a mega-imputation compared to a meta-imputation. We were also able to show that the results of the association analysis would be slightly different with the p-values decreasing by one to two orders of magnitude when conducting a meta-imputation/analysis compared to a mega-imputation/analysis. The possibility of parallelization in the meta-analysis was a computational advantage compared to the mega-analysis.

913F

Epigenetic susceptibility and novel biomarkers for severe influenza A virus infection. *A. Wennerström[1,2], N. Pervjakova[1,3,4], I. Julkunen[1], P. Jousilahti[1], M. Perola[1,2,3,4].* 1) National Institute for Health and Welfare, University of Helsinki, Helsinki FI-00271, Finland; 2) The Institute for Molecular Medicine, University of Helsinki (FIMM);; 3) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu 51010, Estonia; 4) Estonian Genome Center, University of Tartu, Tartu 51010, Estonia.

Influenza viruses represent one of the top challenges for public health. Highly pathogenic influenza infections are substantially important factors of morbidity and mortality, especially in an event of pandemic. Although influenza virus is studied actively, a comprehensive characterization of genetic and epigenetic variants associated with increased infection risk is still missing. Although influenza virus is studied actively, a comprehensive characterization of genetic and epigenetic variants associated with increased infection risk is still missing. Here, we aimed to discover novel associations with influenza virus in Finnish population. The phenotype was defined as a case when a person infected by influenza was admitted to an intensive care unit. We performed a GWAS analysis using 56 cases and 142 controls, and epigenome-wide association study (EWAS) for 56 cases and 520 controls. Genotype data were imputed to the 1000 Genome Phase 1 release 3 reference panel (March 2012). For the EWAS analysis DNA methylation was determined by Illumina Infinium 450K Human Methylation array. SWAN normalization was applied to the data. Probes with detectable methylation level < 5% of samples (detection p-value < 0. 01) were excluded. Also, CpG sites on X and Y chromosomes were discarded, which yielded to 485,513 probes for further analysis. Following discovery analyses, we sought follow-up for SNP and CpG sites reaching 5x10-8. The GWAS approach identified two loci in chromosome 5; one near genes *CCNG1*, *NUDCD2*, *HMMR1* and *MAT2B* and another near FBXL17 gene (best SNP: rs143267366, p = 2. 46x10(-8)). Epigenome-wide association analysis revealed 98 CpG variants. The most significant results were found for *WDR51B* (p= 7. 46x10-14), *MAT2A* (8. 90x10-13) and *S100A12* (1. 07x10-11). However, these results should be replicated in an independent material. The current influenza global trend can be characterized by two factors – increased variety of animal co-circulating viruses and exchanging genetic material that give a rise to novel strains that affect the ability of protection through vaccination. Our results provide new insights into the genetic background linked to viral infection, and may enable new strategies for prevention of influenza A virus infection and other consequences of this disease.

914W

Functional linear models extensions uncover pleiotropic effects of chronic pain phenotypes. *D. V. Zaykin[1], L. Qing[2], G. D. Slade[3], R. Dubner[4], R. B. Fillingim[5], J. D. Greenspan[4], R. Ohrbach[6], W. Maixner[3], L. B. Diatchenko[7,8], O. A. Vsevolozhskaya[2].* 1) Biostatistics and Computational Biology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC, USA; 2) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, MI, USA; 3) Regional Center for Neurosensory Disorders, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 4) Departments of Oral and Maxillofacial Surgery and Neural and Pain Sciences, and Brotman Facial Pain Center, University of Maryland School of Dentistry, Baltimore, MD, USA; 5) Department of Community Dentistry and Behavioral Science, University of Florida, College of Dentistry, and Pain Research and Intervention Center of Excellence, Gainesville, FL, USA; 6) Department of Oral Diagnostic Sciences, University at Buffalo, Buffalo, NY, USA; 7) The Alan Edwards Centre for Research on Pain, McGill University, Montreal, Quebec, Canada; 8) Department of Anesthesia, Faculty of Dentistry, McGill University, Montreal, Quebec, Canada.

Growing scientific evidence suggests that intricate interactions of genetic risk factors with environmental exposures play a major role in the development of chronic pain conditions. In studies of relative contribution of an individual's genetic composition to the perception of pain, the general characteristics of pain sensitivity are typically measured by a wide range of different, yet possibly etiologically related pain phenotypes. Testing each of these pain-perception traits individually is subject to problems of multiple testing and low statistical power. Furthermore, pain-related traits may share common etiology and comprise binary, categorical, and quantitative measurements. In the current study, we propose a novel statistical approach for simultaneous testing of multiple correlated phenotypes, including quantitative binary, categorical or a combination thereof, with the flexibility of adjusting for other covariates. We illustrate our approach with the association analysis between groups of multiple pleiotropic phenotypes and genetic variants of the *P2RX7* gene from the Orofacial Pain: Prospective Evaluation and Risk Assessment (OPPERA) study.

915T

A trans-ethnic meta-analysis of genome wide association studies reveals new loci associated with childhood obesity. *J. P. Bradfield[1], J. F. Felix[4,5,6], V. W. V. Jaddoe[4,5,6], S. F. A. Grant[1,2,3], Early Growth Genetics Consortium.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Divisions of Human Genetics and Endocrinology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 4) The Generation R Study Group, Erasmus MC, University Medical Center Rotterdam, Rotterdam, the Netherlands; 5) Department of Epidemiology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, the Netherlands; 6) Department of Paediatrics, Erasmus MC, University Medical Center Rotterdam, Rotterdam, the Netherlands.

Childhood obesity has more than doubled in the last 30 years. Children who are obese are more likely to be obese as adults and are more at risk for several adult health problems such as type 2 diabetes and heart disease. To search for genetic variants that are associated with childhood obesity, we performed a trans-ethnic meta-analysis of 22 genome wide association studies with European, African, South American and East Asian ancestry. The meta-analysis discovery stage comprises 10,668 cases, defined as greater than the 95th percentile of body mass index (BMI) between 2 and 18 years old, and 12,647 controls, defined as less than the 50th percentile all throughout childhood. Using the MANTRA algorithm, we meta-analyzed approximately 19 million SNPs and found fourteen loci that attained genome wide significance ($P < 5x10-8$). We have identified 4 novel loci (*PHLDA1, METTL15, RBMS3* and *COTL1*) in addition to 10 loci (*FTO, TMEM18, FAIM2, MC4R, SEC16B, ADCY3, TNNI3K, GNPDA2, FHIT* and *TFAP2B*) that had been previously discovered. More than 100 loci were found to be suggestive of association ($P < 5x10-6$), seven of which (*HOXB3, ADCY9, NEGR1, PTPB2, OLFM4, LINGO2* and *SULT1A2*) had previously been found to be associated with BMI or obesity. A sex specific association analysis was also performed. This revealed three new genome wide significant loci (*RBM6, STARD4* and *LINC01524*) among the females. All of these loci will be carried over into our replication effort, further narrowing down the list of potential variants. In summary, we have discovered potential pediatric obesity loci that are being validated by large replication efforts.

916F

Genome-wide association study identifies *EFEMP1* as a new candidate biliary atresia susceptibility gene. *Y. Chen[1,2], C. M. Grochowski[2], M. Gilbert[2], R. Rajagopalan[2], J. Bailey-Wilson[3], D. Stambolian[1], H. C. Lin[1,2], K. M. Loomes[1,2], N. B. Spinner[1,2], M. Devoto[1,2].* 1) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) The Children's Hospital of Philadelphia, Philadelphia, PA; 3) National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

Biliary atresia (BA) is a rare liver disease presenting within the first months of life. It is characterized by obliteration of the extrahepatic biliary tree in a progressive, necroinflammatory manner, leading to cholestasis, fibrosis, cirrhosis, and chronic liver damage, and accounts for 50% of pediatric liver transplantations. The etiology of BA is not understood, and environmental, inflammatory, and genetic risk factors have been proposed. A GWAS in Chinese patients identified a signal on 10q25 upstream of *ADD3* and *XPNPEP1*, which we replicated in European-Americans. In this study, we performed a GWAS in 450 European-American non-syndromic BA patients collected through the Childhood Liver Disease Research Network (ChiLDReN) and 1981 genetically matched controls from the Age-Related Eye Disease Study (AREDS). Genotyping was done with the Illumina Omni2. 5 array. Adjusted logistic regression was carried out to test SNP association with BA. The most significant SNP was rs10865291 on 2p16 (p = 2. 7x10-7; OR=1. 6; 95% CI (1. 3 -1. 9)), in the fifth intron of *EFEMP1*. *EFEMP1* encodes the EGF-containing fibulin-like extracellular matrix protein Fibulin-3 which has been implicated in tissue regeneration and organogenesis. It has also been reported to activate Notch signaling *in vitro*, although with less efficiency than *JAG1.* ddPCR performed on cDNA from BA liver specimens collected at time of liver transplant, from healthy control liver, and from disease control liver (n = 5 each) revealed that *EFEMP1* expression was increased in BA liver samples by 9-fold compared to healthy control liver samples (P-value < 0. 002), although no significant expression difference was detected between the BA and disease control groups. Immunohistochemistry showed that Fibulin-3 was specifically expressed in tubular structures around portal tracts in BA liver. Follow-up co-staining with CK-19 and alpha smooth muscle actin will be performed to determine cell type-specific expression. Ongoing studies include replication of the GWAS in additional BA cohorts of European and African-American descent. In conclusion, we identified a locus on 2p16 within the *EFEMP1* gene as the second candidate region associated with susceptibility to BA using the GWAS approach. *EFEMP1* is highly upregulated in BA and disease control liver, and its protein Fibulin-3 is expressed in the portal regions. The identification of this new candidate susceptibility gene will facilitate characterizing the genetic basis of BA.

917W

A genome-wide investigation of food addiction. *M. C Cornelis[1], A. Flint[2], A. E. Field[2], P. Kraft[2], J. Han[3], R. M. van Dam[4], E. B. Rimm[2].* 1) Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 2) Harvard School of Public Health, Boston, MA; 3) Richard M. Fairbanks School of Public Health, Simon Cancer Center, Indiana University, Indianapolis, IN; 4) Saw Swee Hock School of Public Health and Department of Medicine, Yong Loo Lin School of Medicine, National University of Singapore and National University Health System, Singapore.

Evidence of parallels between drug addiction and eating behavior continues to accumulate. Genetic studies of addictive substances have yielded a number of susceptibly loci that point to common higher-order genetic pathways underlying addiction. To elucidate the relationship between drug addiction and eating behaviors we conducted a genome-wide association study (GWAS) of food addiction, determined by the modified Yale Food Addiction Scale (mYFAS), among 9,314 U. S. women of European ancestry and examined results for enrichment of single-nucleotide polymorphisms (SNPs)(n=44), genes (n=238) and pathways (n=11) implicated in drug addiction. Two loci met GW-significance (P<2. 5×10-8) mapping to 17q21. 31 and 11q13. 4 that harbor genes with no obvious roles in eating behavior. GW results were significantly enriched for gene members of the MAPK signaling pathway (P=0. 02). No candidate SNP or gene for drug addiction was significantly associated with food addiction. A SNP previously linked to illicit drug use, and the candidate genes *LOC100130673*, *HOMER1*, *ZHX2*, *DRD2*, and *SURF6,* were nominally associated with food addiction. A global exploratory pathway analysis yielded significant enrichment for interleukin signaling genes (FDR=0. 003). In the first GWAS of mYFAS, we identified suggestive loci worthy of further follow-up but provide limited support for shared genetic underpinnings of food addiction and drug addiction.

918T

Novel rare and low frequency variants associated with lipoprotein subclasses and triglyceride measures. *J. P. Davis[1], J. R. Huyghe[2], A. U. Jackson[2], H. M. Stringham[2], T. M. Teslovich[2], R. P. Welch[2], C. Fuchsberger[2], A. E. Locke[2], N. Narisu[3], P. S. Chines[3], A. J. Kangas[4], P. Soininen[4,5], M. Ala-Korpela[4,5,6,7], J. Kuusisto[8], F. S. Collins[4], M. Laakso[8], M. Boehnke[2], K. L. Mohlke[1].* 1) Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 3) National Human Genome Research Institute, NIH, Bethesda, MD, USA; 4) Computational Medicine, Institute of Health Sciences, University of Oulu, 90014, Oulu, Finland; 5) Nuclear Magnetic Resonance Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, FIN-70211, Kuopio, Finland; 6) Oulu University Hospital, FIN-90220, Oulu, Finland; 7) Computational Medicine, School of Social and Community Medicine and the Medical Research Council Integrative Epidemiology Unit at the University of Bristol, Bristol, BS8 2BN, UK; 8) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, 70210 Kuopio, Finland.

Genome-wide association studies have identified common genetic variants associated with size and content of plasma lipoproteins and triglycerides, but the contributing role of rare and low frequency coding and noncoding variants is not fully understood. In the METabolic Syndrome In Men (METSIM) study, we examined high-throughput proton NMR-based measurements of 72 lipoprotein subclasses and triglyceride measures in 8,380 men aged 45-74 from Kuopio, Finland. Samples were genotyped with the Illumina Omni Express and ExomeChip Arrays (733,000 total markers) and then imputed with a 19 million variant European reference panel. We performed single-variant and gene-based tests of association with the 72 traits, adjusted for age and lipid-lowering medication use. We identified novel genome-wide associations with one or more trait at three loci, labeled by a nearby gene: (i) *CWC22* (MAF 0. 2%, *P*=6. 8x10-9) associated with phospholipids in medium HDL, (ii) *ANKRD17* (MAF 1. 7%, *P*=3. 3x10-22) associated with concentration of small LDL particles, and (iii) *HECW1* (MAF 0. 5%, *P*=6. 7x10-10) associated with total cholesterol in medium VLDL. In an additional analysis conditioned on known lipid and lipoprotein signals, nine variants located within 1 Mb of a known lipid locus remained significantly (*P*<5x10-8) associated with one or more trait. All of the novel secondary signals were noncoding except a rare missense variant in *LCAT* associated with HDL cholesterol (MAF 0. 5%, *P*=7. 6x10-10). Gene-based tests of association support a functional role for missense variants for *LIPC* (trait: triglycerides in very large HDL, *P*=9. 8x10-11) and *LIPG* (trait: phospholipids in medium HDL, *P*=2. 2x10-16). Genotyping to validate rare imputed variants is underway. At the four novel loci, functional annotation revealed multiple variants in LD (*r2*>0. 7) with lead variants overlapping epigenetic marks of regulatory activity in liver, blood, and adipose, providing several candidates to test in assays of gene function or transcriptional activity. These rare and low frequency coding and noncoding variants associated with lipoprotein subclasses and triglyceride measures may provide further insight to the molecular basis of dyslipidemia and the etiology of metabolic disorders.

Genome-Wide Meta-Analysis on the Sense of Smell among US Older Adults. *J. Dong[1], J. Yang[2], G. Tranah[3], N. Franceschini[4], N. Parimi[3], G. Alkorta-Aranburu[5], Z. Xu[1], A. Alonso[6], S. Cummings[3], M. Fornage[7], X. Huang[8], S. Kritchevsky[9], Y. Liu[10], S. London[1], L. Niu[11], R. Wilson[2], P. De Jager[12], L. Yu[2], A. Singleton[13], T. Harris[14], T. Mosley Jr. [15], J. Pinto[16], D. Bennett[2], H. Chen[1].* 1) Epidemiology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina;; 2) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, Illinois; 3) California Pacific Medical Center Research Institute, San Francisco, California; 4) Department of Epidemiology, University of North Carolina Gillings School of Global Public Health, Chapel Hill, North Carolina; 5) Department of Human Genetics, The University of Chicago, Chicago, Illinois; 6) Division of Epidemiology & Community Health, School of Public Health, University of Minnesota, Minneapolis, Minnesota; 7) Institute of Molecular Medicine and Human Genetics Center, University of Texas Health Science Center at Houston, Houston, Texas; 8) Pennsylvania State University-Milton S. Hershey Medical Center, Hershey, Pennsylvania; 9) Sticht Center on Aging, Wake Forest School of Medicine, Winston-Salem, North Carolina; 10) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, North Carolina; 11) Biostatistics Branch, National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina; 12) Program in Translational Neuro Psychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital; Harvard Medical School; Program in Medical and Population Genetics, Broad Institute, Boston, Massachusetts; 13) Laboratory of Neurogenetics, National Institute on Aging, Bethesda, Maryland; 14) Laboratory of Epidemiology, Demography, and Biometry, National Institute on Aging, Bethesda, Maryland; 15) Division of Geriatrics, Department of Medicine, University of Mississippi Medical Center, Jackson, Mississippi; 16) Section of Otolaryngology-Head and Neck Surgery, Department of Surgery, The University of Chicago Medicine and Biological Sciences, Chicago, Illinois.

Olfactory dysfunction is common among older adults and affects their safety, nutrition, quality of life, and mortality. More importantly, the decreased sense of smell is an early symptom of neurodegenerative diseases such as Parkinson's disease (PD) and Alzheimer's disease (AD). However, the genetic determinants for the sense of smell have been poorly investigated. We here performed the first genome-wide meta-analysis on the sense of smell among 6,252 older US adults of European descent from the Atherosclerosis Risk in Communities study, the Health, Aging, and Body Composition study, and the Rush University Religious Orders Study and Memory and Aging Project. We identified 13 loci with suggestive evidence for an association with the sense of smell ($Pmeta < 1 \times 10\text{-}5$) independent of *ApoE* ϵ4 status, a genetic variation associated with poor sense of smell. Two SNPs at chromosome 17q21. 31 (rs199443 in *NSF*, $P = 3.02 \times 10\text{-}6$; and rs2732614 in *KIAA1267-LRRC37A*, $P = 6.65 \times 10\text{-}6$) exhibited *cis* effects on the expression of microtubule-associated protein tau (*MAPT*, 17q21. 31) in 447 frontal-cortex samples obtained postmortem and profiled by RNA-seq ($P < 1 \times 10\text{-}15$). Gene-based and pathway-enrichment analyses further implicated *MAPT* in the sense of smell. Similar results were obtained after excluding participants who reported a physician-diagnosed PD or use of PD medications. This meta-analysis provides the first evidence that *MAPT*, a major susceptibility gene for PD and possibly for AD, may also play a role in regulating the sense of smell in older adults.

920W

Genome-wide association analysis for chronic vein insufficiency identifies two genes as the first susceptibility loci. *D. Ellinghaus[1], A. Fiebig[1], E. Ellinghaus[1], F. Lai[1], P. Krusche[2], N. Frings[2], C. Schreiber[3], S. Nikolaus[3], C. Gieger[4], W. Lieb[5], P. Rosenstiel[1], S. Schreiber[1,3], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University Kiel, Kiel, Schleswig Holstein, Germany; 2) Capio Mosel-Eifel-Clinic, Bad Bertrich, Germany; 3) Department of General Medicine, University Hospital Schleswig-Holstein (UKSH), Campus Kiel, Germany; 4) Institute of Genetic Epidemiology, Helmholtz Zentrum München, German Research Center for Environmental Health, Neuherberg, Germany; 5) PopGen Biobank, Section Epidemiology, Christian-Albrechts-University of Kiel, Germany.

Advanced chronic venous insufficiency (CVI) is a multifactorial condition and presents one of the most vascular abnormalities, especially in Northern and Western Europe, affecting about 3% of the population. Despite the frequency of CVI, the underlying etiology and pathophysiology are still poorly understood. According to the CEAP guidelines for chronic venous disease, patients with dilated subcutaneous veins of at least 3 mm diameter and without signs of edema or skin changes, are classified as C2. Patients with CVI can be classified as either C3 (edema), C4 (skin changes without ulceration), C5 (healed venous ulcer) or C6 (active venous ulcer). A genetic component has been proposed for many years, strongly indicated by reports on familial clustering and twin studies. The heritability of CVI is estimated about 17%, thereby suggesting genetic risk factors in the etiology of CVI. So far, no gene has been identified as a susceptibility factor for CVI. To further our understanding of the genetic etiology of CVI, we undertook the hitherto first genome-wide association study (GWAS) for this multifactorial condition comprising 9961 individuals in total (discovery and two replication panels). SNP genotype imputation was carried out using HapMap2 and HapMap3 reference haplotypes to predict missing autosomal genotypes. For downstream analyses, we included only SNPs that were imputed with high confidence (estimated r2 between imputed and true genotypes > 0. 8) and had a MAF >= 1%. In total, 1,935,136 quality-controlled autosomal imputed SNP markers were available for association analysis. The combined analysis of discovery and replication stages yielded genome-wide significant evidence (P<5×10-8) for two loci as well as one additional suggestive locus with P<5×10-7. From these analyses we are able to draw insight into the biological underpinnings of CVI.

Trans-ethnic GWAS of pelvic organ prolapse among European American, African American and Hispanic post-menopausal women from the Women's Health Initiative. *A. Giri[1], J. Wu[2], R. Ward[3], K. Hartmann[1,3,4], A. Park[5], K. North[6], M. Graff[6], R. Wallace[7], G. Gareh[8], L. Qi[9], M. Sullivan[10], A. Reiner[11], D. Velez Edwards[1,3,12], T. Edwards[1,4,12].* 1) Institute of Medicine and Public Health, Vanderbilt Epidemiology Center, Vanderbilt University, Nashville, TN; 2) Department of Obstetrics and Gynecology, Center for Women's Health Research, University of North Carolina, Chapel Hill, NC; 3) Department of Obstetrics and Gynecology, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN;; 5) Department of Obstetrics and Gynecology and Urology, Georgetown University Medical Center, Washington, DC; 6) Department of Epidemiology, University of North Carolina, Chapel Hill NC; 7) Department of Epidemiology, University of Iowa, Iowa City, IA; 8) Department of Obstetrics and Gynecology, Loma Linda University, Loma Linda, CA; 9) Department of Public Health Sciences, University of California, Davis, CA; 10) Department of Obstetrics and Gynecology, University of Miami, Miami, FL; 11) Department of Epidemiology, University of Washington, Seattle, WA; 12) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN.

Up to 40% of post-menopausal women are affected by pelvic organ prolapse (POP) and 1 in 5 women will undergo surgery for POP/urinary incontinence in their lifetime. A growing body of evidence supports genetic predisposition for POP. Using validated measurements of POP and existing GWAS data from within the Women's Health Initiative (WHI) Hormone Therapy (HT) trial, we performed a trans-ethnic GWAS study for POP in European American (EA), African American (AA) and Hispanic (HP) women. Women with ≥ 1 pelvic exam at baseline or during follow-up (evaluated for the presence and severity of rectocele, cystocele and uterine prolapse) and for whom GWAS data was available were eligible. Women with grade 0 prolapse were considered controls. Cases were defined as women with any POP (grades 1-3) or moderate/severe POP (grades 2-3). We first performed genotyping platform/race-specific multiple logistic regression analyses between SNPs imputed to the 1000 genomes (all reference panels) and POP (grade 0 vs. 1-3 and grade 0 vs. 2-3) while adjusting for key risk factors including age at POP ascertainment, body mass index, parity and continuous axes of genetic ancestry. We then performed random-effects meta-analyses on effect estimates from all four subsets (AA, HP and 2 subsets of EA women) within the WHI-HT. A total of 7523 any POP cases, 2078 moderate/severe POP cases and 4964 controls were included in our final analyses. While we did not find any genome-wide significant findings, in the grade 0 vs. 1-3 meta-analyses, a common intronic variant in the *ETV6* gene rs11834045 approached GWAS significance. Each unit increase in the T allele vs. the C allele was associated with increased risk for POP with odds ratio (OR) of 1. 17 (95% CI: 1. 10, 1. 23; P=7. 9x10-8); effect estimates were in the same direction in all four datasets. Similar results were observed for this SNP in the grade 0 vs. 2-3 analyses (OR: 1. 16, 95% CI: 1. 07, 1. 26; P: 5. 0x10-4). SNPs upstream of the *SIRPG* gene were nominally associated with POP (rs6034359 {C vs. T}: OR 0. 83; 95% CI: 0. 71, 0. 97; P=1. 3x10-7) when considering grade 0 vs. 1-3 POP. Estimates from the grade 0 vs. 2-3 analyses were also similar as in the grade 0 vs. 1-3 analyses (OR: 0. 85, 95% CI: 0. 76, 0. 94; P: 4. 5x10-4) for this SNP. Meta-analyses with additional cohorts are currently underway. Our results suggest there may beassociationsbetween common SNPs in two novel loci and POP in the first trans-ethnic meta-analysis in EA, HP and AA women.

Polycystic ovary syndrome (PCOS) is a common, highly heritable complex disorder of unknown etiology characterized by hyperandrogenism, chronic anovulation and defects in glucose homeostasis. Increased luteinizing hormone relative to follicle stimulating hormone secretion, insulin resistance and developmental exposure to androgens are hypothesized to play a causal role in PCOS. Here we map common genetic susceptibility loci in European ancestry women for the 1990 National Institutes of Health (USA) PCOS phenotype of hyperandrogenism and anovulation, which confers the highest risk for metabolic morbidities (e. g. insulin resistance and dysglycemia), as well as quantitative reproductive hormone levels. We performed a discovery GWAS (Stage 1) of 984 PCOS case and 2,964 population control women of European ancestry genotyped on the Illumina Omni Express, followed by replication (Stage 2) in 1,799 PCOS case and 1,231 phenotyped reproductively normal control European ancestry women genotyped on the Metabochip. Both stages were imputed (IMPUTE v2) to the 1000 Genomes March 2012 (v3) reference panel, and the resultant genotype call probabilities were used in a logistic regression model between PCOS case-control status and the genotype probabilities under an additive model adjusting for BMI and the first three principal components of ancestry. The *b* and standard errors were combined across the GWAS and replication cohorts using meta-analysis (METAL) under a fixed effects model weighting each strata by sample size. We followed this with a second replication (Stage 3) of the top 24 associations after a meta-analysis of stage 1 and 2 in a UK cohort of 217 PCOS cases and 1,335 population controls. Three loci reached genomewide significance in the three-strata meta-analysis; two novel loci, chr 8p32. 1 *GATA4/NEIL2* (rs804279, A allele, stage-specific OR=0. 74-0. 82, Pmeta=8. 0x10-10), and chr 11p14. 1 *FSHB* (rs11031006, G allele, stage-specific OR=1. 12-1. 41, Pmeta=1. 9x10-8), and one previously found in Han Chinese PCOS GWAS, chr 9q22. 32 *c9orf3/FANCC* (rs10993397, C allele, stage-specific OR= 0. 72-0. 88, Pmeta=4. 6x10-13). The same chr 11p14. 1 SNP near *FSHB* also reached genomewide significance in a meta-analysis of linear regression results of the quantitative luteinizing hormone (LH) levels in the PCOS cases (rs11031006, G allele, stage-specific *b*=0. 60-3. 19 mIU/mL, Pmeta=2. 7x10-16). These findings implicate gonadotropins in the pathogenesis of PCOS.

923W

The Netherlands Twin Register Axiom Biobank platform for GWAS. *J. Hottenga[1,2], E. Ehli[3], A. Abdellaoui[1], I. Fedko[1], G. Willemsen[1], E. J. C. N. de Geus[1,2], C. Grieser[4], G. E. Davies[3], D. I. Boomsma[1].* 1) The Netherlands Twin Register, VU University, Amsterdam, NL; 2) EMGO institute for Health and Care Research, VU University and VU University Medical Center, Amsterdam, NL; 3) Avera Institute for Human Genetics, Sioux Falls, SD, USA; 4) Affymetrix, Santa Clara, CA, USA.

With the prices of SNP arrays rapidly dropping, it is now more cost efficient to generate genotype data by using genome-wide chips than for example by a 30 SNP based Iplex. The Affymetrix Axiom Biobank Array was developed for large genotyping projects, for example the UK Biobank and the Million Veterans Project. We developed a NTR Axiom Biobank Array for the Netherlands Twin Register to get data with respect to twin zygosity, ancestry, a good imputation backbone with enough extra SNP coverage for areas difficult to impute, like the HLA region, mitochondrial SNPs and the X chromosome. Sets of SNPs for known GWAS hits are also included, e. g. SNPs involved in psychiatric, cardiovascular, metabolomic, pharmacogenomic and other phenotypes. To fit the genetic data with earlier NTR genotyping, we constructed the imputation backbone of the chip to be backward compatible with the Affymetrix 6. 0 platform. We have tested the genome-wide coverage and imputation accuracy of the full NTR Axiom Biobank Array and of the combined Affymetrix 6. 0-Axiom backbone using the GoNL and 1000G reference sets. In this experiment two different marker sets were used for testing, i) markers from the combined backbone only (n= 555,029) and ii) a marker set specific to the full custom designed NTR Axiom Biobank Array (n= 618,889). These marker sets were extracted for 249 unrelated females from the GoNL reference set, and then imputed against the full 1000G reference. The concordance of the imputed SNPs was subsequently compared to the original GoNL genotyping in 9. 5M polymorphic GoNL SNPs. Results show that the genome-wide coverage of the full NTR Axiom Biobank Array is 53. 8% with >99% genotype accuracy and 88. 8% with >95% genotype accuracy. 99. 1% of the SNPs have a concordance of 80% or higher without any filtering on R2 imputation quality of SNPs or MAF. For the combined backbone these values are 52. 1%, 87. 6% and 98. 9%, respectively. Furthermore we show that when only the combined backbone is imputed, there is a significant difference in allele frequencies for several SNPs in regions of the genome ($p < 0.00001$); most noticeable on chromosome 1, 6-HLA, 11, 14, 17, 19 and X. This confirms the choice of these regions to be more densely genotyped to improve the overall imputation accuracy. In conclusion, we have developed an improved genome chip to quickly assess 619K SNPs within Dutch individuals, which can be employed for GWAS on biomedical and psychiatric traits. .

924T

Discoveries from platelet count genome-wide association study in the Hispanic Community Health Study: Study Of Latinos (HCHS/SOL). *D. Jain[1], UM. Schick[2,3], JV. Morrison[1], T. Sofer[1], CJ. Hodonsky[4], JP. Davis[4], S. Vadlamudi[4], KL. Mohlke[4], C. Shurmann[3], RJ. Loos[3], CC. Laurie[1], T. Thornton[1], KE. North[4], AP. Reiner[1,2].* 1) University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle,WA; 3) Mt. Sinai School of Medicine, New York, NY; 4) University of North Carolina, Chapel Hill, NC.

Hispanic Latinos are a diverse population in which the genetic variability of platelet count (PLT) has not been analyzed. We performed a genome-wide association study of PLT in 12,491 participants of HCHS/SOL. Participants were genotyped on the Illumina SOL Omni2. 5M array (plus ~150k custom content) and imputed to the 1000 Genomes Phase I reference panel. We implemented linear mixed-model regression adjusting for sex, age, study center, ancestry and sample weights, and including random effects for individual relatedness and sampling design factors. Ten independent loci were significantly (P<5x10-8) associated with PLT in HCHS/SOL, including three novel loci and several known PLT loci (e. g. *ARHGEF3, TPM4*). 49% of the previously identified European platelet-count GWAS loci generalized to HCHS/SOL with directional consistency (FDR 5%). Novel loci included a Native American variant in *ACTN1* (rs117672662, b=0. 61, P=8. 65x10-29), *GABBR1* (rs3131857, b = -0. 16, P = 3. 97x10-10) and a suggestive association near *ETV7* (rs9470264, b = -0. 19, P=5. 64x10-8). The novel associations were successfully replicated in 6,434 Hispanic-American samples from the Women's Health Initiative and BioMe. Conditional analyses identified secondary association signal near *HBS1L-MYB* (rs6934903, b = 0. 20, P = 2. 79x10-8). Additionally, we identified new population-specific variants at known PLT GWAS loci (*MEFC2, BAK1*). Functional annotation of the three novel loci using epigenetic data from megakaryocytes (platelet precursors) identified seven SNPs that localized in putative enhancers or promoters and were in high linkage disequilibrium with the index SNP. In particular, *ACTN1* variant rs117672662 localized in a megakaryocyte-specific putative enhancer in intron 1. Furthermore, transcriptional reporter and gel shift assays in THP-1 monocytes with rs117672662 showed allelic differences in transcriptional activity and protein-binding, supporting a regulatory role. Further investigations will be necessary to identify gene targets of the putative enhancer in which rs117672662 resides. A likely target is *ACTN1*, which harbors causal mutations for congenital macrothrombocytopenia. In conclusion, discovery of a putative functional variant of Native American ancestral background in previously identified familial thrombocytopenia locus (*ACTN1*) as well as two other novel loci (*ETV7* and *GABBR1)* underscore the value of using diverse populations in GWAS.

925F

Genome-Wide Association Study of HIV-Associated Neurocognitive Disorder (HAND): a CHARTER Group Study. *P. Jia[1], A. Kallianpur[2], T. Hulgan[3], W. Bush[4], D. Samuels[5], Z. Zhao[1,6], C. Sinai, New York, NY; 16) Department of Medicine, University of California San Diego, San Diego, CA.

HIV-associated neurocognitive disorder (HAND) complicates HIV infection even during combination antiretroviral therapy (cART) and may be influenced by host genomics. We performed a genome-wide association study (GWAS) of HAND in 1050 consenting participants in the CNS HIV Antiretroviral Therapy Effects Research (CHARTER) Cohort. All participants underwent standardized, comprehensive neurocognitive and neuromedical assessments to determine a Global Deficit Score (GDS) and were classified as having neurocognitive impairment (NCI) by GDS≥0. 5. To minimize confounding by conditions other than HIV, individuals with major neurocognitive confounds such as traumatic brain injury or developmental learning disorders were excluded from analysis. NCI was also categorized according to Frascati definitions [asymptomatic neurocognitive impairment (ANI; n=359), mild neurocognitive disorder (MND; n=92), and HIV-associated dementia (HAD; n=30)]. HAND outcomes included GDS-defined NCI (binary GDS, 366 cases with GDS≥0. 5 and 684 controls with GDS<0. 5), GDS as a continuous variable, dichotomized ANI, MND, or HAD, or combined ANI and MND, each *vs.* the neurocognitively normal referent category. Genotype data was obtained using the Affymetrix Human SNP Array 6. 0 platform. Standard quality control (QC) procedures were conducted. The post-QC dataset included 812 men and 238 women. Multivariable logistic or linear regression-based association tests were performed for each NCI phenotype. The genomic inflation factor implied no systematic inflation (αranging from 0. 99 to 1. 03). GWAS results did not reveal SNPs meeting the genome-wide significance threshold (5. 0×10-8) in any of the six NCI phenotypes. For binary GDS, the most significant SNPs were rs6542826 (p=8. 1×10-7) and rs11681615 (1. 2×10-6), both located in *SH3RF3*. For continuous GDS, the most significant SNP was rs11157436 (p=1. 3×10-7) on chromosome 14 in the T-cell-receptor *alpha* locus. For all HAND, and its milder forms (MND and ANI), the most significant SNP was located upstream of *PTPN3* (p=1. 4×10-7 and p=2. 2×10-7, respectively). Preliminary analysis also suggests enrichment of the functional pathway "essential iron-containing enzymes, flavoproteins or cytochromes" in HAND overall (p=0. 023) and in only milder forms of HAND (p=0. 007). This GWAS, conducted among cART-era participants from a single cohort with robust neurological phenotypes, suggests possible roles for several loci in HAND that require further exploration.

926W

Genome-wide meta-analysis of histological phenotypes provides insights into the genetic architecture of human skeletal muscle. *T. Karaderi[1], N. Oskolkov[2], K. Strom[2,5], S. Keildson[1], C. Ladenvall[2], A. Mahajan[1], L. Lind[3], E. Ingelsson[4], H. Holmberg[5], N. Fuku[6], G. Wang[6], Y. Pitsiladis[6], A. P. Morris[1], R. Scott[7], L. Groop[2], P. Franks[8], C. M. Lindgren[1], O. Hansson[2].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, Malmö, Sweden; 3) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 4) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 5) Swedish Winter Sports Research Centre, Department of Health Sciences, Mid Sweden University, Östersund, Sweden; 6) Centre for Sport and Exercise Science and Medicine, University of Brighton, Brighton, UK; 7) MRC Epidemiology Unit, School of Clinical Medicine, University of Cambridge, Cambridge, UK; 8) Department of Clinical Sciences, Genetic and Molecular Epidemiology, Lund University, Malmö, Sweden.

Muscle fiber-type distribution affects basic processes such as movement and cellular respiration. Athletes in endurance and explosive sports have a higher proportion of slow-twitch type I and fast-twitch type II fibers, respectively. Fiber-type distribution has also been associated with obesity and type 2 diabetes. Insulin resistant individuals tend to have reduced muscle oxidative capacity with less oxidative 'red' type I and more glycolytic 'white' type IIX fibers. Muscle capillary density is also a key determinant of glucose uptake by skeletal muscle; it was observed that impaired glucose tolerance worsens with reduced capillary density. Twin studies showed that ~45% of phenotypic variance is due to a genetic component. Thus, we aimed to identify genetic factors and biological mechanisms related to skeletal muscle histological phenotypes. We conducted a genome-wide fixed-effects meta-analysis of muscle histological phenotypes including capillary density and fiber-type distribution in Swedish males from 3 cohorts (n=656). Genotype data were imputed to 1000 Genomes all ancestries panel (March 2012). In each cohort, phenotypes were inverse rank normalized and tested for association with each imputed variant under an additive model adjusting for age and body mass index. Muscle microarray expression data (n=77) were used for eQTL analysis of associated markers. Follow-up of capillary density was done in elite Swedish cross-country skiers (n=15) and Jamaican sprinters (n=119). Immunohistochemistry staining (IHC) was also performed in skeletal muscle. We identified 11 independent loci (*STEAP*, *NYAP2*, *ADRA1B*, *TNFSF11*, *FAM155A*, *SLC22A10*, *FASLG*, *RBFOX1*, *FOXJ2*, *KCNMA1* and *RAB3GAP2*) at p<5x10-8 associated with six phenotypes. G allele of rs115660502 (minor allele frequency (MAF)=0. 048) was associated with increased capillary density (p=2x10-8) and decreased *RAB3GAP2* expression (FDR=0. 007). G allele had a higher frequency in Swedish skiers (MAF=0. 10, p=0. 127) and a lower frequency in Jamaican sprinters (MAF=0. 004, p=0. 031) compared to respective population controls. RAB3GAP2 protein, the regulatory subunit of Rab3 GTPase-activating complex involved in exocytosis, was also localized to muscle capillaries in IHC staining. These results expand our understanding of muscle architecture, implicating multiple genetic factors. The rs115660502 association indicates that RAB3GAP2 regulates muscle capillary density and may thereby contribute to endurance performance in athletes.

927T

Genome-wide association study of spontaneous preterm birth. *M. Karjalainen[1,2], M. Ojaniemi[1,2], M. Rämet[1,2], M. Hallman[1,2].* 1) PEDEGO Research Center, and Medical Research Center Oulu, University of Oulu, Oulu, Finland; 2) Department of Children and Adolescents, Oulu University Hospital, Oulu, Finland.

Background and aims: Spontaneous preterm birth (SPTB) is a major factor associating with deaths and with lowered quality of life. According to family studies, SPTB has a significant genetic background with a potential role for both maternal and fetal genetic factors. However, little is known about the actual predisposing genes. The aim of the study was to discover genetic variants predisposing to SPTB using a genome-wide association study (GWAS). **Methods**: The study population consisted of mothers with SPTB (gestational age, GA <36 weeks) and SPTB infants, and mothers with exclusively term deliveries (GA 38-41 weeks) and infants born at term recruited in Oulu and Tampere University Hospitals, Finland. Only individuals of Finnish origin were included. DNA samples were genotyped with the Illumina HumanCoreExome BeadChip consisting of approximately 550,000 single-nucleotide polymorphisms (SNPs). The analyses were performed with PLINK, v. 1. 09. In addition to the study of SPTB as a dichotomous trait, GA was studied as a quantitative trait. After quality control, 230 case and 378 control mothers, and 250 case and 418 control infants remained for GWAS. **Results**: We detected potential association signals ($p < 10\text{-}4$) for several SNPs in GWAS. Many of these SNPs were located in the vicinity of genes that can be considered as plausible candidate genes for SPTB; these included e. g. the *IGSF21*, *IFI44*, and *COL23A1* genes encoding immunoglobin superfamily, member 21; interferon induced protein 44; and collagen, type XXIII, alpha 1, respectively. In the next step of the study, we will analyze the most promising SNPs in additional populations from Finland and other countries to assess which associations are replicated. **Conclusions**: In GWAS of spontaneous preterm birth, we detected several suggestive associations. These initial results will have to be replicated in additional populations. Furthermore, the role of the arising candidate genes in the onset of preterm delivery will have to be investigated using functional studies.

Nonsyndromic cleft lip with or without cleft palate (CL/P) is one of the most common birth defects in humans, affecting approximately 1 in 700 newborns. Like many other common diseases, CL/P is phenotypically heterogeneous and has a complex etiology caused by genetic and environmental risk factors. The primary subphenotypes of CL/P are cleft lip (CL) and cleft lip with cleft palate (CLP). Historically CL and CLP have been considered variants of the same defect with a common genetic etiology (CL/P) and are typically combined for genetic analyses. Previous genome-wide association studies (GWAS) have identified at least 15 risk loci explaining approximately 20% of the overall heritability of CL/P. We conducted a GWAS in a multiethnic cohort of 1,319 case-parent trios with CL/P and combined these results with a previously published GWAS of 1,593 trios (Beaty et al. 2010 Nature Genetics) for a total of 2,912 trios. We identified eleven loci associated with CL/P at the genome-wide level (P<10-8) strengthening previous associations with *IRF6*, 8q24, *NTN1*, *ARHGAP29*, and *COL8A1*. Among the SNPs showing evidence of association with 10-8-5 were four other previously identified loci and novel loci near biologically relevant genes including *TP63*, *WNT9B*, *SMAD2*, and *MYCN*. Further, we hypothesized that CL and CLP could have unique risk factors whose signal would be diluted in the combined CL/P analysis. To address this, we stratified our trios by subphenotype (N= 731 CL trios, N=2,181 CLP trios). Some signals from the combined analysis were common to both groups (e. g. *IRF6*, *8q24*) while others were unique to CL or CLP. Specifically, we found three loci that were strongly associated with only CL (P<10-6), but not CLP (P>0. 3). One of these was on 1p36 near *SKI*. The *Ski* knockout mouse has a midline facial cleft, providing support for this unique association with CL. Five other loci had strong signals in only CLP (P<10-6), but not in CL (P>0. 2). Among these were gene deserts on chromosomes 11 and 16, suggesting causal variants may affect non-coding regulatory elements. Overall, these analyses have identified additional novel risk loci contributing to risk of CL/P. Furthermore, our results provide substantial genetic support for the epidemiological observation that CL and CLP could have some distinct risk factors. This work was supported by grants X01-HG00784 and R01-DE016148.

Hakonarson[1,4,5].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Otolaryngology, Head and Neck Surgery, Erasmus University Medical Center, the Netherlands; 3) The Generation R Study, Department of Epidemiology, Erasmus University Medical Center, the Netherlands; 4) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Acute otitis media (AOM) is a common disease ofearly childhood, and the most common reason for antibiotic treatment in children. Environmental, host and genetic factors together account for the etiology of OM, with an estimated heritability of 22-74%. We performed a genome-wide association study (GWAS) investigating genetic susceptibility loci to AOM with age of onset less than 3 years old. Our study was conducted among children of European ancestry at the Children's hospital of Philadelphia (CHOP, n=8,751) and the Generation R study, Erasmus University Medical Center in the Netherlands (GenR, n=2,286). Discovery GWASs were performed at both centers, followed by meta-analysis. A locus at 6q25. 3 reached genome-wide significance (rs2932989, P=4. 4x10-8). We further replicated the results in independent cohorts at CHOP (n=1,840) and GenR (n=2,638). This locus also significantly correlates with methylation probe cg05678571 in gene FNDC1. Therefore, by GWAS, we identified the first genome-wide significant locus associated with this common pediatric disease.

Tobacco and alcohol use are complex behaviors known to be influenced by genetic factors from family studies. Genetic association studies have found common variants associated with tobacco and alcohol use (e. g. *CHRNA5*and*ALDH2*respectively). Recent developments in rare variant genotyping now allow testing association between these behaviors and rare nonsynonymous variants identified through exome sequencing. To this end, the GWAS & Sequencing Consortium of Alcohol and Nicotine use (GSCAN) was formed, which has aggregated exome array association results across 18 cohorts with 5 phenotypes including cigarettes per day (N=34,611), pack years (N=32,285), age of initiation of smoking (N=22,982), smoking initiation (N=51,331), and drinks per week (N=48,890). 17 cohorts genotyped using the Illumina HumanExome array (~250,000 low-frequency markers) and one cohort genotyped with the Illumina HumanCoreExome array (~250,000 low-frequency markers and 250 common tag SNPs). After extensive quality control, a 463,184 variants were found to segregate in the dataset. Among these variants, 158,636/3,731/1,473 are non-synonymous/loss-of-function/splice variants with MAF<1%. To aggregate information between cohorts and enlarge sample sizes, we generated summary association statistics in each cohort and performed single variant analyses on all variants and a variety of gene-based meta-analyses on low-frequency nonsynonymous variants with MAF<1%. We found associations at known loci and identified a novel signal associated with cigarettes per day at rs36015615 in*STARD3*(N=34,611, Beta=1. 3, p=9. 5e-9). This signal did not replicate in two independent cohorts, the Consortium for Genetics of Smoking Behavior (N=28,583, Beta=. 056,*p*=. 84) and the CHD+Exome consortium (N=17,789, Beta=-. 01,*p*=. 94). We will also report results from multivariate single variant and gene based tests. GSCAN continues to aggregate additional samples to increase power for rare variant associations.

931F

A cis-eQTL near the *ZNF682* gene is associated with risk for diabetic nephropathy in Pima Indians. *I. Masindova[1], Y. L. Muller[1], P. Piaggi[1], S. Kobes[1], P. Chen[1], V. Nair[2], M. Kretzler[2], W. C. Knowler[1], R. G. Nelson[1], R. L. Hanson[1], C. Bogardus[1], L. J. Baier[1].* 1) Phoenix Epidemiology and Clinical Research Branch, NIDDK/NIH, Phoenix, AZ; 2) Department of Internal Medicine and Computational Medicine, University of Michigan, Ann Arbor, MI.

Diabetic nephropathy (DN) is a serious chronic complication of type 2 diabetes (T2D) and the leading cause of end-stage renal disease (ESRD). Pima Indians are highly affected by T2D and DN; therefore, the aim of our study was to identify susceptibility loci for DN in this population. A custom Pima Indian Affymetrix Axiom Array has been previously analyzed for 548,206 markers that capture 92% of the common variation (MAF≥5%, redundancy defined as r2≥0. 85) detected in whole genome sequence data from 335 Pima Indians. Subjects genotyped on this array included 1475 full-heritage Pima Indians, of whom 344 had T2D and DN (urinary albumin-to-creatinine ratio ≥300mg/g or presence of ESRD) and 1131 had T2D but not DN. Replication of all variants preliminary associated with DN is ongoing in a second sample of 800 non-full heritage Pima subjects (on average ½ Pima) which included 140 subjects with T2D and DN, and 660 subjects with T2D but not DN. To date, replication of 27 SNPs has been assessed in this independent second sample. SNP rs10407776 associated with DN in the first sample [OR=1. 51 per copy of the G allele, p=2x10-5], replicated in the second sample [OR=1. 35, p=0. 047]) and combining both samples provided the strongest evidence for association with DN [OR=1. 44, p=9. 44x10-6 adjusted for sex, T2D duration and heritage]. This SNP maps 31kb upstream of the gene *ZNF682*. Although 23 additional tagging SNPs across the *ZNF682* genomic region (chr19:20015227-20250277, ~100kb flanking each size of the gene) also nominally associated with DN, conditional analyses suggested that these signals were dependent on rs10407776. Merging genotypic data with expression data of 185 adipose and 190 muscle biopsies of non-diabetic Pima Indians (Affymetrix Human Exon 1. 0 ST Array) and 55 kidney glomeruli from diabetic American Indians (Affymetrix U133 Array) provided evidence that rs10407776 may act as a cis-expression quantitative trait locus (cis-eQTL) to influence *ZNF682* expression while concomitantly influencing risk for DN. The DN risk allele (frequency of G=53%) correlated with lower expression of *ZNF682* in adipose [r=-0. 275, p=1. 60x10-4], muscle [r=-0. 269, p=1. 90x10-4] and kidney glomeruli [r=-0. 316, p=0. 022]. Although *ZNF682* has not been functionally implicated in development of DN, its protein product binds to ubiquitin C and this complex regulates several target genes involved in the pathogenesis of DN.

Background and objectives Gout is a common disease which results from hyperuricemia. Recently, genome-wide association studies (GWASs) of gout have been reported; however, they included self-reported gout cases. Therefore, the relationship between genetic variation and clinical subtypes of gout remains to be clarified. Thus, we first performed a GWAS of clinically-defined gout cases only. **Design, setting, participants & measurements** In this study, GWAS was conducted with 945 male patients with clinically-defined gout cases and 1,213 male controls in a Japanese population. Additionally, a replication study of 1,048 clinically-defined cases and 1,334 controls was performed. **Results** Five gout susceptibility loci were identified at the genome-wide significance level (p< 5. 0 × 10-8), which contained well-known urate transporter genes (*ABCG2* and *SLC2A9*) and additional genes reportedly having relationships with metabolic pathways: rs1260326 (p = 1. 9 × 10-12; OR = 1. 36) of *GCKR* (a gene for glucose and lipid metabolism), rs2188380 (p = 1. 6 × 10-23; OR = 1. 75) of *MYL2-CUX2* (genes associated with cholesterol and diabetes mellitus) and rs4073582 (p = 6. 4 × 10-9; OR = 1. 66) of *CNIH-2* (a gene for regulation of glutamate signaling). The latter two are identified as novel gout loci. Moreover, among the identified SNPs, we demonstrated that the SNPs of *ABCG2* and *SLC2A9* were differentially associated with subtypes of gout and clinical parameters underlying specific subtypes (renal overload type and renal underexcretion type). The effect of the risk allele of each SNP on clinical parameters showed significant linear relationships with the ratio of the case-control ORs for two distinct types of gout (r=0. 96 [p=5. 0×10-4] for urinary urate excretion and r=0. 96 [p=4. 8×10-4] for urate clearance). **Discussion** Our findings provide clues to better understand the pathogenesis of gout and will be helpful to develop companion diagnostics.

933T

Genome-wide meta-analysis of polycystic ovary syndrome in women of European ancestry identifies new loci in hormone pathways. *C. Meun[1], T. Karaderi[2], R. Magi[3], A. W. Drong[2], L. Armstrong[4], L. Broer[5], M. R. Jones[6], F. R. Day[7], PCOS Genetics Consortium.* 1) Reproductive Medicine, Erasmus MC, Rotterdam, Zuid-Holland, Netherlands; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 3) Estonian Genome Center, University of Tartu, Tartu, Estonia; 4) Division of Endocrinology, Metabolism and Molecular Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, Illinois, United States of America; 5) Genetic Laboratory, Department of Internal Medicine, Erasmus MC, Rotterdam, Zuid-Holland, Rottedam; 6) Division of endocrinology, Diabetes and Metabolism, Department of Medicine, Cedar Sinai Medical Center, Los Angeles, California, United States of America; 7) MRC Epidemiology Unit, University of Cambridge, Cambridge, United Kingdom.

Polycystic Ovary Syndrome (PCOS) is the most common heritable endocrine disorder in reproductive-aged women, and a major cause of infertility with a prevalence of ~6-10%. It is characterised by hyperandrogenism, menstrual irregularities and polycystic ovarian morphology, and associated with metabolic disturbances including type 2 diabetes, obesity and dyslipidemia. Previous genome-wide association studies (GWAS) identified 11 loci associated with PCOS in Han Chinese. Our aim is to identify novel loci associated with PCOS in a large collection of European descent populations using meta-analysis of GWAS data. We performed a genomic control corrected inverse-variance weighted fixed-effects meta-analysis in up to 4,890 cases and 20,405 controls of European descent from 6 cohorts (Iceland, the Netherlands, United Kingdom, Estonia and two from the United States). All cases fulfilled either the NIH and/or the Rotterdam diagnostic criteria. Analysis models were adjusted for (1) age only, and (2) age and body mass index (BMI). All data were imputed to the 1000 Genomes March 2012 all ancestries reference panel. EasyQC was used to filter markers with minor allele frequency <1% and imputation quality R2<0. 3 or info<0. 4 within each cohort. Markers present in at least 2 studies and in at least 50% of the effective sample size were included in the final results and ANNOVAR was used to annotate the results. We identified 5 novel loci (*GATA4/NEIL2*, OR=1. 23, PBMI=5. 97x10-11, *FSHB*, OR=1. 33, PBMI=3. 63x10-10; *TMEM135*, OR=1. 21, PBMI=3. 73x10-8; *ZBTB16*, OR=1. 27, PBMI=1. 44x10-8; *XG*, OR=1. 75, PBMI=8. 49x10-11) at genome-wide significance (P<5. 00x10-8). We did not observe anygenome-widesignificantassociations within a 100kb window of the SNPs reported in the Han Chinese GWAS. However, two loci (*DENND1A*, OR=1. 41, PBMI=9. 74x10-7; *YAP1*, OR=1. 39, PBMI=6. 76x10-8) had suggestive P-values (PBMI<1. 00x10-6) and an additional three loci (*C9orf3,* OR=1. 14, P=4. 88x10-6; *RAB5B*, OR=1. 12, P=7. 26x10-5; *TOX3,* OR=1. 16, P=4. 43x10-5) had evidence for association with nominally significant P-values (PBMI<1. 00x10-4). PCOS associations remained significant after adjustment for BMI and therefore, were not considered secondary to BMI association. Observed loci such as *FSHB* and *DENND1A* highlight the role of hormone pathways in PCOS. Our results provide evidence for new genetic loci associated with PCOS, extending our knowledge of the genetic architecture and etiology of this complex endocrine disorder.

934F

A common polymorphism in *HIBCH* is a cobalamin-independent determinant of methylmalonic acid concentrations in blood. *F. Pangilinan[1], A. M. Molloy[2], J. L. Mills[3], B. Shane[4], M. B. O'Neill[1], D. M. McGaughey[1], A. Velkova[1], H. O. Abaan[1], P. M. Ueland[5], H. McNulty[6], M. Ward[6], J. J. Strain[6], C. Cunningham[7], M. Casey[7], C. D. Cropp[8], Y. Kim[8], J. E. Bailey-Wilson[8], A. F. Wilson[8], L. C. Brody[1].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Department of Clinical Medicine, School of Medicine, Trinity College Dublin, Dublin, Ireland; 3) Division of Intramural Population Health Research, Eunice Kennedy Shriver NICHD, Bethesda, MD; 4) Department of Nutritional Sciences and Toxicology, University of California, Berkeley, CA; 5) Section of Pharmacology, Institute of Medicine, University of Bergen and Haukeland University Hospital, Bergen, Norway; 6) Northern Ireland Centre for Food and Health, University of Ulster, Coleraine, Northern Ireland; 7) St James Hospital, Dublin, Ireland; 8) Computational and Statistical Genomics Branch, National Human Genome Research Institute, Bethesda, MD.

Vitamin B12 (cobalamin) deficiency affects up to 20% of older adults, with severe untreated deficiency leading to irreversible neurological damage. Clinical diagnosis of deficiency can be challenging because low serum cobalamin concentrations correlate poorly with symptoms. Serum methylmalonic acid (MMA), a sensitive biomarker regarded as a 'gold standard', is used to confirm a diagnosis of vitamin B12 deficiency. However, the role of genetic factors, other than cobalamin related genes that influence MMA concentrations, is not known. To identify genetic variation that influences MMA levels in blood, we measured serum MMA in 2,210 healthy young Irish adults and carried out a genome-wide association study (GWAS). MMA levels were strongly associated with SNPs in 3-hydroxyisobutyryl-CoA hydrolase (*HIBCH*, p=4. 9x10-52). This hydrolase acts in the valine catabolism pathway that produces methylmalonyl-CoA, the substrate for cobalamin-dependent mutase. The association signal in the *HIBCH* gene accounted for 9. 9% of the variance in MMA concentration. The most highly associated SNP (*HIBCH* rs291466, *c*. 2T>C) codes for a missense change of the ancestral initiator methionine (MAF=0. 43) to a threonine (*p*. Met1Thr). Surprisingly, the threonine (C) allele was associated with increased steady state levels of *HIBCH* mRNA and protein. Threonine (CC) homozygotes had, on average, 46% higher serum MMA than methionine (TT) homozygotes. The association between MMA and *HIBCH* rs291466 is also highly significant in two replication cohorts consisting of 189 pregnant Irish women and 1,481 older Irish adults. Despite pregnancy-related increases in MMA and the cobalamin deficiency seen in up to 20% of older adults, both replication cohorts exhibited significant association of *HIBCH* rs291466 with MMA levels (pregnancy cohort, p<0. 001; older adult cohort, p=2. 5x10-09). Observing such a robust association in the elderly is unexpected as MMA concentrations can increase with age due to impaired renal function and environmental factors unrelated to HIBCH activity. HIBCH is unique to valine catabolism. We suggest that flux through this pathway be further evaluated in situations where protein catabolism is elevated, *e. g*. , the elderly. Additionally, accounting for *HIBCH* rs291466 should increase the utility of MMA in evaluating vitamin B12 status. For example, homozygosity for the threonine (C) allele may contribute to elevated MMA in individuals whose vitamin B12 levels are difficult to interpret.

935W

Genome-wide association study to identify variants predisposing to severe bronchiolitis. *A. M. S. Pasanen[1], M. K. Karjalainen[1], M. Ruotsalainen[2], E. Piippo-Savolainen[2], E. Goksör[3], G. Wennergren[3], M. Hallman[1], M. Rämet[1], M. Korppi[4].* 1) PEDEGO Research Center and Medical Research Center Oulu, University of Oulu, Department of Children and adolescents, Oulu University Hospital, Oulu, Finland; 2) Kuopio University Hospital, Pediatrics, University of Eastern Finland, Kuopio, Finland; 3) Queen Silvia Children's Hospital, Pediatrics, University of Gothenburg, Gothenburg, Sweden; 4) Pediatric Research Center, Tampere University and Tampere University Hospital, Tampere, Finland.

Background and objective: Bronchiolitis is a common lower respiratory tract infection mainly affecting infants under 2 years of age. It is a leading cause of hospitalization for children of that age and considered to be a risk factor for developing asthma. Although candidate gene studies have found some associated loci, the genetic background of bronchiolitis is not well known. The aim of this study is to identify genetic polymorphisms predisposing to severe bronchiolitis and subsequent asthma by genome-wide association study (GWAS). **Methods:** Case-control populations of 217 cases hospitalized for bronchiolitis in infancy and 778 controls were genotyped with genome-wide bead chips of 300,000-700,000 variants. The study populations have been collected in Kuopio and Tampere, Finland and in Gothenburg, Sweden. Cases and some of the controls are followed-up in regard to respiratory health. 684 controls are Finnish population controls from Nordic Control Allele Frequency and Genotype Database (NordiCDB). Genotype imputation has been carried out and statistical analyses have been conducted with plink 1. 9. The most significantly associating variants will be analyzed in independent populations collected in the Netherlands and Finland. **Results**: Potential association signals (p-value ≤10-5) were seen for several single-nucleotide polymorphisms (SNPs). Many of these resided at intergenic regions, suggesting regulatory functions. Some of the best associating SNPs were in or adjacent to genes related to e. g. immune responses or metabolism. Preliminary candidate genes for bronchiolitis included e. g. *TRA* locus, encoding T cell receptor alpha chains, and *VCAN (VERSICAN)*, which interacts with *CCL8* encoding chemokine (C-C motif) ligand 8. In the next stage, the most promising variants are analyzed in an independent population to examine which associations are replicated. **Conclusions**: In GWAS of bronchiolitis, several preliminarily association signals were detected. These include for example variants in genes related to immune responses and metabolism. Many of the best associating variants are at intergenic regions, suggesting regulatory functions. The most promising associating SNPs will be further analyzed in independent replication population to verify real associations. Later, functional studies of relevant candidate genes will be performed.

936T

A genome-wide association study using a custom genotyping array identifies variant in *GPR158* associated with reduced energy expenditure and increased Body Mass Index in American Indians. *P. Piaggi[1], I. Masindova[1], Y. L. Muller[1], G. B. Wiessner[1], P. Chen[1], A. Gale[1], S. Kobes[2], R. L. Hanson[2], C. Bogardus[1], L. J. Baier[1].* 1) Diabetes Molecular Genetics Section, Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Disease, Phoenix, AZ; 2) Diabetes Epidemiology and Clinical Research Section, Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Disease, National Institutes of Health, Phoenix, AZ.

A relatively lower energy expenditure (EE) predicts long-term increases in body weight and fat mass, implying that energy metabolism contributes to the pathogenesis of human obesity. Heritable factors are estimated to explain 40-70% and 10% of the inter-individual variance in body weight and EE, respectively. The aim of this study was to identify genetic variants that negatively affect EE and thereby positively influence Body Mass Index (BMI) in American Indians, an ethnic group with a high prevalence of obesity. 521,709 tag SNPs (minor allele frequency≥5%, r2≥0. 85) derived from whole-genome sequence data of 335 Pima Indians (40x coverage) were genotyped using an Affymetrix Axiom Custom Array in a population-based sample of 3494 full-heritage Pima Indians. Data were analyzed for associations with maximum lifetime BMI (n=2762) and two separate measures of EE when subjects were non-diabetic: resting metabolic rate (RMR) after overnight fasting measured by a ventilated hood system (n=496) and 24h EE measured by a whole-room calorimeter (n=406). Results were adjusted for age, sex, body composition, heritage, family membership and genomic control. Rs11014566 (A/G), which maps to an intron in *GPR158*, demonstrated one of the strongest associations for EE measures (both p<10-2), where the G allele (frequency=0. 60) was associated with higher maximum lifetime BMI (b=+1. 6% per copy, p=2x10-2) and lower EE as assessed by both RMR (b=−39 kcal/day, p=3x10-3) and 24h EE (b=−37 kcal/day, p=7x10-4). To assess replication of the BMI association, rs11014566 was further genotyped in 3950 mixed-heritage American Indians, and it was associated with BMI in this replication sample (b=+2. 0% per copy, p=2x10-3) and in the combined data (b=+1. 8%, p=5x10-5). *GPR158* encodes the G protein-coupled receptor 158 that binds to an N-type voltage-gated calcium channel (*CACNA1B*) in the brain. Cacna1b-deficient mice are protected from obesity. Rs11014566 tags 3 other SNPs, rs144895904, rs34673593, and rs16925884 (r2=0. 86-0. 99) in intron 4, any of which could potentially affect transcriptional regulation. *In vitro* luciferase assays are ongoing to functionally characterize these SNPs. Our results suggest that common variation in *GPR158* may influence EE and obesity in American Indians. Identification of novel genes/gene pathways that influence EE and BMI in humans will lead to a better understanding of the complex pathophysiology of obesity and could potentially lead to new drug targets.

937F

Genetic Variants assocaiated with Facial Shape across Continents. *L. Qiao[1], Ch. Liu[1], Y. J. Yang[2], L. Jin[2], K. Tang[1].* 1) CAS-MPG Partner Institute for Computational Biology, SIBS, Shanghai, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China.

It's a long standing question why people from different ethnic backgrounds look rather different on face. A recent work from our group indicated that there exists strong phenotypic divergence between Europeans (EU) and East Asians (EA), however the genetic basis of such divergence is unknown. In this study, we carried out a genome-wide association study (GWAS) to look for genetic loci responsible for facial morphological differences between Europeans and Han Chinese. Around 1000 Uyghurs from Xinjiang, China were sampled for the stage I GWAS, as Uyghur is a nearly half-way admixed of both Caucasian and East Asian ancestries. Facial features at various biometric spaces were examined, ranging from landmark geometrics to dense shape geometrics. The traits showing strong divergence between EU and EA were queried for signals of association in Uyghurs. A number of candidate loci were identified with GWAS significance. Interestingly, these loci do seem to affect various facial features, including mouth, nose, eyes and cheek bones along an EU-EA trend. Several candidate SNPs were validated in an independent Uyghur sample and a Han Chinese sample, and showed consistent effects on faces. In the upcoming analysis, we are trying to obtain a panel of SNP markers that together can explain a substantial portion of the EU-EA facial divergence.

Genome-wide association study of complication of diabetes mellitus (DM) in Korean populations. *SY. Rhee[1], YA. Shin[2], HM. Kim[2], DW. Lee[2], S. Chon[1], KM. Park[2], HJ. Jung[2], JT. Woo[1].* 1) Kyung Hee University School of Medicine, Seoul, Seoul, South Korea; 2) Theragen-Etex Bio Institute, Advanced Institute of Convergence Technology, Kwanggyo Technovalley, Korea.

Diabetes mellitus (DM) is the most prevalent metabolic diseaseand the leading cause of death worldwide. DM is associated with various complications (retinopathy, nephropathy, coronary artery disease and so on). Multiple genetic factors and environmental exposures have been shown to affect pathogenesis of DM together, and therefore it is very important to find related factors cause for DM complications. Genetic researches have been found several genetic variants relevant to DM complications, but in case of genetic factors for DM retinopathy have not been well-reported in any populations. In this study, we carried out GWA analysis to identify genetic factors influencing DM retinopathy with Korean hospital cohorts. We have collected DM retinopathy diagnosis data from hospital populations through Korea National Diabetes Program (KNDP) during about last 10 years (from 2006 to 2015). The subjects with DM retinopathy were genotyped using the Axiom™ Genome-Wide ASI 1 array comprised of 598,100 SNPs. Association analysis was preformed and built logistic regression model (1. d. f.) using 506,945 SNPs fulfilled the quality control criteria of GWA stages. We are expected to recruit replication cohorts from hospital through KNDP program for further replication analysis. Meta-analysis will be performed for combining statistical values of the GWAS and a replication stage to identify loci associated with DM retinopathy.

939T

Genome-wide association studies of vitiligo implicate 100 loci in disease risk. *S. Santorico[1,2], Y. Jin[2,3], D. Yorgov[1], T. Ferrara[2], R. A. Spritz[2,3].* 1) Mathematical and Statistical Sciences, University of Colorado, Denver, USA; 2) Human Medical Genetics and Genomics Program, University of Colorado School of Medicine, Aurora, Colorado, USA; 3) Department of Pediatrics, University of Colorado School of Medicine, Aurora, Colorado, USA.

Generalized vitiligo (GV) is an autoimmune disease in which white patches of skin and hair result from destruction of melanocytes. Striking skin depigmentation in GV particularly impacts persons of color, with frequent social isolation and psychiatric co-morbidity. In addition, GV patients have ~20% risk of other autoimmune diseases, pointing to shared genetic risk factors and perhaps environmental triggers. In previous work, we discovered and replicated 26 GV loci via two GWAS and 2 via candidate gene studies. Despite this success, only 18% of risk heritability is explained by these loci. We have just completed a third GWAS and combined analysis over all GWAS. After imputation using the 1KGP Phase I reference panel, QC, and ancestry matching, ~660,000 genotyped and ~20,000,000 imputed SNPs were compared in 2853 European-derived white (EUR) cases and 37,412 EUR controls, providing power for common variants to OR 1. 2. The combined analysis yielded 72 novel loci, several with multiple independent association signals, which are undergoing replication in an independent set of 2138 EUR cases and 2262 controls. Of these loci, ~45% encode proteins involved in immune/inflammatory regulation, ~10% apoptosis/autophagy, ~10% encode melanocyte proteins likely involved in GV triggering/targeting, and ~35% encode proteins of unknown function, functions with no evident relationship to GV, or gene deserts. About half of the immunoregulatory loci are shared with other autoimmune diseases with which GV is often comorbid. Many of the immune/inflammatory and apoptosis/autophagy proteins reside in biological pathways of immune triggering, inflammatory response, T-cell activation, and cell killing that may mediate autoimmune triggering by and killing of cells that express the cognate melanocyte protein antigens. For several loci we have already identified causal variation, both coding and regulatory, and for some (*TYR*, *HLA-A*, *HLA-DQA1*/*DRB1*, *NLRP1, SLA*) we have already or are now carrying out functional analyses to determine specific mechanisms of disease causation and functional interaction. We plan to assess heritability explained by all loci achieving replication, which will then be compared to a polygenic risk model, with the long-term goal of optimized prediction of vitiligo risks and subtypes to facilitate clinical application of optimal therapies based on genetic subtyping of disease.

940F

Common Variants in PTGES Associated with Asthma Susceptibility in African Americans. *P. Sleiman[1,2], B. Almoguera[1], J. Connolly[1], F. Mentch[1], L. Vazquez[1], E. Hysinger[1], H. Hakonarson[1,2], The electronic Medical Records and Genomics (eMERGE) Network.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, PA, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, PA, USA.

Asthma is one of the most common chronic diseases in the United States affecting more than 22 million adults and 6 million children. It is characterized by relapsing and remitting symptoms, reversible airway hyper-responsiveness, and chronic inflammation. We performed a meta-analysis of site and ancestry-stratified GWAS to identify variants associated with asthma susceptibility in subjects from the electronic Medical Records and Genomics (eMERGE) Network. Subjects from the eMERGE Network represent a multi-ethnic cohort linked to electronic medical records for phenotype mining from nine participating sites in the US. All cases and controls were defined by an electronic health record (EHR)-based algorithm, which mines health EHRs for pertinent diagnostic (i. e. ICD9 codes) and medication information. The algorithm was validated by manual chart review both internally at CHOP and at two external sites within eMERGE. Positive predictive values were estimated at 96% for the cases and 98% for controls. The meta-analysis included 6,696 cases and 20,114 controls from eight participating eMERGE sites. We identified two genome wide significant loci, the previously reported ORMDL3 locus on chr17q12 in the European ancestry cases and a novel locus on chr9q34 encompassing the prostaglandin E synthase (PTGES) gene in the African American ancestry analysis. PTGES encodes the critical terminal synthetic enzyme required for the processing of COX-2–derived PGH2 to PGE2. Data from animal models and studies of human patients implicate PGE2 in the pathogenesis of asthma. In models of allergic lung disease PGE2 has been shown to be bronchoprotective and anti-inflammatory. In patients with atopic asthma, inhalation of PGE2 blocks bronchoconstriction in response to challenge with inhaled specific allergen and attenuates the recruitment of eosinophils and basophils to the airway. Reduced PGE2 levels also correlate with airway hyperresponsiveness (AHR), a cardinal feature of asthma. Aspirin-exacerbated respiratory disease (AERD), a severe variant of asthma, is associated with deficient COX-2–derived PGE2 production as well as marked tissue eosinophilia and bronchoconstrictive responses to the administration of nonselective COX inhibitors. Here we report the association of common PTGES variants with asthma susceptibility. PTGES, as the dominant PGE2 synthase, may explain the observed PGE2 involvement in asthma and AERD and serve as a potential therapeutic target for both disorders.

941W

Genome-wide association study of urinary electrolytes-adjusted blood pressure. *B. Tayo[1], H. Kramer[1], G. Cao[1], A. Luke[1], X. Zhu[2], R. Cooper[1].* 1) Department of Public Health Sciences, Loyola University Chicago Stritch School of Medicine, Maywood, IL; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Introduction: Genome-wide association studies have led to identification and validation of about 40 susceptibility loci for blood pressure (BP) and hypertension especially among individuals of European ancestry. Even though these genetic variants collectively explain only a small fraction of the heritability for blood pressure phenotypes, similar associations with blood pressure phenotypes remain to be demonstrated in individuals of African ancestry. **Goal:** The aim of our study was to identify genetic variants associated with variations in urinary electrolytes-adjusted blood pressure among individuals of African origin. **Methods:** We obtained mean daily urinary sodium and potassium of three 24-hour urine samples collected from 691 unrelated adult African Americans from Maywood, IL. The study subjects consisted of 251 females and 440 males. All subjects were genotyped using the Affymetrix Genome-Wide Human SNP Array 6. 0. Analyses included genotypes on 785268 autosomal SNPs that passed standard quality control procedures. We tested for associations with systolic and diastolic BP controlling for mean urinary sodium and potassium under additive genetic mode of inheritance using linear regression models. The models also included age, sex, body mass index and age-by-sex interaction as covariates. Population stratification was controlled for by inclusion of principal components in the models. Similarly, we tested for genetic associations with urinary electrolytes. **Results & conclusion:** The top most associated SNPs were found on chromosomes 10 (rs11248449, *p*=2. 49 x 10-6), 8 (rs6586892, *p*=3. 57 x 10-7), 14 (rs4377089, *p*=3. 69 x 10-6) and 1 (rs638859, *p*=1. 70 x 10-6) for diastolic BP, systolic BP, urinary sodium and urinary potassium, respectively. These data represent the first genome-wide association study of electrolytes-adjusted BP in an African ancestry population and also provide preliminary evidence on genetic associations with urinary electrolytes and electrolytes-adjusted BP; additional studies to confirm these findings are required.

942T

A scalable Bayesian method for integrating functional SNP annotations in genome-wide association studies. *J. Yang, X. Zhou, G. Abecasis.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Although genome-wide association studies (GWASs) have identified many SNPs associated with complex traits and common diseases, the biological mechanisms underlying these associations are largely unknown. Here, we propose a Bayesian variable selection model to integrate variant functional annotations, and help understand and prioritize causal variants and mechanisms. Our method improves upon previous approaches by accounting for multiple categories of functional annotations, for genotype correlation due to linkage disequilibrium (LD) and, importantly, by quantifying the proportion of causal variants and relative effect sizes of variants with different functional annotation. To apply our model to very large GWAS and sequencing data sets, we present a novel scalable Bayesian computation method through a block-wise expectation maximization Markov Chain Monte Carlo (EM-MCMC) algorithm. Our algorithm dramatically improves both computational speed and posterior sampling convergence by taking advantage of the block-like LD structure of the human genome. In simulations, we show that our method increases power and identifies more true signals compared with competing methods. In real data, we show that previous greedy approaches and MCMC implementations lead to apparently sub-optimal sets of likely causal variants because they fail to fully explore the set of possible causal variants. We applied our method to a genomewide association study of age-related macular degeneration with ~33 thousand individuals and >12 million genotyped and imputed variants. Our results show that the non-synonymous markers are about 20 times more likely to be causal than the other markers, and that the effect size of associated non-synonymous variants is about 3 times larger than for other variants. Importantly, our method can help prioritize likely functional candidates for follow-up while disentangling the effects of genotype, linkage disequilibrium and functional annotation. In conclusion, our method has the potential to shed light on the biological mechanism of SNP associations and can help prioritize SNPs for downstream analysis.

943F

GWAS of 25(OH) Vitamin D concentrations in Punjabi Sikhs: Results of the Asian Indian Diabetic Heart Study. *B. R. Sapkota[1], R. Hopkins[1], A. Bjonnes[6], S. Ralhan[3], G. S. Wander[3], N. K. Mehra[4], J. R. Singh[5], P. R. Blackett[2], R. Saxena[6], D. K. Sanghera[1].* 1) Department of Pediatrics, Section of Genetics, College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK; 2) Department of Pediatrics, Section of Endocrinology, College of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA; 3) Hero DMC Heart Institute, Ludhiana, India; 4) All India Institute of Medical Sciences and Research, New Delhi, India; 5) Central University of Punjab, Bathinda, Punjab, India; 6) Broad Institute of Massachusetts Institute of Technology and Harvard, Massachusetts General Hospital, Cambridge, MA, USA.

Vitamin D deficiency is implicated in multiple disease conditions and accumulating evidence supports that the variation in serum vitamin D (25(OH)D) levels, including deficiency, is under strong genetic control. However, the underlying genetic mechanism associated with vitamin 25(OH)D concentrations is poorly understood. We earlier reported a very high prevalence of vitamin D deficiency associated with an increased risk for type 2 diabetes and obesity in a Punjabi Sikh diabetic cohort as part of the Asian Indian Diabetic Heart Study (AIDHS). Here we have performed the genome-wide association study (GWAS) of serum 25(OH) D on 3,538 individuals from this Punjabi Sikhs population. Our discovery GWAS comprised of 1,387 subjects followed by validation of 24 putative SNPs (P<10-4) using an independent replication sample (n=2,151) from the same population by direct genotyping. A novel locus at chromosome 20p11. 21 [b = -0. 13, p=4. 47x10-9] was identified to be associated with 25(OH)D concentrations. Another suggestive association signal [b = 0. 90; p=1. 36x10-6] was found within the regulatory region of the *IVL* gene on chromosome 1q21. 3. Additionally, our study replicated 3 of 5 known GWAS genes associated with 25(OH)D concentrations including *GC* (p=0. 007) and *CYP2R1* (p=0. 019) reported in Europeans and the *DAB1* (p=0. 003), reported in Hispanics. Future functional studies in biologically plausible regions associated with 25(OH)D metabolism will provide new molecular insights on genetic drivers of vitamin D status and its implications in health disparities. This study was supported by NIH grants -R01DK082766 (NIDDK) and NOT-HG-11-009 (NHGRI), and VPR Bridge Grant (OUHSC).

A Genome-Wide Association Study of Multi-Comorbidities: Towards a Genomic-Decision Aid for Health and Wellness Forecasting. *K. Shameer[1,2], D. Ruderfer[3], E. Austin[4], R. Miotto[1,2], M. A. Badgeley[1], I. J. Kullo[3], J. T. Dudley[1,2,5].* 1) Department of Genetics and Genomics , Icahn Insititute of Genomics and Multiscale Biology, New YorK, NY. , USA;; 2) Harris Center for Precision Wellness, Mount Sinai Health System, New York, NY 10029, NY; 3) Division of Psychiatric Genomics, Icahn Institute of Genomics and Multiscale Biology, New York, NY 10029; 4) Division of Cardiovascular Disease, Mayo Clinic, Rochester, MN 55905; 5) Population Health Science and Policy, Mount Sinai Health System, New York, NY 10029, NY.

Genome-wide and phenome-wide association studies have expanded our understanding of disease phenotypes and associated genetic variants. No disease presentation is singular in clinical setting and disease manifestations often have pair-wise or higher degree of disease comorbidities. Leveraging genome-wide association studies could aid in the understanding of genetic variants influencing multi-comorbidity. We performed a genome-wide association using Charlson Comorbidity Index (CCI), that aggregates 22 comorbid conditionsas a quantitative trait on a cohort of 15, 335 individuals with electronic health records at the Icahn School of Medicine at Mount Sinai. We replicated the significant associations in the EHR-linked Mayo Vascular Disease Biorepository (n=7902). A phenotyping algorithm was developed based on CCI definitions using three different version count model, index severity weight and age and severity weighted version. Genetic association analyses were performed using PLINK. Four SNPs reached genome-wide significance in the discovery cohort (p<=5x10-8): rs7300363 (*STRAP, EPS8, DERA*), rs115379330 (*TK2, CMTM1, CMTM3, CMTM4, CMTM2, CKLF, CKLF-CMTM1, BEAN1*), rs73388073 (*KCNJ2-CALM2P1*) and rs58231812 (*EPSTI1*) but only rs58231812 (P= 6. 01x10-5) was replicated in the validation cohort. Collectively, the genes mapped to the SNPs are involved in a variety of biological functions (cytokine activity and deoxyribonucleotide metabolic process), pathways (pentose phosphate pathway, pyrimidine metabolism and drug metabolism), tissues (enriched among pituitary gland, parathyroid gland, adipose tissue and juvenile development) and phenotypes (QT interval, tooth development, cardiovascular, neurological, morphological and physiological phenotypes) related to organismal development and normal lifespan. Replicated SNPs in the intronic region of *EPSTI1,* highly expressed in bone marrow and differentially expressed in the setting of various infectious diseases. We plan to replicate our findings in additional samples from various EHR-linked networks and in the process of phenotyping comorbidity phenotypes such as Cumulative Illness Rating Scale (CIRS), Index of Coexisting Disease (INDEX) and Kaplan-Feinstein index (KFI) for comparative analyses. Investigation of genetic variants influencing disease comorbidity will aid in understanding genetic predisposition for disease susceptibility and help in managing complex diseases, wellness and health of patient populations.

945T

Meta-analysis of exome chip variants identifies common and rare variant associations for white blood cell counts in more than 132,000 participants. *U. Schick[1,2], S. M. Tajuddin[3], P. L. Auer[4], G. Lettre[5], A. P. Reiner[6,7] on behalf of the Blood Cell Consortium.* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) The Genetics of Obesity and Related Metabolic Traits Program, The Icahn School of Medicine at Mount Sinai, New York, NY; 3) Laboratory of Epidemiology and Population Sciences, National Institute on Aging, National Institutes of Health, Baltimore, MD; 4) Joseph J. Zilber School of Public Health, University of Wisconsin-Milwaukee, Milwaukee, WI; 5) Montreal Heart Institute and Université de Montréal, Montreal, Quebec H1T 1C8 Canada; 6) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 7) Department of Epidemiology, University of Washington, Seattle, WA.

Total and differential white blood cell counts (WBCC) are clinically important measures that are used to monitor health and disease states. WBCC are heritable traits and genomic association studies have identified more than thirty trait-associated loci. To further characterize genomic variation across the allelic frequency spectrum influencing WBCC traits, we genotyped ~250,000 variants in 18 studies comprising up to 132,764 individuals of European (Eu), African (Af), Hispanic and Asian descent with total and differential (neutrophil, eosinophil, monocyte, basophil, lymphocyte) WBCC. We carried out race-specific (Eu or Af) and race-combined (All) meta-analyses of exome chip variants applying single variant and gene-level tests (VT, SKAT, GRANVIL) in rareMETALS. Thresholds for significance were assessed using Bonferroni correction (single variant P<2x10-7 & gene-level P<3. 1x10-6). We confirmed many common variant associations (e. g. *SH2B3-ATXN2, DARC, ABO)* and other loci harboring rare variants (e. g. *CXCR2, LCT, JAK2*) for WBCC traits. Further, we identified 3 novel rare variant associations and more than a dozen biologically plausible common variant loci. Gene-level tests identified a novel gene *TBX3,* a transcription factor known to be aberrantly methylated in chronic lymphocytic leukemia, for lymphocyte count (GRANVIL P(All)=1. 4x10-6), and two novel genes for neutrophil count (*ZNF439*, GRANVIL P(Af)=7. 0x10-7 & *ORC4C6*, SKAT P(Eu)=2. 6x10-8). Novel common variant associations point to genes with known mutations in myeloid malignancies including *ASXL1* (rs2295764, P(Eu)= 3. 3x10-9) for basophil count and *CD33* (rs3865444 & rs35112940, P(Eu)<1. 6x10-8) for total WBCC. Also, we identified noncoding SNPs in close proximity to regulators of hematopoiesis, specifically *CEBPA (*rs736289, P(Eu)=7. 0x10-9) for basophil count, *CEBPE*-proximal *SLC7A8* (rs11625112, P(Eu)=3. 8x10-8) for monocyte count and *ZMIZ2* (rs1050331, (All)=1. 3x10-8) for total WBCC. Other novel SNPs overlap with known platelet loci including *JMJD1C* noncoding SNPs for total WBCC (rs1935 & rs12355784, P(All|Eu)<3. 6x10-8) and intergenic SNPs near *SIRPA* for total WBCC and lymphocyte count (rs6136489 & rs6045676, P(All|Af)<3. 3x10-8). Many of these SNPs were significant *cis*-eQTL in whole blood for proximate genes (e. g. *ASXL1*, *CD33*, *CEBPA*, *SIRPA)* in the blood eQTL browser. We identify several novel rare and common variant associations for WBCC and efforts are ongoing to carry out replication of these findings.

Genome-wide interaction with insulin secretion risk score reveals novel loci contributing to type 2 diabetes etiology in African Americans. *J. M. Keaton[1,2,3], J. N. Hellwege[2,3], M. C. Y. Ng[2,3], N. D. Palmer[2,3,4], J. S. Pankow[5], M. Fornage[6], J. G. Wilson[7], A. Correa[7], L. J. Rasmussen-Torvik[8], J. I. Rotter[9], S. S. Rich[10], L. E. Wagenknecht[11], B. I. Freedman[12], D. W. Bowden[2,3,4].* 1) Molecular Genetics and Genomics Program, Wake Forest School of Medicine, Winston-Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston-Salem, NC; 3) Center for Diabetes Research, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 5) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 6) University of Texas Health Science Center at Houston, Houston, TX; 7) University of Mississippi Medical Center, Jackson, MS; 8) Department of Preventive Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 9) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute, Harbor-UCLA Medical Center, Torrance, CA; 10) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 11) Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 12) Department of Internal Medicine - Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC.

Type 2 diabetes (T2D) is the result of metabolic defects in insulin secretion and insulin sensitivity, yet most of the ~80 genes associated with T2D risk involve insulin secretion/beta cell biology. We hypothesized that T2D risk includes insulin sensitivity loci that are defined by interaction with insulin secretion loci. To test this hypothesis, SNPs associated with acute insulin response to glucose (AIR), a measure of first-phase insulin secretion, in African Americans from the IRAS Family Study (IRASFS; n=492 subjects) were used to build genetic risk scores (GRS) for T2D and tested for genome-wide interaction in the ARIC, CARDIA, JHS, MESA, and WFSM cohorts (n=2725 cases, 4167 controls). A GRS from 1) novel AIR loci (AIR GRS; AIR P<5x10-4; n=5 SNPs) and 2) a GRS from T2D GWAS SNPs trending towards association with AIR (T2D-IS GRS; n=5) were developed. Unweighted GRS (summation of risk alleles) and weighted GRS (sum of risk alleles at each locus multiplied by their effect sizes) were determined. Each GRS was tested for association with AIR and disposition index (DI), a combinatorial measure of first-phase insulin secretion and insulin sensitivity, in IRASFS. The weighted AIR GRS was associated with AIR in IRASFS (P=4. 96x10-2) and this association improved with BMI adjustment (P=3. 34x10-2). The weighted T2D-IS GRS was associated with DI (P=4. 43x10-2), and this association was robust against BMI adjustment (P=4. 51x10-2). GRS were tested for genome-wide interaction using logistic regression modeling T2D as the outcome followed by meta-analysis of interaction effects. Nominally significant (P<5x10-6) interactions with the AIR GRS were observed at several loci including a mitochondrial ribosomal gene (*MRPL36*, rs4975846, P=2. 03x10-7), a post-transcriptional regulator (*SAMD4A*, rs11627203, P=6. 57x10-7), and a neuromuscular gene (*UTRN*, rs17074194, P=1. 87x10-6). Nominally significant interactions with the T2D-IS GRS included two SNPs at the *DGKB* locus (rs6976381, P=1. 21x10-6; rs6962498, P=3. 71x10-6), a diacylglycerol kinase associated with T2D and fasting glucose levels in published GWAS. The most associated SNPs in both the AIR GRS and T2D-IS GRS interaction analyses were robust against BMI adjustment. These data support the hypothesis that the spectrum of genetic factors contributing to T2D risk includes interactions with insulin secretion loci, and that epistasis modeling is a powerful approach for the detection of candidate insulin resistance genes.

Amino acid variation in HLA class II proteins is a major determinant of humoral response to common viruses. *C. Hammer[1,2,3], M. Begemann[3], P. J. McLaren[1,2], I. Bartha[1,2], A. Michel[4], B. Klose[5], C. Schmitt[5], T. Waterboer[4], M. Pawlita[4], T. F. Schulz[5], H. Ehrenreich[3,6], J. Fellay[1,2].* 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Clinical Neuroscience, Max Planck Institute of Experimental Medicine, Göttingen, Germany; 4) Division of Molecular Diagnostics of Oncogenic Infections, Infections and Cancer Program, German Cancer Research Center, Heidelberg, Germany; 5) Institute of Virology, Hannover Medical School, Hannover, Germany; 6) DFG Research Center for Nanoscale Microscopy & Molecular Physiology of the Brain (CNMPB), Göttingen, Germany.

The magnitude of the human antibody response to viral antigens is highly variable. To explore the impact of human genetic variation on humoral immunity, we performed genome-wide association studies of immunoglobulin G (IgG) response to 14 human pathogenic viruses in 2,363 immunocompetent adults. Significant associations were observed in the major histocompatibility complex (MHC) region on chromosome 6 for influenza A virus, Epstein-Barr virus (EBV), JC polyomavirus (JCPyV) and Merkel Cell polyomavirus (MCPyV) (*P*min = 7 x 10-26). Using local imputation and fine mapping, we identified specific amino acid residues of HLA class II proteins as the most probable causal variants. The strongest associations were observed for amino acid positions in the HLA-DRβ1 protein. We therefore analyzed the potential impact of common HLA-DRβ1 haplotypes on IgG response to influenza A, EBV, JCPyV and MCPyV. This analysis showed no consistency in the associations: the size and directionality of the effects were virus-specific. Most prominently, the amino acid haplotypes present in the classical alleles *HLA-DRB1*15:01* or **16:01* associated with influenza A seropositivity and with higher anti-EBV IgG levels, but with JCPyV and MCPyV seronegativity. In contrast, the haplotype present in *HLA-DRB1*01:01* associated with MCPyV seropositivity and with higher anti-EBV IgG levels, but with influenza A seronegativity. Variable amino acid residues explained between 2. 5% (JCPyV serostatus) and 5. 4% (EBV EBNA IgG levels) of the phenotypic variance. We also compared our results to reported HLA associations with autoimmune disorders. Striking similarities were observed in the genetic underpinning of IgG response to influenza A and narcolepsy, and of antibodies against Epstein-Barr virus and multiple sclerosis. The results of this study emphasize that HLA class II variation plays a central and pathogen-specific role in the modulation of humoral immune response to viral infection.

Background and statement of purpose: Emerging data suggests that altered blood levels of amino acids and acylcarnitines are associated with common metabolic diseases in adults. Therefore, our aim was to identify common genetic determinants for blood metabolites to better understand pathways contributing to human physiology and common diseases. **Methods:**We applied a targeted mass-spectrometry-based method to analyze whole blood spots for 96 amino acids, acylcarnitines and metabolite ratios in a cohort of 2,107 adults. Using chip-based technology and HapMap-based imputation, we performed genome-wide association (GWA) to identify genetic modifiers of metabolite concentrations. Discovered hits were analyzed for replication in an independent cohort. Furthermore, we used Illumina HT-12 v4 Expression BeadChips to study gene expression in peripheral mononuclear cells in order to analyze causal relations between SNPs, gene-expression and metabolite levels. **Results:**We discovered and replicated six novel loci associated with blood levels of total acylcarnitine, arginine , propionylcarnitine, 2-hydroxyisovalerylcarnitine, stearoylcarnitine, and aspartic acid traits. Several SNPs associated with blood metabolites in our study overlap with previously identified loci for human diseases suggesting a shared genetic basis or pathomechanisms involving metabolic alterations. Causal analyses resulted in following putative causative genes: *SLC22A16* for total acylcarnitines, *ARG1* for arginine, *HLCS* for 2-hydroxyisovalerylcarnitine, *JAM3* for stearoylcarnitine via a trans-effect at chromosome 1, and *PPP1R16A* for aspartic acid traits. Additionally, we report replication and provide additional functional evidence for ten loci that have previously been published for metabolites in several tissues. **Conclusion:**The integrative analysis of SNP, gene-expression and metabolite data revealed novel insights into the genetic regulations of human metabolism. At several examples, we provide evidence for metabolite regulation via gene-expression and observed overlaps with GWAS loci for common diseases. In consequence, , our findings provide strong candidates for future functional studies directed to understand human metabolism and pathogenesis of related diseases.

Genetic association in narcolepsy suggests autoimmune origin. *HM. Ollila[1], R. Hillary[1], J. Faraco[1], L. Ling[1], J. Hallmayer[2], F. Han[3], E. Mignot[1].* 1) Stanford University, Palo Alto, CA. , USA; 2) Department of Psychiatry & Behavioral Sciences, Stanford University School of Medicine, Stanford, CA, USA; 3) Department of Surgery, Peking University People's Hospital, Beijing, China.

IntroductionType 1 Narcolepsy is characterized by sleepiness, REM sleep abnormalities and loss of muscle tone triggered by positive emotions (cataplexy). The cause of type 1 narcolepsy is a loss of neurons producing the hypocretin/orexin peptide of likely autoimmune origin. Narcolepsy is strongly associated with Human leukocyte antigen (HLA) DQB1*06:02, with 98 percent of narcoleptics carry this allele. Our aim was to further study genetic predisposition to narcolepsy and to determine if other HLA alleles also affect narcolepsy predisposition. **Methods**We performed GWAS in Asian, African American and Caucasian samples with 6,000 cases and 30,000 controls. In addition, direct (subsample) and imputed HLA genotyping at high resolution (8-digit) was performed using HIBAG. Case control marching and conditional analysis were performed. **Findings and conclusions**In addition to well-known DQB1 effects, HLA-DPA1*01:03~DPB1*04:02 was highly protective, while other alleles at DPB1 and HLA-Class I increased susceptibility. In addition, we found significant SNP associations with age of onset and with comparison before or after 2009 pandemic H1N1 influenza. Additional genome-wide significant associations were seen with variants in TCRA, TCRB, P2RY11, ZNF365, IL10RB-IFNAR1 and other genes known to be involved in autoimmunity. Our results highlight the importance of HLA in narcolepsy, and together with functional studies, support the autoimmune origins of narcolepsy.

950W

Preliminary Genetic Association Analysis of Obstructive Sleep Apnea (OSA) and Obesity in Patients from Colombia. *L. A. Morford[1], J. K. Hartsfield, Jr. [1], P. Hidalgo[2], L. Wilches-Buitrago[3], C. A. Morillo[4], L. Otero[3].* 1) Dept Oral Health Science, Center for the Biologic Basis of Oral/Systemic Diseases, Hereditary Genetics/Genomics Core, Univ of Kentucky, Lexington, KY USA; 2) Pontificia Universidad Javeriana - Sleep Clinic, Hospital Universitario San Ignacio. Bogotá, Colombia; 3) Pontificia Universidad Javeriana. Bogotá, Colombia; 4) McMaster University. Hamilton, Ontario, Canada.

Obstructive Sleep apnea (OSA) is a highly prevalent breathing disorder that is frequently associated with obesity. In this pilot-level Genome-wide Association Study (GWAS) of 542,585 Single Nucleotide Polymorphisms (SNPs), we sought to identify genetic markers associated with the combined phenotype of **BOTH** OSA and obesity. Ethics approval for the study was obtained from the ethical committee of Faculty of Medicine of Pontificia Universidad Javeriana and Hospital Universitario San Ignacio. DNA obtained from 58 Colombian subjects (29 males and 29 females; 40 to 75 years old) diagnosed with **BOTH** OSA and obesity was compared to the DNA obtained from 232 individuals (132 males and 100 females; 40 to 75 years old) who presented with **ONLY** one of the two phenotypes or neither phenotype. Patients were classified as having OSA by overnight polysomnography with an AHI ≥ 5 events/hour, and all individuals with a Body Mass Index (BMI) ≥ 30 kg/m2 were classified as obese. We excluded patients diagnosed with any mental and/or neurological diseases, as well as individuals with Central Sleep Apnea. The preliminary data showed a significant association with the combined phenotype of OSA plus obesity and SNP rs2292662 within the Ataxin-7 (ATXN7) gene on Chromosome 3 (p= 2. 70E-08; OR=4. 3). ATXN7 is a transcription factor that plays a role in histone acetylation and deubiquitination during the process of chromatin remodelling. Borderline associations were also independently detected between the combined phenotype and genetic markers near or within genes for p21 Protein-Activated Kinase-7 (PAK7) on Chromosome 20 (p= 1. 92E-07; OR= 34. 3), Ubiquitin Specific-Protease 25 (USP25) on Chromosome 21 (p=2. 28E-07; OR=19. 4) and Neuron Navigator-2 (NAV2) on Chromosome 11 (p=2. 02E-06; OR=3. 3). Although genes like ATXN7 and USP25 have not previously been associated with the duel phenotype of OSA and obesity, these preliminary results suggest that chromatin remodelling may play a role in duel disease generation and/or maintenance. Our ongoing and future investigations should help to better understand the complex gene interaction networks involved in obesity and other diseases associated to OSA. This research was funded by Colciencias. Grant 537, contract 369.

951T

Phenome Wide Association Study of Human MHC Region in Marshfield Clinic PMRP. *J. Liu[1], Z. Ye[2], J. Mayer[2], C. Green[3], L. Rolak[4], C. Cold[5], S. J. Hebbring[1].* 1) Center for Human Genetics, Marshfield Clinic Research Foundation, Marshfield, WI; 2) Biomedical Informatics Research Center, Marshfield Clinic Research Foundation, Marshfield, Wisconsin, USA; 3) Department of Dermatology, Marshfield Clinic, Marshfield, Wisconsin, USA; 4) Department of Neurology, Marshfield Clinic, Marshfield, Wisconsin, USA; 5) Department of Pathologist, Marshfield Clinic, Marshfield, Wisconsin, USA.

Over 160 disease phenotypes have been mapped to the major histocompatibility complex (MHC) region on chromosome 6 by GWAS, suggesting that the MHC region as a whole may be involved in the etiologies of many phenotypes, including unstudied diseases. The phenome-wide association study (PheWAS), a powerful and complementary approach to GWAS, has demonstrated its ability to discover and rediscover genetic associations. In the current study, we systematically explored the MHC region by associating 3067 variants with 6221 phenotypes by PheWAS in a cohort of 7481 subjects from Marshfield Clinic Personalize Medicine Research Projects (PMRP). Results showed that expected associations previously identified by GWAS could be identified by PheWAS (eg. psoriasis, ankylosing spondylitis, and type I diabetes). Importantly, novel associations with 13 diseases not previously assessed by GWAS (eg. Lichen Planus) were also identified and replicated in an independent population. Many of these associated diseases appear to be immune or immune related disorders. These results demonstrate that the PheWAS approach is a powerful and novel method to discover and rediscover SNP-disease associations, and further emphasize the importance of the MHC region in human health.

952F

Pervasive pleiotropy between psychiatric disorders and immune disorders revealed by integrative analysis of multiple GWAS. *Q. Wang[1,2,3], C. Yang[3,4,5], J. Gelernter[2,3,6,7], H. Zhao[1,4,7,8].* 1) Program in Computational Biology and Bioinformatics, Yale University, New Haven, Connecticut, USA; 2) Department of Psychiatry, Yale School of Medicine, New Haven, Connecticut, USA; 3) VA CT Healthcare Center, West Haven, Connecticut, USA; 4) Department of Biostatistics, Yale School of Public Health, New Haven, Con- necticut, USA; 5) Department of Mathematics, Hong Kong Baptist University, Hong Kong SAR; 6) Department of Neurobiology, Yale School of Medicine, New Haven, Connecti- cut, USA; 7) Department of Genetics, Yale School of Medicine, West Haven, Connecticut, USA; 8) VA Cooperative Studies Program Coordinating Center, West Haven, Con- necticut, USA.

Although some existing epidemiological observations and molecular experiments suggested that brain disorders in the realm of psychiatry may be influenced by immune dysregulation, the degree of genetic overlap between psychiatric disorders and immune disorders has not been well established. We investigated this issue by integrative analysis of genome-wide association studies of 18 complex human traits/diseases (five psychiatric disorders, seven immune disorders, and others) and multiple genome-wide annotation resources (Central nervous system genes, immune-related expression-quantitative trait loci (eQTL) and DNase I hypertensive sites from 98 cell-lines). We detected pleiotropy in 24 of the 35 psychiatric-immune disorder pairs. The strongest pleiotropy was observed for schizophrenia-rheumatoid arthritis with MHC region included in the analysis (p = 3. 9e-285), and schizophrenia-Crohns disease with MHC region excluded (p = 1. 1e-36). Significant enrichment (>1. 4 fold) of immune-related eQTL was observed in four psychiatric disorders. Genomic regions responsible for pleiotropy between psychiatric disorders and immune disorders were detected. The MHC region on chromosome 6 appears to be the most important with other regions, such as cytoband 1p13. 2, also playing significant roles in pleiotropy. We also found that most alleles shared between schizophrenia and Crohns disease have the same effect direction, with similar trend found for other disorder pairs, such as bipolar-Crohn's disease. Our results offer a novel birds-eye view of the genetic relationship and demonstrate strong evidence for pervasive pleiotropy between psychiatric disorders and immune disorders. Our findings might open new routes for prevention and treatment strategies for these disorders based on a new appreciation of the importance of immunological mechanisms in mediating risk of many psychiatric diseases.

953W

Common susceptibility variants are shared between schizophrenia and psoriasis in the Han Chinese population. *XY. Yin[1,2,3,4], NE. Wineinger[2], KC. Wilhelmsen[4], JJ. Liu[5], NJ. Schork[3], XJ. Zhang[1].* 1) Institute of Dermatology, Anhui Medical University, Hefei, Anhui, China; 2) The Scripps Translational Science Institute, La Jolla, USA; 3) Human Biology, J. Craig Venter Institute, La Jolla, USA; 4) Department of Genetics, and Renaissance Computing Institute, University of North Carolina at Chapel Hill, Chapel Hill, NC 27517, USA; 5) Human Genetics, Genome Institute of Singapore, A*ASTAR, Singapore 138672, Singapore.

Background: Previous studies have shown that individuals with schizophrenia have a higher likelihood of developing psoriasis than a typical person. This suggests that there might be a shared genetic etiology between the two conditions. **Aims**: To characterize the potential shared genetic susceptibility between schizophrenia and psoriasis using genome-wide marker genotype data. **Methods**: We applied a marker-based co-heritability estimation procedure, polygenic score analysis, gene set enrichment test and a LASSO regression model on 1,139 psoriatic and 744 schizophrenic subjects, and 1,678 controls both genotyped on ~500,000 single nucleotide variants (SNVs). **Results**: In the combined cohort, we estimated that a large fraction of psoriasis and schizophrenia risk could be attributed to common variants (*h*2SNP =29%, s. e. = 5. 0%, P = 2. 00 ×10-8), with a co-heritability estimate between the traits of 21%. We found that five variants within HLA region reached genome wide significance when both conditions were analyzed together (P < 5. 00×10-8), which collectively conferred a significant risk effect (odds ratio of highest risk quartile=6. 03, P < 2. 00 ×10-16). Variants contributing most to the shared heritable component between psoriasis and schizophrenia were enriched in antigen processing and cell endoplasmic reticulum. **Conclusions**: We found evidences for a shared genetic etiology between schizophrenia and psoriasis. The mechanism for this shared genetic basis likely involves immune and calcium signaling pathways.

Meta-analysis of exome array data identifies two novel regions associated with lung function. *V. E. Jackson[1,2], L. V. Wain[1,2], I. Sayers[3], I. P. Hall[3], M. D. Tobin[1,2], SpiroMeta Consortium.* 1) Departments of Health Sciences and Genetics, Adrian Building, University of Leicester, Leicester, UK; 2) National Institute for Health Research (NIHR) Leicester Respiratory Biomedical Research Unit, Glenfield Hospital, Leicester, UK; 3) Division of Respiratory Medicine, University Hospital of Nottingham, Nottingham, UK.

Lung function measures are an important predictor of mortality and morbidity and are used in the diagnosis of a number of diseases, including chronic obstructive pulmonary disease (COPD). A number of large-scale genome-wide association studies (GWAS) have successfully identified single nucleotide polymorphisms (SNPs) influencing lung function in over 50 regions; however these so far identified regions only account for a small proportion of the estimated heritability. We utilised genotype data from the exome array, which predominately measures low frequency, coding variation, in attempt to uncover some of the so-called missing heritability. We carried out discovery meta-analyses of exome array data and three lung function measures: forced expiratory volume in one second (FEV1), forced vital capacity (FVC) and the ratio ofFEV1 to FVC (FEV1/FVC). These analyses included 23,751 individuals of European ancestry, from 11 studies, genotyped using the Illumina Human Exome BeadChip. Each trait was adjusted for age, sex, height and ancestry principal components and familial relationships, as appropriate, and stratified by ever smoking status. We have utilised single variant association analysis methods, traditionally employed in GWAS, along with gene-based methods, which test for the joint effect of several variants in a gene. We performed all analyses in ever smokers and never smokers separately, in addition to in all samples combined. We followed up the most significant single variant and gene associations (P<10-4) in up to 93,390 independent samples. Through our single variant association analyses, we identified signals within two novel regions: both associations were with intergenic SNPs located close to *LY86* (P=1. 1x10-13) and *FGF10* (P=1. 9x10-8). *LY86* may play a role in the immune response to bacterial lipopolysaccharide (LPS) and cytokine production. *FGF10* is involved in several biological processes, including branching morphogenesis of the lung. Bioinformatics follow-up of these SNPs are now underway, to identify potential mechanisms underlying these associations.

Genome-wide association analysis of a custom Pima Indian genotyping array identifies a female specific effect of common variation near *TH*/*MIR4686* on risk for type 2 diabetes and reduced insulin secretion. *L. Baier, P. Chen, P. Piaggi, Y. Muller, A. Nair, S. Kobes, W. Knowler, C. Bogardus, R. Hanson.* PECRB, NIDDK/NIH, Phoenix, AZ.

To optimize capture of genetic information in American Indians, we designed an entirelycustom Affymetrix Axiom array based on whole genome sequence data from 335 Pima Indians. High quality genotypes were obtained on 548,206 variants which tagged (r2 within 300 kb windows) 92% of the 5M common variants (minor allele frequency ≥0. 05) detected in the Pima genomes. This array was used to genotype 3,637 full heritage Pimas (stage 1) who had participated in a longitudinal study of type 2 diabetes (T2D); stage 1 data analysis is complete. Recently, 4,060American Indians from the same longitudinal study, who are largely of mixed heritage,were genotyped with the array (stage 2), but analysis of stage 2 array data is ongoing. However, 408 variants associated with T2D in stage 1 were prioritized for expedited genotyping (Illumina BeadXpress) in the mixed heritage sample and analysis of these 408 variants iscomplete. Among the prioritized variants, rs11564707 (C/G; frequency of G= 0. 45 and 0. 40 in full and mixed heritage Pima Indians) provided the strongest association with T2D, where it independently associated in each sample (full heritage: *P*=8x10-7; OR[95%CI] per copy of G allele=1. 33[1. 19-1. 49] andmixed heritage: *P*=5x10-3; OR= 1. 22[1. 10-1. 40], adjusted for age, sex, birth year, family membership and ancestry). Combining both samples provided a genome-wide significant association with T2D(*P* = 2. 2x10-8, OR=1. 28[1. 18-1. 40]). However, there was a significant gender x genotype interaction (*P*=0. 001) for T2D such that this association was entirely driven by the 4,175 females (*P*=2. 5x10-9; OR=1. 41[1. 26-1. 58]); the association in 3,314 males wasnot signficant(*P*=0. 14; OR= 1. 11[0. 97-1. 27]). This female specific association was also observed for measures of early insulin secretion assessed in full heritage Pima Indians who were normal glucose tolerant. Both the 30 minute insulin levels during a 75g oral glucose tolerance test and the insulin response to a 25g intravenous glucose bolus were reduced in females (both *P*<0. 01) but not males. Rs11564707 maps near the microRNA 4686 and the 5'region of the *TH* gene, and tags 11 nearby variants with an r2>0. 99 (including a novel T>TTTTGTTTG insertion at chr11:2,204,322). *TH* encodes tyrosine hydroxylase and studies have suggested TH activity in pancreatic islets and in the paracrine control of glucose induced insulin secretion; however, future functional studies are required to establish the causative variant and affected gene.

956W

Analysis of sex-by-SNP interaction among geographically distinct cohorts reveals novel suggestive loci for IgA nephropathy. *N. Mladkova[1], Y. Li[1], F. Scolari[2], D. Cusi[3], J. Novak[4], B. Kiryluk[1].* 1) Department of Nephrology, Columbia University Medical Center, Columbia University, New York, NY. USA; 2) Division of Nephrology, Azienda Ospedaliera Spedali Civili of Brescia, Montichiari Hospital, University of Brescia, Brescia, Italy. [2] Department of Medical and Surgical Specialties, Radiological Sciences, University of Brescia, Brescia, Italy; 3) Renal Division, DMCO (Dipartimento di Medicina, Chirurgia e Odontoiatria), San Paolo Hospital, School of Medicine, University of Milan, Milan, Italy; 4) Department of Microbiology, University of Alabama at Birmingham, Birmingham, Alabama, USA; 5) Department of Medicine, University of Alabama at Birmingham, Birmingham, Alabama, USA; 6) John Walls Renal Unit, University Hospitals of Leicester, Leicester, UK; 7) Department of Infection, Immunity and Inflammation, University of Leicester, Leicester, UK; 8) INSERM, Centre for Research in Epidemiology and Population Health, Villejuif, France; 9) Renal Division, Peking University First Hospital, Peking University Institute of Nephrology, Beijing, China; 10) Department of Genetics, Yale University School of Medicine, New Haven, Connecticut, USA. [2] Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, Connecticut, USA; 11) University Paris-Sud, Villejuif, France.

Background: IgA nephropathy (IgAN) represents the most common form of primary glomerulonephritis in the world. The disease is characterized by deposits of IgA1-containing immune complexes in kidney filtration units leading to kidney damage. IgAN is highly prevalent in East Asia, of intermediate prevalence in Europe and extremely rare in Africa. Although the disease is equally frequent in males and females in Asia, it is more common in European males, with a male-to-female ratio exceeding 3:1. This suggests a complex interaction between gender and ethnicity on disease risk. Methods: We performed genome-wide screen for sex-by-SNP interaction in previously describedbi-ethnic cohort of European ancestry (2017 cases and 8199 controls) and Asians (1194 cases and 902 controls). All individuals were typed with high-density SNP chips and imputed using ethnicity-matched 1000 Genomes reference panels (Minimac2). We tested for sex-by-SNP interaction using logistic regression under additive genotype coding. The results from individual cohorts were combined using fixed-effects meta-analysis (METAL). Results: The top interaction signal resides in the inter-genic region on chr. 13 (rs9595757, P≤3. 4e-07). The second suggestive locus resides on chr. 14 (rs11108444, P= 1. 0e-06, intronic variant in *ELK3*, a transcription factor involved in B-cell development and *IGH* gene regulation). The third locus resides within the Smith-Magenis syndrome region on chr. 17 (rs6502579, P= 2. 2e-06, intronic variant in *NT5M*). Another promising locus intersects *HS3ST3A1* on chr. 17 (rs8079179, P=5. 5e-06). The genetic variation in *HS3ST3A1* has previously been associated with Plasmodium falciparum parasitemia. Conclusions: This analysis of sex-by-SNP interaction in a large bi-ethnic cohort of IgAN identified several new suggestive loci. Many of those loci are located within genes involved in the immune system regulation and warrant further investigation in additional Asian and European cohorts.

957T

Do myopia genes vary with age? *J. W. L. Tideman[1,2], J. Guggenheim[3], Q. Fan[4], S. M. Saw[4,5,6,7], C. Williams[8], V. W. V. Jaddoe[2], J. R. Polling[1,9], C. C. W. Klaver[1,2], CREAM Consortium.* 1) Epidemiology, Erasmus Medical Center, Rotterdam, Zuid-Holland, Netherlands; 2) Department of Ophthalmology; Erasmus Medical Centre Rotterdam, The Netherlands; 3) School of Optometry & Vision Sciences, Cardiff University, Cardiff, UK; 4) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore, Singapore; 5) Saw Swee Hock School of Public Health, National University Health Systems, National University of Singapore, Singapore, Singapore; 6) Department of Ophthalmology, National University Health Systems, National University of Singapore, Singapore; 7) DUKE-National University of Singapore Graduate Medical School, Singapore, Singapore; 8) School of Social and Community Medicine, University of Bristol, Bristol, UK; 9) Department of Orthoptics & Optometry, University of Applied Sciences, Faculty of Health, Utrecht, the Netherlands.

Purpose:GWA-studies performed in adults identified many genetic loci associated with refractive error and myopia. Knowledge of their age of onset in children may help understand the development of myopia, and identify a timeframe for specific therapies. We compared the effect of the individual risk variants on ocular biometry in three age categories (<10, 10 – 25 and >25 years). **Methods:** The study population consisted of three age-groups identified from the international CREAM consortium: 5,490 children aged <10 years; 5,000 children aged 10-25 years; and 13,274 adults >25 years. In these age-groups, we compared the effect sizes (betas) of the 39 top hits of the currently known genetic loci on the axial length/corneal radius (AL/CR) ratio, a good proxy for refractive error. The association between individual SNPs and AL/CR was studied using linear regression analysis, adjusting for age and sex, and for principal components when applicable. In addition, we also investigated a total genetic risk score based on the sum of all risk alleles. All analyses were bonferroni-adjusted. **Results:** In the age-group <10 years, three genetic variants (near *GJD2, KCNQ5, ZIC2,* respectively) were found to be significantly associated with AL/CR. In the age-group 10-25 years, five genetic variants (*BMP2, TOX, KCNQ5, A2BP1* and *CACNA1D*) were significantly associated. Genetic variants near *BMP2* and *BICC1* showed a significant increase between <10 years and 10 – 25 years; genetic variants near *LAMA2* and *MYO1D* showed a significant increase from the two younger age-groups to adults. The genetic risk score was associated with AL/CR in all three age-groups, and increased from 0. 0018 (P = <5*10-9) in <10 years, 0. 0032 (P = 5*10^-15) in 10-25 year olds, to 0. 0051 (P 1*10^-72) per risk allele in adults. **Conclusion:** A number of genes associated with refractive error in adults already have a significant effect on ocular biometry in young children. The genes *KCNQ5* and *ZIC2* appear to have all their effect on AL/CR early in life. Most genes (*LAMA2, GJD2*) have an early effect which progresses with age, and some genes (*MYO1D,PABPCP2*) have no observable effect at all <10 years. Our results provide insights on the age period in which myopia genes exert their effect.

958F

Common genetic variants associated with thyroid function may be risk alleles for Hashimoto's disease and Graves' disease. *P. Campbell[1], T. H. Brix[2], S. G. Wilson[1,3,4], L. C. Ward[1], J. Hui[5], J. P. Beilby[5,6], L. Hegedus[2], J. P. Walsh[1,3].* 1) Endocrinology & Diabetes, Sir Charles Gairdner Hospital, Perth, Western Australia, Australia; 2) Department of Endocrinology and Metabolism, Odense University Hospital, Odense, Denmark; 3) School of Medicine and Pharmacology, University of Western Australia, Crawley, Australia; 4) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 5) Pathwest Laboratory Medicine WA, Nedlands, WA, Australia; 6) School of Pathology and Laboratory Medicine, University of Western Australia, Nedlands, WA, Australia.

Recent studies have identified common genetic variants associated with TSH, free T4 and thyroid peroxidase antibodies, but it is unclear whether these differ between patients with Hashimoto's disease and Graves' disease. We genotyped 11 common variants in a discovery cohort of 203 Australian patients with autoimmune thyroid disease (AITD). Two variants with significant or suggestive associations were analysed in a replication cohort of 384 Danish patients. In addition, we compared our results against 3960 healthy controls defined as TPOAb negative with TSH levels within 0·4-4·0 mU/l and no history of thyroid disease. Genotyping was performed using TaqMan allelic discrimination 5¤nuclease assays (Applied Biosystems) with fluorescence measured by a Victor2 Multilabel Plate-Reader (Perkin-Elmer) as per the manufacturer's protocol. Binary association tests were performed using general linear modelling in r v3. 1. 0 and snptest v2. 3. 0, adjusting for sex. For rs753760 (*PDE10A*), the minor allele frequency in Graves' disease and Hashimoto's disease was 0·38 vs. 0·23, respectively, (P=6·42×10-4) in the discovery cohort, 0·29 vs. 0·24 (P=0·147) in the replication cohort and 0·32 vs. 0·24 in combined analysis (P=0·0021; all analyses adjusted for sex). In healthy controls, the frequency was 0·29, significantly different from Hashimoto's disease but not Graves' disease. *PDE10A* has been implicated in cAMP degradation in response to TSH stimulation of thyrocytes and has been positively associated with TSH. It is plausible, therefore that the variant influences disease ascertainment rather than pathogenesis. For rs4889009 (*MAF* gene region), the frequency of the minor G-allele in Graves' disease and Hashimoto's disease was 0·48 vs. 0·36 (P=0·0156) in the discovery cohort, 0·48 vs. 0·34 (P=1·83 × 10-4) in the replication cohort and 0·48 vs. 0·35 in the combined analysis (P=7·53×10-6); in controls, the frequency was 0·38, significantly different from Graves' disease but not Hashimoto's disease. There are three variants within 4kb of each other associated with thyroid volume (rs17767491), goitre (rs3813579) and serum TSH (rs3813582). Two of these variants (rs17767491 and rs3813582) are in moderate LD with rs4889009 (r^2=0·686 for each) suggesting that this region may be a susceptibility locus for Graves' disease. Our data shows that common variants in *PDE10A* and *MAF* gene regions may influence whether patients with AITD develop Graves' disease or Hashimoto's disease.

959W

DQA1 gene and type 1 diabetes. *Y. Lee[1,2,3,4], F. Lo[6,7], C. Huang[1,5], W. Ting[1,5], Y. Lien[1], C. Lin[1], W. Lin[1], C. Chan[1].* 1) Dept Pediatrics & Med Res, Mackay Memorial Hosp, New Taipei City, Taiwan; 2) Department of Pediatrics, School of Medicine, College of Medicine, Taipei Medical University; 3) Institute of Biomedical Sciences, MacKay Medical College; 4) Department of Medicine, MacKay Medical College; 5) Department of Nursing, MacKay Medicine, Nursing and Management College; 6) College of Medicine, Chang Gung University; 7) Department of Pediatrics, Chang Gung Memorial Hospital, Taiwan.

Type 1 diabetes (T1D) is an autoimmune disease characterized by T cell-mediated destruction of pancreatic b cells and the presence of autoantibodies against several b cell autoantigens. Both genetic susceptibility and environmental factors contribute to the pathogenesis. An analysis of combined data of Caucasians, Africans, and Japanese shows that DR4 haplotype –associated susceptibility might be determined by the DQA1 locus. We reported association between DQA1 gene and type 1 diabetes in Han Chinese in Taiwan. **Patients**The subjects were 359 T1D patients. T1D was diagnosed on the basis of clinical manifestations and laboratory evidence. **Controls** The 385 control subjects included hospital personnel and individuals who underwent routine health examinations or minor surgery. None had a history of autoimmune disease. All patients and controls were Han Chinese in Taiwan. **Genotyping of the DQA1 gene**We used sequencing-based typing to genotype the DQA1 gene. **Statistical analysis**Statistical difference in allele distributions between patients and controls were assessed by the chi-square test. Odds ratios (OR) and 95% confidence intervals were also calculated. The Bonferroni correction, $Pc = 1 - (1-P)^n$, was used for multiple comparisons where *Pc* is the corrected *P* value, *P* the uncorrected value, and n the number of comparisons. In this study, n is 8. A *Pc* value of less than 0. 05 was considered statistically significant. **Results**The DQA1*03:01 allele was the most frequent in patients (51. 3%) and controls (31. 4%). It was also significant more frequent in patients than in controls, OR (95%CI) = 2. 29 (1. 85-2. 83), *Pc* = 6. 31E-14. The DQA1*05:01 allele was the second most frequent in patients (38. 3%) and in controls (20. 5%) and conferred susceptibility of T1D, OR = 2. 40 (1. 91-3. 02), *Pc* = 3. 60E-13. Allele DQA1*06:01 was significantly less frequent in patients than in controls (0. 3% vs. 9. 6%) and rendered protection against T1D, OR = 0. 03 (0. 01-0. 06), *Pc* = 2. 66E-15. So were *01:01 [OR=0. 19 (0. 11-0. 32), *Pc* = 1. 23E-08], 01:02 [OR = 0. 21 (0. 14-0. 30), *Pc* <1. 00E-15], and 01:03 [OR = 0. 16 (0. 09-0. 28), *Pc* = 6. 82E-09]. **Conclusion**DQA1 is associated with type 1 diabetes in Han Chinese in Taiwan. DQA1*03:01 and *05:01 confer susceptibility of T1D while *01:01, *01:02, *01:03, and *06:01 render protection against T1D.

960T

Estrogen receptor alpha gene (ESR1) variant is associated with specific clinical features of systemic lupus erythematosus patients in a Brazilian population . *S. E. Lofgren, D. G. Suterio, M. N. Drehmer, I. R. Souza.* Biologia Celular, Embriologia e Genetica, Universidade Federal de Santa Catarina, Florianopolis, SC, Brazil.

Background: Systemic Lupus Erythematosus (SLE), as well as several other autoimmune diseases, is considered to be a women's disease, since around 90% of patients are female. The mechanisms behind this gender bias are not well understood but several studies suggest an important role of male and female hormones. Estrogens are known to have a modulatory effect on several immune responses, many of which are correlated to autoimmune diseases. Here we analyzed a genetic variant in the estrogen receptor-αgene (*ESR1*), implicated in the hormonal regulation of immune cells, for susceptibility and severity of SLE. Material and methods: Genomic DNA was extracted from peripheral white blood cells from 420 individuals (260 healthy controls and 166 SLE patients) by phenol-chlorophorm protocol. Samples were genotyped for the putative functional polymorphism rs2234693 in the*ESR1*gene by pre-designed TaqMan genotyping assay. Allele and genotype frequencies were analyzed in cases and controls and also considering all ACR classification criteria for SLE and other relevant clinical and familial features. Statistical analyses were performed with Unphased software. Results: The tested SNP was not associated with SLE susceptibility*per se*but within the patient group could be related to some specific clinical manifestations. The minor allele rs2234693-C was correlated with the absence of arthritis as well as of anti-ANA and anti-RNP autoantibodies. It could also be associated withnon-occurrence of other autoimmune diseases in the family. On the other hand, the same variant was correlated with the presence of nephritis and discoid rash. Conclusions: In the context of SLE, the minor allele of the*ESR1*gene rs2234693-C was associated with renal and cutaneous involvement. On the contrary, the associated C allele may be considered a protective variant forarthritis and the production of unspecific autoantibodies as well asfamilial occurrence of autoimmune diseases. Overall, our study indicates that the minor C allele is correlated withclinical features thatmay be considereda milder manifestation of the disease. Our results might contribute to the understanding of the influence of genetic polymorphisms in the estrogen pathway and SLE susceptibility.

961F

Association of WNT pathway gene polymorphisms with nonsyndromic oligodontia. *N. Dinckan[1,2,3], Z. O. Uyguner[3], H. Kayserili[4], J. T. Hecht[2,5,6], A. Letra[1,2,6].* 1) Department of Endodontics, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 2) Center for Craniofacial Research, University of Texas Health Science Center School of Dentistry at Houston, Houston, TX; 3) Department of Medical Genetics, School of Medicine, Istanbul University, Istanbul, Turkey; 4) Department of Medical Genetics, School of Medicine, Koc University, Istanbul, Turkey; 5) Department of Pediatrics, University of Texas Health Science Center at Houston Medical School, Houston, TX; 6) Pediatric Research Center, University of Texas Health Science Center at Houston Medical School, Houston TX.

Tooth agenesis is the most common developmental abnormality of human dentition and is characterized by the congenital absence of one or more permanent teeth. Oligodontia is the term used to describe severe tooth agenesis, where six or more permanent teeth are missing. Oligodontia may occur as an isolated clinical entity or as a part of a syndrome. Investigations on model organisms have revealed hundreds of genes either directly or indirectly involved in the regulation of tooth development that could contribute to the etiology of oligodontia. The WNT gene pathway regulates multiple developmental processes during craniofacial and tooth development, and variations in WNT pathway genes have been reported in individuals with tooth agenesis. We investigated 34 SNPs in/nearby 12 WNT pathway genes (*WNT3, WNT3A, WNT5A, WNT8A, WNT9B, WNT10A, WNT11, AXIN1, AXIN2, APC, LRP5, LRP6*) for association with oligodontia in 23 Turkish Caucasian multiplex families presenting an average of 6-18 missing teeth. Families were ascertained through probands, and additional relatives were recruited. Genotypes were generated using Taqman Chemistry in a ViiA7 sequence detection instrument. Family-based single SNP association tests were performed using FBAT software. Pairwise-haplotype analysis was performed using the 'hbat' function in FBAT. Bonferroni correction was used to adjust for multiple testing and p-values ≤ 0. 001 were considered statistically significant for the single SNP analyses. We found borderline association for *WNT3A* rs752107 (P=0. 006) and rs1745420 (P=0. 04), *APC* rs861674 (P= 0. 006) and *AXIN2* rs7591 (P=0. 04) with oligodontia. *APC* SNP haplotypes (rs861674; rs2431238) showed strong association with oligodontia (P=0. 001). *WNT3A* rs752107 and *AXIN2* rs7591 are located in the 3' UTR and are predicted to bind to miR-128, and miR-205, respectively, and could have a regulatory role. Our results continue to support a role for WNT pathway genes in the pathogenesis of tooth agenesis, particularly in oligodontia. Further studies should elucidate the mechanism of how these genes contribute to tooth agenesis phenotypes.

962W

Meta-analysis of genome-wide imputed GWAS confirms known significant loci and identifies new suggestive loci in patients with Dupuytren´s disease. *K. Becker[1,2], S. Siegert[1], M. R. Toliat[1], G. H. Dolmans[3], P. M. N. Werker[3], M. Nothnagel[1], P. Nürnberg[1,2], H. C. Hennies[1,2,4].* 1) Cologne Center for Genomics, Cologne, North Rhine-Westphalia, Germany; 2) Cluster of Excellence on Cellular Stress Responses in Aging-associated Diseases, University of Cologne, Cologne, Germany; 3) University of Groningen and Dept. of Plastic Surgery, University Medical Center Groningen, Groningen, the Netherlands; 4) Div. of Human Genetics, Innsbruck Medical University, Innsbruck, Austria.

Dupuytren´s disease, a fibromatosis of the connective tissue in the palm leading to flexion contracture of single fingers, is a common complex disease with a strong genetic component. In a first large GWAS study, nine loci were found to be associated with this disease. Much of the inherited risk in Dupuytren´s disease still needs to be discovered, and the already identified loci explain ~1% of the heritability in this disease. We have now included 1,580 cases and 4,491 controls in a meta-analysis of three genome-wide imputed GWAS datasets. The same quality control criteria were applied to each GWAS dataset and each dataset was imputed separately with IMPUTE2 and the 1000 Genomes reference set. GWAMA was used for the genome-wide association meta-analysis. We used a fixed effects model adjusting for population stratification. We used both the meta-analysis dataset and a whole transcriptome expression dataset (12 cases and 12 controls) to perform extensive network and pathway analysis. Here we have replicated seven previously identified loci, six of these on genome-wide significance level (p-values < 5E-08). The strongest association signal was observed on chromosome 7p14, for SNP rs17171229, with p=1. 11E-28; OR: 2. 02. This imputed SNP gave a slightly stronger signal than the previous top SNP rs16879765 (p=1. 52E-27; OR: 2. 02). We did not observe suggestive association for two previous significant loci on chromosomes 1p36 and 7q31. In addition we identified 14 new suggestive loci (p-value < 1E-05). Strikingly, four of the significantly confirmed loci contain genes that code for Wnt signaling proteins. Some of our newly identified suggestive loci also contain genes associated with Wnt signaling and thus present excellent candidates for replication. In addition we compared the genome-wide expression of genes in patient- and control-derived tissue samples and found the Wnt/β-catenin pathway to be the major deregulated pathway in patient samples. Network analysis provided further evidence that the Wnt signaling pathway in conjunction with other pathways may play an important role in Dupuytren´s disease. Thus we were able to replicate for the first time previously identified susceptibility loci for Dupuytren´s disease in a meta-analysis of genome-wide imputed GWAS datasets. Our findings further corroborate the strong genetic basis for Dupuytren´s disease. Genomic sequencing of the GWAS loci is one next step to identify underlying causative genetic variants.

Association of *PLEKHA7*, *COL11A1*, *ST18 -PCMTD1* and *ABCC5* Polymorphisms with primary angle-closure glaucoma. *J. Chen[1], Y. Jiang[1], Y. Zheng[1], Y. Huang[1], C. Huang[1], H. Chen[1], C. Pang[1,2], M. Zhang[1].* 1) Joint Shantou International Eye Center, Shantou University & the Chinese University of Hong Kong, Shantou, Guangdong, China; 2) Department of Ophthalmology & Visual Sciences, Chinese University of Hong Kong, Hong Kong, China.

Purpose: Primary angle-closure glaucoma (PACG) is one of the leading causes of irreversible blindness in Asians. Recently genome-wide association studies (GWAS) have identified four susceptibility loci associated with PACG: *PLEKHA7, COL11A1*, *ST18-PCMTD1* and *ABCC5*. The current study aimed to investigate the association of these four loci with two subtypes of PACG and ocular biometric parameters, including central corneal thickness, anterior chamber depth, lens thickness, vitreous chamber depth and axial length. **Methods:** In total 762 unrelated controls and 762 unrelated PACG patients, including 400 acute PACG (APACG) and 362 chronic PACG (CPACG) were recruited from Joint Shantou International Eye Center. Four single nucleotide polymorphisms (SNP) including *PLEKHA7* rs11024102, *COL11A1* rs3753841*, ST18-PCMTD1* rs1015213 and *ABCC5* rs1401999 reported by previous GWAS were genotyped in all participants with Taqman SNP genotype assay. Disease association and quantitative trait association were analyzed by logistic and linear regression respectively, controlled for sex and age. All *P* values were adjusted by Bonferroni correction for multiple comparisons. **Results:** *PLEKHA7* rs11024102 was significantly associated with PACG in the dominant model (*P* = 0. 05, odds ratio [OR] = 1. 35). *COL11A1* rs3753841 was significantly associated with PACG and with APACG in the recessive (*P* = 0. 028, OR = 1. 64 for PACG and *P* = 0. 012, OR = 1. 91 for APACG respectively) and additive models (*P* = 0. 008, OR = 1. 30 for PACG; *P* = 0. 047, OR = 1. 30 for APACG respectively). However, for *PCMTD1-ST18* rs1015213 and *ABCC5* rs1401999, there was no any significant association with patient groups in any model (all *P* > 0. 05). Moreover, comparison between APACG and CPACG showed no significant difference between the two subtypes in the four SNPs (all *P* > 0. 05). In quantitative trait association analysis, *COL11A1* rs3753841 was significantly associated with anterior chamber depth (*P* = 0. 004, b ± SE = -0. 082 ± 0. 019 mm). No significant association with any ocular biometric parameter was found in the other three SNPs (all *P* > 0. 05). **Conclusions:** In our study, *PLEKHA7* rs11024102 and *COL11A1* rs3753841 were associated with PACG, confirming the previous GWAS reports. Our results further showed that *COL11A1* was associated with APACG. However, no statistically difference was found between APACG and CPACG in the four SNPs. In addition, the minor allele G of *COL11AL* rs3753841 was correlated with narrower anterior chamber.

964F

Polymorphisms in Macrophage Migration Inhibitory Factor (MIF) And Disposition To Biliary Atresia Among Children. *k. Sadek[1, 2], M. Abdel-Rahman[2, 3, 5], S. Ezzat[4, 5].* 1) Immunogenetics Department, Division of Human Genetics and Genome Research, National Research Centre Egypt; 2) Division of Human Genetics and Department of Ophthalmology, The Ohio State University, Columbus, Ohio, US; 3) Department of Pathology, National Liver Institute, Menoufiya University, Egypt; 4) Department of Public Health, National Liver Institute, Menoufiya University, Egypt; 5) National Liver Institute Sustainable Sciences Institute Collaborative Research Center, Menoufiya University, Egypt.

BACKGROUNDTwo polymorphisms in the promoter region of *MIF* gene, rs755622 (-173 G/C) and rs5844572 (-794 CATT5–8) have been linked to susceptibility or severity of several inflammatory diseases. The two polymorphisms influence the basal and/or induced transcriptional activity of *MIF.* One of these polymorphisms, rs755622, has been implicated in the susceptibility to biliary atresia (BA), while the other polymorphism has not been studied in BA patients. The aim of this study was to investigate the association between these two polymorphisms and BA susceptibility and outcome in Egyptian patients. **METHODS**We conducted a retrospective study of 33 Egyptian infants with confirmed diagnosis of BA. The allele frequency in the population was assessed in 141 healthy adults from the same geographical location. In BA cases, DNA was extracted from paraffin embedded surgically resected tissues. DNA was extracted from the peripheral blood of the controls. Samples were tested for the rs755622 using Taqman real-time PCR and for the rs5844572 using and fluorescence-based genotyping. **RESULTS**Table 1 and 2 summarizes the results of the study. No statistical differences were observed in the allele frequencies between patients and controls. The frequency of the rs755622 C/G and C/C alleles (associated with activation of *MIF)* were observed more frequently in BA patients with marked fibrosis (9/14, 64%) compared with BA patients with mild to moderate fibrosis (5/14, 36%). The difference was statistically not significant. For the rs5844572 polymorphism the frequency of homozygous and heterozygous short repeats (5/5 or 5,X) was higher (11/18, 61. 1%) in BA patients with mild to moderate fibrosis compared with BA patients with marked fibrosis (2/14, 14. 3%), the difference was statistically significant (p= . 007). **CONCLUSION**The result of this study shows no association between *MIF* rs755622 and rs5844572 polymorphisms and susceptibility to BA. However, it suggests that these polymorphisms, in particular rs5844572, may be linked to the degree of fibrosis. This suggests that in patients with high-risk allelotypes of the rs755622 and rs5844572 earlier surgical intervention may be required for better outcome for native liver. **ACKNOWLEDGEMENTS** This project was funded in part by the Sustainable Sciences Institute.

965W

Interactive analyses of *INS* (rs689), *INSR* (rs1799816) and *PPP1R3A* (rs1799999) polymorphisms with Type 2 Diabetes risk in Brahmin group of North-West India. *A. Bhanwer, J. Sokhi.* Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

Type 2 diabetes (T2D) is a complex disorder and its pathogenesis is assumed to involve genetic variations in the candidate genes. The interactions between the genes involved in insulin signaling and secretory pathways are believed to play an important role in determining an individual predisposition to T2D. The 'Brahmins' who constitute a prominent community in India, are the highest of the four Hindu castes. Their traditional occupation is to concern themselves with the spiritual guidance of the people, conduct rituals at marriages, births, deaths and other ceremonies. Till date, strict endogamy practices makes them unique as compared to the rest of the world. Moreover, the studies have reported that people belonging to different caste groups are responsible for their variable susceptibility to disease predisposition. So, in the present study, polymorphisms in genes influencing insulin signaling pathways are studied for their association with T2D in Brahmins from North-West India. The present case-control study enrolled 366 participants (166 T2D cases and age and sex matched 200 healthy controls) with written informed consent. Genotyping was done using PCR-RFLP method. The statistical analysis was carried out using SPSS v16. 0 and Gene-gene interactions were studied through MDR software v3. 0. 2. In case of *INS* (rs689 A>T) and *INSR* (rs1799816 G>A) polymorphism, a significant association was observed in the genotype and allele frequency distribution among T2D cases and controls (p<0. 05). Further, genotype model analysis indicated that the AT genotype of *INS* A>T polymorphism provided >2. 0 fold increased risk towards T2D (p=0. 001), the GA genotype of *INSR* G>A polymorphism showed nearly 2. 4 fold risk of T2D (p=0. 005) after correction for age, sex, BMI, WC, WHR whereas no association of *PPP1R3A* C>A polymorphism with T2D was observed in Brahmins. The interactive analyses revealed nearly 2 fold increased risk of T2D (p<0. 0001). Furthermore, AA-GA-CA and AT-GG-CA genotypes combinations of three polymorphisms (p=0. 0432; p=0. 0026 respectively) indicated 3 fold higher chances of developing T2D in Brahmins of North-West India. In conclusion, our results provided the evidences for the interactions between the genes belonging to same signaling cascade. It also revealed that the cumulative effect of more than one polymorphism can help understanding the better picture of a complex trait like T2D in different population groups.

966T

Genetic Risk Score Based on Type 2 Diabetes Variants Predicts Longitudinal Decline in β-cell Function in Mexican Americans at Risk for Type 2 Diabetes. *M. Black[1], J. Wu[1], YH. Shu[1], E. Trigo[2], K. Taylor[3], J. Rotter[3], R. M. Watanabe[4,5,6], T. A. Buchanan[2,4,6], A. H. Xiang[1].* 1) Department of Research & Evaluation, Kaiser Permanente Southern California, Pasadena, CA; 2) Department of Medicine Keck School of Medicine, the University of Southern California, Los Angeles, CA; 3) Institute for Translational Genomics and Population Sciences, Los Angeles BioMedical Research Institute at Harbor-University of California Los Angeles Medical Center, Torrance, CA; 4) Department of Preventive Medicine, Keck School of Medicine of USC, Los Angeles, CA; 5) USC Diabetes and Obesity Research Institute, Los Angeles, CA; 6) Department of Physiology & Biophysics, Keck School of Medicine of USC, Los Angeles, CA.

Across the genome, associations between 62 variants and type 2 diabetes mellitus (T2DM) have been robustly replicated in various populations. However, association of these variants with longitudinal decline in β-cell compensation for insulin resistance has not been comprehensively assessed. We examined association between these variants, each residing in a distinct gene or intergenic region, and the rate of change in β-cell function in 373 BetaGene participants (mean±SD age: 35. 0±8. 2 years; 74. 8% female) with baseline and follow-up phenotyping (mean±SD length of follow-up: 4. 6±1. 5 years). β-cell function (disposition index; DI) was estimated from frequently sampled intravenous glucose tolerance tests with Minimal Model analysis. Genotyping was performed on the Illumina OmniExpress platform. An additive genetic model was assumed for all SNPs, and all models were adjusted for age, sex and baseline BMI. We tested each variant individually and jointly using an unweighted genetic risk score (GRS) constructed by summing the number of risk alleles across the 62 loci for each subject, where risk allele was defined by the observed direction of effect in univariate association analyses of SNP vs. rate of change in DI using BetaGene data. The GRS was approximately normally distributed (mean±SD: 63. 1±5. 3). Only 3 SNPs were individually associated with the rate of change in DI at a nominal significance level: *KCNK16* rs3734621 (p=0. 009), *HMG20A* rs7177055 (p=0. 019), *PRC1* rs12899811 (p=0. 033). However, the GRS was highly associated with the rate of change in DI (p=1. 40x10-8). Participants in the highest GRS tertile (65<GRS<77) had an average decline in DI of 885 units per year, whereas those in the lowest GRS tertile (48<GRS<61) had an average decline in DI of 62 units per year. These data provide evidence that a GRS based on SNPs associated with T2DM can significantly predict longitudinal decline in β-cell function over time in Mexican Americans at risk for T2DM.

967F

Interaction Analysis of *CAPN10* and *PGC-1*αGenes with Type 2 Diabetes in Three Unrelated Endogamous Groups of North-West India (Punjab): A Case-Control and Meta-Analysis Study. *R. Sharma[1], R. Kapoor[2], A. Bhanwer[1].* 1) Human Genetics, Guru Nanak Dev University, AMRITSAR, Punjab, India; 2) Heart Station and Diabetes Clinic, Amritsar, India.

Type 2 Diabetes (T2D) is caused by αcell dysfunction and/or insulin resistance, which is promoted by multifactorial genetic or environmental factors. To assess the influence of ethnicity, the association of *CAPN10* and *PGC-1ć* genes was investigated in total of 1125 samples (554 T2D cases and 571 controls) from Bania, Brahmin and Jat Sikh endogamous groups of North-West India (Punjab). Single-locus analysis showed significant difference in association of *CAPN10* (SNP-43, SNP-19, SNP-63) and *PGC-1ć*(Thr612Met, Thr528Thr, Gly482Ser, Thr394Thr, IVS2+52C>A) variants with T2D among studied groups. However, no association of *PGC-1ć* (Asp475Asp) polymorphism was seen in any group. Haplotype analysis depicted that in *CAPN10*, 212-haplotype in Bania group, 221-haplotype in Brahmin, 211 and 221-haplotypes in Jat Sikh group conferred increased risk towards T2D. *PGC-1ć* haplotypes GAGGCC, GAGGTA in Bania, GGGGCA, GGGGTC in Brahmin; GAAGTC, GGGGTC in Jat Sikh group provide 1. 5-5 fold increased T2D risk. Strong synergistic interactions were observed between *CAPN10* SNP-63, *PGC-1ć*Gly482Ser polymorphisms in Bania; *CAPN10* SNP-43, *PGC-1ć*Thr528Thr and Thr394Thr SNPs in Brahmin; *PGC-1ć*Thr528Thr, Gly482Ser, Thr394Thr variants in Jat Sikh group. Further, meta-analyses revealed that D-allele of *CAPN10* SNP-19 [p=0. 01, OR=1. 08 (1. 01-1. 2) at 95% CI] confer 1. 08-fold increased risk towards T2D predisposition. Similarly, minor alleles of *PGC-1ć*Gly482Ser [p=0. 006, OR=1. 23 (1. 06-1. 45) at 95% CI] and Thr394Thr [p=0. 00, OR=1. 41 (1. 20-1. 67) at 95% CI] showed significant overall association with T2D risk after conducting meta-analyses. Differential pattern of association of *CAPN10* and *PGC-1ć* genes affecting risk of T2D in studied ethnic groups emphasize the role of genetic heterogeneity. Knowledge of the ethnicity and nature of variation in risk factors needs serious attention for disease risk calculation and proper medical intervention. Therefore, further large-scale and better designed population-based studies are needed to ascertain the impact of ethnicity and studied variants on diabetes risk.

The mechanism of cleft palate after palatal fusion. *S. Suzuki, H. Imura, N. Natsume.* Div. Research and Treatment for Oral and Maxillofac. Congenital Anomalies. , Aichi-Gakuin University, Nagoya City, Aichi, Japan.

Palatal formation starts with an elevation in bilateral palatine processes onto the tongue in the form of vertical shelves, followed by a downward migration (elevation stage). The elevated palatine processes then elongate and contact each other at the midline (contact stage). Adhesion and self-decomposition of the epithelium occur at the contact location, and mesenchymal tissues then fuse (fusion stage). Cleft palate must therefore be induced by a disruption during the developmental process of the palatal shelves. Cleft palate can be occured due to a failure in the elevation of palatal shelves, failure in elevated palatal shelves to initiate contact, failure in proper fusion, or breakdown subsequent to fusion. However, we reported that some embryos appeared to develop cleft palates after palatal fusion by TCDD(2,3,7,8-Tetrachlorodibenzodioxin). On the other hand, the same present status has been reported in mesenchyme homeobox 2(MEOX2) knockout mouse. We observed MEOX2 gene from the blood from patients with cleft palate and performed PCR-Direct Sequence for 99 cleft palate patients. All patients were informed and consented. This study was approved by institutional review boards. There were two genetic variants , rs2237493 and rs113582077,were observed but we could not find significant differences between cases and controls. Further functional investigation will be required.

969T

An investigation of toll-like receptors in tuberculosis susceptibility reveals sex-specific associations for *TLR8* polymorphisms. *M. Salie, M. Daya, L. A. Lucas, R. M. Warren, G. D. van der Spuy, P. D. van Helden, E. G. Hoal, M. Moller.* Biomedical Science, Stellenbosch University, Tygerberg, Western Cape, South Africa.

Toll-like receptors (TLRs) are involved in the recognition of conserved microbial structures, leading to activation of an inflammatory response and formation of an adaptive immune response. Twenty-three polymorphisms in five *TLR* genes were genotyped in 623 tuberculosis cases and 473 healthy controls in a population-based case-control association study in a South African population. We detected sex-specific associations for *TLR8* polymorphisms, with rs3761624 (OR=1. 54, *P*<0. 001), rs3764879 (OR=1. 41, *P*=0. 011) and rs3764880 (OR=1. 42, *P*=0. 011) associated in females and rs3764879 (OR=0. 72, *P*=0. 013) and rs3764880 (OR=0. 75, *P*=0. 036) associated in males. Epistatic interactions between the *TLR* genes were investigated and the *TLR1*_rs4833095 polymorphism was shown to interact with *TLR2*_rs3804100 and (GT)n microsattelite (*P*=0. 002) and alter susceptibility to TB. We also studied the role of *TLRs* in disease caused by different *Mycobacterium tuberculosis* genotypes in 257 tuberculosis cases, and identified associations between specific *TLR* polymorphisms and disease caused by specific strains. This study provides further evidence that the TLRs play an important role in the outcome of tuberculosis disease, and suggests a partial explanation for the male bias in tuberculosis ratios.

970F

Genetic associations with non-fasting metabolite concentrations. *D. O. Mook-Kanamori[1, 2, 3], R. Li-Gao[1], R. de Mutsert[1], K. Willems van Dijk[4, 5], F. R. Rosendaal[1].* 1) Clinical Epidemiology, Leiden University Medical Center, Leiden, South Holland, Netherlands; 2) Public Health and Primary Care, Leiden University Medical Center, Leiden, South Holland, Netherlands; 3) BESC, Epidemiology Section, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia; 4) Human Genetics, Leiden University Medical Center, Leiden, South Holland, Netherlands; 5) Endocrinology, Leiden University Medical Center, Leiden, South Holland, Netherlands.

In 2011, two genome-wide association studies described fifteen loci (*FADS1, ACADS, ACADM, ACADL, ELOVL2, CPS1, PLEKHH1, SYNE2, SPTLC3, ETFDH, SLC16A9, ACSL1, SCD, SLC22A4* and *PHGDH*) that showed strong associations with a wide range of metabolite concentrations as measured by the Biocrates Absolute*IDQ*TM p150 kit. These studies suggested that genetic variants could explain a large proportion of phenotypic variance by taking metabolites as endophenotypes. Their findings were limited to metabolite concentrations in the fasting state. However, the human body resides in a non-fasting state for the greater part of the day. Therefore, our objective was to examine these associations in non-fasting metabolite concentrations. This study was embedded in the Netherlands Epidemiology of Obesity (NEO) study, a population-based prospective cohort of 6,671 persons aged 45-65 years. In 477 participants (56% males, mean BMI 30. 4 kg/m2) the metabolite concentrations were measured by the Biocrates Absolute*IDQ*TM p150 kit both fasting and 150 minutes after a meal challenge (600 kCal, 16 En% protein, 50 En% CHO, 34 En% fat). Genotyping was performed using the Illumina HumanCoreExome array. Additive models were used to assess the associations between the genetic variants in the fifteen loci with the metabolites in a fasting state, a postprandial state and with the metabolite response to the meal. After Bonferroni correction, we replicated thirteen out of the fifteen loci that were associated with the fasting metabolites (except *SYNE2* and *SCD*). For nine of the fifteen associated loci, the metabolite concentrations changed significantly after the meal (except for *FADS1*, *ELOVL2, PLEKHH1, SYNE2, SPTLC3* and *ACSL1*), ranging from 6% to 23%. For seven of these nine loci there were also associations with the postprandial metabolite concentrations (Beta (P-value)): *ACADS* (-0. 13 (9. 6*10-12)*, ACADM* (0. 06 (6. 8*10-5)*, ACADL* (0. 17 (7. 7*10-18)*, CPS1* (0. 15 (4. 6*10-8)*, SLC16A9* (-0. 10 (5. 2*10-9)*, SLC22A4* (-0. 07 (2. 0*10-4) and *PHGDH* (0. 05 (2. 7*10-3). The fifteen loci were not associated with the metabolite responses to the meal. In conclusion, our findings suggest that the associations between these loci and metabolite concentrations are not influenced by the fasting state of the participants. A genome-wide association study on non-fasting metabolites is required to identify genetic variants that are specifically associated with non-fasting metabolite concentrations.

971W

Rare genomic variants in *PARD3* are potential risk factors for human cranial neural tube defec. *X Chen[1,2,3], Yu An[4], Yonghui Gao[1,5], Liu Guo[6], Lei Rui[7], Hua Xie[1], Mei Sun[3], Hong Shao[2], Siv. I Hung[2], Xiaoming Sheng[2], Jizhen Zou[8], Yihua Bao[1], Hongyan Guan[9], Bo Niu[10], Zandong Li[7], Richard Finnell[11], James F Gusella[3,12], Ting Zhang[1], Bai-Lin Wu[2,4,13].* 1) Capital Institute of Pediatrics, Beijing, Beijing, China; 2) Department of Laboratory Medicine, Children's Hospital Boston, Boston, MA, 02115, USA; 3) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA, 02114, US; 4) Children's Hospital and Institutes of Biomedical Science, Shanghai Medical College of Fudan University, Shanghai, 200032, China; 5) Institute of Acu-moxibustion, China Academy of Chinese Medical Sciences, Beijing, 100700, China; 6) Department of Neurology, Affiliated Children's Hospital of Capital Institute of Pediatrics, Beijing, 100020, China; 7) State Key Laboratories for Agrobiotechnology, China Agricultural University, Beijing, 100193, China; 8) Department of Pathology, Affiliated Children's Hospital of Capital Institute of Pediatrics, Beijing, 100020, China; 9) Department of Integrated Early Childhood Development, Capital Institute of Pediatrics, Beijing, 100020, China; 10) Department of Biotechnology, Capital Institute of Pediatrics, Beijing, 100020, China; 11) Dell Pediatric Research Institute, Department of Nutritional Sciences, The University of Texas at Austin, Austin, Texas 78723 USA; 12) Department of Genetics, Harvard Medical School, Boston, MA, 02115, USA; 13) Department of Pathology, Harvard Medical School, Boston, MA 02115, USA.

The genetic etiology of human neural tube defects (NTDs) is largely unknown, although rare mutations of the planar cell polarity (PCP) genes have been shown to contribute to human NTD susceptibility. The increasing evidence for interactions between PCP and the apical–basal polarity (ABP) pathway, and the confirmed role of ABP proteins in zebrafish neurulation, prompted us to hypothesize that rare genomic variants of the core ABP gene, *PARD3,* are associated with susceptibility to human NTDs. In this study, we identified five rare genomic variants of *PARD3* from 100 Chinese cranial NTD cases, including one microdeletion and four single nucleotide variants. Overall, rare *PARD3* genomic variants are significantly associated with increased risk for cranial NTDs (5/100 *vs.* 0/100, $p<0.05$). By contrast, none of rare, NTD-specific SNV was found in 1044 Han Chinese controls. Over-expression analysis in HEK293T and MDCK cells confirmed a loss-of function model for two *PARD3* variants (D783G and P913Q), resulting in defective tight junction formation via disrupted aPKC binding. *PARD3* knockdown by siRNA in human neural progenitor cells gave rise to abnormal cell polarity. *cPard3* knockdown in chick embryos using a shRNA lentivirus delivered by *in ovo* microinjection resulted in significant more embryos with small tail phenotype, reduced epithelial polarization and ectopic hinge-like invagination occurs on the neuroepithelial tissue of chick neural tube due to the insufficiency of cPard3. Our studies suggest that rare, loss-of-function variants of *PARD3* are potential risk factors for human cranial NTDs, possibly by disrupting apical tight junction formation and epithelial polarization process.

972T

Replication of GWAS findings for cleft lip/palate in a Han Chinese population. *Z. Jia[1,2], Q. Yu[1,2], J. Ma[1,2], S. He[1,2], B. Shi[1,2].* 1) State Key Laboratory of Oral Disease, West China hospital of Stomatology, Sichuan University, Chengdu, Sichuan, China; 2) Department of Cleft Lip and Palate Surgery, West China Hospital of Stomatology, Sichuan University, chengdu, China;.

Background: Isolated cleft lip with or without cleft palate (CL/P) is one of the most common birth defects, with a prevalence of 1/700 in Asian. Genome wide association (GWA) study as the most powerful tool already identified numerous susceptible loci, however, these loci require multiple replications across populations to validate for etiologic SNP. **Methods:** In this study, we replicated 37 SNPs which has the most significant p values in published GWA studies, genotyping by using SNPscan among 309 NSCL/P trios (143 NSCLO and 166 NSCLP) from Western Han Chinese. We performed the transmission disequilibrium test (TDT) on individual SNPs and gene-gene (GxG) interaction analyses on the family data. Parent-of-Origin effects were assessed by separately considering transmissions from heterozygous fathers versus heterozygous mothers to affected offspring. **Results:** Allelic TDT results showed that T allele at rs2235371 (IRF6) and C allele at rs12063989 (24kb 3' of DIEXF) was uniquely associated with NSCLO (p=0. 00015 and 0. 00016, ORtransmission=0. 48 and 0. 49, 95%CI: 0. 33-0. 71 and 0. 34-0. 72, respectively). Individual SNP TDT analysis did not show rs742071 was associated with any of the three cleft groups (NSCLO, NSCLP and NSCL/P); While, T allele of rs742071 (PAX7) is paternally under-transmitted (p= 0. 0043) and parent-of-origin effects is also significant (Z=-2. 88 and p=0. 004). Genotypic TDT for epistatic interactions showed that rs2235371 interacts with rs11119388 (SYT14) (p= 1. 10E-12) among NSCL/P group. **Conclusions:**This study further confirmed that IRF6 gene rs2235371 was associated NSCLO from Asian populations. Rs2235371 interacts with rs11119388 (p= 1. 10E-12) among NSCL/P group, suggesting they may act in the same pathway. These findings provide solid support for IRF6 gene playing a critical role in human CL/P.

973F

Genotyping analysis of 3 RET polymorphisms demonstrates low somatic mutation rate in Chinese Hirschsprung disease patient. *Q. Jiang[1], Z. Zhang[2], Q. Li[2], W. Cheng[3], GL. Qiao[2], P. Xiao[4], L. Gan[2], L. Su[5], CY. Miao[6], L. Li[2].* 1) Department of Medical Genetics, Capital Institute of Pediatrics, Beijing, China; 2) Department of Pediatric Surgery, Capital Institute of Pediatrics, Beijing, China; 3) Department of Surgery, Beijing United Family Hospital, China; Department of Paediatrics and Surgery, Faculty of Medicine, Nursing and Health Sciences, Monash University, Victoria, Australia; 4) Department of Pathology, Capital Institute of Pediatrics Affiliated Children's Hospital, Beijing, China; 5) Anhui Medical University, Hefei, China; 6) Peking University Capital Institute of Pediatrics Teaching Hospital, Beijing, China.

Background: Genetic mosaicism has been reported for both coding and non-coding sequences in the RET gene in Hirschsprung disease (HSCR) patients. This study aimed to investigate somatic mutation rate in Chinese population by comparing both homozygous genotype percentage and risk allele frequency of 3 RET single nucleotide polymorphisms (SNPs) among blood and colon samples. Methods: DNA was extracted from 59 HSCR blood samples, 59 control blood samples and 76 fresh frozen colon tissue samples (grouped into ganglionic, transitional and aganglionic level). Genotype status of rs2435357 and rs2506030 was examined by competitive allele specific hydrolysis probes (Taqman) PCR technology, and rs2506004 was examined by Sanger sequencing. Homozygous genotype percentage and risk allele frequency were calculated for each type of sample and compared by chi-square test. P<0. 05 was regarded as being statistically significant. Results: Colon tissue DNA samples showed similar frequency of SNPs as that of the blood DNA samples in HSCR patients, both of which are significantly higher than the control blood group (rs2435357 TT genotype: 71. 2%, 74. 7% versus 22. 0% in HSCR blood, HSCR colon and control blood DNA respectively, P=0. 000; rs2506004 AA genotype: 72. 4%, 83. 1% versus 25. 5%, P=0. 000; rs2506030 GG genotype: 79. 7%, 77. 2% versus 54. 2%, P=0. 000 and 0. 004). With respect to DNA extracted from ganglionic, transitional and aganglionic levels, no statistically significant difference was demonstrated in those 3 regions (rs2435357: p=0. 897; rs2506004: p=0. 740; rs2506030: P=0. 901). Conclusion: Our data does not support the notion that high frequency of somatic changes as an underlying etiology of Chinese HSCR population.

Targeted next generation sequencing identifies genetic regions influencing the development of chronic obstructive pulmonary disorder in a population from northern Sweden. *J. Klar[1], H. Matsson[2], C. Söderhäll[2], M. Lamontagne[3], S. Gudmundsson[1], H. Backman[4], A. Lindberg[4], E. Rönmark[4], D. Sin[5], D. S. Postma[6], Y. Bossé[3], J. Kere[2], B. Lundbäck[7], N. Dahl[1].* 1) Department for Immunology, genetics and pathology, Uppsala University, Uppsala, Sweden; 2) Department of Biosciences and Nutrition and Center for Innovative Medicine (CIMED), Karolinska Institutet, Huddinge, Sweden; 3) Institut universitaire de cardiologie et de pneumologie de Québec, Department of Molecular Medicine, Laval University, Québec, Canada; 4) The OLIN studies, Sunderby Hospital of Norrbotten, Luleå, Sweden; 5) The University of British Columbia Center for Heart Lung Innovation, St-Paul's Hospital, Vancouver, Canada; 6) Center Groningen, GRIAC research institute, University of Groningen, Groningen, The Netherlands; 7) Krefting Research Centre, Institute of Medicine, University of Gothenburg, Sweden.

Background: Chronic obstructive pulmonary disease (COPD) is a common disease in Sweden, affecting approximately one in six in age >40 years, with severe impact on health and quality of life. COPD results from environmental factors, especially cigarette smoking, with contributions from yet unknown genetic background factors and by gene-environment interactions. The general objective of this project is to get insight into the mechanisms and interactions of specific genes and genetic pathways that contribute to the development of COPD. **Aim:** To investigate candidate genes, with emphasis on genes important for lung development and homeostasis, in defined populations of smokers and non-smokers in search for genetic variations associated with development of COPD. **Methods:** We conducted a candidate gene analysis on 22 genes implicated in lung development and 71 genes and regions previously associated with COPD. Targeted enrichment (HaloPlex; Agilent) and high throughput sequencing (Illumina) was performed on patients and healthy controls retrieved from the Swedish Obstructive Lung Disease in Norrbotten (OLIN) Studies sample set. Pairwise linkage disequilibrium (LD) analysis was performed using SNAP and the variant data set from the CEU population panel of the 1000 genome project. Lung eQTL was calculated using genotyping and gene expression data from patients who underwent lung surgery. **Results:** We identified a total of 2,151 SNPs of which 74, distributed in 45 gene regions, have significantly different allele frequencies in COPD cases than controls. We identified six regions with associated variants in pairwise LD ($r2 > 0.7$, $D' = 1.0$). The variants in all six regions were confirmed to likely form haplotypes in the carriers. Seven associated variants were detected and significantly associated with gene expression. **Conclusion:** In summary, this study identified genetic variants at several loci significantly associated with COPD and replicated several previous GWAS results. In addition, we identified several regions in LD associated to COPD in the Swedish population. We further indicate the advantage of using less heterogeneous populations in the studies of complex disorders, as we, although using a small sample set, were able to detect genetic variants significantly associated to COPD.

975T

Genetic variant near *PLXDC2* gene influences the risk of primary open-angle glaucoma by increasing intraocular pressure. *F. Mabuchi[1], N. Mabuchi[1], Y. Sakurada[1], S. Yoneyama[1], K. Kashiwagi[1], Z. Yamagata[2], H. Iijima[1].* 1) Dept Ophthalmology, Univ Yamanashi, Chuo, Yamanashi, Japan; 2) Dept Health Sciences, Univ Yamanashi, Chuo, Yamanashi, Japan.

Purpose: To assess the association between the genetic variants previously reported to be associated with primary open-angle glaucoma (POAG) in the Japanese population and the phenotypic features, including intraocular pressure (IOP). **Methods:** Six hundred sixty one Japanese patients, including 417 patients with POAG (210 patients with normal tension glaucoma: NTG and 207 patients with high tension glaucoma: HTG) and 244 control subjects without glaucoma, were analyzed for 3 genetic variants reported to be associated with POAG; rs547984 (near gene: *ZP4*), rs7081455 (*PLXDC2*), and rs7961953 (*TMTC2*). Allele frequency differences were compared between POAG (NTG or HTG) patients and control subjects. A logistic regression model was used to study the effects of genotyped alleles when comparing POAG patients with control subjects. Demographic and clinical features, including maximum IOP and vertical cup-to-disc ratio (VCDR), were compared between alleles or genotypes. A multiple linear regression analysis was carried out to confirm the association between the risk alleles and maximum IOP or VCDR. **Results:** There were significant differences in the rs7081455 (*PLXDC2*) allele frequencies between the HTG (P = 0. 011) or POAG (P = 0. 005) patients and control subjects. Adjusted for age and gender, an almost 1. 5 increased risk of HTG (P = 0. 012) and POAG (P = 0. 0042) was found with the G allele of rs7081455 (*PLXDC2*). Maximum IOP (23. 5 ± 10. 3mmHg, mean ± standard deviation) in patients with GG genotype of rs7081455 (*PLXDC2*) was significantly higher (P = 0. 0073) than that (19. 9 ± 7. 4mmHg) in patients with TT genotype. VCDR (0. 72 ± 0. 27) in patients with risk G allele of rs7081455 (*PLXDC2*) was significantly larger (P = 0. 0088) than that (0. 72 ± 0. 27) in patients without G allele. A linear regression analysis confirmed significant association between the G allele of rs7081455 (*PLXDC2*) and maximum IOP (P = 0. 012) or VCDR (P = 0. 014). **Conclusion:** Genetic variant near *PLXDC2* gene is considered to influence the risk of POAG by increasing IOP.

976F

Gene-hormone therapy interaction and fracture risk in postmenopausal women. *Y. Wang[1], J. Wactawski-Wende[1], L. Sucheston-Campbell[2], L. Preus[1,2], J. Nie[1], R. D. Jackson[3], S. Handelman[4], R. Nassir[5], C. Crandall[6], H. M. Ochs-Balcom[1].* 1) Department of Epidemiology and Environmental Health, University at Buffalo, Buffalo, NY; 2) Cancer Prevention and Control, Division of Cancer Prevention and Population Sciences, Roswell Park Cancer Institute, Buffalo, NY; 3) Department of Internal Medicine, Division of Endocrinology, Diabetes and Metabolism, The Ohio State University, Columbus, OH; 4) Center for Pharmacogenomics, Department of Molecular Virology, Immunology and Medical Genetics, The Ohio State University, Columbus, OH; 5) Department of Biochemistry and Molecular Medicine, University of California Davis, Davis, CA; 6) Division of General Internal Medicine and Health Sciences Research, David Geffen School of Medicine at University of California, Los Angeles, Los Angeles, CA.

Given the completed meta-genome-wide association studies (GWAS) and known protective effects of hormone therapy (HT) on bone, we hypothesized that HT modifies the association of a fracture genetic risk score (GRS) comprising 16 meta-GWAS significant fracture-associated SNPs with fracture (total body, central body, lower limb, and upper limb). In 9,922 European Americans in Women's Health Initiative (WHI) HT randomized trials, including 1608 incident fractures from 1993 to 2005, we studied this interaction using Cox proportional hazards models and case-only analyses. In Cox models, the fracture region with the most significant interaction was central body fracture (pelvis, spine, hip, clavicle and scapula); however this multiplicative interaction term did not meet statistical significance (p-interaction=0. 19) regardless of covariate inclusion (age, trial, and sub-study (GARNET, WHIMS+)). In case-only analyses, we saw borderline evidence for multiplicative GRS-HT interaction for central body fracture; p=0. 13. In z-score-stratified models, women in the highest GRS category who were not randomized to HT were at the highest fracture risk: adjusted hazard ratio (HR)=2. 38 (95% CI: 1. 15-4. 91) compared to women in the lowest genetic risk category who were randomized to HT: 0. 97 (95% CI: 0. 43-2. 18). Additive interaction for central body fracture estimated using RERI (relative excess risk due to interaction) was marginally significant in the highest GRS category for central fracture; RERI=1. 10 (95% CI: -0. 06-2. 27), p=0. 06. Our results support exploration of genetic risk score as another factor in determining potential risk and benefit ratio of hormone therapy use for fracture prevention.

977W

Exploring interactions between genetic variation under linkage peaks and cigarette smoking on body weight in families. *K. L. Edwards[1], J. Y. Wan[1], C. Ziadeh[1], N. Shridhar[2], T. M. Norden-Krichmar[1], S. A. Santorico[3].* 1) Dept. of Epidemiology, University of California, Irvine, CA; 2) Dept. of Epidemiology, University of Washington, Seattle, WA; 3) Dept. of Mathematical and Statistical Sciences, University of Colorado, Denver.

The Metabolic Syndrome (MetS) is a complex condition characterized by a cluster of risk factors, including obesity, lipid abnormalities, hypertension and glucose intolerance. Previous work using families and linkage analysis identified chromosomal regions with evidence for linkage to both individual and clusters of MetS traits. Examining evidence for gene x environment (GxE) interactions under these linkage peaks provides a unique opportunity to further characterize the genetic and environmental underpinnings of complex disease and to explore sources of missing heritability. Cigarette smoking is an ubiquitous exposure that is known to influence MetS phenotypes and regulate gene expression via epigenetic modification. Ordered subset analysis (OSA) was used to examine evidence for interactions between smoking and genetic variation on body weight in 69 European American families, comprised of 495 subjects. OSA aims to reduce genetic heterogeneity by finding the subset of families with similar smoking backgrounds that maximize evidence for linkage. OSA was conduced using a variance components approach as implemented in SOLAR. Statistical significance was assessed by permutation testing. Families were subsetted using the proportion of smoking family members and in a separate analysis the average number of packs per day for the family. A subset of 12 families with 49 total subjects (large proportion of whom reported ever smoking) provided evidencefor linkage with body weight (LOD=1. 74, P=0. 05 at 132 cM in the chromome 2 linkage region). When the average number of packs per day was used to subset families, evidence for linkage was found in the chromsome 2 linkage region between 136-137 cM (LOD=2. 2, P=0. 01, 40 families, 293 total subjects). These results support not only the presence of a gene(s) that influences body weight in the previously identified linkage region on chromosome 2, but one that is also modified by smoking. Additional results will be presented for additional previously identified linkage regions, including those in Mexican, Japanese and African American families. Overall, it appears that evidence for linkage with body weight is modified by smoking. Targeting previously identified linkage regions may be a fruitful way to identify GxE.

978T

Genome-wide analysis of gene interactions with an environmental risk score for colorectal cancer risk. *M. Du[1], J. Gong[1], M. J. Gunter[2], A. Toland[3], S. I. Berndt[4], H. Brenner[5], A. T. Chan[6], J. Chang-Claude[5], M. Hoffmeister[5], J. Jeon[1], L. Le Marchand[7], W. Li[8], Y. Lin[1], J. D. Potter[1], M. L. Slattery[9], A. Vargas[10], P. A. Newcomb[1], U. Peters[1], E. White[1], L. Hsu[1].* 1) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) School of Public Health, Department of Epidemiology and Biostatistics, Imperial College London, London, W2 1PG, United Kingdom; 3) Department of Molecular Virology, Immunology, & Medical Genetics, Department of Internal Medicine Division of Human Genetics, The Ohio State University, Columbus, OH; 4) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD; 5) Division of Clinical Epidemiology and Aging Research, German Cancer Research Center (DKFZ), Heidelberg, Germany; 6) Division of Gastroenterology, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 7) Epidemiology Program, University of Hawaii Cancer Center, Honolulu, HI; 8) Division of Preventive and Behavioral Medicine, Departments of Medicine, University of Massachusetts Medical School, Worcester, MA; 9) Department of Internal Medicine, University of Utah Health Sciences Center, Salt Lake City, UT; 10) Cancer Prevention Fellowship Program, National Cancer Institute, Bethesda, MD.

Numerous environmental factors contribute to colorectal cancer (CRC) development. Studies examining gene interactions with individual risk factors have provided biological insight into these associations. However, many predictors have additive effects and a score combining known CRC risk factors may better characterize an individual's overall environmental risk profile. Use of such a composite score may increase statistical power to detect gene interactions, which can, in turn, inform preventive strategies. To study genome-wide gene interactions with combined environmental risk of CRC, we examined 7,945 CRC cases and 8,893 controls of European ancestry in the Genetics and Epidemiology of Colorectal Cancer Consortium. Using a reference panel of 955 participants who underwent sequencing, we imputed whole-genome sequence data into remaining participants with genome-wide array data. To assess overall environmental risk of CRC, we calculated an environmental risk score (ERS) comprising 17 established or probable CRC risk factors based on published findings. To test for multiplicative interactions, we used multivariable logistic regression and defined statistical significance using the conventional genome-wide α=5E-08. We further explored interactions using the potentially more powerful 2-stage Cocktail approach. The ERS was associated with increased risk of CRC (OR highest vs. lowest quartile=2. 41, 95% CI: 2. 20-2. 64). We observed a quantitative interaction between the ERS and a variant on chromosome 12q21. 33 using logistic regression (MAF=0. 26, OR-interaction=0. 87, *P*=6. 5E-09). For the highest vs. lowest ERS quartile, the association with CRC risk was stronger in participants carrying one (OR=3. 00, 95% CI: 2. 58-3. 50) or two (OR=3. 68, 95% CI: 2. 52-5. 39) copies of the minor allele compared to those with two copies of the major allele (OR=1. 97, 95% CI: 1. 74-2. 22). This variant is in the intergenic region between *BTG1* and *CLLU1*, genes which regulate cell growth and differentiation and have been implicated in cancer (chronic lymphocytic leukemia) and cardiovascular disease. There were no statistically significant interactions using the Cocktail approach. We identified a novel SNP interaction with an ERS for CRC risk—suggesting that aggregating known risk factors can help uncover gene interactions. These data suggest that the combined influence of environmental factors on CRC may be modified by common genetic variation, and warrant replication and further investigation.

979F

Interaction between variants in *CLU* and *MS4A4E* modulates Alzheimer's disease risk. *M. Ebbert[1], K. Boehme[1], M. Wadsworth[1], S. Mukherjeeb[2], P. Crane[2], P. Ridge[1], J. Kauwe[1], Alzheimer's Disease Neuroimaging Initiative, Alzheimer's Disease Genetics Consortium.* 1) Department of Biology, Brigham Young University, Provo, UT; 2) Department of Medicine, University of Washington, Seattle, Washington 98105, USA.

Epistasis affects many human phenotypes and likely plays a critical role in Alzheimer's disease (AD), but most AD studies focus on single loci. Here, we present strong evidence supporting epistasis between two top AD loci that modulate AD risk with a combined odds ratio (OR) of 2. 51, which is higher than any single AD locus except *APOEϵ4*, *APP*, and *TREM2.* This analysis was performed using the largest dataset employed in an epistasis study, to date. Ebbert et al. recently reported two potential gene-gene interactions between rs11136000 (*CLU*) and rs670139 (*MS4A4E*) (SF=3. 81, p=0. 016), and rs3865444 (*CD33*) and rs670139 (*MS4A4E*) (SF=5. 31, p=0. 003) using the Cache County data, but the interactions have not yet been replicated. Using nine independent datasets (3838 cases, 4532 controls) from the Alzheimer's Disease Genetics Consortium (ADGC), we tested each interaction, controlling for age, gender, and *APOEϵ4* dose. We then performed two meta-analyses per interaction (ADGC only and with Cache) using METAL, and performed a rigorous 10,000 permutations analysis to empirically test the resulting p-value's probability. We repeated the meta-analyses in *APOEϵ4* carrier and non-carrier strata, estimated the combined OR and combined population attributable fraction (cPAF) for both. We also collected CSF and plasma from 500+ individuals and measured nearly 200 human disease-specific biomarkers, including Aβ40, Aβ42, Tau, and pTau, to test their association with the interactions. Our results support the *CLU-MS4A4E* interaction (ADGC: SF=2. 37, p=0. 007; with Cache: SF=2. 71, p=0. 0004) and found a potential dosage effect using the ADGC data between rs11136000:C/C and rs670139:G/T (with Cache: SF=1. 73, p=0. 02). Empirical permutation p-values support the main interaction (ADGC: p=0. 03; with Cache: p=0. 002). The *CD33-MS4A4E* interaction did not replicate. We found an association for *CLU-MS4A4E* in Cache County with*APOEϵ4* negative individuals (SF=4. 75, p=0. 005) that replicates when including Cache in the meta-analysis (SF=2. 08, p=0. 004). The estimated combined OR and cPAF for *CLU-MS4A4E* are 2. 51 and 8. 0, respectively. Association tests between the interactions and biomarker levels are in process. The *CLU-MS4A4E* interaction replicates in a large case-control series, with possible dosage and APOE*ϵ4* effects. The *CLU-MS4A4E* OR is higher than any single AD locus except *APOEϵ4*, *APP*, and *TREM2*. We estimate an 8% decrease in Alzheimer's disease incidence without the *CLU-MS4A4E* risk alleles.

980W

A Genome-Wide Gene-Environment Interaction Study on Dyslipidemia between Genes and Obesity Traits. *M. Kang, J. Sung.* Complex Disease and Genetic Epidemiology Branch, Department of Epidemiology, School of Public Health, Seoul National University, Seoul, Republic of Korea.

IntroductionOne purpose of the human genomic studies is applying the best knowledge to personalized health promotion. A genome-wide gene-environment interaction(GWGEI) is an approach particularly designed for this end. Dyslipidemia is a known risk factor of CVD. Using common types of lipid problems, reduced HDL, elevated LDL, total cholesterol, and TG, we investigated the genes that modify the effect of obesity on dyslipidemia. Despite successful identification of dozens of SNPs related to lipid traits, relatively fewer studies were performed about genes that modify the effects of important risk factors. **Methods-**To examine GWGEI between genes and obesity traits, 12,321 individuals were involved from two population cohorts in Korea: 3,479 from the Healthy Twin Study, 8,842 from the Korean Association Resource(KARE). We conducted an exhaustive GWI search for 4. 1 million SNP markers and their interactions with obesity traits: BMI over 25kg/m2(overweight), WHR above 0. 90 for males, 0. 85 for females(obesity), and waist circumference above 102cm for males, 88cm for females(abdominal obesity). We applied EDGxE, the method using marginal association and case-only test statistics for GxE, and Cocktail methods, where significance of interaction p-value is gradually increased by the initial marginal p-value of the trait GWAS. All two-way interactions, case-only tests, and GxE correlation tests were performed to estimate significance of GxE interactions. **Results**For HDL, we identified 2 loci interacted with WHR near *ASAH2*, and 5 loci interacted with abdominal obesity near *CEP112*. For log-transformed TG, we identified 6 loci interacted with WHR near *APOA5* and *RCAN1*, and 49 loci interacted with abdominal obesity near *BUD13*, *NPR2*, and *LINGO2*. As WHR exceeds the criteria for obesity, about 3. 0% with two minor alleles of *RCAN1* showed steeper rises in TG levels than others. On the other hand, about 3. 5% with two minor alleles of *LINGO2* did not show changes in TG levels by any changes in waist circumference. **Conclusion**Our findings suggest that some individuals are particularly susceptible to abnormal lipid profile even if they are in normal range of obesity indices. The identified SNPs might be used as genetic markers to give a personalized guideline for management of lipid profiles. **Acknowledgements**This work was supported by the Post-Genome Technology Development Program(10050164, Developing Korean Reference Genome) funded by the Ministry of Trade, Industry&Energy(MOTIE, Korea).

Interaction between genotypes at *OPRM1* and *CHRNA5* and an adolescent substance prevention intervention on smoking during high school. *D. J. Vandenbergh[1,2,3], GL. Schlomer[1,4], HH. Cleveland[4], AE. Schink[3], ME. Feinberg[5], JM. Neiderhiser[6], MT. Greenberg[1,5], RL. Spoth[7], C. Redmond[7].* 1) Biobehavioral Health, Penn State University, University Park, PA; 2) The Institute for the Neurosciences, Penn State University, University Park, PA; 3) Molecular and Cellular Integrative Biosciences Program, Penn State University, University Park, PA; 4) Department of Human Development and Family Studies, Penn State University, University Park, PA; 5) Bennett Pierce Prevention Research Center, Penn State University, University Park, PA; 6) Department of Psychology, Penn State University, University Park, PA; 7) Partnerships in Prevention Science Institute, Iowa State University, Ames IA.

Adolescent smoking is reduced by prevention intervention programs, but not all individuals respond. We tested whether genetic risk of smoking, based on genotype at SNP rs1799971 (A118G) in the mu opioid receptor (*OPRM1*) gene, would be reduced in response to a substance use prevention/intervention program. We further tested for epistasis between rs1799971 and rs16969968 (N398D) in the *CHRNA5* gene on smoking, to incorporate the effect of this nicotinic receptor subunit gene, which we have shown previously to interact with the intervention to reduce smoking. Participants (N = 1,688) were randomly assigned to either control condition or a family based intervention in grade 6 and a school-based drug preventive intervention in grade 7. Smoking in the past month was assessed in grades 9–12 using a four-point scale (0 = never smoked, 1 = smoked but not in last month, 2 = one or a few times, 3 = about once a week or more). There was no main effect of genotype at *OPRM1* (coded as presence/absence of the G allele) or intervention, but the interaction was significant (b = –0. 27, p < 0. 01). In addition, we created a polygenic risk score by summing rs1799971 and rs16969968 (coded 1 for A/A genotype, 0 for others). Although there was no main effect of the polygenic risk score, the interaction with condition was significant (b = –0. 27, p < 0. 001). These results suggest that preventive interventions can reduce the genetic risk for smoking, which may involve interaction of multiple addiction-relevant genes.

982F

Genome-wide gene by disease interaction analysis identifies common SNPs at 17q21. 2 that are associated with increased body mass index only among asthmatics. *L. Wang, W. Murk, A. DeWan.* Chronic Disease Epidemiology, Yale University, New Haven, CT.

Background: Asthma and obesity are risk factors for one another, and their comorbidity is a growing medical problem. Although genetic factors are believed to play an essential role in this relationship, to our knowledge, no single nucleotide polymorphism (SNP) has been identified to be associated with both conditions. To explore comorbid susceptibility loci, we hypothesized that the genetic effects on one of the phenotypes is modified by the other phenotype, which provides a novel model supporting a gene by disease interaction analysis in a GWAS framework. **Methods:** We performed a genome-wide gene by asthma interaction analysis for the outcome of body mass index (BMI) in the Multi-Ethnic Study of Atherosclerosis (MESA) study (N=2474 Caucasians, 257 asthmatics) and replicated findings in the Framingham Heart Study (FHS) offspring cohort (N=1408 Caucasians, 382 asthmatics). The tagging SNP in the replicated region rs2107212, was further examined in stratified analyses. **Results:** In MESA, we identified three genetic regions: 7p21. 3, 10q25. 3 and 17q21. 2. Interactions involving SNPs clustered in 17q21. 2 were replicated in FHS. In both MESA and FHS asthmatics, subjects carrying the A allele for rs2107212 had higher BMI than non-carriers, which was not the case for non-asthmatics. Meta-analysis of MESA and FHS showed that the overall odds of being obese increased by 1. 89 fold for each additional A allele in the asthmatic population (p= 4. 3 × 10-5). We further examined BMI change subsequent to asthma diagnosis over a period of 26 years in FHS and demonstrated greater BMI increase among asthmatics compared to non-asthmatics. Asthmatics carrying the A allele at rs2107212 had significantly greater net BMI increase over the 26-year period compared to non-asthmatics. **Conclusions:** We applied a genome-wide gene by disease interaction analysis and found that common variants in 17q21. 2 are associated with asthma-related obesity. Chromosome 17q21 has been repeatedly reported to be associated with asthma. Although the region covering the *ORMDL3*, *GSDMA* and *GSDMB* genes has been the most replicated one, the identified 17q21. 2 keratin cluster has also been shown to be associated with asthma in a previous GWAS study. Our findings could benefit targeted obesity prevention among asthmatics and help elucidate pathways involved in the comorbidity of asthma and obesity.

Metabolites of the one-carbon metabolism and the beneficial effects of the gene-Mediterranean diet interaction. *A. Hadjisavvas[1,2], M. G Kakkoura[1,2], K. Sokratous[1], C. A Demetriou[3], M. A Loizidou[1], K. Kyriacou[1,2].* 1) Electron Microscope/Molecular Pathology, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 2) The Cyprus School of Molecular Medicine, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus; 3) Neurology Clinic D, The Cyprus Institute of Neurology and Genetics, Nicosia, Cyprus.

Mediterranean diet (MD) has been shown to decrease breast cancer (BC) risk in the Cypriot women of the MASTOS case-control study (Demetriou *et al.* 2012). However, the prominent molecular mechanisms involved in the interplay between MD and BC risk are still poorly understood. One-carbon metabolism (OCM), where the biological processes of DNA methylation and DNA synthesis are interconnected, is a prominent pathway for studying gene-diet interactions and dietary effects. Particularly, we have previously shown that single nucleotide polymorphisms (SNPs) in two OCM genes, the methylenetetrahydrofolate reductase (*MTHFR* 677C>T, rs1801133; 1298A>C, rs1801131) and methionine synthase (*MTR* 2756A>G, rs1805087) could act as effect modifiers on the association between BC and MD (Kakkoura *et al.* 2015). In our study, we selected to quantify a range of one-carbon metabolites in the serum of women, in order to investigate further the importance of the association between SNPs, MD and BC and to gain insights into the underlying molecular mechanisms. Sera from the controls of the MASTOS study were divided into two groups; low and high adherence to the MD, which was previously, determined as a dietary pattern rich in vegetables, fruit, legumes, fish and olive oil (Demetriou *et al.* 2012). A rapid ultra-performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS) method was used to quantify four one-carbon metabolites of interest (Acquity *I*-Class system coupled to a Xevo-TQD MS system, Waters, UK). These included Vitamins B2, B6, B12 and glutathione. Metabolites were monitored in multiple-reaction monitoring mode and their levels were quantified in 92 samples using external calibration curves. Adjusted coefficient values were determined by linear regression analysis. Vitamin B6 (pyridoxal) was found to be statistically significantly higher (by 0. 4 ng/mL) in serum of women with a high adherence to MD compared to those with a low adherence to MD. No statistically significant associations were observed for the remaining metabolites. Vitamin B6 is a critical coenzyme in the OCM, facilitating the transfer of methyl groups for DNA synthesis and methylation, which are important processes preventing carcinogenesis (Lurie *et al.* 2012). High adherence to the MD was associated with higher serum levels of Vitamin B6, suggesting that Vitamin B6 could be a key player in the OCM via which the MD exerts its anticarcinogenic effects.

African ancestry is associated with intraocular pressure in Latinos. *X. Gao[1], D. Nannini[1], M. Torres[2], Y. Chen[3], K. Taylor[3], J. Rotter[3], R. Varma[2].* 1) Department of Ophthalmology and Visual Sciences, University of Illinois at Chicago, Chicago, IL; 2) USC Eye Institute, Department of Ophthalmology, University of Southern California, Los Angeles, CA; 3) Institute for Translational Genomics and Population Sciences, Los Angeles Biomedical Research Institute at Harbor-UCLA, Torrance, CA.

Intraocular pressure (IOP) is a main risk factor, as well as the only modifiable risk factor, for glaucoma. Racial differences have been observed in IOP measurements with individuals of African descent experiencing the highest IOP measurements when compared to Non-Hispanic Whites and Latinos. The purpose of this study is to examine the relationship between genetic ancestry and IOP in Latinos. We evaluated the genetic ancestry of 3541 Latinos recruited from the Los Angeles Latino Eye Study and assessed the association between IOP and genetic ancestry. Study participants were genotyped using the Illumina OmniExpress BeadChip. We used the program STRUCTURE to estimate individual genetic ancestry. Univariate and multivariate regression analyses were performed to investigate the relationship between genetic ancestry and IOP. African ancestry was significantly associated with IOP in Latinos in our univariate analysis (P = 0. 002). After adjusting for known risk factors, such as age, sex, body mass index, systolic blood pressure, central corneal thickness and type 2 diabetes, African ancestry remained positively associated with IOP (P = 0. 0005). The main association was modified by a significant interaction between African ancestry and systolic blood pressure (P = 0. 037). When stratified by hypertension status, individuals with hypertension experienced a larger increase in IOP with increasing African ancestry. To our knowledge, we demonstrate for the first time that African ancestry and its interaction with hypertension are positively associated with IOP in Latinos.

985F

Reproductive Performance and PON1 L55M Gene Polymorphism in Women Occupationally Exposed to Organophosphate Pesticides. *M. Hema Prasad[1], P. Priyanka[1], B. Chaitanya[1], L. Chandana[1], M. Sailaja[1], P. P Reddy[2], A. Jyothy[1].* 1) Dept of Environmental Toxicology, Institute Of Genetics And Hospital For Genetic Diseases, Hyderabad, Telangana, India; 2) Bhagawan Mahavir Hospital and Research Centre ,Masab Tank,Hyderabad ,Telangana,India.

Background: Organophosphate pesticides (OPs) are a group of toxic insecticides used in agriculture for protection against pests. They persist as environmental contaminants and pose significant risk to human health by causing respiratory disorders, nervous system disorders and certain cancers. Human paraoxonase 1 (PON1) is a lipoprotein-associated enzyme involved in the detoxification of OPs by hydrolyzing the bioactive oxons. PON1 L55M gene polymorphism has been associated with reduced paraoxonase enzyme stability in humans. Earlier studies indicated that exposure to OPs affect reproductive system , which can lead to infertility and an adverse birth out come. In India women agricultural workers are at high risk as they are constantly exposed to OPs during their work. Hence, the present investigation is aimed to study the reproductive performance and association of PON1 L55M gene polymorphism in women occupationally exposed to OPs. **Materials and methods:** In the present study 150 women agricultural workers and 150 age and sex matched healthy controls with same socio economic status were selected. Epidemiological data was collected from exposed and controls using a standard questionnaire. Serum paraoxonase levels were analyzed by ELISA kit method. Gene polymorphisms were detected by using PCR and RFLP. **Results:** Reproductive history of exposed group showed an increased incidence of abortions(13. 10%), still births(3. 77%), premature births(4. 31%), neonatal deaths(3. 41%) and congenital malformations(2. 15%) when compared to controls (4. 88%, 1. 05%, 2. 62%, 1. 41% and 0. 71%) respectively. Serum paraoxonase levels were significantly decreased in the exposed (7. 35 ng/mL) when compared to controls (11. 63 ng/mL). PON1 L55M gene polymorphism results revealed that the frequency of mutant 'A' allele was significantly higher in exposed (34%) when compared to controls (25%) (p=0. 03 & OR=1. 492). **Conclusions:** The epidemiological data revealed an impaired reproductive performance in exposed group when compared to controls which might be attributed to the exposure of women agricultural workers to Organophosphate pesticides. The results also showed significant association of PON-1 L55M gene polymorphism and decreased level of PON-1 in women occupationally exposed to pesticides. **Keywords:** Infertility, Polymorphism, Respiratory System, Nervous System, Cancer.

Obesity is a serious risk factor for cardiometabolic disease. However, variants identified in the recent meta-GWAS on body mass index (BMI) explain only 2. 7% of BMI variance. Taken together with the continuous increase in the worldwide prevalence of obesity, gene-environment interactions (GxEs) likely play a major role in obesity. Accordingly, we hypothesized that obesity activates regulatory DNA variants in adipose tissue and influences gene expression profiles, leading to allele-dependent responses to obesity. Consequently, these regulatory variants may display context-specific expression signatures that differ in the obese vs. non-obese conditions and can be mapped as context-specific expression quantitative trait loci (cseQTL). To identify obesity cseQTLs, we performed eQTL mapping (FDR<1%) using 7,932,277 SNPs with adipose RNA-sequence data on 17,210 expressed genes in 582 men from the Finnish METSIM cohort. We considered the eQTLs only observed in the obese group, but not in the non-obese or overall groups as obese eQTLs (OB), and vice versa for non-obese (NOB). We tested the OB and NOB eQTL genes (egenes) for replication in an independent METSIM cohort (n=771) using adipose microarray data (FDR<5%). Overall, we discovered 1,631 OB egenes, regulated by 17,851 cis (+/-1Mb) variants, and 840 NOB egenes, regulated by 6,134 cis variants. Of these, 55% of the OB and 41% of the NOB egenes were consistent across RNA-seq and microarrays. In both groups, 95% of the independent eQTLs display a nominally significant interaction (P<0. 05) between variants and obesity status using a likelihood ratio test. Furthermore, the OB egenes exhibit higher cis heritability in the OB than NOB groups (p<0. 001 by permutation), suggesting different local regulatory mechanisms. The expression of the top 64 replicated genes with the highest differential cis heritability explains 4. 6% of BMI variance and 3. 6-9. 3% of other metabolic traits, including lipid and amino acid levels. When searching for potential drivers of context-specificity, we observed that estrogen signaling genes were enriched among OB vs. NOB egenes (P=0. 001), including a GWAS BMI gene, *HSD17B12*, that converts estrone into the most active estrogen, estradiol, in adipocytes. In summary, we demonstrate cseQTLs as a new form of GxE in obesity. Specifically, OB egenes exhibit variant-dependent transcriptional regulation mediated by obesity and involve genes in the estrogen pathway as regulators of male obesity.

987T

Evidence for a causal association between obesity and multiple sclerosis through direct and indirect pathways: Results from the Kaiser Permanente MS Research Program. *L. F. Barcellos[1,2], M. Gianfrancesco[1], X. Shao[1], B. Rhead[1], L. Shen[2], H. Quach[1], A. Bernstein[3], C. Shaefer[2,4].* 1) Div Epidemiology-SPH, Univ California, Berkeley, Berkeley, CA; 2) Kaiser Permanente Division of Research, Oakland, CA; 3) Palm Drive Hospital, Sebastopol, CA; 4) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) [MIM 126200] is a demyelinating autoimmune disease that involves both genetic and environmental risk factors. While childhood and adolescent obesity has been associated with a two-fold increased risk of MS, a causal relationship has not been determined. Direct and indirect effects of 97 obesity variants based on a recent genome-wide association study were examined using regression-based mediation analysis to estimate the causal association between obesity and MS susceptibility. Each obesity variant was analyzed to measure the direct and indirect effect of having no risk alleles (*a*=0) versus having two risk alleles (*a*=1) on MS susceptibility, controlled for gender, year of birth, ancestry as determined from EIGENSTRAT components, smoking, education, and number of *HLA-DRB1*15:01* alleles, the strongest genetic predictor of MS. The mediator was defined as self-reported body-mass index (BMI) at age 18 or in one's 20's. Analyses were bootstrapped using 100 replications. Participants included non-Hispanic White members of Kaiser Permanente (1,200 MS cases, 10,000 controls). Common and rare variant data for each candidate gene were obtained through genome-wide association profiling and imputation. Results showed that 29 of the 97 obesity variants demonstrated indirect effects on MS through BMI (odds ratios [ORs] ranging from 1. 01 – 1. 05; p<0. 001). Additionally, 15 variants were directly associated with MS; specifically, 7 were associated with an increased risk of disease (rs1460676, rs11727676, rs13107325, rs17405819, rs12286929, rs2650492, rs6091540; ORs ranging from 1. 18-1. 65; p<0. 001), and 8 were protective of MS (rs7599312, rs11057405, rs9540493, rs10132280, rs4787491, rs9925964, rs3810291, rs2836754; ORs ranging from 0. 67-0. 82; p<0. 001), implying that alternate mechanisms are involved in MS susceptibility that are not mediated by BMI. This research for the first time establishes a causal association between obesity and MS and identifies new variants demonstrating a direct effect on disease susceptibility. Findings have implications for interventions targeting a reduction in MS and extend the understanding of how obesity might increase the risk of developing other autoimmune and neurologic diseases.

988F

Identification of novel candidate genes and pathways for Parkinson Disease through gene-based association tests of rare sequence variants. *K. Nuytemans, L. Maldonado, B. J. Rich, K. John-Williams, E. R. Martin, G. Beecham, W. K. Scott, J. M. Vance.* John P Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL.

Previously, we reported association of several biological pathways (KEGG) with Parkinson Disease (PD) risk using GWAS data (based on common variants with low risk effects) (Edwards et al. PlosOne 2010). Alternatively, the presence of rare variants (RVs) with intermediate risk are believed to explain some of the missing heritability in neurodegenerative disorders. Exons are enriched for these rare intermediate-risk RVs, which can be detected through high throughput sequencing. Identification of genes or pathways with accumulation of RV differences in cases versus controls will further our understanding of PD mechanisms. In order to assess association of genes with PD risk, we performed SKAT-O analyses *in* two datasets with RVs filtered on frequency and/or gene location: WES on 396 cases vs 222 controls and follow-up targeted sequencing of 375 genes in 330 cases vs 166 controls. Results were combined across datasets using SeqMeta. Nominally significant genes (p<0. 05) in both datasets include *CASP6* (apoptosis) and *AP5M1* (lysosomal transport). Top genes nominally significant in the SeqMeta analyses include *TUBA4A* (recently identified in amyotrophic lateral sclerosis) and *ABCB6* (mitochondrial transporter). None of these gene associations remain significant after multiple testing adjustment. Subsequent enrichment analyses in KEGG pathways of the gene-based results were performed using WEB-based GEne SeT AnaLysis Toolkit and GeneSet Enrichment Analyses (GSEA). We observed evidence (adjusted p<0. 05) for association with PD risk for the ABC transporters, olfactory transduction, pancreatic secretion and vascular smooth muscle contraction pathways. Over 50% of the genes contributing to the latter two pathways overlap with the larger calcium signaling pathway (associated in original GWAS pathway study and nominally significant here (p=0. 07)), suggesting that these signals might reflect the effect of the calcium signaling pathway. These data indicate we can detect novel candidate genes for PD using the RV gene-based approach; either genes with functions previously linked to PD or other neurodegenerative disorders (e. g. *CASP6*, *AP5M1, TUBA4A*) or genes with novel functions (e. g. *ABCB6*). The pathway analyses confirm the involvement of olfactory function and calcium signaling in PD development, and provide further evidence for ABC transporters contributing to PD. Further studies are needed to assess the overall involvement of ABC transporters in PD pathogenesis.

989W

Mitochondria haplogroup analysis in primary open angle glaucoma suggests an association with haplogroup T2. *J. L. Wiggs[1], D. Navarro[1], L. Shen[1], J. N. Cooke Bailey[2], J. L. Haines[2], L. R. Pasquale[1], X. Gai[1], NEIGHBORHOOD consortium.* 1) Dept Ophthalmology, Harvard Med Sch, MEEI, Boston, MA; 2) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH.

Primary open angle glaucoma (POAG) is an age-related neurodegenerative disease that is a leading cause of blindness worldwide. Several lines of evidence suggest that mitochondrial dysfunction contributes to glaucoma, and may be an important factor influencing susceptibility to retinal ganglion cell apoptosis and optic nerve degeneration. Previous studies investigating mitochondrial DNA variants in glaucoma have reported conflicting results and have been generally underpowered. The purpose of this study is to investigate the association of mitochondrial DNA (mtDNA) variants and haplogroups with POAG in a large case/control cohort. 2871 cases and 2866 controls were genotyped using both the Illumina 660W and the Illumina HumanExome arrays. Combining the mtDNA SNPs from both platforms, 154 variants were available for single variant analysis after quality control (>0. 98 call rate, MAF > 0. 005). One SNP (m. 12705C>T) demonstrated nominally significant association (initial p-value=0. 00086 and Bonferroni corrected P-value= 0. 13) in the single variant analysis using a logistic regression model that included age and sex as co-variants. Using custom tools based on PhyloTree, 15 mtDNA European haplogroups were identified using 294 unique mtDNA SNP positions represented on the two platforms combined. After comparing haplogroup frequencies in cases and controls the T2 haplogroup was significantly associated with POAG (p = 0. 002, Fisher's exact test Bonferroni corrected). These results support a role for mitochondria in glaucoma and suggest that further studies investigating mtDNA and epistatic interactions with nuclear genes would be of interest.

990T

Cytochrome P450 and Matrix Metalloproteinase Genetic Modifiers of Disease Severity in Cerebral Cavernous Malformation Type 1. *H. Choquet[1], E. Trapani[2, 10], L. Goitre[2, 10], L. Trabalzini[3, 10], A. Akers[4], M. Fontanella[5, 10], B. L. Hart[6], L. A. Morrison[7], L. Pawlikowska[1, 8], H. Kim[1, 8, 9], S. F. Retta[2, 10].* 1) Center for Cerebrovascular Research, Department of Anesthesia & Perioperative Care, University of California, San Francisco, San Francisco, CA, USA; 2) Department of Clinical and Biological Sciences, University of Torino, Orbassano (TO), Italy; 3) Department of Biotechnology, Chemistry and Pharmacy, University of Siena, Siena, Italy; 4) Angioma Alliance, Durham, North Carolina, USA; 5) Department of Neurosurgery, Spedali Civili and University of Brescia, Brescia, Italy; 6) Department of Radiology, University of New Mexico, Albuquerque, New Mexico, USA; 7) Departments of Neurology and Pediatrics, University of New Mexico, Albuquerque, New Mexico, USA; 8) Institute for Human Genetics, University of California, San Francisco, California, USA; 9) Department of Epidemiology and Biostatistics, University of California, San Francisco, California, USA; 10) CCM Italia research network (www. ccmitalia. unito. it).

Background: Familial Cerebral Cavernous Malformation Type 1 (CCM1) is an autosomal dominant disease caused by *CCM1* mutations, and characterized by multiple brain lesions. CCM lesions manifest across a range of different phenotypes, including wide differences in lesion number, size and susceptibility to intracerebral hemorrhage (ICH). Oxidative stress plays an important role in cerebrovascular disease pathogenesis, raising the possibility that inter-individual variability in genes related to oxidative stress may contribute to the phenotypic differences observed in CCM1 disease. Here, we investigated whether candidate oxidative stress-related cytochrome P450 (CYP) and matrix metalloproteinase (MMP) single nucleotide polymorphisms (SNPs) grouped by superfamily, family or gene, or analyzed individually influence the severity of CCM1 disease. *Methods:* Clinical assessment and cerebral susceptibility-weighted magnetic resonance imaging were performed to determine total and large (≥5 mm in diameter) lesion counts as well as ICH in 188 CCM1 patients harboring the founder *CCM1* 'common Hispanic mutation' (CCM1-CHM). Samples were genotyped on the Affymetrix Axiom Genome-Wide LAT1 Human Array. We analyzed 1,122 SNPs grouped by CYP and MMP superfamily, family or gene for association with total or large lesion count and ICH adjusted for age and gender, using the SNP "set-based test" (PLINK v1. 07) which corrects *P*-values for the multiple SNPs tested within a set. SNPs bearing the associations were then analyzed individually. *Results:* The CYP superfamily was borderline associated with total lesion count (*P*=0. 057) and large lesion count (*P*=0. 088) in contrast to the MMP superfamily. The CYP4 and CYP8 families were associated with either large lesion count or total lesion count (*P*=0. 014), and two other families (CYP46 and the MMP Stromelysins) were associated with ICH (*P*=0. 011 and 0. 007, respectively). *CYP4F12* rs11085971, *CYP8A1* rs5628, *CYP46A1* rs10151332, and *MMP3* rs117153070 single SNPs mainly bearing the above-mentioned associations were also individually associated with CCM1 disease severity. *Conclusions:* Overall, our candidate oxidative stress-related SNP set approach outlined CYP and MMP families and identified suggestive SNPs that may impact the severity of CCM1 disease, including the development of numerous and large CCM lesions and ICH. These novel genetic risk factors of prognostic value could serve as early objective predictors of disease outcome.

991F

Identification of NSCL/P candidate genes following knockdown of *crispld2*. *B. Chiquet[1,2], L. Maili[1], R. Plant[1], J. Dyke[4], R. Boyer[4], Q. Yuan[1], E. Swindell[1], A. Letra[1,3], S. Blanton[5], J. Hecht[1,4].* 1) Dept Pediatrics, Univ Texas Med Sch, Houston, Houston, TX; 2) Department of Pediatric Dentistry, UTHouston School of Dentistry, Houston, TX; 3) Department of Endodontics, UTHouston School of Dentistry, Houston, TX; 4) University of Texas School of Dentistry, Houston, TX; 5) John P. Hussman Institute for Human Genomics, University of Miami Health System, Miami, FL.

Orofacial development is a multifaceted process involving many tightly regulated gene signaling pathways. Perturbation of any of these genes can lead to malformations, including cleft lip and palate. We and others have shown that *CRISPLD2* is associated with nonsyndromic cleft lip with or without cleft palate (NSCL/P). Recently we have shown that Crispld2 knockdown in zebrafish alters neural crest cell migration patterns, resulting in abnormal jaw and palate development. To identify genes that are affected by knockdown of Crispld2, RNA profiling was completed comparing RNA expression levels of wild-type and Crispld2 knockdown zebrafish embryo heads at 16 hours. 349 unique genes were found to be differentially expressed. Pathway analysis of these genes identified a network of eight genes previously implicated in orofacial development: *BAG3, CASP8, FGFR1, FOS, HOXb1b, JAG2, KIF1B,* and *MMP2.* Quantitative mRNA expression analysis confirmed the differential expression of *CASP8, FGFR1, FOS, KIF1B,* and *MMP2* transcripts in total body RNA extracted from the anterior half of developing 16h post fertilization zebrafish embryos. We genotyped our nonHispanic white and Hispanic NSCLP datasets with 26 SNPs in these eight genes; data were then stratified by ethnicity and presence or absence of a family history of clefting and analyzed using FBAT and APL. We identified significant associations between *FOS*/rs1046117 and NSCL/P in our nonHispanic white all and negative family history dataset (p=0. 0005) and *MMP2*/rs243836 in our Hispanic positive family history dataset (p=0. 002). Significant haplotype associations were also identified in *FGFR1* and *JAG2* in our nonHispanic white dataset and in *MMP2* for our Hispanic dataset (p<0. 002). Gene-gene interaction analysis was also performed revealing twenty-two significant interactions among *KIF1B-MMP2*, *CASP8-JAG2*, *CASP-FOS*, *HOXA1-JAG2*, *BAG3-FOS*, *BAG3-JAG2*, *FOS-JAG2*, and *JAG2-MMP2* (p≤0. 002). Overall, the strongest associations with NSCL/P were seen with *FOS* and *MMP2* genes. The results of this study demonstrate a unique method of identifying NSCL/P candidate genes. Additionally, they may offer valuable insights towards potential mechanisms through which *CRISPLD2* may function during orofacial development.

SNPs, Linkage Disequilibrium and Transcriptional Factor Binding Sites Associated with Acute Mountain Sickness among Han Chinese at the Qinghai-Tibetan Plateau. *N. Buroker[1], X-H. Ning[2], Z-N. Zhou[4], K. Li[3], W-J. Cen[3], X-F. Wu[4], W-Z. Zhu[5], CR. Scott[1], S-H. Chen[1].* 1) Pediatrics, 356320, University of Washington, Seattle, WA; 2) Division of Cardiology, Seattle Children's Hospital. Institute. Foundation, Seattle, WA USA; 3) Lhasa People Hospital, Tibet; 4) Laboratory of Hypoxia Physiology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, China; 5) Center for Cardiovascular Biology and Regenerative Medicine, University of Washington, Seattle, WA USA.

Acute mountain sickness (AMS) occurs in up to 50% of individuals ascending to high altitudes greater than 2600 meters. An AMS Han Chinese and a normal Han group were compared. 17 simple nucleotide polymorphisms (SNPs) within 9 genes that have been associated with AMS were analyzed with respect to linkage disequilibrium (LD) between intra- and intergenic SNP alleles and alterations in transcriptional factor binding sites (TFBS). Included in the study was the angiotensin-converting enzyme (ACE) (rs4340), the angiotensinogen (*AGT*) (rs699) and the angotensin II type 1 receptor (*AGTR1*) (rs5186) SNPs from the renin-angiotension system (RAS) as well as the *GNB3* (rs2071057) SNP from G-protein signaling and a LDL apolipoprotein B (*APOB*) (rs693) SNP. The endothetal Per-Arnt-Sim (PAS) domain protein 1 (*EPAS1*) SNP and two egl nine homolog 1 (*EGLN1*) SNPS (rs480902 and rs516651) from the hypoxia-inducible factor (HIF) oxygen signaling pathway were included. SNPs analyzed in the vascular endothelial growth factor (VEGF*)* signaling pathway are the v-akt murine thymoma viral oncogene homolog 3 (*AKT3*) (rs4590656 and rs2291409), the endothelial cell nitric oxide synthase 3 (*eNOS3*) (rs1007311 and rs1799983) and the (*VEGFA*) (rs79469752, rs13207351, rs28357093, rs1570360 and rs3025039). These SNP alleles alter the TFBS for TF binding. Pair-wise LD was computed between SNPs. An increase in LD occurred in 32 pair-wise comparisons while a decrease was found in 22 pair-wise comparisons between the AMS and controls. Increases and decreases in LD pairs were found within and between signaling pathways and systems indicating the interaction of SNP alleles or potential TFBS from different areas of the genome. The most drastic change in TFBS occurs with ACE (I/D) SNP (rs4340) where the ACE-I allele generates 84 potential TFBS while the ACE-D allele generates only four binding sites. The alteration in TFBS generated by the 17 SNPs is discussed with respect to AMS.

993T

Neural Tube Defect candidate genes are associated with a fumonisin B1 biomarker among at-risk Guatemalan women. *M. Garrett[1], K. Soldano[1], R. Riley[4], O. Torres[5,6], J. Matute[6], K. Voss[4], J. Gelineau-Van Waes[3], S. Gregory[2], A. Ashley-Koch[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 3) Department of Pharmacology, Creighton University, School of Medicine, Omaha, NE; 4) Toxicology and Mycotoxin Research Unit, R. B. Russell Research Center, USDA - ARS, Athens, GA; 5) Laboratorio Diagnostico Molecular S. A. , Guatemala City, Guatemala; 6) Centro de Investigaciones en Nutricion y Salud, Guatemala City, Guatemala.

Neural tube defects (NTDs) are congenital defects occurring when the neural tube fails to close during embryonic development. The incidence of NTDs is particularly high in Guatemala, China, and the Transkei of South Africa, where maize is a dietary staple. Fumonisin B1 (FB1), a mycotoxin produced by the mold *Fusarium verticillioides* which contaminates corn, may contribute to this increased risk (Marasas et al. , 2004). FB1 inhibits ceramide synthase causing depletion of complex sphingolipids and increased production of the sphingolipid metabolites sphingosine 1-P (So1P) and sphinganine 1-P (Sa1P), which can be used as biomarkers of FB1 exposure (Merrill et al. , 2001). To investigate genetic mechanisms disrupting sphingolipid biosynthesis, we ascertained women from Guatemalan departamentos with high and low FB1 exposure. FB1 was measured in urine; So1P and Sa1P levels were measured in blood. DNA was extracted from blood spots and 259 single nucleotide polymorphisms (SNPs) in 25 genes that are either known NTD or sphingolipid metabolism genes were genotyped. Quality control (QC) was performed with PLINK (Purcell et al. , 2007) and principal component (PC) analysis was run using EIGENSOFT (Patterson et al. , 2006). After QC, 627 samples and 253 SNPs remained. Linear regression in PLINK was used to test for association between each SNP and sphingolipid metabolites (So1P and Sa1P), controlling for age, departamento, two PCs, and FB1. False-discovery rate (FDR) q-values were calculated in SAS (SAS Systems, Cary, NC). rs2296783 in TCF7L2 was significantly associated with Sa1P, such that for each additional T allele, Sa1P concentration decreased (FDR q=0. 0311). Five SNPs in TCF7L2, S1PR3, TEAD1, DAAM1, and VANGL1 were nominally associated with Sa1P levels (FDR q-values < 0. 2). TCF7L2 is involved in blood glucose homeostasis, common SNPs in which have been associated with type 2 diabetes (Grant et al. , 2006). However, several TCF7L2 splice variants have been identified that disrupt the wnt signaling pathway (Prokunina-Olsson et al. , 2009), which has been heavily implicated in NTDs. Also, maternal SNPs in TCF7L2 have been associated with increased risk of having an NTD-affected pregnancy among obese women (Lupo et al. , 2012). These data provide increased support for a connection between sphingolipid metabolism (altered by FB1 exposure) and NTDs. Future work is needed to replicate these findings and understand the functional mechanisms leading to these associations.

994F

Regulatory annotations implicate thousands of independent disease-associated variants. *A. K. Sarkar[1,2], L. D. Ward[1,2], M. Kellis[1,2].* 1) CSAIL, Massachusetts Institute of Technology, Cambridge, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA.

For most complex traits, known genetic associations only explain a small fraction of the narrow sense heritability (the “missing heritability problem”), prompting intense debate on the genetic basis of complex traits. Here, we use epigenomic annotations across 127 tissues and cell types to investigate the role of weakly associated variants in complex disease. Focusing on Type 1 Diabetes (T1D), we show that weakly associated variants are significantly enriched in immune cell enhancers across thousands of independent loci and additionally enriched in accessible chromatin, in T1D–relevant pathways, and near relevant regulatory motifs. These results are robust to controlling for linkage disequilibrium both between weakly associated variants and between non-coding and coding variants. Moreover, weakly associated variants explain the bulk of heritability attributable to all common variants, suggesting a dramatically larger number of loci than currently suspected may underlie T1D and other complex traits.

995W

Cholesterol transport and beta-amyloid regulation polygenic risk scores as predictors of beta-amyloid levels in a sample at increased risk for Alzheimer’s disease. *B. F. Darst[1], R. L. Koscik[2], B. T. Christian[3], A. M. Racine[4], J. M. Oh[4], B. P. Hermann[2,5], C. M. Carlsson[2,4,6], K. Hogan[7], S. C. Johnson[2,4,7], C. D. Engelman[1,2].* 1) Department of Population Health Sciences, University of Wisconsin, Madison, Madison, WI; 2) Wisconsin Alzheimer’s Institute, University of Wisconsin School of Medicine and Public Health, Madison, WI; 3) Department of Medical Physics, University of Wisconsin School of Medicine and Public Health, Madison, WI; 4) Alzheimer’s Diseases Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI; 5) Department of Neurology, University of Wisconsin School of Medicine and Public Health, Madison, WI; 6) Geriatric Research Education and Clinical Center, Wm. S. Middleton Memorial VA Hospital, Madison, WI; 7) Department of Anesthesiology, University of Wisconsin School of Medicine and Public Health, Madison, WI.

Background: Although large genome-wide association studies have collectively identified thousands of genetic variants associated with complex diseases, individual variants often have very small effects. Polygenic risk scores (PRS) combine the effects of these variants, often increasing power. Use of disease-related biomarkers can further increase power. For example, accumulation of beta-amyloid (Ab) between nerve cells in the brain is a hallmark of Alzheimer’s disease (AD) pathology and may be used as a biomarker of AD. Methods: Participants were from the Wisconsin Registry for Alzheimer’s Prevention, a longitudinal family-based study of initially asymptomatic adults enriched for a parental history of AD. Using the genes associated with AD in the International Genomics of Alzheimer’s Project’s (IGAP) meta-analysis, we identified clusters of genes that grouped into pathways involved in Ab deposition: Ab regulation (*SORL1*, *PICALM*, *ABCA7*, *CLU*, and *APOE*) and cholesterol transport (*ABCA7*, *CLU*, and *APOE*). Two pathway-specific weighted PRS were formed using the single most significant variant in each gene in the IGAP meta-analysis. Mixed models were used to assess whether each PRS was associated with cerebral Ab deposition in eight regions-of-interest measured using Pittsburgh compound B positron emission tomography (PET) in 168 individuals, and with cerebral spinal fluid (CSF) Ab42/Ab40 levels in 111 individuals. Results: A higher cholesterol PRS was associated with greater PET Ab (P=. 003) and lower CSF Ab (P<. 0001), both indicating a higher risk for developing AD. *APOE* alone was a significant predictor of PET Ab (P=. 01) and CSF Ab (P<. 0001) and, as expected, removing *APOE* from the cholesterol PRS attenuated the associations (P=. 19 and P=. 02, respectively). Similarly, a higher Ab PRS was associated with greater PET Ab (P=. 002) and lower CSF Ab (P<. 0001), and removing *APOE* from the Ab PRS attenuated the associations (P=. 21 and P=. 11, respectively). Conclusion: Although the statistical significance between the pathway-specific PRS and Ab levels are largely driven by *APOE*, there is consistent evidence for a combined effect of variants in other genes with elevated Ab deposition, despite the relatively small sample size. Cholesterol transport and Ab regulation PRS may be informative in explaining variations in Ab levels. Moreover, the use of pathway-specific PRS to examine specific biomarkers of disease is a promising new use of genome-wide association findings.

Genome-wide gene-set analysis identifies different patterns of genetic sharing across complex phenotypes. *H. Gui[1], J. Kwan[2], P. Sham[1,2,3], S. Cherny[1,2,3], M. Li[1,2].* 1) Centre for Genomic Sciences, The University of Hong Kong, Hong Kong SAR, China; 2) Department of Psychiatry, The University of Hong Kong, Hong Kong SAR, China; 3) The State Key Laboratory of Brain and Cognitive Sciences, The University of Hong Kong, Hong Kong SAR, China.

As an important complement to individual SNP analysis and gene-based analysis for a typical genome-wide association study (GWAS), GWAS gene-set analysis has the potential to discover hidden disease susceptibility genes by combining statistical evidence with biological knowledge. Recently a gene-set analytical tool 'MAGMA' has been developed to handle polygenic traits using more reasonable and powerful competitive test. Here we adopt both classical gene-set enrichment analysis (hypergeometric test implemented in KGG; http://statgenpro.psychiatry.hku.hk/limx/kgg/) and MAGMA on GWAS summary statistics of six diseases or traits (Crohn's disease (CD), rheumatoid arthritis (RA), schizophrenia (SCZ), bipolar disorder (BPD), low-density cholesterol (LDL) and high-density cholesterol (HDL) level) to look for pathways/gene-sets important for their normal functioning or abnormal pathogenesis. Though no gene-set was significantly associated with two psychiatric diseases, we found a few gene-sets enriched with susceptibility genes for other four phenotypes. Interestingly those LDL/HDL shared gene-sets involving in lipid metabolism or transport are mainly due to pleiotropic apolipoprotein genes for both phenotypes; however, those CD/RA shared gene-sets are ascribed to different phenotype-specific genes which are all important to immune response. Our study reveals that genetic sharing at advanced gene-set level can sometimes provide better perspective to explain disease comorbidity.

Integrated molecular phenotyping in chondrocytes identifies genes and pathways disrupted in osteoarthritis. *J. Steinberg[1], G. Ritchie[1,2], T. I. Roumeliotis[1], A. L. A. Binch[3], R. Coyle[1], M. Pardo[1], C. L. Le Maitre[3], J. Choudhary[1], J. M. Wilkinson[4], E. Zeggini[1].* 1) Wellcome Trust Sanger Institute, Cambridge, UK; 2) European Molecular Biology Laboratory, European Bioinformatics Institute, Cambridge, UK; 3) Biomolecular Sciences Research Centre, Sheffield Hallam University, Sheffield, UK; 4) Department of Human Metabolism, The Mellanby Centre for Bone Research, University of Sheffield, Beech Hill Road, Sheffield, UK.

Osteoarthritis (OA) is a degenerative joint disease that affects over 40% of individuals over the age of 70, and is a leading cause of pain and loss of physical function. OA is a disease of cartilage degeneration, but the underlying molecular changes are poorly understood. There is no treatment for OA; instead, disease management targets pain and joint stiffness, and culminates in joint replacement surgery. To gain insights into the molecular etiology of OA, we applied a genome-wide multi-omics approach based on DNA methylation, gene transcription and relative protein abundance. We compared chondrocyte samples extracted from affected and relatively healthy articular cartilage from the joints of 12 OA patients. Importantly, we aimed to identify genes and biological pathways that show association on several molecular levels. In the first step, we identified 271 differentially methylated regions containing 296 unique genes, 349 differentially expressed genes, and 209 proteins with evidence for differential abundance. Integration analysis highlighted genes that are consistently affected, including *AQP1*, *CLEC3B* and *COL1A1*, coding for aquaporin-1, tetranectin and a collagen protein, respectively. The carbonic anhydrase inhibitor Acetazolamide is a known inhibitor of aquaporin-1, suggesting a possible therapeutic route. The thrombolytic agent Tenecteplase, an engineered form of fibrin-specific tPA, binds to tetranectin; the consequences of this binding in OA warrant investigation. We carried out gene set enrichment tests for Gene Ontology (GO), and separately, KEGG and Reactome gene sets, in all three data types. For each gene set, we combined the three association *p*-values using the geometric mean, and obtained an empirical *p*-value for the combined statistic. We identified several consistently implicated biological pathways converging on extracellular matrix organization, collagen formation, cell signaling or adhesion, and skeletal system development. We found that several of these gene sets also show evidence for association from OA GWAS data, although not more so than some other gene sets. These results provide a first view of the integrated molecular landscape underpinning OA development in primary chondrocytes, point to potential therapeutic avenues, and highlight the translational potential of integrated functional genomics.

998W

Identification of disease-specific eQTLs in asthma and COPD cases but not healthy controls. *D. C. Croteau-Chonka[1], M. van den Berge[2], P. J. Castaldi[1], C. P. Hersh[1], V. J. Carey[1], E. K. Silverman[1], A. Spira[3], P. Zanen[4], C. Wijmenga[5], H. M. Boezen[6], H. J. M. Groen[2], W. Mali[7], G. H. Koppelman[8], D. S. Postma[2], S. T. Weiss[1], B. A. Raby[1].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) University of Groningen, University Medical Center Groningen, Department of Pulmonology, Groningen, The Netherlands; 3) Division of Computational Biomedicine, Departments of Medicine and Pathology, Boston University, Boston, MA; 4) Department of Pulmonology, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Department of Genetics, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands; 6) University of Groningen, University Medical Center Groningen, Department of Epidemiology, Groningen, The Netherlands; 7) Department of Radiology, University Medical Center Utrecht, Utrecht, The Netherlands; 8) University of Groningen, University Medical Center Groningen, Department of Pediatric Pulmonology and Pediatric Allergology, Beatrix Children's Hospital, Groningen, The Netherlands.

RATIONALE: Epidemiological data supports an etiological link between asthma and chronic obstructive pulmonary disease (COPD), suggesting that COPD susceptibility is increased among asthmatics. We hypothesize that fixed airway obstruction (and ultimately COPD) susceptibility in asthma is conferred by regulatory genetic variants that induce critical perturbations of specific genes in immunoregulatory cells. The aim of this study was to determine the overlap of expression quantitative trait loci (eQTL) identified in asthma and COPD cases and to prioritize candidates for further disease-susceptibility testing and functional characterization. **METHODS:** We performed a fixed-effects meta-analysis of eQTL associations in whole blood samples from three cohorts: Childhood Asthma Management Program [CAMP] (202 asthma cases), COPD Pathology: Addressing Critical gaps, Early Treatment & diagnosis and Innovative Concepts [COPACETIC] (158 COPD cases and 267 controls), and Evaluation of COPD Longitudinally to Identify Predictive Surrogate Endpoints [ECLIPSE] (121 COPD cases). To detect disease-specific eQTL shared between asthma and COPD cases but not observed in healthy controls, we formally tested eQTL identified by meta-analysis for evidence of heterogeneity (Cochran's *Q* test). **RESULTS:** Using this combined cohort of 748 subjects, we identified 4,513 significant eQTLs (444 genes) at a very conservative Bonferronithreshold of $P < 7.7E-08$ among 646,919 SNP-gene pairs tested. For a subset of 135 eQTLs (28 genes), significant associations were noted in the asthma and COPD cases ($P < 0.05$) but not in the healthy controls. Among these were regulatory variants targeting *ASRGL1*, a gene previously associated with the COPD biomarker CC16, and ones targeting *CHI3L2* and *ORMDL1*, which are in the same families as two reported asthma genes. Pathways enriched among shared disease-specific eQTL genes (FDR < 5%) included targets of *MIRNA-34B* (expressed in COPD sputum and associated with emphysema) and of *MIRNA-18A* (associated with asthma). **CONCLUSION:** Preliminary association meta-analysis results suggest the existence of disease eQTLs both common and specific to asthma and COPD with potential links to known genetic risk factors for respiratory diseases and to relevant inflammatory biology pathways. The identification of eQTLs via disease-ascertained study cohorts helps inform our understanding of important genetically-modified disease pathways.

A cell type specific gene expression signature of Alzheimer's disease pathogenesis from meta-analysis of publically available microarray data. *J. Chen, A. Zhang.* Verge Analytics Inc. , Mountain View, CA.

Alzheimer's disease (AD) is the leading cause of dementia worldwide and a growing public health concern. However, the key molecular pathways and gene networks involved in AD are not clearly understood. In order to gain a clearer understanding of disease pathogenesis, we performed a meta-analysis of 31 published gene expression studies in AD patients, mouse models, and cell models, across several cell types and microarray platforms. The raw data from each study was preprocessed (background subtraction and normalization) and quality controlled. Differentially expressed genes between the AD and control conditions were identified for each condition. Using Weighted Gene Coexpression Network Analysis (WGCNA), we found several gene network modules correlated with disease and that were preserved between multiple experiments. We then leveraged data from the International Genomics of Alzheimer's Project (IGAP) genome-wide association meta-analysis to predict the causality of the identified gene network modules. Using these approaches, we derived a gene network signature of Alzheimer's disease through meta-analysis of raw microarray data.

1000F

Promoter polymorphisms in Wnt signaling pathway are associated with tuberculosis risk in Chinese subjects. *X. Hu, J. Y. Zhang, Z. Z. Zhao, X. B. Song, X. J. Lu, B. W. Ying, L. L. Wang.* West China Hospital, Chengdu , China.

Introduction: Compelling studies have indicated that Wnt signaling pathway plays an important role in the development of tuberculosis, however, the exact mechanism remains unknown. For the first time, we took a pathway based candidate gene approach in Chinese population to investigate the associations of promoter polymorphisms within Wnt signaling pathway with tuberculosis. **Methods:** Twenty-three single nucleotide polymorphisms (SNPs) from promoter regions of five key genes in the Wnt signaling pathway (Wif1, Dkk1, Sfrp1, Wnt3a, Wnt5a, Ctnnbl) were selected via searching the dbSNP database. The genotype analyses were conducted by the Massarray method for 973 unrelated Chinese subjects. Inflammatory markers C-reactive protein (CRP), erythrocyte sedimentation rate (ESR) and hematocrit (Hct) were also detected using IMMAGE® 800 and Test® 1. Gene mRNA expressions were measured by real-time PCR on a subset of 416 subjects whose buffy coat fractions were available. Logistic regression analyses were conducted to test the associations of polymorphisms with tuberculosis risk and inflammatory markers. **Results:** The study group comprised of 478 tuberculosis patients and 495 control subjects, and no significant differences in age and sex were observed (p=0. 105, 0. 343, respectively). Genotype distributions of all SNPs agreed with Hardy-Weinberg equilibrium (p all > 0. 05). Rs3864004, rs9859392 and rs9870255 of Ctnnb1 gene and rs4736958 in Sfrp1 gene were associated with decreased tuberculosis risk, from allele and genotype distributions and dominant model (p all <0. 05). The T allele and recessive mode of rs7832767 in Sfrp1 may increase the risk of tuberculosis [OR = 1. 26(1. 03-1. 53), 1. 99(1. 25-3. 16), p=0. 022, 0. 004, respectively]. MRNA expressions of Ctnnb1 and Wnt3a in tuberculosis cases were significantly higher than those in healthy controls (15. 21 ± 3. 10 *vs.* 5. 28 ± 1. 09, 0. 09 ± 0. 02 *vs.* 0. 59 ± 0. 16, p both<0. 001, respectively), while the genotype distributions of these target SNPs were not associated with mRNA expression (p all>0. 05). Rs4736958 and rs7832767 related to CRP expression level (p=0. 016, 0. 018), and heterozygous TC patients showed a higher level of CRP. **Conclusions:** Ctnnb1 and Sfrp1 promoter polymorphisms are associated with tuberculosis susceptibility. Further functional studies are warranted to verify our results.

Mining Longitudinal BMI, as a Cachexia Proxy, for Common Genetic Determinants among COPD and Cancer Cases in the Framingham Heart Study. *M-L. N. McDonald[1], M. Mattheisen[1,2], S. Won[3], M. H. Cho[1,4], M. Hardin[1,4], G. O'Connor[5,6], C. Hersh[1,4], E. K. Silverman[1,4].* 1) Channing Division of Network Medicine, Brigham & Women's Hosp/Harvard Sch Med, Boston, MA; 2) Department of Biomedicine and Centre for integrative Sequencing (iSEQ), Aarhus University, Aarhus, Denmark; 3) Department of Public Health Science, Seoul National University, South Korea; 4) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) The National Heart, Lung, and Blood Institute's Framingham Heart Study, Framingham, MA; 6) Section of Pulmonary, Allergy, and Critical Care Medicine, Department of Medicine, Boston University School of Medicine, Boston, MA.

Cachexia, a rapid change in weight including the loss of muscle, is an ominous prognostic indicator for many chronic diseases including chronic obstructive pulmonary disease (COPD) and cancer. However, the majority of population-based studies of cachexia employ cross-sectional body mass index (BMI) to classify cases. To test the hypothesis that shared genetic variants influence cachexia in COPD and cancer cases, we analyzed longitudinal BMI data as a proxy for cachexia using data from the Framingham Heart Study (FHS). To achieve this aim, we ran 6 genome-wide association studies (GWAS) within COPD (N=344), all cancer (N=1085), breast cancer (N=233), prostate cancer (N=231), gastrointestinal (GI) cancer (N=231) and lung cancer (N=112) cases. We used a two step procedure by first calculating a BMI slope phenotype using a random slope and intercept linear mixed model accounting for age, sex and change in smoking status as fixed effects. Only participants with BMI measurements at 3 consecutive time points in the Original or Offspring cohorts were included in the analysis. As the second step, generalized estimating equations (GEE) were used to test for association between 418,365 SNPs and BMI slopes. Two SNPs reached a level of genome-wide significance: rs2024759, an intergenic variant, among lung cancer cases (b=-0. 083, *P*=2. 9x10-8) and rs4751240, in *DOCK1,* among GI cancer cases (b=0. 10, *P*=4. 0x10-9). We performed gene-set enrichment analysis of 7 genes (*ASIC2, CDH13, CNTN4, CSMD1, DLG2, ERBB4, FHIT*) common to the top 1% of the 6 GWAS and *DOCK1* to discover gene-sets relevant to cachexia including those involved with steroid hormone pathways. This list of genes was input to GeneMANIA as a query list to reveal a highly connected disease network module via physical interactions, genetic interactions, co-expression and co-localization. In summary, we were unable to demonstrate that shared genetic variants influence changes in BMI among COPD and cancer cases in the FHS. However, we were able to provide evidence for a common disease network module comprising genes relevant to cachexia in COPD and cancer cases.

Novel pathways identified from blood-based transcriptomic profiling of kidney function and chronic kidney disease in the Framingham Heart Study. *A. Y. Chu[1], Q. Yang[2], S. Hwang[1], D. Levy[1], C. S. Fox[1].* 1) NIH/NHLBI Framingham, Framingham, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston MA.

Chronic kidney disease (CKD) is a global public health concern and is associated with increased risk for end-stage renal disease, cardiovascular disease and all-cause mortality. Over 50 genetic loci have been identified in genome-wide associations studies of estimated glomerular filtration rate (eGFR), a measurement of kidney filtration used to diagnose CKD. However, these variants explain a small proportion of total heritability of eGFR indicating that additional factors, such as gene expression and DNA methylation may be involved in kidney function and subsequently CKD. We aimed to identify novel genes and pathways associated with kidney function by testing the correlation of gene expression levels measured on the Affymetrix Human Exon ST Array from whole blood of 5,624 Framingham Heart Study participants with cross-sectionally measured eGFR (calculated using serum creatinine level and the Modification of Diet in Renal Disease [MDRD] equation) and CKD (eGFR<60mL/min/1. 73 m2; Ncases=340 and Ncontrols=5,284) and to perform pathway analysis using the Gene Ontology (GO) database using the WebGestalt interface (http://bioinfo. vanderbilt. edu/webgestalt/). Of the 17,873 transcripts tested, 219 were correlated with both eGFR (false discovery rate [FDR]<0. 01) and differentially expressed in CKD (FDR<0. 01) including *PIP5K1B*, a known eGFR locus from GWAS. The majority of pathways identified by analysis of the GO database (all padj[multiple testing adjusted] <0. 01) were involved in renal system development, and macromolecule modification and metabolism. However, additional pathways related to DNA damage and cell cycle regulation (padj<0. 01) were also significantly enriched for genes correlated with kidney function and CKD. When the list of 219 genes was stratified by direction of differential expression with CKD status, the 157 genes with higher expression levels among those with CKD were enriched in pathways involving protein metabolism and modification (padj<0. 01) whereas the 62 genes with lower expression levels among those with CKD were enriched in pathways involving metabolism of organic and aromatic compounds (padj<0. 01). Our results suggest that in addition to pathways for kidney development (the organ's structural framework) and processing and filtering xenobiotics (a primary function of the renal system), mechanisms and genes involved in DNA stability and cellular turnover may potentially influence CKD risk.

1003F

Whole exome sequencing of very early-onset inflammatory bowel disease shows both family-based and case/control associations with *CCDC40* and *MAPK12*. *C. J. Cardinale[1], Z. Wei[2], L. Tian[1], L. Lima[1], N. Dawany[3], M. Devoto[4], R. N. Baldassano[3], H. Hakonarson[1], J. R. Kelsen[3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Computer Science, New Jersey Institute of Technology, Newark, NJ; 3) Division of Gastroenterology, Children's Hospital of Philadelphia, Philadelphia, PA; 4) Division of Genetics and Molecular Biology, Children's Hospital of Philadelphia, Philadelphia, PA.

We performed whole exome sequencing on 309 samples including 118 probands and 191 parents and family members in a trio setting for very early-onset inflammatory bowel disease (VEOIBD), that is, IBD with an onset before age 5 years. GATK was employed for multi-sample variant calling for these trios, followed by rigorous QC, which yielded a set of 292,084 variants with high quality. We then performed the transmission disequilibrium test (TDT) for these variants to identify overtransmission of non-synonymous SNVs. We found statistically significant nsSNPs in *PZP*, *SLC7A6OS*, *PCSK5*, and *MAPK12* ($P < 0.001$, $\alpha 2$). In a complimentary analysis we performed case/control association by utilizing a healthy control cohort of 253 exomes for prioritizing nsSNPs (genomic inflation = 1. 0). The top hits were two intron-retaining variants in *CCDC40* (coiled coil domain containing 40) a protein involved in the function of motile cilia ($P < 5.19 \cdot 10\text{-}8$). *MAPK12* was also found in the case/control analysis at $P < 4.97 \cdot 10\text{-}5$. *MAPK12* encodes ERK6, a p38 MAP kinase which is part of the intracellular signaling pathway activated by proinflammatory cytokines or physical stress leading to direct activation of transcription factors. We conclude that rare non-synonymous SNVs within the *CCDC40*

and *MAPK12* genes are associated with VEOIBD.

1004W

Mutational burden in candidate genes for Chiari Type I Malformation is associated with the co-occurrence of connective tissue disorders. *K. Soldano[1], M. Garrett[1], H. Cope[1], S. Gregory[2], A. Ashley-Koch[1].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham,NC.

Chiari Type I Malformation (CMI) is characterized by herniation of the cerebellar tonsils below the foramen magnum, resulting in significant neurologic morbidity. Some forms of CMI co-occur with connective tissue disorders (CTD) and may have a unique patho-mechanism due to cranio-cervical instability. Thus, CMI with CTD (CTD+) may have different genetic risk factors than CMI without a history of CTD (CTD-). Based on previous whole genome linkage analyses (Markunas et al. , 2013 and 2014), we prioritized 28 CMI-relevant candidate genes located under linkage peaks for deep sequencing to identify putative functional variants. The TruSeq Custom Amplicon assay (Illumina, San Diego, CA) was used to amplify coding and highly conserved regulatory regions of these genes. The resulting 1528 amplicons were sequenced on an Illumina MiSeq. Primers were trimmed from raw reads using FASTX-Toolkit and reads were aligned using BWA (Li and Durbin, 2009). Variants were called and quality filtered according to best practices in GATK (Van der Auwera et al. , 2013) and were annotated using ANNOVAR (Wang et al. , 2010). 801 variants remained after processing. To determine if rare variants (MAF < 5%) were associated with CTD status, we used the gene-based optimal sequence kernel association test (SKAT-O; Wu et al. , 2011; Lee et al. , 2012). CTD+ patients were more likely than CTD- patients to have rare variants in *LHX4* (OR=2. 6, p=0. 02) while CTD+ patients were less likely than CTD- patients to have rare variants in *MAFF* (OR=0. 24, p=0. 03). Restricting analysis to coding variants revealed an association with *NCOR1*, such that CTD+ patients were less likely than CTD- patients to have rare coding variants (OR=0. 15, p=0. 04). All three genes may play a role in CMI pathogenesis. Mutations in *LHX4* are associated with combined pituitary hormone deficiencies, a small sella turcica, and Chiari malformations (Machinis et al. , 2001; Tajima et al. , 2007; Castinetti et al. , 2008). *MAFF* is a transcription factor and the murine ortholog is expressed in cartilage and bone (Onodera et al. , 1999). *NCOR1* mediates ligand-independent transcription repression of thyroid-hormone and retinoic-acid receptors and is part of a complex which includes histone deacetylases and transcriptional regulators. In summary, we have preliminary evidence that rare variants in CMI linkage regions are differentially associated with CTD+ and CTD- forms of CMI. Replication is warranted to investigate these associations further.

1005T

Identifying genetic variants underlying self-reported composing and arranging. *J. Oikkonen[1,5], T. Kuusi[2], P. Peltonen[1], P. Raijas[3], L. Ukkola-Vuoti[4], K. Karma[2], P. Onkamo[5], I. Järvelä[1].* 1) Department of medical genetics, University of Helsinki, P. O. Box 63, FI-00014 HY, Finland; 2) Sibelius Academy, University of the Arts Helsinki, P. O. Box 30, FI-00097 Uniarts, Finland; 3) Conservatory of Joensuu, Rantakatu 31, 80100 Joensuu; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, P. O. Box 20, FI-00014 HY, Finland; 5) Department of Biosciences, University of Helsinki, P. O. Box 56, FI-00014 HY, Finland.

Composing and arranging music are complex behavioral phenotypes. These creative activities in music have been shown to enhance certain brain areas including prefrontal cortex, premotor areas, amygdala and auditory cortex, but their molecular mechanisms are largely unknown. We wanted to study the molecular background of these activities with genome-wide linkage and linkage disequilibrium methods. We studied music-educated individuals who were asked if they had composed or arranged music. Our material consisted of families and unrelated individuals comprising totally 474 individuals. The participants were genotyped for over 700k SNPs. In the families, we estimated the heritability of composing as 58% and arranging as much as 70%. These heritabilities fall within the range of previously estimated heritabilities for music-related traits. The genome-wide linkage analysis using MERLIN showed evidence for creatively non-active phenotype at 18q21 (LOD score 3. 1), which contains for example cadherin genes. The creatively active phenotypes were only suggestively linked to any genetic region. At chromosome 4q, these regions did however overlap with regions previously linked with musical aptitude. Joint linkage and linkage disequilibrium analysis was performed as 2-stage analysis with families and unrelated individuals. First, the SNPs were pruned with simple association analysis to exclude unlikely markers. Then, the included SNPs were more comprehensively analyzed with Pseudomarker. The joint analysis showed no significant SNPs with the studied traits. However, pathway analysis of the suggestively identified SNPs showed overrepresentation of cerebellar memory functions. The cerebellum has been previously linked to music memory and memory functions have been proposed to be important in musical creativity. This study increases evidence about music phenotypes linked to chromosome 4, warranting more detailed analysis of the region. We also propose memory pathways to be important in creative activity in music.

Combined Linkage and Association Analyses Identify ANGPT2 Associated with Nocturnal Oxygen Saturation. *H. Wang[1], B. Cade[2], H. Chen[3], R. Saxena[4], K. Gleason[2], T. Feng[1], E. Larkin[5], S. Patel[2], S. Sunyaev[2], X. Lin[3], S. Redline[2], X. Zhu[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Division of Sleep Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Department of Biostatistics, School of Public Health, Harvard University, Boston, MA; 4) Center for Human Genetics Research, Harvard Medical School, Harvard University, Boston, MA; 5) Vanderbilt University Institute for Medicine and Public Health, Vanderbilt Medical Center, Nashville, TN.

Although sleep disordered breathing (SDB) affects a large proportion of the population and is associated with significant cardiovascular and neuropsychiatric morbidity, its genetic determinants are not clear. Overnight oxygen desaturation is a feature of SDB which has significant clinical relevance and is relatively easily measured, and thus scalable for use in large samples. In this study, we performed combined linkage and association analyses of average nocturnal oxygen saturation level during sleep in a well-characterized sample of European American families collected from the Cleveland Family Study, followed up by gene-based association tests in an independent sample as a replication. We identified two rare haplotypes in *ANGPT2* that are significantly associated with the phenotype and account for 5% of phenotypic variation. *ANGPT2* encodes angiopoietin-2 (Ang-2), an endothelial growth factor that modulates vascular and inflammatory responses to lung injury. Our study provides the first evidence to date for variants in *ANGPT2* influencing nocturnal oxygen saturation level.

1007W

Association of asthma with innate immune genetic variants and interactions with early life viral infections. *L. Akhabir[1], A. Eslami[1], A. B. Becker[2], A. J. Sandford[1], P. P. Pare[1], D. Daley[1].* 1) The UBC James Hogg Research Centre, University of British Columbia, Vancouver, British Columbia, Canada; 2) The Children's Hospital Research Institute of Manitoba, University of Manitoba, Winnipeg, Alberta, Canada.

Background: Asthma is a complex disease with a major global burden in health, quality of life and economics. 2. 4 million Canadians (8% of the population) were afflicted with the disease in 2013. The heritability of asthma is high (48 to 79%), and a variety of factors contribute to susceptibility, including genetic predisposition, environmental exposures, lifestyle and interactions between these factors. Viral infections at an early age have been associated with asthma development and exacerbations. Innate immunity is paramount for sensing and fighting pathogens. We previously showed significant interaction of polymorphisms in innate immune genes with early life viral infections in children from a high risk birth cohort, the Canadian asthma primary prevention study (CAPPS) in asthma development at age 7. Objective: The objective of this study is to investigate the main genetic effects and interactions of the innate immune variants with asthma and related phenotypes (atopy and airway hyperesponsiveness (AHR)) in the CAPPS children at age 15. Methods: 434 CAPPS family trios were used in the analyses of 321 variants in 34 innate immunity genes. Genotyping data were obtained from dense genotyping in candidate genes studies. Family-based analyses were performed using general additive allelic likelihood ratio tests as implemented in the UNPHASED program. Case/control analyses for main genetic and viral effects and SNP-virus interactions were performed using logistic regression in R. Results: Genotypes were included in the analyses for samples with call rates >90% and <4 Mendelian inconsistencies. In the family-based analyses, a total of 29 SNPs showed nominally significant associations with asthma, atopy and AHR. *LBP* rs5741812 was significantly associated with both atopy and AHR (p=0. 0076 and 0. 0211 respectively). 9 SNPs showed significant SNP-virus interaction for atopy. The most significant was *IL1R2* rs4851519 with p=0. 00179. Permutation testing is ongoing to obtain empirical p values and confirm these findings. Case control analyses main effects and SNP-virus interactions in unrelated subjects are in progress. Conclusion: We identified significant interactions between SNPs in innate immune genes and viral infection during the first year of life for atopy at age 15. Interactions between *IL1R2* variants and viral infection seem persistent as we previously found a significant SNP-virus interaction for this gene using phenotypes from the CAPPS children at age 7.

1008T

Whole genome linkage study for caries risk in Guatemalans identifies novel genetic regions. *M. Govil[1], N. Mukhopadhyay[1], C. A. Sanchez[1], F. W. -B. Deleyiannis[2], K. Neiswanger[1], J. M. Resick[1], A. R. Vieira[1], A. M. Letra[3], R. M. Silva[3], M. L. Marazita[1].* 1) Craniofac/Dental Gen/Oral Biol, Univ Pittsburgh, Pittsburgh, PA; 2) Department of Surgery, Plastic and Reconstructive Surgery, University of Colorado School of Medicine, Denver, Colorado; 3) Department of Endodontics and Craniofacial Research Center, The University of Texas Health Science Center School of Dentistry at Houston, Houston, Texas.

Dental caries is a substantial global health risk for individuals of all ages. Both genetic and environmental factors contribute to caries risk. In this study, we sought to identify susceptibility genes for lifelong caries risk in families from rural Guatemala with mixed Caucasian and Native American ancestry. Genome-wide non-parametric linkage analysis was carried out for a novel age-adjusted quantitative caries phenotype. For subjects aged 2-60 years, we measured the number of decayed primary and permanent teeth excluding precavitated lesions, and missing or filled teeth. There were 52 individuals with no caries. Caries indices of affected individuals ranged from 1 to 28, with a mean of 7. 32 (SD=6. 36). Indices were adjusted for age using LOESS fitting with a second-degree polynomial. Linkage analysis included 636 individuals from 117 pedigrees, 474 with known phenotype. Genotyping was performed with the Illumina HumanHap 550 SNP panel. Multipoint genome-wide nonparametric quantitative linkage analysis was carried out using the Merlin-regress program. Prior to linkage analysis, SNPs were thinned out on the basis of linkage disequilibrium, and remaining SNPs analyzed as clusters based on a 0. 1 correlation threshold to account for any residual linkage disequilibrium. Significant linkage peaks were observed on chromosome bands 6p22. 1 (LOD=5. 86, near HLA region), 15q21. 1 (LOD=3. 25, *DOUX2*), 18q22. 1 (LOD=14. 71, *CDH7* and *CDH19*) and 22q11. 23 (LOD=9. 72, *MMP11*, *SMARCB1*, *SLC2A10*). The HLA region is associated with periodontitis, diabetes type 1, host defense and inflammatory outcomes. *DOUX2* plays a role in antimicrobial defense at mucosal surfaces. *CDH7* and *CDH19* are calcium dependent cell-cell adhesion glycoproteins. *MMP11* is involved in embryo development, *SLC2A10* belongs to the glucose transporter subfamily, and heterozygous mutations in *SMARCB1* cause MRD15 (mental retardation, autosomal dominant 15) with abnormal delayed dentition as a clinical trait. These findings are distinct from prior caries studies involving cohorts with ancestries different from the current work (Caucasians from Appalachia and Iowa, African-Americans from Pittsburgh and Iowa). This work was supported by NIH-NIDCR R00-DE018085, U01-DE018903, R21-DE016930, R01-DE016148. Visits to Guatemala were in collaboration with Children of the Americas. All analyses were conducted on a Centos 276-node cluster, Indy, supported by the School of Dental Medicine at the University of Pittsburgh.

1009F

Child's *HLA-DRB1* genotype increases maternal risk of systemic lupus erythematosus (SLE): results from the Mother-Child Immunogenetic Study in Autoimmunity (MCIS). *G. I. Cruz[1], X. Shao[2], H. Quach[2], K. Ho[3], K. Sterba[3], J. A. Noble[4], N. A. Patsopoulos[5], M. P. Busch[6], D. J. Triulzi[7], W. S. W. Wong[8], B. D. Solomon[8], J. E. Niederhuber[8], L. A. Criswell[3], L. F. Barcellos[1, 2].* 1) School of Public Health, University of California Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genomics Lab, California Institute for Quantitative Biosciences (QB3), University of California Berkeley, Berkeley, CA; 3) Rosalind Russell / Ephraim P. Engleman Rheumatology Research Center, Department of Medicine, University of California San Francisco, San Francisco, CA; 4) Children's Hospital Oakland Research Institute, Oakland, CA; 5) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Department of Neurology, Brigham & Women's Hospital, Boston, MA; Division of Genetics, Department of Medicine, Brigham & Women's Hospital, Harvard Medical School, Boston, MA; 6) Blood Systems Research Institute, San Francisco, CA; 7) Institute of Transfusion Medicine and Department of Pathology, University of Pittsburgh, Pittsburgh, PA; 8) Division of Medical Genomics, Inova Translational Medicine Institute, Falls Church, VA.

SLE [MIM 152700] disproportionately affects women of reproductive age and pregnant patients are more likely to experience flares. Fetal microchimerism (FMC), or the persistence of a small population of cells in the mother, is a natural consequence of pregnancy. Risk of SLE is possibly increased through fetal HLA-antigen molecular mimicry. The causes of SLE are unknown but genetic and environmental factors, including Epstein-Barr virus (EBV) infection, are suspected. The strongest genetic association is with *HLA-DRB1* alleles **03:01, *15:01, *08:01*. We hypothesize that compared to controls, SLE cases are more likely to have children with a) *DRB1*-associated risk alleles and/or b) *DRB1*04:01* that encodes a homologous amino acid sequence to EBV. We investigated mother-child HLA relationships in 218 SLE and 349 control mothers (and their 881 children) from the Mother-Child Immunogenetic Study (MCIS). The MCIS is a study with over 9,000 individuals: cases were recruited at UC San Francisco; controls were recruited from the Blood Centers of the Pacific, the Institute for Transfusion Medicine at the University of Pittsburgh, and from studies at the Inova Translational Medicine Institute (ITMI). Comprehensive MHC region SNP genotyping was conducted using the Illumina MHC, ImmunoChip, and 660K arrays for MCIS participants and whole genome sequencing for ITMI controls. Classical two-field HLA alleles were imputed using SNP2HLA. Clinical data were abstracted from medical records. We selected mothers of European ancestry using multidimensional scaling and ancestry informative markers to minimize any impact of population stratification. We used logistic regression models to estimate odds ratios (ORs) and 95% confidence intervals (CIs) for the association between SLE and having any children who carry *DRB1* risk alleles or *DRB1*04:01*. Initial findings reveal an increased risk of SLE among mothers with children who carry *DRB1*15:01* (OR 2. 26; 95% CI, 1. 39-3. 66) and **04:01* (OR 1. 73; 95% CI, 1. 14-2. 64), both adjusted for maternal genotype. Furthermore, we observed a stronger association between children who carry *DRB1*15:01* and the SLE complication lupus nephritis compared to controls (OR 2. 75; 95% CI, 1. 12-6. 76, n=383). These findings support the hypothesis that a child's genotype influences a mother's risk of disease, independent of the mother's genotype. This is the first study to demonstrate an association between a child's *DRB1* genotype and risk of SLE in the mother.

1010W

Gene-based analysis in a family-based sample using Generalized Least Square(GLS) approach identified novel IBD locus supported by strong eQTL evidence. *D. Li, T. Haritunians, X. Yan, S. Targan, D. McGovern.* Cedars-Sinai Medical Center, Los Angeles, CA.

More than 160 genetic loci have been identified in Inflammatory Bowel Disease (IBD), mostly via single SNP analysis. Gene-based analysis, which combines signals from all the SNPs in a gene, might provide additional insights to this complex disease. With the complicated and related data structure, family-based samples remain a challenge for gene-based analysis. Previously we proposed a Generalized Least Square (GLS) based approach for gene-based analysis in family-based samples to address this challenge, with its power validated in simulated GAW18 data. Here we applied this approach to an IBD cohort with complex family structure which consists of 3812 IBD cases and 7854 non-IBD controls, all genotyped by ImmunoChipv1. In addition to the known IBD genes such as IL23R and NOD2, we identified a novel IBD association with LRRC16A, which contains 26 common and rare SNPs with a gene-based p-value of 1. 68E-6, significant for the estimated ~25000 genes in the genome. The gene-based result is driven by multiple independent SNPs with weak effects in LRRC6A, and the p-value for the top SNP rs7752195 is 1. 07E-6. Bioinformatic analyses via established eQTL datasets indicate that the top SNP is a strong eQTL for BTN3A2, a gene about 700 kb downstream of LRRC16A. This eQTL is validated in multiple datasets from multiple tissues (In seeQTL, eQTL p = 5. 96E-51(monocyte) and 6. 76E-5(LCL); in SCANdb, eQTL p=8E-9 (LCL); in GeneVar, eQTL p=0. 0025 (LCL); in GTex, eQTL p=0. 004(Colon), 0. 008(blood) and 0. 001(adipose)). Interestingly, the gene BTN3A2 has a p-value of 1. 39E-4 in our gene-based analysis, again with multiple independent weak signals independent of the signals in LRRC16A. BTN3A2 codes for a subunit of CD277, which plays an important role in regulating adaptive immune response. Those results indicate that the proposed GLS approach can be a powerful way for gene-based analysis in family-based samples, and LRRC16A might contribute to IBD via long distance regulation of BTN3A2.

1011T

Analysis of Comorbidities of Multiple Sclerosis Patients using an Electronic Medical Record-linked DNA Biobank. *S. Frodsham[1], J. Denny[2], M. Davis[1].* 1) Department of Microbiology and Molecular Biology, BYU, Provo, UT; 2) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Genome wide association studies (GWAS) have identified relationships between many different genes and diseases. GWAS studies scan whole genomes of many individuals and then associate genetic variants with disease that the individuals have. In contrast, a phenome wide association study (PheWAS), looks at the phenotypes of many individuals and associates those phenotypes with one or more genetic variants. Electronic medical records (EMR) linked to DNA biobanks provide both clinical and genetic data of patients. This study utilizes one such EMR-linked DNA biobank called BioVU from Vanderbilt University. The quantity and quality of data made available to us by BioVU are large enough to provide significant results when doing statistical analysis on the data. Data of insufficient quality were identified and removed using PLINK. Initially, we used ICD-9 billing codes and regular expressions to identify individuals diagnosed with MS and rheumatoid arthritis (RA), a common comorbidity. In this study we analyzed 1,003 patients (28 with RA) with 106 SNPs previously associated with a risk of developing MS were analyzed to see if any variants known to be risk factors for MS were actually associated with simultaneous development of both diseases. While no SNPs in the analysis passed the significance threshold, the number of SNPs in close proximity to the significance threshold warranted further investigation within a wider scope of phenotypes observed in MS patients. By studying a wider variety of phenotypes, we hope to identify diseases with genetic variants that strongly correlate to an increased risk of development of MS. PheWAS analysis was performed using a package within the statistical computing program, R. The study population consists of 1,003 individuals diagnosed with multiple sclerosis, the primary phenotype of interest in this study. ICD9 billing codes contained within the EMRs identified the comorborbidities or secondary phenotypes analyzed in this study. Using these secondary phenotypes, the PheWAS may identify significant genetic variants within this population of MS patients.

The Role of Mendelian Genes in Complex Disease Risk. *K. P. Shah[1], E. Gamazon[2], J. Denny[2], L. Bastarache[2], H. K. Im[1], D. Nicolae[1], A. Rzhetsky[1], N. J. Cox[2].* 1) Medicine, University of Chicago, Chicago, IL; 2) Vanderbilt Genetics Institute, Nashville, TN.

Mendelian diseases are typically severe and often involve multiple organ systems. Rare DNA mutations in approximately 2,000 genes are known to cause Mendelian diseases. Individuals with Mendelian diseases are also at risk for comorbid complex diseases later in life. Some genes have been found to provide a common genetic basis for Mendelian and complex diseases. Thus, by focusing Mendelian genes, we can gain insights into patterns of disease risk and the underlying biological mechanisms of disease. Using transcriptome data from the GTEx pilot project, we show that Mendelian genes tend to be both more broadly and more highly expressed across a wide range of tissues, but have less inter-individual variability in expression. Furthermore, we found that prediction of gene expression using genomic data performed equally well for Mendelian genes. Using a large electronic medical records database, BioVU, we found that lower predicted expression of Mendelian genes is associated with similar phenotypes to those found in patients with the same Mendelian disease. For example, individuals homozygous for mutations in *PEX19* are known to have Zellweger syndrome (ZS) resulting from disordered peroxisome biogenesis. ZS is characterized by hypotonia, distinctive facies, seizures, kidney failure, coagulopathies, boney stippling of patella and long bones, and early death. Similar to ZS patients, we found low predicted expression of *PEX19* in individuals from BioVU was associated with epilepsy (convulsions and partial epilepsy), kidney disease and failure, and fracture of the patella. Thus, even just decreased expression of the gene can result in phenotypic consequences similar to those observed for the Mendelian disease. Higher predicted expression of *PEX19* was associated with several cancer phenotypes, as would be predicted based on prior studies on genes regulating the expression of genes involved in peroxisome biogenesis. Our results suggest that even subtle changes in the expression of Mendelian disease genes have phenotypic consequences that are relevant to human health. Systematically annotating the phenotypes associated with varied expression of Mendelian genes will shed light on the continuum between Mendelian and complex diseases and allow us to gain more general insights into complex disease biology through this particularly well studied class of genes.

1013W

Study of the genetic architecture of diabetic retinopathy in African Americans from a de-identified medical records system. *N. Restrepo[1], R. Goodloe[2], E. Farber-Eger[2], D. Crawford[1,3].* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Vanderbilt Genomics Institute, Vanderbilt University, Nashville, TN; 3) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

Diabetic retinopathy (DR) is the leading cause of blindness in working age adults in the U. S. DR is caused by abnormalities in the microvasculature of the retina and presents in ~80% of type 1 and 40% of type 2 diabetics. Prevalence rates are higher in African American (AA) diabetics (36. 7%) compared to European American (EA) diabetics (24. 8%) which may be explained, in part, by higher rates of diabetes in AA. Still, the overall trend is higher even after accounting for differences in risk factors, suggesting that other population-specific variables are at play. Identification of genes that play a role in DR have been limited and most studies to-date have been performed in EA populations. Our study proposes to explore the genetic architecture of DR in AA, prior studies of which are altogether missing or uninformative. We have performed a genetic association study of DR in AA from the Epidemiologic Architecture for Genes Linked to Environment (EAGLE) study. AA DR cases (n=119) and controls (n=434) were identified in BioVU, the Vanderbilt University Medical Center DNA repository linked to de-identified EMR. Cases and controls were identified via a combination of International Classification of Diseases diagnostic codes, Current Procedural Terminology billing codes, and manual review of clinical records. Individuals were genotyped on the Metabochip, a targeted array. Single SNP tests of association were performed for common variants (MAF>0. 05) using logistic regression assuming an additive genetic model adjusted for age, sex, and mean blood serum glucose levels. We did not replicate associations previously described in other studies for SNPs within *AGER* and *TCF712*. Overall, no test was significant after Bonferroni correction. Of interest for future studies is rs7076968 on chr 10, located within the intergenic region of *ZCCHC24-EIF5AL1* (p=7. 60x10-6; OR=5. 54). In the general EAGLE BioVU AA population (n=11,521), this SNP has a MAF of 5. 5%. The MAF was lower in T2D controls (MAF=3. 5%) and notably higher in DR cases (MAF=9. 7%). Additionally, we identified several variants nominally associated at p<10-4 located in genes known to play a role in epithelial and endothelial tight cellular junctions (rs820626: p=5. 11x10-5; OR=2. 28 and rs17062682: p=3. 2x10-4; OR=2. 12). Although underpowered, this study highlights the need for further studies among AA to determine if lack of generalization is due to differences in LD or differences in the genetic risk factors for DR.

1014T

Bioinformatics Infrastructure for the Partners Biobank Initiative. *E. A. Tsai[1,2,3], J. Peirce[4], K. Embree[5,6], A. Brown[1], N. T. Boutin[5,6], S. S. Amr[1,3,7], S. T. Weiss[1,2,3], M. S. Lebo[1,3,7].* 1) Personalized Medicine, Partners Healthcare, Cambridge, MA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 3) Department of Medicine, Harvard Medical School, Boston, MA; 4) Customer Solutions, Illumina Inc. , San Diego, CA; 5) Partners Biobank, Partners Healthcare, Cambridge, MA; 6) Information Systems, Partners Healthcare, Cambridge, MA; 7) Department of Pathology, Brigham and Women's Hospital, Boston, MA.

The Partners HealthCare Biobank is a large research data and sample repository enrolling subjects who receive their clinical care at Massachusetts General Hospital or Brigham and Women's Hospital. IRB-approved institutional investigators have access to data from the patient's Electronic Medical Record as well as additional health information collected in a self-reported survey. A query tool called the Biobank Portal enables investigators to search the Biobank's database based on clinical data, survey data, sample attributes, and consent attributes. DNA samples from 25,000 consented subjects will be genotyped over two years and made available via the Biobank Portal. This resource will enable investigators to study how genetic background influences an individual's health or contribute to disease development and progression. DNA from peripheral blood is genotyped using Illumina Infinium Multi-Ethnic Genotyping Array (MEGA) with 1. 8 million SNPs including exome content (>50,000 loss of function variants) and ethnic variant SNPs; to date more than 5,000 individuals have been genotyped. Here, we describe the bioinformatics infrastructure that processes, stores, and delivers this genotype data to investigators. The iScan instrument and Illumina LIMS generate binary intensity data (IDAT) files, which are converted to binary Genotype Call (GTC) files. Our process 1) performs data quality control (QC), 2) stores data in a scalable Elasticsearch database, 3) delivers genotype data in PED format, 4) calls copy number variations (CNVs) based on the GTC file, and 5) imputes the genotype at additional sites of variation using the 1000 Genomes Phase 3 dataset. We will discuss how to assess the data quality for high-capacity biobank projects, including periodic inspection for trends and deviations and gender-based checks for inverted sample plates or mislabeled samples, and storage of metadata such as QC metrics as well as genotype and CNV data in database format for compression and easy retrieval. Imputation is performed using IMPUTE2, with increased power to impute SNPs in non-Caucasian cohorts due to the ethnic-specific SNP content. CNVs are called based on the intensity data using PennCNV. The genotype data will be delivered to the investigators for association or meta-analysis studies. This bioinformatics infrastructure is scalable to accommodate the large volume of data processing, storage, and retrieval.

Possibilities in Unbiased Population Based Research Using Neonatal Screening Biobanks. *J. Grauholm[1,3], C. H. Hansen[1,3], M. Bækvad-Hansen[1,3], J. B. Poulsen[1,3], D. M. Hougaard[2,3], M. V. Hollegaard[1,3].* 1) Neonatal Genetics, Statens Serum institute, Copenhagen, Capital Region, Denmark; 2) Danish Center for Neontal Screening, Statens Serum institute, Copenhagen, Capital Region, Denmark; 3) Department of Congenital Disorders, Statens Serum institute, Copenhagen, Capital Region, Denmark.

The Danish Neonatal Screening Biobank (DNSB) has been storing excess neonatal dried blood spots (neoDBS) samples from the neonatal screening since 1982. Currently DNSB holds more than two million individuals, or almost all Danes born since 1982. Denmark has a long tradition and goodwill from the population to collect all sorts of observations throughout life and to store them in large registries. As all Danes have a unique person identifier number (CPR), it is possible to connect registries and biobanks. This allows researchers to study the etiology of numerous diseases in extraordinary detail. The accessible amount of biological material on a neoDBS sample for research purposes is however limited, one to two 3. 2mm disks, which equals 3-6uL whole-blood. Consequently, it is important to adapt low input methods and design protocols that allows generation of high-quality data on low-concentrated samples. Here we present the genetic methods that we are currently using in DNSB studies of common and complex diseases. To gain recommended amounts of *DNA* for NGS and array genotyping, it is necessary to whole-genome amplify the neoDBS extracted DNA. While it is a robust process, it is critical to confirm technical consistency and accuracy in genetic sequencing and array studies. *DNA methylation profiling* of neonatal DBS samples offers an insight to early life epigenetics, and inherited epigenetics. In this early stage of life, environmental exposures to the child have been minimal. Collected without notably bias, and at proximately the same time of life, the neoDBS samples is close of being the perfect sample for studying methylation events of e. g. birth and birth related complications. *RNA* is an important intermediate between DNA and protein, with many functions. RNA array profiling and RNA-seq is possible on neoDBS. We present data that show that RNA is stable on neoDBS for decades, and usable for research. We also present evidence that the blood born markers of gender, as identified by the Genotype-Tissue Expression consortium, remains stable despite the spotting. In conclusion, this abstract shows how neoDBS from DNSB can be used for reliable DNA genotyping, DNA methylation- and RNA- profiling. The technological advancement, and the continuously expansion of neoDBS samples will, in the years to come, increase the number of diseases that can be studied, and hopefully help to better understand the etiology of disease.

Correlation Between Genetic Ancestry Proportions and Thousands of Common Disease States in Admixed Populations. *J. Jeff[1], D. Park[2], B. Glicksberg[3], G. Belbin[1,3], E. Bottinger[1,4], N. S. Abul-Husn[1,3,4,6], N. Zaitlin[5], E. E. Kenny[1,3,6,7].* 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY,; 2) Department of Bioengineering and Therapeutic Sciences Medicine, University of California San Francisco, CA; 3) Department of Genetics and Genomic Sciences,Icahn School of Medicine at Mount Sinai, New York, NY; 4) Department of Medicine,Icahn School of Medicine at Mount Sinai, New York, NY; 5) Department of Medicine, University of California San Francisco, CA; 6) Institute for Genomics and Multiscale Biology,Icahn School of Medicine at Mount Sinai, New York, NY; 7) Center for Statistical Genetics,Icahn School of Medicine at Mount Sinai, New York, NY.

Over 14,000 medical billing codes (ICD-9) are used to classify diseases, injures, health encounters, and procedures. ICD-9 codes are localized in electronic medical records (EMR) for billing purposes but have been recently used to define disease status for thousands of diseases. Phenome-Wide Associations Studies (PheWAS) are a hypothesis-free approach that tests several phenotypes with a single genetic variant. Such approaches have provided insight into novel pleiotropic effects and disease pathways of common diseases. Big data resources such as EMRs, with thousands of possible phenotypes, provide endless opportunities for PheWAS. The Bio*Me* Biobank at Mount Sinai, is a cohort of >32,000 multi-ethnic patients, including 3,705 African Americans (AA) and 5,104 Hispanic/Latinos (HL), with rich phenotype data from EMRs linked to DNA samples. The admixed AA and HL individuals contain varying proportions of African (AFR), European (EUR) and Native American (NA) genetic ancestry, and previous studies have linked genetic ancestry proportion with risk for several complex diseases. To investigate the relationship between ancestry proportion and disease risk we tested estimates of genetic ancestry proportion for an association with thousands of ICD-9 codes in Bio*Me*. Genetic ancestry proportion was estimated from >1 million SNPs and were consistent with published estimates for AFR, EUR, and NA ancestry in AA (82% AFR, 16% EUR, 1. 6% NA) and HL (28% AFR, 54% EUR, 18% NA). To define common disease states, we assigned disease status to each patient for ICD-9 codes where n ≥20, resulting in 1,728 and 1,263 ICD-9 codes in AA and HL, respectively. All tests were stratified by self-reported ancestry and each component of genetic ancestry was regressed on age, sex, BMI, and ICD-9 code. We identified 18 correlations at P≤8. 7E-5in AA or HL. We observed known correlations between AFR ancestry and anemia (b=0. 03, P=2. 7E-9, AA; b=0. 21, P=3. 18E-8, HL), sickle-cell trait (SCT) (b=0. 04, P=0. 01, AA; b=0. 21, P=1. 9E-8, HL) and uterine fibroids (b=0. 03, P=0. 003, AA; b=0. 05, P=3. 3E-8, HL). We also replicated association with NA ancestry and asthma (b=-0. 03, P=1. 8E-9) in HL. We identified significant pleiotropic effects between AFR ancestry and diseases with overlapping features such as acute venous thrombosis (b=0. 04,P=0. 008) and SCT (b=0. 03, P=0. 01). Replication of these findings in an independent cohort is underway, and may point to novel disease etiologies in these populations.

Discovery of disease-specific eQTLs aids interpretation of GWAS results in systemic lupus erythematosus. *A. Wuster[1,2], R. R. Graham[1], M. J. Townsend[3], T. W. Behrens[1], T. Bhangale[1,2].* 1) Department of Human Genetics, Genentech Inc, South San Francisco, CA; 2) Department of Computational Biology, Genentech Inc, South San Francisco, CA; 3) Department of Immunology Diagnostic Discovery, Genentech Inc, South San Francisco, CA.

A large proportion of GWAS disease associations can be attributed to variants affecting gene expression (expression quantitative trait loci or eQTLs). There is increasing evidence that many eQTLs are not only specific to tissues but also to the presence of certain stimuli, suggesting that some may only be seen in a stimulated or disease state. For example systemic lupus erythematosus (SLE), a complex autoimmune disease, may be regarded as a state in which cells are under stimulation by inflammatory cytokines such as IFN-α Discovering eQTLs specific to SLE and characterizing the eQTL differences between healthy and SLE blood may aid understanding of the disease process, uncover biomarkers, and suggest new drug targets. To this end, we identified eQTLs in whole blood samples from 83 SLE patients of European descent for which we have generated genotyping and RNA-sequencing data. As controls, we used whole blood eQTL data from the GTEx project. We developed an unbiased and computationally efficient approach to discover eQTLs that are specific to the case or control groups. Our algorithm does this by quantifying significant differences in eQTL signal strength between groups. We identified 307 cis-eQTLs that are specific to or significantly stronger in SLE patients compared to healthy controls (FDR < 0. 05), and whose SLE specificity was confirmed in a validation cohort. We also identified 60 eQTLs that were specific to or significantly stronger in controls. One possible mechanism for SLE-specific eQTLs could be differential activity of transcriptional regulators between cases and controls. Supporting this hypothesis, we found that regulators of the 307 SLE-specific eQTL genes, including MIFT, ARID5B, and SMC3, were differentially expressed between SLE patients and controls. Of 98 independent variants identified in SLE GWAS studies to date, 24 were significant (FDR < 0. 05) eQTLs for a gene other than the one reported by the GWAS, including ULK3, USF1, BTN3A2 and TMEM80. 11 of those eQTLs were specific to SLE patients. Our findings indicate that some eQTLs are only present in tissues from SLE patients, and that a sizable proportion of those eQTLs are relevant for the interpretation of other genetic data including GWAS results. Our approach is adaptable to the identification of subgroup-specific eQTLs in other conditions and diseases.

Enhanced methods for gene expression imputation from genetic variation data. *N. Mancuso[1], H. Shi[2], A. Gusev[*3,4], B. Pasaniuc[*1,2,5].* 1) Pathology & Laboratory Medicine, David Geffen School of Medicine, University of California at Los Angeles, Los Angeles, California, USA; 2) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, California, USA; 3) Departments of Epidemiology and Biostatistics, Harvard T. H. Chan School of Public Health, Boston, Massachusetts, USA; 4) Medical and Population Genetics, Broad Institute, Cambridge, Massachusetts, USA; 5) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, California, USA.

Genome-wide association studies (GWAS) have discovered thousands of variants that contribute risk to complex traits. Although a large proportion of GWAS risk variants overlap eQTL loci, the underlying mechanisms leading from genetic variation to gene expression to disease risk are still largely not understood. An attempt to bridge this gap is by estimating the aggregate contribution that eQTL SNPs have on complex traits. Ideally this would be accomplished through large-scale studies that measure genetic variation, gene expression as well as disease phenotypes in many individuals. However measuring gene expression in large numbers of tissues and individuals is prohibitive due to cost and specimen availability. An alternative approach is to computationally predict gene expression directly from genetic variation. In this work, we present methods for imputing gene expression from dense genotype data. In particular we explore the efficiency of the best linear unbiased predictor (BLUP), a Bayesian BLUP and various linear models while accounting for population structure. We present an ensemble predictor that incorporates multiple methods to improve gene expression prediction in simulations and real data analyses. *Contributed Equally.

Metabolomic profiles during an oral glucose challenge in 470 non-diabetic community residents: Associations with clamp-evaluated insulin sensitivity. *C. Nowak[1], J. Sundström1[1], A. Ganna[2], S. Salihovic[1], T. Fall[1], E. Ingelsson[1,3].* 1) Medical Sciences Department, Molecular Epidemiology, Uppsala University, Uppsala, Sweden; 2) Massachusetts General Hospital, Harvard Medical School and Broad Institute, Boston, Massachusetts, USA; 3) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, California, USA.

Changes in blood metabolite levels during metabolic challenges such as the oral glucose tolerance test (OGTT) can reveal distinct biochemical alterations preceding type 2 diabetes. Our aim was to study 192 circulating metabolites measured using liquid chromatography/mass spectrometry in repeated blood samples during an OGTT in relation to insulin sensitivity. Metabolite profiling was done in 470 non-diabetic men (mean age 70. 6 ± 0. 6 years, BMI 26. 0 ± 3. 3 kg/m2) at time points 0, 30, and 120 minutes during an OGTT, respectively. Insulin sensitivity (M/I ratio, i. e. glucose disposal divided by mean insulin concentration) measured by a hyperinsulinemic-euglycemic clamp was assessed as the dependent variable in linear regression models with metabolite intensities at the three time points as independent variables. Analyses were adjusted for age and sample quality indicators (previous thawing, storage time, possible hemolysis, and whether plasma or serum samples were used). After Bonferroni correction for multiple testing, 33 out of 192 metabolites were significantly associated with M/I ratio. These included seven glycerophospho- and six glycerolipids, six unsaturated and one saturated fatty acid, four glycerophosphoethanolamines, three acylcarnitines, three bile acids, one monosaccharide, one steroid derivative, and propranolol. Graphical comparisons of confounder-adjusted metabolite trajectories following glucose challenge revealed distinct temporal patterns related to insulin sensitivity and metabolite class. Adjustment for BMI confirmed overall trajectory associations with clamp M/I, but altered time point-specific relationships. In particular, adjustment for adiposity reversed most positive associations between fasting lipid metabolite levels with insulin sensitivity to an inverse relationship (i. e. lower metabolite levels were associated with increased insulin sensitivity), but strengthened their statistical significance whilst weakening associations at 30 and 120 minutes after glucose ingestion. Associations of non-lipid metabolites remained largely unaffected by adjustment for BMI. Metabolite trajectories following an oral glucose challenge revealed distinct temporal patterns associated with insulin sensitivity that may help clarify early metabolic changes and biochemical alterations associated with diabetes pathology.

Assessing the Genetic Predisposition of Education on Myopia: a Mendelian Randomization Study. *G. Cuellar-Partdia[1], Y. Lu[1], P. F. Kho[1], A. W Hewitt[2], H. E. Wichmann[3,4], S. Yazar[5], D. Stambolian[6], J. E. Bailey-Wilson[7], R. Wojciechowski[8], J. J. Wang[9], P. Mitchell[9], D. A. Mackey[5], S. MacGregor[1].* 1) QIMR Berghofer Medical Research Institute, Brisbane, Australia; 2) School of Medicine, Menzies Research Institute Tasmania, University of Tasmania, Hobart, Australia; 3) Helmholtz Centre Munich, Institute of Epidemiology I, Neuherberg, Germany; 4) Institute of Medical Statistics and Epidemiology, Technical University Munich, Germany; 5) Centre for Ophthalmology and Visual Science, Lions Eye Institute, University of Western Australia, Perth, Australia; 6) Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA, USA; 7) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD, USA; 8) Wilmer Eye Institute, Johns Hopkins Medical Institutions, Baltimore, MD USA; 9) Centre for vision Research, Department of Ophthalmology, University of Sydney, Sydney, Australia.

Myopia is the largest cause of uncorrected visual impairments globally and its recent dramatic increase in the population has made it a major public health problem. Educational attainment has been consistently reported to be correlated to myopia. Nonetheless, correlation does not imply causation. Observational studies reporting the correlation of educational attainment and myopia do not tell us if education causes myopia or if instead there are confounding factors underlying the association. In this work, we use a two-step least squares instrumental-variable (IV) approach to estimate the causal effect of education on refractive error, specifically myopia. We used the results from the educational attainment GWAS from the Social Science Genetic Association Consortium to define a polygenic risk score (PGRS) and tested the PGRS in three cohorts of late middle age and elderly Caucasian individuals (*N*=4514). Using the PGRS as an IV, we estimated that each z-score increase in education (approximately 2 years of education) results in a reduction of 0. 91 ± 0. 27 diopters (*P*=6. 80x10-4) in the three cohorts combined. Our estimate of the effect of education on myopia was higher (*P*=0. 01) than the observed estimate in the three cohorts combined (0. 26 ± 0. 03 diopters reduction per education z-score [~2 years] increase). This suggests that observational studies may actually underestimate the true effect. Our Mendelian Randomization (MR) analysis provides new evidence for a causal role of educational attainment on refractive error.

Bone marrow mesenchymal stem cell molecular signatures in multiple sclerosis. *F. B. S. Briggs[1], M. Cameron[1], P. Wilkinson[1], M. Li[1], S. Planchon Pope[2], J. A. Cohen[2].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, School of Medicine, Cleveland, OH; 2) Mellen Center for Multiple Sclerosis Treatment and Research, Cleveland Clinic, Cleveland, OH.

Background: The majority of multiple sclerosis (MS) patients present with relapsing remitting (RR) disease course and most will develop secondary progressive (SP), however factors precipitating transition are unknown. Adult mesenchymal stem cells (MSCs), including bone marrow (BM) MSCs, are immunomodulatory and neuroprotective; however, these properties may be diminished in MS patients. Wehypothesize that molecular signatures in BM-MSCs distinguish MS patients by disease course (RR vs SP) and from healthy controls (HCs). A robust BM-MSC molecular signature can dramatically transform diagnosis, treatment choice and treatment response prediction. **Methods:**BM-MSCs were collected, isolated and cultured using standard procedures. Subjects were non-Hispanic white. Cells from 4 age (+/- 5 yrs) and gender frequency-matched SP and HC (SP/HC) pairs were collected at passage 1. Cells from 3 frequency-matched RR and SP (RR/SP) pairs were collected at passage 3. RNA was isolated using the Qiagen AllPrep procedure. RNA-seq data was generated via an Illumina HiSeq 2500 (paired-end, 100 cycle, 50x106mapped reads/sample); and were aligned using*STAR aligner*and counted with*HTSeq*. Genes with at least 1 count/106for 3 subjects were analyzed using*EdgeR*. Pathway activity of top-ranking genes (by nominal p-values) was evaluated using gene set variation analysis (GSVA). **Results:**In the SP/HC pairs, there was evidence for differential pathway activation in interleukin binding, adaptive immune response, cytotoxic cell activity, apoptotic DNA fragmentation,p53 signaling, JAK/STAT signaling, and IL6, IL12, and IL3 pathways (*P*<0. 05) between SP and HC BM-MSCs. In RR/SP pairs differential pathway activity was observed for interferon-inducible genes, T cell proliferation, caspase regulation, apoptotic DNA fragmentation, and IL2, IL5, IL6, IL7, and IL12 pathways (*P*FDR<0. 001). Close analysis of distinguishing expression signatures reveals a reciprocal relationship between type I and type II interferon responses in RR vs SP BM-MCSs, with SP being more type II interferon response aligned (downregulated (*P*FDR<0. 001): IFI6, IFI27, IFI35, IFIT1, IFIT2, and IFIT3; upregulated (*P*FDR<0. 05): IL7 and IL18R1). This reciprocal relationship may further impact downstream processes, altering T cell activation, apoptosis signaling and effector responses (e. g. caspases) that would have a profound cumulative immunomodulatory effect which may contribute to disease course transition in MS patients.

Inherited cerebellar ataxias (CA) are neurodegenerative disorders, clinically characterized by a cerebellar syndrome, often accompanied by other neurological or non-neurological signs during disease evolution. All transmission modes have been described; in autosomal dominant (AD) forms, more than 30 causative genes are implicated, but the molecular diagnosis remains unknow in about 40% of the patients. Implication of ion channels has long been an on-going topic in the genetics of CA and causative mutations in several channel genes have been recently described. In a large family with AD CA and mild pyramidal signs, without any mutation in previously known CA genes, we aimed at the identification of the causative variant. With a combined approach of linkage analysis and whole exome sequencing, we identified an arginine-to-histidine mutation in the segment S4 of the T-type Cav3. 1 channel protein, encoded by CACNA1G gene. Further screening of 483 index individuals allowed the description of two additional carriers of that same mutation. Electrophysiological experiments were performed in HEK293T cells to compare the properties of the R1715H mutant to the WT Cav3. 1 channels. These results revealed that R1715H channel showed a significant positive shift of current-voltage relationship and the steady-state activation curve, as well as a higher slope factor of the inactivation curve. Taken together, these data establish CACNA1G as a causative gene in AD CA. CACNA1G was a convincing candidate in the pathology as it is highly expressed in the cerebellum. Our study extends further our knowledge of the link between calcium channelopathies and progressive, not only episodic, CA. .

1023T

Identification of candidate genes for IQ discrepancy in extended families with autism using whole exome sequencing data. *A. Q. Nato[1], N. H. Chapman[1], H. K. Sohi[1], J. M. Viskochil[2], H. Coon[2], E. M. Wijsman[1,3,4].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA; 2) Department of Psychiatry, University of Utah, Salt Lake City, UT, USA; 3) Department of Biostatistics, University of Washington, Seattle, WA, USA; 4) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

Autism spectrum disorders (ASDs) are neurodevelopmental disorders characterized by repetitive behavior and impairments in communication skills and social behavior. Performance IQ (PIQ) is often greater than verbal IQ (VIQ) in individuals with ASD. As a follow-up to an earlier analysis that identified a region of interest (ROI) on chromosome (chr) 15 and other regions in both a previous sample and the sample used here, we are focusing on identifying candidate genes within the chr 15 ROI using whole exome sequencing (WES) data. Our sample here consists of four extended high-risk families with ASD, which ranged from 72 to 202 individuals. The measures used to define IQ discrepancy are as follows: Wechsler block design and DAS pattern construction subtests (BD) to represent PIQ, and Wechsler vocabulary and DAS naming vocabulary and word definition subtests (VOC) to represent VIQ (BD-VOC). The ROI on chr 15 spans ~18 cM (79 cM - 97 cM). We obtained WES data (66 individuals), and identified 14,039 variants on chr 15. 2,588 variants in 229 genes are within the ROI. Within each family, we excluded indels and selected single nucleotide variants (SNVs) which have ≥ 2 copies, resulting in 421 SNVs (range: 254-342). We further selected SNVs that are nonsynonymous (from SeattleSeq 137 annotation) and have minor allele frequency < 0. 05 (from 1000 Genomes European genotype data). This filtration step resulted in 65 nonsynonymous SNVs (range: 12-27) in 41 genes (range: 11-24), where 13 SNVs and 18 genes with nonsynonymous SNVs are observed in 2-4 families. 7 of these SNVs are predicted by PolyPhen to be possibly- or probably-damaging. We used PBAP for file manipulation and then imputed genotype data for the remaining 390 individuals using GIGI based on the available sequence information and the inheritance vectors that were previously used in our linkage analysis. The dosages of both observed and imputed data are used as a measure of gene burden. Using gene burden as a covariate, we are performing variance components linkage analyses in SOLAR, using models allowing for additive effects with dominance in both the major gene and polygenic components, to identify genes that *as covariates* decrease the linkage signal on chr 15, thereby implicating them as the candidate loci. A similar approach will also be performed on other genomic regions with evidence for linkage in these families (1q, 2q, 3p, 7p, and 16q).

1024F

Language impairment in autism spectrum disorder: a sensitive indicator of functioning in genomic copy number changes? *C. W. Bartlett[1], J. F. Flax[2], A. D. Shindhelm[1], B. Green[2], S. Buyske[2,3], L. M. Brzustowicz[2].* 1) Battelle Ctr Mathematical Med, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Genetics, Rutgers University, Piscataway, NJ; 3) Department of Statistics, Rutgers University, Piscataway, NJ.

Introduction: Autism is a spectrum disorder (ASD) with behavioral, genetic, and medical characteristics varying in magnitude and complexity. Approximately 25% of individuals on the spectrum never achieve functional language. On the other end of the spectrum, individuals can be verbally fluent and lead relatively independent lives depending upon the degree of their social and behavioral issues. Recent research suggests that lower IQ is associated with a greater number of loss-of-function mutations and that these occurred in sporadic cases of ASD as opposed to multiplex families. In this family genetics study of ASD, copy number variants (CNVs) in individuals with ASD were compared between those with minimal language and those who were verbal at least at the phrase level of language. **Methods:** We divided 115 individuals with ASD into: 1) higher and lower functioning groups based on the Autism Diagnostic Observation Schedule (ADOS) and 2) clinical diagnosis of language impairment versus normal language. For ADOS classification, individuals who were at least 5 years old who had only very minimal language were considered lower functioning while children less than five years of age and all other individuals on the autism spectrum were considered higher functioning and received different versions of the assessment. All samples had CNV inferred from SNP array data using PennCNV. We assessed group burden using logistic regression analysis and followed up with linear regression on standardized language scores. To further assess the impact of CNVs on language we performed regression on an additional 294 family members. **Results**: The ADOS-based high/low groups did not show a difference in total numbers, total length, number of deletions or duplications. However, for the clinical diagnosis of language impairment versus language normal groups, total CNV length was different between the groups (P=0. 013). We then assessed if language was a surrogate for functioning in this population. Using all ASD subjects with quantitative language scores, both CNV total and CNV length predicted language (P=0. 012, P=0. 037, respectively). Follow-up using our total family set that includes quantitative language data on an additional 294 samples, the same conclusion held for CNV total (P=0. 037) but not for CNV length (P>0. 05). **Discussion:** Language impairment within autism spectrum disorder appears to be a sensitive indicator of functioning with regard to genomic copy number changes.

1025W

Two microdeletions that segregate independently in a family, suggesting three candidate genes for autism and motor delay at 12q12 and two candidate genes for cerebral palsy at Xp22. 13. *JDJ. Labonne[1,2], LC. Layman[1,2,3], HG. Kim[1,2].* 1) Section of Reproductive Endocrinology, Infertility & Genetics, Department of Obstetrics and Gynecoloy, Georgia Regents University, Augusta, GA 30912, USA; 2) Department of Neuroscience and Regenerative Medicine, Georgia Regents University, Augusta, GA 30912, USA; 3) Neuroscience Program, Medical College of Georgia, Georgia Regents University, Augusta, GA 30912, USA.

With the advent of high resolution microarray technologies, an increasing number of pathogenic copy number variations (CNVs) are being discovered in human patients. Microdeletions in the 12q12 region are rare, in part because of the close proximity to the centromere. We report a family with two microdeletions segregating independently at 12q12 and Xp22. 31. The patient (DGDP289), who possesses only the 12q12 microdeletion, is a 5-year-old boy displaying pervasive developmental disorder (PDD) and autism. He presents with learning disability, severe speech delay as well as gross and fine motor delay. He inherited the chromosomal anomaly from his father, who in turn inherited it from his mother. The patient's father suffers from depression and difficulties in mathematics, while the paternal grandmother has had lifelong learning difficulties. The Xp22. 31 microdeletion found in the patient's 3-year-old brother contains at least five genes, including *STS* and *VCX*. He displays ichthyosis and cerebral palsy. This Xp22. 31 genomic deletion was inherited from his healthy mother, who is a carrier. Cerebral palsy features may be caused by gene(s) deleted in this interval, possibly by *PNPLA4*. The *VCX3A* gene also located at Xp22. 31 has been previously shown to be associated with intellectual disability. It is possible that *VCX3A* may be involved in cerebral palsy due to a position effect if its expression is altered in the patient's brother. We refined the boundaries of the proximal and distal breakpoints of the 12q12 microdeletion and found it contains only four genes, including *SLC2A13*, *LRRK2*, *MUC19* and *CNTN1*. We compared the 12q12 microdeletion with previous reports and 8 CNV cases in the DECIPHER database. We also determined the transcript levels of three candidate genes namely, *LRRK2*, *SLC2A13* and *CNTN1*. The *LRRK2* gene is involved in Parkinson's disease; *SLC2A13* is predominantly expressed in the brain and *CNTN1* acts a ligand for Notch. We propose that the autistic features displayed by patient DGDP289 are caused primarily by *LRRK2*, with *SLC2A13* and *CNTN1* as possible additional contributors to the phenotype.

Integrative Analysis of Human Protein Complexes Reveals Biochemical Activities and Convergent Mechanisms of Action in Autism Spectrum Disorders. *J. Li[1], Z. Ma[1], R. Malty[4], H. Aioki[4], M. Shi[1], K. Jin[4,5], D. Wall[2], Z. Zhang[5], A. Urban[1,3], J. Hallmayer[3], M. Babu[4], M. Snyder[1].* 1) Genetics, Stanford University, Stanford, CA; 2) Pediatrics, Stanford University, Stanford, CA; 3) Psychiatry & Behavioral Sciences, Stanford University, Stanford, CA; 4) Department of Biochemistry, Research and Innovation Centre, University of Regina, Canada; 5) Banting and Best Department of Medical Research, Terrence Donnelly Center for Cellular and Biomolecular Research, University of Toronto, Toronto.

ASD is hallmarked by its extreme genetic heterogeneity. Recent studies have devised integrative and computational frameworks to infer molecular pathways in ASD. Ideally, however, the direct and physical organization of the genetic elements in ASD should be experimentally determined in a cellular context relevant to the disease. In this study, we systematically analyzed experimentally characterized human protein complexes implicated in ASD. By examining the ubiquitously expressed protein complexes, we identified the subunits associated with those implicated in ASD and observed that the co-complexed subunits operate in fundamental biological processes (e. g. chromatin remodeling intracellular transport) in human and their orthologs are involved in brain development in the mouse. This analysis also identified HDAC1/2 in the NuRD complex, which preferentially interact with and positively regulate the expression of ASD gene candidate orthologs in the embryonic mouse brain. With mass spectrometry analysis in neuronal culture, we purified and proteome-wide identified the subunits co-complexed with five proteins in idiopathic ASD (ANK2, CHD8, CUL3, DYRK1A, POGZ), FMRP in Fragile X syndrome, and HDAC1. The identified proteins formed an interactive network, displayed preferential expression in early fetal brain development, exhibited increased mutational burden for deleterious mutations in ASD patients and were strongly regulated by FMRP and MeCP2 causal for two ASD related phenotypes, Fragile X and Rett syndromes, respectively. Overall, this study reveals biochemically validated protein complexes associated with ASD, defines an ASD-associated protein complex network in an ASD relevant cell type, and suggests a shared molecular basis between the idiopathic and syndromic forms of ASD.

Effect of Vitamin D supplementation on NFE2L2 or Nrf2 gene expression in multiple sclerosis patients. *r. Amirinejad[1], m. a. sahraeian[2], b. mohamad soltani[1], m. behmanesh[1].* 1) genetics, tarbiat modares uiversity, tehran, tehran, Iran; 2) Tehran University of Medical Sciences.

INTRUDUCTION: Inflammation and oxidative stress are demonstrated a crucial role to promote tissue damage in multiple sclerosis (MS) in early stages. reports confirmed important obligation of anti-oxidative pathways for tissue protection in Inflammatory-nervous diseases like MS, particularly involving the transcription factor nuclear factor (erythroid-derived 2)-related factor 2 (Nrf2). Nrf2 is referred to as the "master regulator" of the antioxidant response, modulating the expression of hundreds of genes, including the familiar antioxidant enzymes, immune and inflammatory responds. Epidemiological studies showed that vitamin D has immune and immunomodulating effects on MS disease . Inverse relationship between exposure to UV and MS disease implicated this hypothesis that improvement in EDSS in RRMS patients treatment may attenuate oxidative stress and prevent the progression of multiple sclerosis through Nrf2 pathway. Mtherial and Method: Blood samples were collected from 20 relapsing remitting Multiple sclerosis patients and levels of vitaminD were measured. 15 vitamin D deficiency patients selected and treated with vitamin D supplemented. *Peripheral blood mononuclear cell*(*PBMC*)was *collected* from whole bloodby *ficoll*density gradient separation method from 15 patients before and 2 months after vitamin D therapy and 15 age and sex-matched controls obtained. RNA from PBMC was isolated using RNX- Plus(sinaclon) and *did*the*DNase treatment* for all RNA samples. three micrograms of total RNA was used in 20 ml of reverse transcription reaction,was used 2-steps RT-PCR Kit (sinaclon). Quantitative real time PCR was performed using evagreen master mix(TAKARA) in Applied Biosystems StepOne™ System. The melting curve of each sample was measured to ensure the specificity of the products. Data were normalized to the internal control GAPDH and analyzed using $\Delta\Delta$Ct method. Result: in this study we observed that the expression of nrf2 gene in RRMS patients after vitaminD therapy 1. 9 fold increased. improvement in Expanded Disability Status Scale was seen. Discussion: Our results implicates the positive role of vitamin D, on EDSS in patients with RRMS. the ability of vitamin D in reducing the oxidative stress performance by upregulation of nrf2 gene may be associated with the reduction of EDSS scores in MS patients. to further assess Nrf2 downstream target genes that have antioxidant response elements need to be studied.

Association analysis of rs823144 polymorphism of RAB7L1 gene in Parkinson's disease in Iranian population. *B. Emamalizadeh[1], M. Rahimi[1], H. Darvish[1], A. Khaligh[2].* 1) Department of Medical Genetics, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 2) Iranian Research Center of Healthy Aging, Medical University of Sabzevar, Sabzevar, Iran.

Recent genome-wide association studies (GWAS) explored some new lociin association with Parkinson's disease. RAB7L1 is an important gene in one of neurological pathways, located in PARK16 locus, and its variants influence the risk for PD. We performed a case control study to examine association between rs823144 SNP in RAB7L1 gene and Parkinson's disease risk. **Methods:**blood samples of 980 patients and healthy controls were collected to analysis the frequency distribution of RAB7L1 polymorphisms (rs823144) using polymerase chain reaction-restriction fragment length polymorphism (PCR – RFLP) method. **Results:**Approximately 6. 3 percent of participants were C/C homozygous, 59. 1 percent were A/A Homozygous and 34. 6 percent were heterozygous. Significant association was found between presence of minor allele (C) and decreased risk of PD development ($P < 0.01$, OR = 1. 342). **Conclusion**: our dataconfirms the association between rs823144 and decreased risk of PD.

1029T

Mapping Genes using a Hidden Markov Model for Bipolar Affective Disorder in Consanguineous Families. *R. S. Harripaul[1,2,3], M. Ohadi[5], N. Moghimi[1,2,3], J. B. Vincent[1,2,3,4].* 1) Molecular Neuropsychiatry & Development (MiND) Lab, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Neurogenetics, Centre for Addiction and Mental Dealth, Toronto, Ontario, Canada; 3) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 4) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 5) The Social Welfare and Rehabilitation Sciences University, Tehran, Iran.

Bipolar Affective Disorder (BD) is a psychiatric disorder characterized by transitions between depression and mania, including a high rate of suicide (6% over age 20) and self-harm (30-40%). This debilitating condition has no known cause, and both genetic and environmental factors contribute to its complex phenotype. We hypothesize that in rare cases, autosomal recessive mutations contribute to BD. To identify these genetic loci, 34 consanguineous Iranian families were genotyped with Affymetrix 5. 0 Single Nucleotide Polymorphism microarray chips. This genotype information was analyzed with the FSuite analysis pipeline and dCHIP to identify homozygous-by-descent (HBD) regions and a HBD Genome Wide Association study to identify novel recessive loci where risk variants may reside was performed. Whole Exome and Sanger sequencing were used to search for homozygous coding mutations within these HBD regions. Large runs of homozygosity have been identified in BD probands, including a 400 Kb loci that traverses the GRIK6 glutamate receptor gene. We have also identified 48 CNVs of interest that may disrupt candidate genes such as SYN3, SLC39A11 and S100A10. In addition, we looked for Copy Number Variations (CNVs) and 43 large HBD regions were identified. We identified large HBD regions such as the 56 Mb region on chromosome 8 (harboring candidate genes such as IMPA1, IMPAD1), a 10 Mb region on chromosome 17 (including SLC6A4) and a 7 Mb region on 5q35-2-qter including genes DRD1 and GRM6. Rare variants have been identified in more than one family for a number of genes. For instance, for ABCA13, one homozygous nonsense and one homozygous non-synonymous variant were identified in separate families. Some potential variants identified in this study have been previously implicated in Bipolar Affective Disorder, Schizophrenia and Depression while others have no known function and need further characterization.

1030F

Analysis of rs1572931 polymorphism of *RAB7L1* gene in Parkinson's disease in Iranian patients. *A. Khaligh[1], M. Rahimi[2], H. Darvish[2], B. Emamalizadeh[2].* 1) Iranian Research Center of Healthy Aging, Medical University of Sabzevar, Sabzevar, Iran. , Tehran, Tehran, Iran; 2) Department of Medical Genetics, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Genetic association studies have recently made increasing data about the genetic contribution to Parkinson's disease and this has led to significant developments in discovery of pathogenesis of the PD. A large number of differenttypes of polymorphisms, particularly single nucleotide polymorphisms, have been investigated in PD in different populations by association studies. Thers1572931polymorphism of*RAB7L1* gene, located in the promoter region, is recently studied and shown to be strongly associated with reduced risk of PD. **Subjects and methods***:*We examined the association ofrs1572931polymorphism with Parkinson's disease in 480 Patients and 480 normal controls by PCR-RFLP in Iraniansubjects. **Results***:*Asignificant difference in genotype and allele frequencies was observed between patients and controls (OR = 0. 71, 95% CI= 0. 56-0. 90, *p*= 0. 003). The TT genotype and the T allele were both significantly less frequent in PD cases. **Conclusion***:*Our results confirmed the protective effect of thers1572931SNP on Parkinson's disease and replicated the results of previous studies. We suggest further studies in other populations.

1031W

Small CNVs in Major Depressive Disorder. *DL. Nuñez Ríos[1], MC. Lattig Matiz[1], Y. Gómez Maquet[2].* 1) Departamento de ciencias Biológicas. Facultad de ciencias. Universidad de los Andes. Bogotá; 2) Departamento de psicología. Facultad de ciencias sociales. Universidad de los Andes. Bogotá.

Major Depressive Disorder (MDD) is a major public health problem in the overall global population with high prevalence in children and adolescents and a tendency to decrease life expectancy in affected individuals. Although the etiology of depression is still not fully understood, genetic factors play a powerful role in the development of MDD with a heritability of up to 40% as demonstrated by twin studies. Nonetheless, gene identification has been difficult probably due to the low penetrance and multifactorial mode of MDD. Copy Number Variations (CNVs) are chromosome structural variations that include one or more genes and have been associated with schizophrenia, intellectual disability, autism and some cases of MDD. Most studies in psychiatric disorders have reported large CNVs (>100kb) that include recurrent regions such as 15q13. 3, 16p11. 2, 22q11. 2. In the present study, nineteen patients with clinical diagnosis of MDD and seventeen healthy patients were screened by array Comparative Genome Hybridization (aCGH) using Agilent 4x180k platform. We did not find any of the recurrent CNVs reported to date in our cohort; however, we did detect three rare small CNVs (deletion in 4q22. 1, 5p13. 2 and 17q25. 1) that were not present in the control group. The deletion 4q22. 1 (46kb) was present in 11/19 patients (57,8%) and includes NUDT9 [OMIM606022] and SPARCL1 [OMIM606041] genes. SPARCL-1 (secreted protein, acidic, rich in cysteine)-like 1 also known as Hevin and SC1, is a protein associated with neuronal migration and formation, maturation and plasticity of excitatory synapses. Studies in human post-morten nucleus accumbens from depressed patients reported a decrease in SPARCL-1. The 5p13. 2 deletion (38kb) was found in 5/19 patients (26,3%) and involves the alanine glyoxylate aminotransferase 2 (AGXT2[OMIM 612471]) gene which has been associated with psychiatric disorders. The 17q25. 1 deletion (86kb) was detected in 12/19 patients (63,1%) and includes ACOX1 [OMIM 264470] and CDK3 [OMIM 123828] genes. ACOX1 (acyl-CoA oxidase 1, palmitoyl), is related with pathogenesis of neurological disorder. Most CNV studies suggest that genomic disorders of the nervous system are consequence of large CNV, however recent studies have associated small CNV (<100kb) to autism. Here we report a small MDD cohort from an understudied population such as Colombia with three small CNVs that affect genes related with neuronal activity, thus suggesting a role in the pathogenesis of MDD.

1032T

A novel neurogenetic disorder with *STARD9* mutation. *N. Okamoto[1], F. Miya[2], T. Tsunoda[2], M. Kato[3], S. Saitoh[4], M. Yamasaki[5], Y. Kanemura[6,7], K. Kosaki[8].* 1) Dept Medical Genetics, Osaka Med Ctr/Res Inst, Osaka, Japan; 2) Laboratory for Medical Science Mathematics, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 3) Department of Pediatrics, Showa University School of Medicine, Tokyo, Japan; 4) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 5) Department of Pediatric Neurosurgery, Takatsuki General Hospital, Osaka, Japan; 6) Division of Regenerative Medicine, Institute for Clinical Research, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 7) Department of Neurosurgery, Osaka National Hospital, National Hospital Organization, Osaka, Japan; 8) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan.

[**INTRODUCTION**]There are 45 mammalian kinesin family member (KIF) genes and the encoded proteins are classified into 15 kinesin families that are grouped according to the position of the motor domain in the molecule. The number of KIF genes involved in neurogenetic disorder is increasing. Two of the KIF is specifically enriched at the centrioles, Kif24 at the mother centriole and STARD9/Kif16a at the daughter centriole. STARD9 is a large protein with an N-terminal kinesin motor domain, an FHA phosphoprotein binding domain, and a C-terminal START lipid/sterol binding domain. During cell division, STARD9 is enriched at the daughter centriole. STARD9 is required for pericentriolar material (PCM) cohesion and bipolar spindle assembly. Torres et al. (Cell 2011) showed that STARD9-depleted cells have fragmented PCM, form multipolar spindles, activate the spindle assembly checkpoint, arrest in mitosis, and undergo apoptosis. We identified a mutation in the *STARD9* gene by WES in a patient with severe ID, microcephaly, epilepsy and cortical blindness. [**CLINICAL REPORT]**The 5-year-old female was the first child of healthy and non-consanguineous Japanese parents. She was hypotonic and her developmental milestones were markedly delayed. She experienced a generalized tonic seizure at 6 months old. Brain MRI revealed mildly enlarged lateral ventricles. Physical examination identified microcephaly and dysmorphic features including sparse eyebrow, epicanthal folds, flat nasal bridge, low set ears, short philtrum, high arched palate and prominent Cupid's bow. She showed axial hypotonia. Deep tendon reflexes were absent. Ophthalmological investigation revealed cortical blindness. She could no sit or crawl at 6 years old. She spoke no meaningful words. Her physical growth was also delayed. [**METHODS**]With the approval of our institutional ethics committee, the samples were analyzed using WES. Precise methods have been reported in another article (Okamoto et al. J Hum Genet 2014). [**RESULTS]** The patient was homozygous for a deletion in exon23 of the *STARD9* (c. 11760delC:p. L3920fs,). Her parents were heterozygous for the mutation. This mutation is predicted to eliminate the C-terminal START lipid/sterol binding domain. [**DISCUSSION**]There have been no reports on the association of the *STARD9* mutation and genetic disorders. We suppose that abnormality of *STARD9* causes a novel neurogenetic syndrome.

1033F

Copy Number Change (CNC) in chromosomal region 3p26. 3, is consistently associated with the ADHD phenotype in a large sibship. *N. Kapalanga[1,2], D. Kwiatkowski[1], T. Trudeau[1].* 1) Department of Pediatrics, Schulich School of Medicine, Western University London, Ontario, Canada; 2) Pediatrics/Genetics, GBHS, Owen Sound, Ontario, Canada.

The contribution of genetics to the etiopathogenesis of ADHD has been estimated to be between70 to 80 percent. The evidence for genetic susceptibility to ADHD has been gathered from genome-wide associationstudies, family studies and candidate gene study approaches. While the involvement of genetic factors in susceptibility to ADHD is incontrovertible specific ADHD genes have not been identified. Even in families with clear heritability of the ADHD phenotype specificgenes have not been identified. Only one confirmed candidate gene locationon chromosome 16 has been repeatedly linked to ADHD. In this study we report on a GAIN of 0. 46 Copy Number Change (CNC) in chromosomal region 3p26. 3, that consistently associated with the ADHD phenotype ina largesibship. Ina pediatric clinic, we routinely order array CGH and Fragile X testing in all individuals who present with a history of ADHD associated with other neurodevelopmental comorbidities, in at least two first degree relatives. A family presented at clinic consultationwith seven siblings who all had varying degrees of the ADHD phenotype. Two of the sibling were from a previous marriage and thus had a different father. Momalso had the ADHDphenotype. The Conners' Parent and Teacher Rating Scale – Revised (S) was administered to all seven siblings. Further, array CGH, Fragile X testing and routine CBC and SMA were ordered for each sibling. Six of the seven siblings fulfilled criteria for ADHD. Allsix siblingsfulfilling criteria for ADHD were found to have a GAIN of 0. 46 Copy Number Change (CNC) in chromosomal region 3p26. 3. Mom was was also found to have the same CNC. Thesibling who did not fulfill criteria for ADHD did not carry the CNC. The Fragile X test was negative in all siblings. The CBC and SMA were within normal limits in all siblings. This CNC is predicted to include the promoter of CNTN4. Disruption of this gene has been associated with developmental delay and certain clinical features of the 3p deletion syndrome. In view of the consistent association of this CNC with the ADHD phenotype in this family, it is not inconceivable that a gene in chromosomal region 3p26. 3 is involved in the etiopathogenesis of ADHD. A multigenerational study and testing of extended members of this family will be undertaken. Further, a candidate gene approach focusing on chromosomal region 3p26. 3 could be used to study other ADHD patients to identify an ADHD gene at this region. .

1034W

Missense mutations in *GPT2* are associated with autosomal recessive nonsyndromic intellectual disability. *T. Lobo-Prada[1,2,3,4], S. Uebe[4], H. Sticht[5], A. B. Ekici[4], S. Bogantes[2], A. Reis[4], A. Leal[1,3,4].* 1) School of Biology, University of Costa Rica, San Jose, San Jose, Costa Rica; 2) School of Medicine, University of Costa Rica, San Jose, San Jose, Costa Rica; 3) Neuroscience Research Center, University of Costa Rica, San Jose, Costa Rica; 4) Institut für Humangenetik, Universitét Erlangen-Nürnberg, Erlangen, Germany; 5) Institut für Biochemie, Universitét Erlangen-Nürnberg, Erlangen, Germany.

Nonsyndromic intellectual disability is a heterogeneous disease that affects the central nervous system impairing patients to develop independently. Despite that numerous candidate genes have been involved in the etiology of the disease it is noteworthy that for about half of the patients it is still not possible to establish the cause of the disease. Nevertheless, recently, with the combination of exome sequencing and microarray technology it has become possible to identify rare genetic variants associated with this disease especially in consanguineous families. We identified a large Costa Rican family with four adult siblings, three females and one male affected with nonsyndromic severe intellectual disability, spastic paraparesis and severe language delay whose parents were first degree cousins. After extensive search for common genetic variants, CNVs and microdeletions we performed whole exome sequencing and identified a novel missense mutation, p. G96R, c. G286A in glutamate pyruvate transaminase 2 (*GPT2)* in all affected individuals. *GPT2* encodes a pyrodoxal enzyme involved in the production of neurotransmitter glutamate and is highly expressed in the white matter of brain and cerebellum. This variant is highly conserved in evolution and all in silico prediction algorithms used indicated that it is pathogenic. Protein modeling of GPT2 predicted that the mutation is localized in a loop where the substrate binds to the active site of the enzyme, therefore, suggesting that the catalytic activity is impaired. Recently, a further single distantly consanguineous family with three toddler siblings, two males and one female, with static developmental encephalopathy associated with severe intellectual disability, carrying a homozygous mutation in *GPT2,* p. S153R, c. C459G was reported. With our report of a second case we confirm *GPT2* as a novel cause of autosomal recessive nonsyndromic intellectual disability and support the premise that *GPT2* is highly important for the neurodevelopment of the central nervous system.

1035T

Effects of *DCDC2* and *KIAA0319* in a case-control sample for reading disability in African American and Hispanic American children. *D. T. Truong[1], N. R. Powers[1,2], J. D. Eicher[2], J. R. Gruen[1,2,3], Genes, Reading, and Dyslexia Study.* 1) Pediatrics, Yale University School of Medicine, New Haven, CT; 2) Genetics, Yale University, New Haven, CT; 3) Investigative Medicine, Yale University School of Medicine, New Haven, CT.

Reading disability (RD) is the most prevalent neurodevelopmental disorder diagnosed in school-aged children, and is characterized by a specific and unexpected difficulty in reading ability despite normal intelligence. The etiology of RD is complex with a strong genetic component reflected by heritability estimates ranging from 60% to 87%. Several genomic regions have been associated with RD, but *DCDC2* and *KIAA0319* are the most replicated candidate risk genes. Previously, our lab identified a highly polymorphic compound short tandem repeat within the breakpoints of a 2,445bp microdeletion in intron 2 of *DCDC2* (READ1) that mediates *DCDC2* enhancer activity, and is also strongly associated with RD in clinical studies. In *KIAA0319*, a putative functional SNP (rs9461045) is linked to reduced expression and impaired reading performance. Furthermore, there is evidence of epistasis between variation tagging rs9461045 and alleles 5 and 6 of READ1, independently, that yields non-additive reductions in reading and language performance. These studies have contributed to our understanding of the genetics of RD, but they primarily represent populations of European (EUR) ancestry, with Hispanic American (HA) and African American (AA) populations largely underrepresented. Therefore, it is unclear if genetic variants previously identified in EURs are informative in HA and AA groups. Thus, the purpose of this study is to examine READ1, *KIAA0319* (rs9461045), and their epistatic effects on reading behavior in the Genes, Reading, and Dyslexia (GRaD) study—a unique case-control cohort for RD comprised of 540 African American and 951 Hispanic American children. We performed a single marker analysis examining READ1 alleles previously associated with RD and language impairment in EURs (alleles 3, 5, 6, and deletion) and rs9461045 in *KIAA0319*. We found a significant association with allele 6 (p=3. 85×10-3) and rs9461045 (p=2. 77×10-3) on the Test of Word Reading Efficiency (TOWRE) in AA children. No associations with reading-related performance were observed in HA children. Examination of epistasis between READ1 alleles and rs9461045 on reading and language-related performance in the GRaD study is forthcoming. Results from the single marker analysis indicate overlapping genetic variation associated with reading-related performance across AA and EUR populations, and further support *DCDC2* and *KIAA0319* as risk genes for RD in this sample. .

1036F

Genetic susceptibility loci for late-onset Alzheimer's disease and the prevalence of subjective memory loss in healthy, older adults. *D. A. Carere[1,2], A. Bhushan[3,4], L. B. Chibnik[3,4,5], R. C. Green[2,4], W. C. Willett[3], P. Kraft[1].* 1) Program in Genetic Epidemiology and Statistical Genetics, Harvard T. H. Chan School of Public Health, Boston, MA; 2) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 3) Department of Epidemiology, Harvard T. H. Chan School of Public Health, Boston, MA; 4) Harvard Medical School, Boston, MA; 5) Department of Neurology, Brigham and Women's Hospital, Boston, MA.

Background: Subjective memory complaints (SMCs) in healthy adults have been linked to later development of Alzheimer's disease (AD). We investigated whether*apolipoprotein-E*(*APOE*) genotype and 19 AD-associated single nucleotide polymorphisms (AD-SNPs) are associated with SMCs. **Methods**: Analyses were restricted to Health Professionals Follow-up Study (HPFS) and Nurses' Health Study (NHS) participants with SMC and genotype data. SMCs were measured by 6 yes/no survey questions (e. g. , Do you have trouble finding your way around familiar streets?) in 2008 or 2012, and we computed a count of complaints (SMCscore, 0-6). Non-genetic AD risk factors (e. g. , depression) were surveyed at the same time. Genotyping and genome-wide imputation of HPFS/NHS participants had previously been performed. *APOE*genotype was inferred from 2 SNPs; weighted AD-SNP risk scores were computed from 19 other AD-associated SNPs (SNPscore). We performed linear regression of SMCscore on*APOE*genotype and SNPscore, adjusted for age and ancestry. In secondary analyses, we adjusted for non-genetic AD risk factors; evaluated effect modification by*APOE*genotype (SNPscore only), age, and gender; and excluded participants recruited for genotyping to studies of cardiovascular disease. **Results**: Among 5,022 HPFS participants (male; mean age = 76. 4±7. 7, standard deviation; SMCscore = 0. 84±1. 16) and 7,347 female NHS participants (female; age = 78. 7±6. 5; SMCscore = 0. 81±1. 23), 53. 3% reported no SMCs, and <5% reported ≥4 SMCs. *APOE*genotype was significantly associated with SMCscore, but the effect was limited to the*e3e4*(b = 0. 11; 95% confidence interval = 0. 06, 0. 15) and*e4e4*genotypes (b = 0. 38; 0. 21, 0. 56). There was no significant association between SNPscore and SMCscore, with or without adjustment for*APOE*genotype and non-genetic AD risk factors (b = 0. 05; -0. 02, 0. 12). The effect of*APOE*genotype was non-significant among women <75 years (b = 0. 06; 95% CI = -0. 06, 0. 12) but significant among women ≥75 years (b = 0. 18; 95% CI = 0. 10, 0. 25). Excluding cardiovascular disease study participants, the effect of SNPscore on SMCscore was similar to that of*APOE*genotype in our primary analysis (b = 0. 11; 0. 06, 0. 18). **Conclusion**:*APOE*status is associated with SMCs in older adults. The association between AD-SNPs and SMCs among non-cardiovascular disease study participants warrants further investigation given the complex relationship between AD, vascular dementia, metabolic disease, and*APOE*status.

1037W

Aging-related miRNAs are associated with schizophrenia and verbal memory impairment. *E. Quillen[1], M. A. Carless[1], J. Neary[1], R. C. Gur[2], M. F. Pogue-Geile[3], J. Blangero[4], H. H. H. Göring[4], V. L. Nimgaonkar[5], R. E. Gur[2], L. Almasy[4].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Departments of Psychiatry, Neurology and Radiology, University of Pennsylvania Medical Center, Philadelphia, PA, USA; 3) Department of Psychology, University of Pittsburgh, Pittsburgh, PA, USA; 4) South Texas Diabetes and Obesity Institute, University of Texas Health Science Center at San Antonio, Regional Academic Health Center, Harlingen, TX, USA; 5) Department of Psychiatry and Human Genetics, University of Pittsburgh Medical Center, Pittsburgh, PA, USA.

Mounting evidence supports a role for aging-related microRNAs (miRNAs) in a wide variety of disorders including heart disease, the metabolic syndrome, muscle disorders, and neurodegenerative diseases. Altered expression may be, in effect, prematurely aging the tissue and contributing to the onset of symptoms. To investigate a role for aging-related miRNAs in schizophrenia (SCZ), fourteen miRNAs previously shown to alter activity of canonical aging pathways were selected for analysis in 419 individuals from the Multiplex-Multigenerational Genetic Investigation of Schizophrenia (MGI). MGI is a family-based study of SCZ and related endophenotypes including measures of disordered cognition. SCZ has a heritability of 0. 92 in these families. Reduced verbal memory (VMEM) is an important endophenotype for SCZ from a clinical perspective because it is a byproduct of SCZ that is resistant to current treatments and a useful endophenotype due to its relatively large heritability (h2 =0. 52) and negative genetic correlation with the disease, suggesting overlapping genetic influences. miRNAs were extracted from lymphoblastoid cell lines and sequenced on the Illumina GA*IIx* utilizing TruSeq small RNA technology. All observed mature human miRNAs were normalized to reads per million (RPM) and aligned with 100% identity and a seed of 12 bases to mirBase version 20 using NextGENe software. Association analysis was performed in SOLAR to assess the age- and sex-adjusted relationship between miRNA expression and VMEM and SCZ while controlling for pedigree structure. Of the fourteen miRNAs considered, seven were nominally associated ($p < 0.05$) with SCZ and/or VMEM demonstrating that aging-related miRNAs are associated with SCZ more often than expected by chance. After Bonferroni correction, miR-206 is significantly associated with VMEM ($p = 0.0008$) and let-7 is significantly associated with SCZ ($p = 0.0015$). miR-206 targets the insulin-like growth factor 1 pathway which has been shown to play a major role in aging in multiple model organisms. miR-206 expression has also been shown to regulate the brain-derived neurotrophic factor in Alzheimer's disease, but associations with SCZ have been mixed. Similarly, let-7, which is known to target DAF-12 signaling has been associated with both decreased lifespan and Alzheimer's in model organisms. Taken together, these findings support a role for early-life changes in miRNA normally associated with aging in schizophrenia and verbal memory.

1038T

Neurodevelopmental Copy Number Variants and Clinical Risk: a Pediatric Medical Record Population Study. *K. Ahn[1], F. Mentch[2], C. Kao[2], H. Hakonarson[2], J. Rapoport[1].* 1) Child Psychiatry Branch, National Inst Mental Health, NIH, Bethesda, MD; 2) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Background: Chromosomal copy number variants (CNVs) associated with schizophrenia have been shown to have a broad etiological risk for neurodevelopmental disorders such as autism or intellectual deficiency and some involve other categories of disease. Their overall penetrance more broadly defined remains unknown within pediatric populations. **Method:** Selected CNVs were screened utilizing Taqman within a population sample of 60,000 pediatric patents. CNV carriers were examined with respect to pre-scored pediatric records and compared to disorders in 5:1 matched non carrier group for each individual CNV. Prevalence for 14 disorder categories were estimated. **Results:** Five of these CNVs (MYT1L (dup), 22q11 dup, 16p11. 2 (deletions and duplications), and 15q11. 3 (deletions and duplications) were detected in the pediatric population at expected rates derived from large control population studies. MYT1L dup did not contribute to increased risk of any disorder category. Having any of the other CNVs showed an increase for four of the 14 disease categoriesafter Bonferroni correction: congenital deficit, surgery, digestive system disorder or mental disorder (preimarily developmental delay). When individual CNVs were examined in relation to their matched non carriers, significant associations were found between 22q11duplication, and gastro intestinal reflux disorder which was more likely to be present in the presence of developmental delay; 16p11. 2del was associated with both mental and nervous system disorders. 15q13. 3 trend for association with mental disorders. Notably, pediatric records did not indicate increased risk for subjects with MYT1L duplication. . **Conclusion:** A broader concept of overall clinical penetrance is of importance for both genetic counseling and understanding the pathophysiology of these disorders. Psychiatric follow-up is needed to complete this study and is ongoing. . This is also the first report of a CNV association (22q11 duplication) for pediatric GERD, and may represent a delay in vagal nerve maturation.

1039F

Using a tiered cross-disorder approach to identify and confirm candidate genes for brain disorders. *A. Gonzalez-Mantilla[1], A. Moreno-De-Luca[1,2,3], D. H. Ledbetter[1,2], C. L. Martin[1,2].* 1) Autism & Developmental Medicine Institute, Geisinger Health System, Danville , PA; 2) Genomic Medicine Institute; 3) Department of Radiology, Geisinger Health System.

Developmental brain disorders (DBD) are a group of clinically and genetically heterogeneous disorders characterized by high heritability. We used a tiered, cross-disorder approach to identify novel candidate genes and provide additional evidence for genes previously associated with DBD. We based our analyses on studies showing that the identification of two independent *de novo* loss-of-function variants (LoF) in the same gene among unrelated cases with a DBD is a powerful method to reliably identify disease causative genes. Initially, we conducted a phenotype-based review of studies that used whole genome or exome sequencing, chromosomal microarrays, and/or targeted sequencing to evaluate large cohorts of cases with intellectual disability, autism, epilepsy, schizophrenia, attention deficit hyperactivity disorder, or bipolar disorder and annotated all LoF variants and associated phenotypes. We selected genes with two or more LoF variants (which also included intragenic/single gene deletions) and conducted a genotype-based literature review focused on each of the candidate genes to identify additional LoF variants and phenotypes from smaller cohort studies and case reports to compile a comprehensive cross-disorder, genotype-phenotype knowledge base. We ranked the candidate genes into four tiers based on the level of evidence: tier one includes genes with three or more *de novo* LoF variants; tier two, genes with two *de novo* LoF variants; tier three, genes with at least one *de novo* LoF variant; and tier four, genes with only inherited LoF variants. The phenotype-based literature review identified 1,807 cases with LoF variants involving 973 genes from 108 studies. Filtering our results to genes with two or more LoF variants identified in at least two unrelated cases, resulted in 232 genes. The genotype-based review identified 358 additional cases with LoF variants in 68 candidate genes from 147 studies, for a total of 232 genes where LoF variants were found twice or more in a sample of 1,417 cases. Forty-nine genes were ranked in tier one, 47 in tier two, 67 in tier three, and 69 in tier four. We identified 6 novel candidate genes and provided additional evidence for 5 novel putative candidate genes. By integrating genomic data from structural and sequence LoF variants and phenotype data from six apparently distinct DBD, the yield of gene discovery increased over what would be obtained if each disorder and type of genomic variant were analyzed independently.

1040W

Association analysis of polymorphisms in the dopaminergic pathway and cognitive measures in the Diabetes Heart Study. *S. E. Martelle[1, 2], L. M. Raffield[1], A. J. Cox[3], B. I. Freedman[4], C. E. Hugenschmidt[5], J. D. Williamson[5], D. W. Bowden[2].* 1) Integrative Physiology and Pharmacology, Wake Forest School of Medicine, Winston Salem, NC; 2) Center for Genomics and Personalized Medicine Research, Wake Forest School of Medicine, Winston Salem, NC; 3) Molecular Basis of Disease, Griffith University, Southport, Brisbane, QLD, Australia; 4) Department of Internal Medicine, Nephrology, Wake Forest School of Medicine, Winston Salem, NC; 5) Department of Internal Medicine, Gerontology and Geriatric Medicine, Wake Forest School of Medicine, Winston Salem, NC.

A wealth of epidemiological and imaging studies have established an association between type 2 diabetes (T2D) and accelerated cognitive decline. It is less clear, however, the exact mechanism linking T2D and reduced cognitive function. The monoamine system can be altered by T2D and is extensively involved in cognition. The present study tested candidate polymorphisms in genes of the DA pathway (e. g. *DDC*, *TH*, *DRD2*, *DRD3*, and *DAT1*) for association with variation in cognitive performance in a large and well-described familial cohort of T2D patients and related controls of European ancestry (n = 893). Previous analyses in the cohort, known as Diabetes Heart Study (DHS) – Mind, showed that cognitive measures are significantly heritable. Thus, we hypothesized that sequence variants in genes linked to DA metabolism are associated with cognitive function as assessed by (1) the Digit Symbol Substitution Task; (2) the Modified Mini-Mental State Examination; (3) the Stroop Task; (4) the Rey Auditory-Verbal Learning Task (RAVLT); and (5) the Controlled Oral Word Association Task for Phonemic and Semantic Fluency in this cohort. From a total of 13 SNPs (7 genes/regions) selected to form an a priori set of candidate variants, one coding variant from the dopamine decarboxylase gene (rs10499695) was associated with poorer performance on a subset of RAVLT measuring retroactive interference (p = 0. 001, b = -0. 45). Furthermore, the well-documented DAT1 3'-UTR VNTR was genotyped in the cohort and showed no evidence of association with any cognitive task. Additional analyses of loci of interest were performed using data from an Affymetrix® Genome-Wide Human SNP Array 5. 0 and 1000 Genomes imputation from this array in a subset of the cohort (n = 572). 499 SNPs were extracted from the *DAT1*, *DDC*, *DRD2*, *DRD3*, and *TH* genes. Nominal associations (p < 0. 005) in *DAT1*, *DDC* and *TH* with Stroop and RAVLT performance were revealed, but rs10499695 failed to reach significance (p=0. 039) in this subset of individuals. In conclusion, these data suggest a possible role of dopaminergic genes in cognitive performance in T2D.

1041T

Epigenetics of serotonin 1B receptor: analysis of suicidal behavior in mood disorder and schizophrenia. *A. Bani-Fatemi[1,2], A. Howe[1], N. Hettige[1,2], C. Zai[1], J. Kennedy[1,2,3], V. De Luca[1,2,3].* 1) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto, Ontario, Canada.

Background: Several studies have suggested that suicidal behavior is partially determined by genetic factors supporting a search for candidate genes involved in the neurobiology of serotonin system. HTR1B has been highlighted in the literature as being involved in suicidal behavior. We analyzed parent-of-origin effect (POE) in suicide attempters and differential expression of HTR1B rs6296 alleles in suicide victims. **Methods:** We compared the C861G (rs6296) allele-specific mRNA levels in the frontal cortex of suicide (n=13) and non-suicide victims (n=13) from the Stanley Medical Research post-mortem brain collection. We also performed a family-based association study and QTDT analyses of C861G rs6296 polymorphism in 162 nuclear families with at least one subject affected by bipolar disorder with suicidal behavior and then we tested the rare and common variants in the HTR1B promoter for linkage disequilibrium with the C861G in an unrelated sample of suicide attempters and non-attempters. **Results:** We observed no alterations in the C/G expression ratio in suicide victims compared to controls (p=0. 370); however, individuals with comorbid alcohol abuse (p=0. 009) and substance abuse (p=0. 03) were found to have a greater C/G ratio. There was no preferential transmission of C861G variant and suicidal behavior severity scores in both maternal and paternal meiosis (p>0. 05). When comparing the linkage disequilibrium between the C861G and the cis-acting SNPs, we did not find any difference in suicide attempters and non-attempters. **Conclusions:** The novelty of the present study was to combine two different molecular strategies to understand the effect of the promoter variants in differentiating the expression between the maternal and paternal chromosomes. We found that the promoter variants are likely to influence the different expression of the rs6296 SNP. No evidence of allelic imbalance or POE of rs6296 in suicidal behavior was found. Further research is required to assess these main effects in larger cohorts.

1042F

Exploration of a multiplex family with synesthesia and autism using whole genome sequencing. *A. Mathieu[1,2,3], A. Maruani[1,2,3,4], S. Calderari[1,2,3,5], F. Amsellem[1,2,3,4,5], L. Bouvet[6], J. Buratti[1,2,3,5], T. Bourgeron[1,2,3,5], L. Mottron[7], R. Delorme[1,2,3,4].* 1) Human Genetics and Cognitive Functions Unit, Institut Pasteur, Paris, France; 2) CNRS UMR 3571 : Genes, Synapses and Cognition, Institut Pasteur, Paris, France; 3) Université Paris Diderot, Sorbonne Paris Cité, Human Genetics and Cognitive Functions, Paris, France; 4) Assistance Publique-Hôpitaux de Paris, Robert Debré Hospital, Department of Child and Adolescent Psychiatry, Paris, France; 5) FondaMental Foundation, Créteil, France; 6) Unité de recherche interdisciplinaire OCTOGONE, Université Toulouse Jean Jaurès, Toulouse, France; 7) Centre d'excellence en trouble envahissants du développement de l'Université de Montréal (CETEDUM), Hôpital Rivière-des-Prairies et Département de Psychiatrie, Montréal, Canada.

Autism occurs in 1% of the population and is characterized by impaired social communication as well as by restricted interests, and repetitive behaviors. Synesthesia affects approximately 1-4% of the non-autistic population and occurs when perceiving a class of elements within one sensory modality triggers the perception of another class of elements in another modality. Synesthesia is reported more frequently in individuals with autism compared with general population. However, the genetic factors increasing the risk of synesthesia remain unknown. Here, we analyzed a three-generation multiplex family including members with autism, synesthesia or both using whole genome sequencing. The family is composed of 46 individuals (26 males and 20 females), among which two are autistic individuals without synesthesia, 3 are autistic and synaesthetes autism (including one with savant syndrome, PMID 24600416), and 10 non autistic synaesthetes only. We first performed a SNP genotyping using 1 Omni and 2. 5 Omni Illumina BeadChip arrays for 29 individuals. Then, whole genome sequencing was performed on 23 patients. For linkage analysis, we used Alohomora software to combine the pedigree information, allele frequencies and map position of the SNPs. We used Merlin to perform the non parametric (NPL) and parametric linkage analysis. The haplotype segregating with synesthesia was ascertained by Merlin and visualized by HaploPainter. For ASD or for the combination of ASD and synesthesia, linkage analysis revealed no significant LOD score. Concerning synesthesia only, a single region showed a LOD score of 2. 5 and NLP score of 1. 6 on chromosome 10. The minimal interval of 1. 89 Mb (chr10 135656 to 2027751) includes 17 genes. We could not detect copy number variant (CNV) associated with the trait. Among the variants identified using whole genome sequencing, a stopgain mutation of the isopentenyl diphosphate:dimethylallyl diphosphate isomerase type 2 *(IDI-2)* was segregating with synesthesia. In summary, this pilot linkage and sequencing study revealed a new candidate genomic region for synesthesia. Further analyses are in progress to replicate this finding and to validate mutations of IDI-2 as risk factors for this complex trait.

1043W

Targeted neurogenesis pathway-based gene analysis identifies *ADORA2A* associated with hippocampal volume in mild cognitive impairment and Alzheimer's disease. *E. Horgusluoglu[1], K. Nho[2], S. Risacher[2], AJ. Saykin[1,2,3,4].* 1) Medical and Molecular Genetics, Indiana University, School of Medicine, Indianapolis, IN; 2) Center for Neuroimaging, Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN; 3) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN; 4) Indiana Alzheimer's Disease Center, Indiana University School of Medicine, Indianapolis, IN.

Background: New neurons are generated throughout adulthood in the olfactory bulb and dentate gyrus of the hippocampus, and are incorporated into hippocampal networks during construction and maintenance of neural circuits and in turn contribute to learning and memory. Numerous intrinsic and extrinsic factors such as growth factors, transcription factors, and cell cycle regulators control neural stem cells proliferation, differentiation, and maintenance into mature neurons. However, the genetic mechanisms controlling adult hippocampal neurogenesis remain unclear. To address this issue we performed a gene-based association analysis of neurogenesis pathway-related candidate genes using data from the Alzheimer's Disease Neuroimaging Initiative (ADNI). Methods**:** Neurogenesis-related genes were curated from existing databases (Qiagen RT2 Profiler PCR Arrays and Mammalian Adult Neurogenesis Gene Ontology (MANGO)). The gene list was filtered by AD susceptibility genes from the Alzgene database (http://www. alzgene. org/) and large-scale GWAS (Lambert,et al. 2013, *Nature*). Caucasian non-Hispanic individuals (N=1,525) with AD or mild cognitive impairment (MCI) and cognitively normal older adults from the ADNI cohort with MRI and genotyping data were included. Gene-based association analysis of neurogenesis pathway-related candidate genes was performed. Baseline bilateral hippocampus and hippocampal subfield (CA4 and dentate gyrus (CA4DG)) volumes were extracted from MRI and served as phenotypes. Gender, age, intracranial volume, MRI field strength, and diagnosis at scanning were entered as covariates. The empirical *p* value from permutation testing for each gene wascalculated to adjustfor the number of significant SNPs in each gene. Results: *ADORA2A* was significantly associated with total hippocampal volume and CA4DG ($p<0.001$). For the most significant SNP (rs9608282) in *ADORA2A,* dosage of the minor allele (T) increased hippocampal volume. rs9608282 was also associated with composite memory score ($p= 0.0076$). We replicated the association between rs9608282 (*ADORA2A*) and total hippocampal volume in the independent AddNeuroMed cohort. Conclusion: *ADORA2A*-mediated control of neuroinflammation modulates adult neurogenesis and the inhibition of *ADORA2A* prevents Aβ-induced neurotoxicity. Targeted pathway-based genetic analysis combined with brain imaging endophenotypes appears promising to help elucidate disease pathophysiology and identify potential therapeutic targets.

1044T

Don't lose the forest for the trees- new insights into Juvenile Psychosis from chromosomal microarrays. *C. A. Brownstein[1], P. Agrawal[2], M. C. Towne[2], V. Lip[4], A. H. Beggs[1], J. Gonzalez-Heydrich[3].* 1) Division of Genetics and Genomics, The Research Connection, The Manton Center for Orphan Disease Research, and the Developmental Neuropsychiatry Program, Boston Children's Hospital, Boston, MA; 2) Division of Genetics and Genomics, The Manton Center for Orphan Disease Research, Boston Children's Hospital, Boston, MA; 3) The Developmental Neuropsychiatry Program, Boston Children's Hospital, Boston, MA; 4) Claritas Genomics, Cambridge, MA.

New candidate genes and regions for schizoaffective disorders including schizophrenia are being discovered at a rapid rate. However, this family of illnesses are still considered to be highly heritable neuropsychiatric disorders of complex genetic etiology. Copy number variation (CNV) is a highly topical area of research in schizophrenia, but the clinical relevance is uncertain and the translation to clinical practice is under-studied. However, genome overlap between psychiatric disorders means that when a CNV is implicated in a related mental health disorder, the evidence becomes more convincing. Regions that have been implicated in autism have been also implicated in schizophrenia. Here, we describe a cohort of juvenile patients with auditory and visual hallucinations at a tertiary children's hospital. Forty-one families have been identified with having a child showing signs of psychosis before 11 years of age. 28 families have been consented thus far. 13/21 patients have had abnormal chromosomal microarray results (8 deletions, 4 duplications, 1 LOH). Genes affected by the copy number variations include ABCC6, NOMO1, NPIP, NTAN1, RRN3, PDXDC1, FLJ00285, FLJ00285, LOC100288332, DQ599532, MPV17L, C16orf45, KIAA0430, NDE1, MYH11, FOPNL, ABCC1, DDHD2, CPPED1, SMARCA4, CTSB, GATA4, NEIL2, BLK, TDH, MTMR9, XKR6, PINX1, RP1L1, UNQ9391, MSRA, TNKS, PPP1R3B, ERI1, CLDN23, PRAGMIN, DEFB109, HE2, SPAG11A, SPAG11B, DEFB107B, LOZ93432, MOXD2P, TRYX3, PRSS58, LOC730441, TRY2P, and TCRBV,Genes that have been identified as candidates in other mental health disorders include NTAN1, NDE1, SMARCA4, and ABCC1. Boston Children's Hospital is developing the infrastructure needed for large-scale psychiatric research and treatment discovery with the creation of the Developmental Neuropsychiatry Program (DNP). The DNP is investigating therapeutics to prevent the development of schizophrenia in at-risk children by working with the youngest patients (some of which are described here), creating neuronal cell cultures to identify cell autonomous effects, and constructing models of neural networks. The study of rare Mendelian forms of Juvenile Psychosis are an effective way to discover new candidate genes for the condition. Syndromic patients with very early onset psychosis likely increases the chances of finding a CNV with CMA. Don't lose the forest for the trees-CMAs are less expensive than exome and still yield valuable insights.

1045F

Genetic Association Study Suggests FOXA1 Could Be a Common Regulator of Epilepsy Electroencephalogram Endophenotype and Reading Disability Comorbidity. *N. Panjwani[1], J. Crosbie[3,4], P. Arnold[1,3,4], R. Schachar[1,3,4], D. K. Pal[5], L. J. Strug[1,2].* 1) Genetics and Genome Biology, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 2) Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Neurosciences and Mental Health Program, Research Institute, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 4) Department of Psychiatry, The Hospital for Sick Children, University of Toronto, Toronto, Ontario, Canada; 5) Department of Basic and Clinical Neuroscience, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK.

IntroductionRolandic epilepsy (RE) is a neurodevelopmental disorder characterized by seizures and centrotemporal sharp waves (CTS) on electroencephalogram. Patients and relatives have high risk of literacy impairments (RDG). We have identified linkage of CTS in RE to 11p13 and association with markers in the *ELP4-PAX6* locus (Strug et al. 2009), although this association was not replicated (Reinthaler et al. 2014). We have also found linkage of RDG in RE to the 1q42 locus (Strug et al. 2012), but there have been no replication studies. We therefore aimed to clarify the evidence for the two loci in RE-associated CTS and RDG in an independent collection of RE families and population-based controls. **Methods**RE families from North America and Europe (214 individuals with CTS, 140 with RDG) and 749 sex and ethnicity matched controls from the Ontario Science Centre (N=749) were genotyped on the HumanCoreExome and HumanOmniExpress BeadChips. We used generalized estimating equations with a logit link and independence correlation structure for association analysis, corrected for sex and population structure. We fine-mapped the loci using imputation for significant regions, defined as –log10P=2. 514 for the *ELP4-PAX6* and –log10P=4. 445 for 1q42. **Results**One genotyped SNP (rs662702) reached regional significance at the *ELP4-PAX6* locus (OR=2. 07; –log10P = 2. 79). Results remained consistent when patients were geographically grouped: North Americans OR=2. 11, –log10P=2. 12; and Europeans OR=1. 92, –log10P=1. 68. Similarly, one genotyped SNP reached regional significance for RDG, rs1495855, –log10P=5. 08, OR=2. 28, along with 10 nearby imputed SNPs in linkage disequilibrium (LD). The CTS associated rs662702 is in the 3'-UTR of *PAX6* while rs1495855 for the RDG is intergenic. Interestingly, both SNPs are located at or in complete LD with reported FOXA1 transcription factor binding regions while histone marks suggest enhancer activity in neurons (Ward and Kellis, 2011; Boyle et al 2012). **Discussion**We report replication of both the 11p13 CTS locus and 1q42 RDG locus. Changes in the 3'UTR of *PAX6,* an important mediator of forebrain development (Georgala et al 2011), may influence PAX6 levels. FoxA factors regulate regional brain and neuronal specification and differentiation (Lin et al. 2009). Furthermore, histone modifications suggest enhancer activity in early neurodevelopment. These results stimulate new mechanistic hypotheses in common neurodevelopmental disorders.

1046W

Exome sequencing in a cohort of patients with microcephaly and related conditions – identification of known and novel disease genes and the lessons learned. *A. T. Pagnamenta[1], M. F. Howard[1], N. Popitsch[1], S. J. L. Knight[1], N. Galjart[2], A. Goriely[3], D. A. Keays[4], J. C. Taylor[1], U. Kini[5].* 1) National Institute for Health Research Biomedical Research Centre, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford OX3 7BN, UK; 2) Department of Cell Biology, Erasmus Medical Center, 3015 GE Rotterdam, Netherlands; 3) Weatherall Institute of Molecular Medicine, University of Oxford, Oxford OX3 9DS, United Kingdom; 4) Institute of Molecular Pathology, Vienna 1030, Austria; 5) Department of Clinical Genetics, Oxford University Hospitals NHS Trust, Oxford OX3 9DU, UK.

Background: Development of the brain requires a delicate balance between cellular proliferation, differentiation, organisation, migration and apoptosis. When this process is disrupted, structural abnormalities may result. Due to significant levels of genetic heterogeneity and the complexity of the processes involved, we assessed the diagnostic value of whole-exome sequencing (WES) for patients with microcephaly and related conditions. **Methods:** Over 200 subjects with brain malformations were recruited. After excluding likely causal CNVs, 19 families with microcephaly and related conditions were selected. 7 of these families were reported to be consanguineous and for these, SNP arrays were used to identify regions of autozygosity. Exomes were captured from patient DNA samples using commercially available kits and sequenced on the Illumina HiSeq platform. **Results:** Likely causative variants were identified in 6 genes which were novel at the time of discovery. ENCODE data helped us identify a novel variant located 4bp upstream of the *PIGY* transcription start site which cosegregated with microcephaly and disrupts a consensus SP1 binding site. Using qPCR and deep Ion PGM sequencing, we showed that this variant leads to reduced *PIGY* expression. In another affected sib pair, we identified a *CLASP1* p. G1220S mutation located within a 26Mb region of shared autozygosity for which protein interaction studies are currently underway. A boy with microcephaly and cerebellar vermis atrophy harbored a *de novo* p. C29* variant in *SOX11,* a gene recently associated with Coffin-Siris syndrome*.* A girl with progressive microcephaly was found to harbor a 7bp deletion in *GPT2* within a 34Mb region of autozygosity. This variant was overlooked initially as it was in 73% of reads and erroneously called heterozygous, emphasizing the benefits of having a flexible filtering strategy. Mutations in *GPT2* have recently been reported in developmental encephalopathy. In 2 other families we identified *PGAP3* and *PI4KA* as novel disease genes, which we have described elsewhere. Presumed causative variants were also detected within well-established disease genes including *de novo* mutations in *CASK*/*PCDH19*, compound heterozygous variants in *CDK5RAP2*/*ASPM* and a homozygous *TBC1D24* substitution. **Conclusions:** Likely pathogenic variants were identified in 63% of cases, in both known and novel disease genes, highlighting the benefits of WES over gene panel approaches in this heterogeneous group of patients.

1047T

Gene-gene interaction analysis of mitochondria-related genes in the risk of Parkinson's disease and Alzheimer's disease. *S. J. Chung[1], J. Kim[1], Y. J. Kim[1], S. You[2], M. Kim[3], S. Y. Kim[4], J. Lee[1].* 1) Neurology, Asan Medical Center, Seoul, Seoul, South Korea; 2) Department of Neurology, Dongsan Medical Center, Keimyung University, Daegu, Korea; 3) Department of Neurology, Bobath Memorial Hospital, Seongnam, Republic of Korea; 4) Department of Psychiatry, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea.

Objectives: To investigate the role of genetic interaction among mitochondria-related genes in the development of Parkinson's disease (PD) and Alzheimer's disease (AD). **Background:** Mitochondrial dysfunction in the substantia nigra has been documented in patients with PD. It is also recognized as major contributor in Aß-mediated neurotoxicity in AD. The importance of mitochondria to the cause and pathogenesis of PD and AD has been reinforced by the identification of specific mutations in the mitochondria-linked genes. **Methods:** The mortalin (*HSPA9*), *parkin*, *PINK1*, *DJ1*, and *COQ2* genes were selected. For *HSPA9*, direct sequencing using an automated DNA sequencer (ABI 3730, Applied Biosystems, CA, USA) for the entire coding region (17 exons) and exon-intron boundary of 50 bp was performed in 24 AD patients, 24 PD patients, and 24 controls. The genetic variants with minor allele frequency (MAF) > 1% from sequencing data were selected for the second-stage genotyping. Common (MAF > 5%) and low-frequency (MAF = 1 – 5%) genetic variants were also selected using the HapMap and 1000 Genomes Project JPT and CHB samples to select variants in the *HSPA9*, *parkin*, *PINK1*, *DJ1*, and *COQ2* genes. We genotyped genetic variants (8 in *HSPA9*, 10 in *parkin*, 4 in *PINK1*, 6 in *DJ1*, and 2 in *COQ2*) in 400 AD cases, 500 PD cases, and 500 controls, using the Fluidigm high-throughput platform. Logistic regression analysis with additive coding schemes as a primary analysis was performed. **Results:** The high-risk group carrying more than 4 risk alleles in the *HSPA9* SNP rs41295739, *parkin* SNP rs9356040, *PINK1* SNP rs76795760, *DJ1* SNP rs2235733, and *COQ2* variant M128V had significantly increased risk of PD compared with the low-risk group carrying 0-2 risk alleles (= 0. 01 for 4 vs 0-2 risk alleles). The high-risk group carrying more than 3 risk alleles in the *HSPA9* SNP rs41295739, *parkin* SNP rs1784590, *PINK1* SNP rs1043424, *DJ1* SNP rs34124834, and *COQ2* SNP rs148156462 had significantly increased risk of AD compared with the low-risk group carrying 0-2 risk alleles (= 0. 039 for 4 vs 0-2 risk alleles). **Conclusions:** Our results suggest that genetic interaction among mitochondria-linked genes may play a role in the development of PD and AD.

1048F

Deletion in *ABCA7* associated with Alzheimer's disease in African Americans. *H. N. Cukier[1], B. W. Kunkle[1], S. Rolati[1], K. L. Hamilton-Nelson[1], M. A. Kohli[1], B. A. Dombroski[2], B. N. The *ATP-binding cassette, sub-family A (ABC1), member 7* (*ABCA7*) gene has been implicated as a risk factor in Alzheimer's disease (AD) in both African American (AA) and Caucasian (CA) populations, each with distinct polymorphisms of differing effect sizes. The effect in AA is significantly higher, comparable to that found in CA for *APOE ε4*. The AA risk allele, rs115550680, is monomorphic in CA (1,000 Genomes) and located 13. 2 kb upstream of the CA risk allele, rs4147929. Despite numerous studies implicating *ABCA7*, the underlying damaging alleles conveying the genome-wide signals have yet to be revealed. We performed custom capture sequencing of a 150 kb region encompassing the *ABCA7* region on 40 AA individuals with AD and 37 control AA carrying the AA risk allele. Data were processed via GATK and BWA, and deletions identified with Pindel. 1,120 SNVs were detected by sequencing. 11 variants had different frequencies in cases and controls (p<0. 1). In addition, a 44 base pair deletion (rs142076058) was identified in all 77 risk genotype carriers, signifying that it could be in high linkage disequilibrium with the AA risk allele. This deletion was further assessed in two AA cohorts – HIHG (cases:494, controls >65 yrs:494) and ADGC (cases:521, controls >65 yrs:890). Analyses for each cohort were adjusted for gender, age, and *APOE* status. In the HIHG cohort, the deletion was present in more cases (14%) compared to controls (10%) and correlated significantly with disease (p=0. 0002, OR=2. 1 [CI:1. 4-3. 1]). The AA risk allele is similarly significant (p=0. 0008, OR=2. 0 [CI:1. 3-3. 0]). There were 3 discordant individuals with the deletion alone; all 3 presented with AD, demonstrating that the deletion could be the underlying, causative variant. The association was then replicated in the ADGC cohort (p=0. 0097, OR=1. 6 [CI:1. 1-2. 3]). Joint analysis of the AA cohorts resulted in an increased effect size (p=0. 0003, OR=1. 6 [CI:1. 3-2. 1]). The deletion was found in only 0. 09% of our CA cohort. Reverse transcription-PCR from RNA extracted from the blood of AA individuals with and without the deletion demonstrated that the deleted allele produces a stable, detectable RNA strand. The deletion falls in the 14th exon of *ABCA7* and is predicted to result in a frameshift and truncating mutation (p. Arg578Alafs) that could interfere with protein function. This *ABCA7* deletion could represent an ethnic-specific, pathogenic alteration in Alzheimer's disease.

Towards the identification of new genes in recessive Parkinson's disease. *V. Drouet[1], A. Nicolas[1], M. Jacoupy[1], F. Cormier-Dequaire[1,2], M. Sabahtou[3], S. Liebau[4], E. Lohmann[5,6], M. Tazir[7], A-L. Leutenegger[8], A. Singleton[9], O. Corti[1], S. Lesage[1], A. Brice[1,10] for the French PDG group and the IPDGC consortium.* 1) Sorbonne Universités, UPMC Univ Paris 06 UMR S 1127, Inserm U 1127, CNRS UMR 7225/NEB, Institut du Cerveau et de la Moelle épinière, ICM, Paris, France; 2) Centre d'Investigation Clinique Pitié Neurosciences CIC-1422, Paris, France, Paris, France; 3) Fondation Jean Dausset-CEPH, Paris, France; 4) Institute of Neuroanatomy, Eberhard Karls University Tübingen, Tübingen, Germany; 5) Movement Disorders Unit, Department of Neurology, Istanbul Faculty of Medicine, Istanbul University, Istanbul, Turkey; 6) Department of Neurodegenerative Diseases, Hertie Institute for Clinical Brain Research, University of Tübingen, Tübingen, Germany; 7) Service de neurologie CHU Mustapha, Alger, Algérie; 8) Inserm U946, Université Paris Diderot, Institut Universitaire d'Hématologie, UMR946, Paris, France; 9) Laboratory of Neurogenetics, National Institute on Aging, Bethesda, MD 20892, USA; 10) AP-HP, Hôpital de la Salpêtrière, Department of Genetics and Cytogenetics, Paris, France.

Autosomal recessive early-onset Parkinson's disease (PD) is clinically and genetically heterogeneous: mutations in three genes, *PARK2*, *PINK1* (PARK6) and *DJ-1* (PARK7), cause phenotypes similar to idiopathic PD with a good and prolonged response to dopaminergic therapy. Mutations in other genes, *ATP13A2* (PARK9), *PLA2G6* (PARK14), *FBXO7* (PARK15), *DNAJC6* (PARK19), and *SYNJ1* (PARK20), cause more severe disease, a poor response to levodopa and additional clinical signs: dystonia, cognitive impairment, neuro-behavioural abnormalities, pyramidal signs, ophthalmoparesis, and autonomic dysfunction. In approximately 50% of the familial cases with early-onset PD, mutations in these genes are not detected, suggesting further genetic heterogeneity with the involvement of one or, more probably, several other genes. To identify new genes implicated in this disorder, we selected 140 early-onset (<55 years) PD families or isolated cases with known or suspected consanguinity, excluded for *PARK2*, *PINK1*, *PARK7*, and *LRRK2* G2019S mutation. We performed genome-wide SNP genotyping to detect genomic rearrangement and regions of homozygosity. Then, exome sequencing in 62 cases with confirmed consanguinity (inbreeding coefficient F≠0) were carried out. We prioritized homozygous variants predicted to produce frameshifts, stop codons or splicing defects, which: 1) would disrupt protein function; 2) were rare (allele frequency <1%) or novel but absent in the homozygous state in 530 Caucasian controls and 6503 exomes in the EVS database; 3) fell within homozygous intervals. Preliminary analyses of the exome data led to the identification of deleterious mutations in *ATP13A2*, *FBXO7* in 2 affected sibpairs, and a list of 44 new candidate genes. Functional validation of the best candidate genes is in progress. The identification of new genes involved in early-onset autosomal recessive PD will improve diagnosis and genetic counselling in patients and their relatives. It will also open new avenues of research on the mechanism of neurodegeneration in PD and allow the development of currently unavailable, innovative, mechanistically-based treatments to cure or slow the progression of the disease.

1050T

Molecular study of PMP22 gene duplication by MLPA and point mutations of MPZ and MFN2 genes in Charcot–Marie –Tooth patients in northwest of Iran. *P. Aob[1], A. Biglari[1], M. r. Ranjouri[1], S. Mansouri derakhshan[2], M. Shekari khaniani[2].* 1) Medical Genetic Department, Faculty of Medicine, Zanjan university of medical science, Zanjan, Iran; 2) Medical Genetic Department, Faculty of Medicine, Tabriz University of Medical Sciences, Tabriz, Iran.

Back ground: Charcot-Marie-tooth (CMT) is one of the sensory and motor neuropathies with a frequency of 1 in 2500. Clinical manifestations of CMT include slowly progressive distal weakness, sensory loss and foot deformities, which spreads proximally as the disease progresses. The syndrome represents a genetically and clinically heterogeneous group of inherited disorders classified into demyelinating form (CMT1) and axonal form (CMT2). This disorder has been related to mutations in more than 45 genes affecting glial or neuronal functions. **Objective:** Since there is no information on the frequency of CMT1A, CMT1B and CMT2A neuropathies in northwest of Iran, the aim of the present study was to estimate the frequency of genetic subtypes of CMT in this population. **Material and Methods:** From whole peripheral blood of 30 unrelated patients with a suspected diagnosis of CMT total genomic DNA was extracted by salting-out. DNA samples were analyzed by MLPA kit for detection of PMP22, COX10 and TEKT3 (located in the CMT1A/HNPP region) duplication, and KIF1B mutation. MLPA data analysis were performed using GeneMarker V2. 6. 3. Furthermore, PCR amplification and direct sequencing methods were used for the point mutations of MPZ and MFN2 genes in samples negative in MLPA analysis. **Results**: The MLPA method identified 6 patients with CMT1A/HNPP region rearrangements (including PMP22, COX10 and TEKT3 genes), 2 patients with only PMP22 duplication and 1 patient with COX10 duplication. No mutation were found in KIF1B gene. Also, the point mutation in *MPZ* and *MFN2* were found by direct sequencing in 2 and 1 patients, respectively. In total, the frequency of CMT1A, CMT1B and CMT2A were estimated 30%, 6. 6% and 3. 3%, respectively. **Discussion:** The data presented here provide an overview of frequencies of genetic subtypes of CMT patients in the Northwest of Iran for the first time. We analyzed the most frequently mutated genes associated with CMT in a selected cohort of patients and were able to achieve a molecular diagnosis in 40 % of patients (12/30). Finally, the screening of PMP22, MPZ and MFN2 mutations, which are the genes involved in 90% of CMT cases, showed that they have a low frequency in the population we studied. Therefore, it is possible that the rare mutations known to play a part in CMT are the cause of the disease in the population. Hence, whole genome sequencing is suggested to achieve an exact molecular diagnosis.

1051F

A *LRRK2* haplotype provides protection for Korean multiple system atrophy. *E. Scott[1], I. Guella[1], S. Bortnick[1], B. S. Jeon[2], M. J. Farrer[1].* 1) Djavad Mowafaghian Centre for Brain Health, Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 2) Department of Neurology, Clinical Research Institute and Movement Disorder Center, Seoul National University Hospital, Seoul, South Korea.

Multiple system atrophy (MSA) is a rare, sporadic, adult-onset neurodegenerative disorder that is similar in both clinical and pathological presentation to Parkinson's disease (PD). MSA is characterized by progressive autonomic dysfunction in addition to parkinsonian features (MSA-P subtype) or cerebellar features (MSA-C subtype). In PD, mutations in the *LRRK2* gene are recognized as one of the most common genetic causes to date. Polymorphic variants in *LRRK2* have been previously associated with PD susceptibility in both Caucasian and Asian PD patients. Recently, a protective haplotype in *LRRK2* was implicated in a Caucasian MSA cohort. Herein, we evaluate the association between common *LRRK2* exonic variants and MSA in the Korean population. 12 SNPs selected from previous *LRRK2* MSA and PD studies were genotyped by Sequenom iPLEX in 312 MSA patients and 477 controls. No significant nominal associations for the 12 SNPs were detected after correcting for multiple testing. However, non-significant trends towards protective association were observed for rs7308720, rs7133914, and rs11175964. After haplotype analysis, one large, significant protective haplotype that spans the majority of the coding region of *LRRK2* was observed (OR = 0. 65, p = 0. 027). This protective haplotype exists only when the A alleles are found at both rs7133914 and rs11175964, such that if the G alleles are present at these two SNPs, the haplotype becomes a risk haplotype. In conclusion, our study replicates, in the Korean population, the association observed between *LRRK2* and MSA. Moreover, our findings narrow down the previously-reported association to two variants (rs7133914 and rs11175964) within the ROC domain of *LRRK2*, suggesting that these variants confer the protection against MSA. The GTPase activity of LRRK2 is localized to the ROC domain, thus it is suggested that rs7133914 and/or rs11175964 alter the GTPase activity to provide protection. In addition, our findings suggest a possible association between MSA and Crohn's disease through a shared variant in *LRRK2* (rs3761863), such that individuals with MSA may be more susceptible to developing Crohn's disease. Further studies are warranted to confirm the roles of rs7133914 and rs11175964 in protection as well as the association of rs3761863 in development of Crohn's disease in MSA patients.

1052W

Parkinson's disease and genetic variability in a French Canadian isolate. *L. Sellmer[1], E. M. Bernhardi[1], I. Guella[1], M. McKenzie[1], E. Poucher[2], M. J. Farrer[1].* 1) Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Centre Medical Berger, 1000 Chemin Sainte-Foy, Quebec City, QC, Canada.

Parkinson's disease (PD) is a progressive neurodegenerative disorder with a global prevalence of about 4% by age 80. Even though most cases of PD are idiopathic, over 10% of patients report a positive family history of PD. Several genes have been implicated in autosomal-dominant PD, however, a larger portion of familial cases remain unexplained. Recently, we were able to obtain samples from 22 families of a French Canadian community; members of this community descend from *Les filles du roi.* The King's Daughters consisted of approx. 800 French women from northern and western France who immigrated to what is today called Quebec in the 17th century. The French Canadian community investigated in this study shows a seemingly very high prevalence of PD for which no genetic cause has been described. In order to investigate the underlying genetic components in this population isolate, we investigated sequence variability and exon dosage in genes known to cause PD. Subsequently, we performed Whole Exome Sequencing (WES) of 25 members of selected pedigrees. In addition, informative samples of each pedigree were genotyped on the Illumina MEGA SNP array. Discriminant Analysis of Principal Components (DAPC) performed in various Caucasian populations indicates that French Canadians are distinct in their genetic profile from the Faroese, another population isolate, Norwegians and other Caucasians. Mendelian sharing ratios above 0. 41 for unrelated individuals show that supposedly unrelated individuals from this French Canadian community are more closely related than to be expected, confirming a common founder. Large runs of homozygosity shared across multiple families were imputed from genotyping on the MEGA platform and further support relatedness and a common underlying genetic cause for disease. However, no genetic variability in known PD genes was observed in any of the investigated samples, suggesting that novel, population-specific variability could underlie disease in this population isolate. Herein, we have performed a comprehensive analysis of the genetic profile of an inbred community with a high prevalence of PD. Mutations in known genes linked to PD cannot explain this occurrence and further exome sequencing and comparative analysis within and among pedigrees with multi-incident PD are on-going.

1053T

Association between serotonin transporter VNTR and depression at 12 months post aneurysmal subarachnoid hemorrhage. *A. Stanfill, P. Sherwood, E. Crago, S. Poloyac, Y. Conley.* University of Pittsburgh, Pittsburgh, PA.

The VNTR in the second intron of the serotonin transporter gene (*SLC6A4*) has been associated with the development of post stroke depression (PSD) in ischemic stroke; however it has not been investigated with development of PSD in aneurysmal stroke. Aneurysmal subarachnoid hemorrhage (aSAH) patients are also likely to experience depression, which can affect mental acuity, lengthen recovery times, and can result in reductions in quality of life. The 9/12 and 12/12 genotypes are high risk, the 10/12 genotype is intermediate risk, and the 10/10 genotype is low risk in studies of PSD following ischemic stroke. The purpose of this study is to determine whether the association between this VNTR and PSD holds for aSAH patients. Blood samples were collected from 135 aSAH patients at time of admission. The DNA template was extracted and the samples were genotyped using PCR-RFLP. Subjects were divided into depression risk categories (high, intermediate, low) based upon VNTR genotype. Demographic information was obtained from hospitalization records, and depressive symptoms were measured at twelve months post stroke using the Beck's Depression Inventory II (BDI-II). This instrument is a 21 item self-report measure on which subjects rate depressive symptoms and attitudes on a 5-point Likert scale, and has established validity with clinically diagnosed depression. The sample was 80% female, 92% Caucasian, and 55. 08 ± 10. 31 years. Mean Fisher score at time of admission was 2. 65 ± 0. 68 and the mode was 2. Significant associations with PSD were found between all 3 genotype risk categories (ANOVA, p=0. 05), and between high risk and low risk genotypes (point biserial correlation r=0. 23, p=0. 04). For exploratory and hypothesis generating purposes, a multiple regression model with genotype, age, race, gender, and Fisher score at time of admission was significant to predict PSD (R2=0. 16, p=0. 004). These results support the association found between VNTR genotype and PSD for subarachnoid hemorrhage. This information could be used in the future to identify patients most at risk for PSD, which would then allow for targeted medical intervention prior to the development of severe symptoms.

Childhood Maltreatment Associates with Long Non-Coding RNAs Differentially Expressed in the Rostral Anterior Cingulate Cortex. *Y. Zhou, P. E Lutz, G. Turecki.* McGill Group for Suicide Studies, McGill University, Montreal, Quebec, Canada.

Background: Childhood maltreatment (CM) has been strongly associated with the dysregulation of key genes underlying various stress response systems. Changes incurred during early life may lead to lifetime negative consequences contributing to suicide etiology. Recently, long non-coding RNAs (lncRNAs) have been implicated in brain development as well as in various neurodegenerative diseases and neuropsychiatric disorders. Whether lncRNAs play a significant role in translating the effects of CM into biological programs of gene regulation remains to be investigated. Our **objectives** are (i) to investigate whether CM associates with changes in lncRNAs expression in specific brain regions, and (ii) to test whether these lncRNAs regulate the expression of other genes underlying important cellular processes. **Methods:** We performed high throughput RNA-sequencing (RNA-seq) in the rostral anterior cingulate cortex (rACC), a brain region implicated in emotional regulation. We compared 26 suicide completers with a history of CM and 24 age-matched controls free of psychiatric disorders who died by accident or naturally, and with no history of CM. Then, we used reverse transcription quantitative polymerase chain reaction (RT-qPCR) to validate the expression of one of the differentially expressed lncRNAs in the original two groups of subjects as well as in a third group of 25 suicide completers without a history of CM. **Results:** 8 differentially expressed lncRNAs were identified from the RNA-seq results. There was a significant increase in the expression of the lncRNA RP11-273G15. 2 in suicide completers with a history of CM compared to controls. Validation using RT-qPCR showed a similar pattern of expression whereby RP11-273G15. 2 expression was higher in suicides exposed to CM compared to both controls and suicides not exposed to CM. Furthermore, the expression of RP11-273G15. 2 was significantly correlated with 7 nearby genes; 4 were lymphocyte antigen 6 (LY6) genes and 2 were genes encoding zinc finger proteins. **Conclusions:** Exposure to CM may increase the expression of RP11-273G15. 2 in the rACC. Possible molecular mechanisms underlying the regulation of lncRNA expression, such as epigenetic modifications, remain to be investigated. Additionally, RP11-273G15. 2 may regulate the expression of a subset of LY6 genes and zinc finger proteins, which may underlie important cellular processes that contribute to suicide etiology.

1055W

Follow-up of the SNP rs1156026 association with schizophrenia in a Quebec sample reveals a complex interplay with DNAJC15 deletions in predicting schizophrenia and bipolar disorder. *A. Bureau[1,2], Y. C. Chagnon[2,3], J. Croteau[2], A. Fournier[2], M. -A. Roy[2,3], T. Paccalet[2], C. Mérette[2,3], M. Maziade[2,3].* 1) Médecine sociale et préventive, Univ Laval, Québec, PQ, Canada; 2) Centre de recherche du Centre intégré universitaire en santé et services sociaux de Québec, PQ, Canada; 3) Psychiatrie et neurosciences, Univ Laval, Québec, PQ, Canada.

Single nucleotide polymorphism rs1156026 at 13q13-q14 was previously associated to schizophrenia (SZ) (Bureau et al. Biol Psychiatry 74(6): 444–450, 2013). Sequencing of 5 Mb of surrounding genomic DNA was undertaken in 12 subjects from 8 Eastern Quebec kindreds carrying the rs1156026 associated T allele. Genomic DNA was captured using custom microchips (Nimblegen, Roche; IBIS Laval University) and sequenced on a Illumina HiSeq sequencer (Génome Québec). Deleted forms of the deletion/insertions rs10569822, rs113886253 and rs146020684 were found on a haplotype segregating with the major psychosis (MP) phenotype comprising SZ, bipolar disorder (BP) and schizoaffective disorder in kindreds linked to the 13q13-q14 region (Maziade et al. EJHG, 17(8): 1034-1042, 2009). These deletions located in introns of the *DNAJC15* gene were genotyped in 1180 available subjects from 48 kindreds using custom specific PCR primers and DNA sequencers (LiCor). The three deletions were in strong linkage disequilibrium (r2 > 0. 9) and were significantly associated to BP (odds ratio (OR) = 1. 79, p = 0. 038 for rs10569822), but not to SZ or MP when compared to non-affected adult relatives in the 10 kindreds linked to the 13q13-q14 region (N=228). We next examined the association of the deletions and rs1156026 jointly, using a dominant model. We observed that the deletions were associated to BP among carriers of the T allele of SNP rs1156026 in the linked kindreds (OR = 3. 94, p=0. 012, for rs10569822). This association was not observed in subjects with the CC genotype of SNP rs1156026. We also observed that the odds ratio for SZ between carriers and non-carriers of the T allele of rs1156026 was independent of the deletions. These results reveal a complex interplay between genetic variants at 13q13-q14 and the risk of psychotic disorders, with some genotype combinations conferring risk of SZ and others conferring risk of BP.

1056T

Genetic and functional analysis of neurodevelopmental genes associated with schizophrenia in Indian population. *A. Jajodia[1], H. Kaur[1], K. Kumari[2], R. Baghel[1], M. Sood[2], R. Chadda[2], S. Jain[3].* 1) Genomic and Molecular Medicine Unit, CSIR-Institute of Genomics and Integrative Biology, Delhi, India; 2) Department of Psychiatry, All India Institute of Medical Sciences, Ansari Nagar, New Delhi 110029, India; 3) Molecular Genetic Laboratory, Department of Psychiatry, National Institute of Mental Health and Neuro Sciences, Hosur Road, Bengaluru 560029, India.

Schizophrenia is a complex psychiatric disorder with lifetime prevalence of about 1% worldwide. Several genotyping studies have suggested a strong genetic component to the disease. The present study was conducted to identify the genetic markers that are differentially associated with the disease in two ethnically diverse Indian populations, belonging to Indo-European and Dravidian ancestry. The genotyping study was performed using a custom panel of 1536 SNPs in 840 schizophrenia cases and 876 controls (351 patients and 385 controls from North India; and 436 patients, 401 controls and 143 familial samples from South India). Meta-analysis of these populations identified three strongly associated variants: STT3A (rs548181, p = 1. 47 × 10–5), NRG1 (rs17603876, p = 8. 66 × 10–5) and GRM7 (rs3864075, p = 4. 06 × 10–3). Further, this data was compared with the data from the Schizophrenia Psychiatric Genome-Wide Association Study Consortium (PGC-SCZ) using meta-analysis, which supported rs548181 (p = 1. 39 × 10–7) variant in STT3A. In addition, combined analysis of sporadic case–control association and a transmission disequilibrium test in familial samples from South Indian population identified three associations: rs1062613 (p = 3. 12 × 10–3), a functional promoter variant of HTR3A; rs6710782 (p = 3. 50 × 10–3), an intronic variant of ERBB4; and rs891903 (p = 1. 05× 10–2), an intronic variant of EBF1. All these genes are involved in various neurodevelopmental processes. Variant rs1062613 present in the gene coding for serotonin receptor was further studied for its functional role. Our in silico simulation and in vitro gel shift assays revealed that the transcription factor CTCF (CCCTC-binding factor) binds at the polymorphic site rs1062613 (C/T). The polymorphism affects the DNA binding efficiency of CTCF, with a stronger affinity towards the wild-type C-allele. Moreover, the binding was found to be dependent on methylation at the C-allele. CTCF was found to bind with a greater strength to methylated cytosine. Our results suggest the role of epigenetic mechanisms in the development of schizophrenia by modulating transcription factor binding. The results support the risk variants observed in the earlier published work and suggest a potential role of neurodevelopmental genes in conferring risk towards schizophrenia.

1057F

Follow-up of linkage signals in the Quebec Kindred sample of schizophrenia and bipolar disorder using RNA expression and large scale SNVs analysis reveals potential candidate genes. *Y. Chagnon[1,3], A. Bureau[1,2], J. Croteau[1], A. Fournier[1], M-A. Roy[1,3], T. Paccalet[1], M. Maziade[1,3], C. Mérette[1,3].* 1) Centre de Recherche, Centre de recherche du CIUSSS Quebec, Quebec, PQ, Canada; 2) Médecine sociale et préventive, Univ Laval, Québec, PQ, Canada; 3) Psychiatrie et neurosciences, Univ Laval, Québec, PQ, Canada.

Introduction. Schizophrenia (SZ) and bipolar disorder (BP) are heritable but genome-wide association (GWA) studies have only partially uncovered possible involved genes. To further investigate linkage signals obtained in our sample of 48 extended pedigrees, we combined large scale RNA expression and single nucleotide variants (SNV) association analysis. **Methods.** We evaluated RNA expression in immortalized lymphocytes (IML) and SNVs in 453 subjects affected by SZ (N=59) or BP (N=84) and their unaffected relatives (N=313) from a subsample of 17 large kindreds of French-Canadian origin. Illumina microchips were used (HumanHT-12 Expression Beachip v4 and Infinium Human OmniExpress24; Génome Québec). We focused our analysis to the 12 linked chromosomal regions (LCR) previously identified in our large kindreds (Maziade Mol Psy 2005; Maziade EJHG 2009). After selection of the significantly detectable expressed probes using Illumina criteria, a statistical adjustement of RNA expression values was made for age, sex, housekeeping genes, and microchip. Residual expression data were then compared between affected and unaffected subjects, taking familial correlation into account. The probes showing some evidence of differential expression between unaffected subjects and SZ, BP or SZ+BP (p≤0. 01) were then evaluated for association (Zhao Biometrics 2014) with SNVs located at no more than 50 kb from the corresponding genes. **Results.** Of the 19195 probes showing significantly detectable expression in IMLs, 338 (SZ),187 (BP), and324 (SZ+BP) showed a differential expression between affected and unaffected family members. In LCRs, the strongest results for SZ+BP was observed for ITGB5 (p=8x10-5; p=0. 06 after Bonferroni) and, for SZ, was with the candidate gene ATXN1 (p=0. 002). RNA expressions of these two genes were confirmed by qPCR. Approximatly 197 SNVs were located within 50 kb of ATXN1 from which 92 were not in strong LD (r2 ≤ 0. 8) and showed a minor allele frequency (MAF) of at least 5%. Association to SZ+BP trough expression of ATXN1 was detected for nine of these SNVs (0. 0042≤p≤0. 045). This is consistent with our previously observed association with SZ and BP symptoms and the SCA1 repeat within ATXN1 (Chagnon Am Soc Hum Genet 2004). No significant SNV was observed for ITGB5. **Conclusion.** RNA expression maybe useful to identify potential candidate genes for SZ and BP within LCR (cis effect) while between LCRs, or trans effects, remain to be evaluated.

1058W

Next-generation profiling to identify the molecular etiology of Parkinson's dementia. *A. Henderson-Smith[1], J. Corneveaux[1], L. Cuyugan[2], M. Huentelman[1], W. Liang[2], T. Beach[3], T. Dunckley[1,3].* 1) Neurogenomics, TGen, Phoenix, AZ; 2) Collaborative Sequencing Center, TGen, Phoenix, AZ; 3) Banner Sun Health Research Institute, Sun City, AZ.

Parkinson's disease (PD) is characterized by degeneration of mid-brain dopaminergic neurons and a high prevalence of dementia associated with the spread of degenerative pathology to vulnerable cortical regions, including the posterior cingulate cortex. RNA sequencing (RNA-seq) is an attractive approach to uncovering the etiology of this and other complex neurodegenerative diseases. The present mRNA-seq study includes differential gene expression and alternative splicing analyses of the posterior cingulate cortex from neurologically normal control patients, patients with Parkinson's disease (PD), and patients with Parkinson's Dementia (PD-D). Genes overexpressed in both disease states were predictably involved with an immune response, while shared underexpressed genes function in signal transduction or a cytoskeleton component. Alternative splicing analysis produced a pattern of immune and RNA processing disturbances. Genes with the greatest degree of differential expression did not overlap with genes exhibiting significant alternative splicing activity. Resulting variation from the two types of expression analyses indicates the importance of broadening expression studies to include exon-level changes since there can be significant splicing activity with potential structural consequences, a subtlety that is not detected when examining differential gene expression alone, or is under-represented with probe-limited arrays.

1059T

Quantitative trait loci analysis of the serotonin-NAS-melatonin pathway in Autism Spectrum Disorders. *M. Benabou[1,2,3], A. Mathieu[1,2,4], J. Buratti[1,2,4], G. Huguet[1,2,4], R. Delorme[1,2,5,6], M. Leboyer[6,7,8,9], C. Pagan[10], J. Callebert[10], JM. Launay[10], T. Bourgeron[1,2,4,6].* 1) Human Genetics and Cognitive Functions Unit, Institut Pasteur, Paris, France; 2) CNRS UMR3571 Genes, Synapses and Cognition, Institut Pasteur, Paris, France; 3) University Paris Descartes, Sorbonne Paris Cité, Paris, France; 4) University Paris Diderot, Sorbonne Paris Cité, Paris, France; 5) AP-HP Department of Child and Adolescent Psychiatry, Robert Debré University Hospital, Paris, France; 6) Fondation Fondamental, Créteil, France; 7) AP-HP Department of Psychiatry, Henri Mondor-Albert Chenevier Hospital, Créteil, France; 8) INSERM U955, Institut Mondor de Recherche Biomédicale, Psychiatric Genetics, Créteil, France; 9) Faculty of Medicine, University Paris-Est, Créteil, France; 10) Service de Biochimie et Biologie Moléculaire, Department of Biochemistry, University Hospital Lariboisière, AP-HP, INSERM U942, Paris, France.

Increased blood serotonin and decreased melatonin have been repeatedly reported in patients with in Autism Spectrum Disorders (ASD). These observations have suggested that a disruption of the serotonin-NAS-melatonin pathway could be a risk factor for ASD. Several mutations affecting the main enzymes of this pathway, AANAT and ASMT were identified, but the underlying mechanisms of these biochemical anomalies remain largely unknown. It was previously shown that blood serotonin and melatonin levels are inheritable, but the genetic variants associated with these quantitative traits are unknown. Here, we measured serotonin blood level, the intermediate molecule N-acetylserotonin (NAS) and melatonin, as well as enzyme activity of AANAT and ASMT in a large cohort of 1196 individuals including 286 families with ASD and 308 controls. In addition, for a subset of these individuals (260 patients with ASD, 385 parents, 129 unaffected siblings, 30 affected siblings, 6 other relatives and 118 controls), we have genotyped more than 400 000 SNPs. We observed that serotonin and NAS levels were significantly increased in patients with ASD compared with the control group, while melatonin level, ASMT and AANAT activities were decreased ($p<0.0001$ for each trait). Each trait showed a significant parent-offspring correlation, which was particularly high for NAS (serotonin: 14%, $p=0.001$; AANAT: 27%, $p<0.0001$; NAS: 37%, $p<0.0001$; ASMT: 24%, $p<0.0001$; melatonin: 20%, $p=0.004$). The heritability of each trait was relatively high, particularly for NAS (serotonin: 30%, $p<0.0001$; AANAT: 38%, $p<0.0001$; NAS: 61%, $p<0.0001$; ASMT: 34%, $p=0.0002$; melatonin: 28%, $p=0.0003$). Our pilot genome wide quantitative trait loci (QTL) analysis has identified 5 genome wide significant SNPs. Three were identified for melatonin levels in patients and 2 of them (rs7993991/punadjusted=6.3x10-8 and rs11872926/punadjusted=1.2x10-7) were located in genes (*DNAJC3* and *DLGAP1* respectively). Two SNPs were also identified for NAS in the control group, but none of them was found in a known gene. In summary, our analyses provide the first estimates of the heritability for the whole serotonin-NAS-melatonin pathway in humans. The candidate SNPs associated with these traits should be confirmed in larger cohorts.

1060F

Function-based GWAS identifies novel candidate genes in autism spectrum disorder. *L. K. Davis[1], E. R. Gamazon[2], J. S Sutcliffe[3], E. H. Cook[4], N. J. Cox[2].* 1) Section Genetic Medicine, The University of Chicago, Chicago, IL; 2) Vanderbilt Genetics Institute, Division of Genetic Medicine, Department of Medicine, Vanderbilt University, Nashville, TN; 3) Vanderbilt Brain Institute, Division of Genetic Medicine, Department of Medicine, Vanderbilt University, Nashville, TN; 4) Department of Psychiatry, University of Illinois, Chicago, IL.

ASD is highly heritable and polygenic, with risk spread across thousands of DNA variants throughout the genome. Here we demonstrate a 'functional-unit' based GWAS, which, instead of utilizing all SNPs on the array (the vast majority of which will fall under the null expectation of no association), requires only a subset of SNPs that are coding (i. e. , missense, nonsense or frameshift) as well those that have been show by previous studies to be cis- or trans-eQTLs involved in regulating gene expression in brain. Coding variants and eQTLs are then assigned to the genes that they affect for a gene-based association analysis. The main objective of this study is to use biologically informative genomic annotations to effectively reduce the number of multiple tests conducted, thereby maximizing power to detect meaningful associations. We applied our method to both a discovery (N = 2,274) and replication sample (N = 2,976), and conducted a meta-analysis including both sets of results. We constructed gene-level annotations for each known gene in the human genome by annotating each gene with regulatory variation (i. e. , eQTLs) previously identified in the parietal cortex and the cerebellum as well as coding variants (nonsense, frameshift, and missense) within the gene. A gene-level p-value was obtained using a combined statistic that integrates SNP-level evidence, derived from the traditional single-variant test, for association with the trait. A total of 13,487 genes, represented by at least two variants, were annotated and included in each analysis. A Bonferroni corrected p-value of 3.7x10-6 was imposed to correct for the number of gene-based tests conducted. The most significant associations discovered were ZNF204P (2x10-5) within the AGRE/iControl analysis and ITFG2 (2x10-5) within the SSC/SAGE analysis, although neither result exceeded the threshold for genome-wide significance. However, upon meta-analysis, three genes were found to exceed genome-wide significance including ITFG2 (p=1.01x10-6), MTHFD2 (p=1.05x10-6), and ZNF2 (p=1.83x10-6). We present a novel gene-based approach to GWAS, which incorporates functional annotations including brain eQTLs and coding variants in a noise-reduction GWAS framework. We present meta-analysis data implicating three genes (ITGF2, MTHFD2, and ZNF2) and evaluate their potential as ASD candidate genes.

1061W

Linkage analysis revisited: three regions of potential risk found in extended multiplex Autism Spectrum Disorder (ASD) families. *s. Iuzi[1], J. Jaworski[1], M. L. Cuccaro[1,2], E. R. Martin[1,2], A. J. Griswold[1], H. N. Cukier[1], S. Slifer[1], I. Konidari[1], P. L. Whitehead[1], J. R. Gilbert[1,2], J. L. Haines[3], M. A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miller School of Medicine, miami, FL; 2) Dr. John T. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA.

Autism spectrum disorder (ASD) is a highly prevalent neurodevelopmental disorder with a complex genetic architecture. It is characterized by severe deficits in three main areas: social interactions skills; verbal and non-verbal communication skills; behaviors and interests. The search for ASD genes has only identified ~25% of genetic components to date. Linkage studies are still considered a very useful tool to identify loci of interest in the presence of allelic heterogeneity, especially with large and well characterized pedigrees. We ascertained 86 extended of European ancestry with multiple cases of ASD and performed genome-wide genotyping followed by extensive parametric two-point and multipoint linkage analysis. For the parametric two-point models we assumed a dominant affecteds only model for analysis Two point results showed 31 autosomal regions with HLOD >3. 3. Of these, enhanced significance was noted at 3q24, 12q14 and 15q21 loci with HLOD>4. 4, HLOD>5. 4 and HLOD>3. 5, respectively. Multipoint parametric analysis confirmed our findings on the 3q24, 12q14 and 15q21 loci showing HLOD>2. 5, HLOD>2. 9 and HLOD>3, respectively, three regions previously implicated in ASD risk. These linkage regions will be compared with sequence data generated from the families in order to identify rare variants segregating with disease risk.

1062T

The burden of Multiple Sclerosis variants in continental Italians and Sardinians. *S. Sanna[1], N. Barizzone[2,3], I. Zara[4], M. Sorosina[5], S. Lupoli[6], E. Porcu[1,7], M. Pitzalis[1], M. Recent studies identified >100 non-HLA Multiple Sclerosis (MS) susceptibility variants in Northern European populations, but their role in Southern Europeans is unclear. Here we investigated the cumulative impact of those variants in two Mediterranean populations: continental Italians and Sardinians. We calculated four weighted Genetic Risk Scores (wGRSs) using a log additive sum of risk alleles at up to 102 non-HLA MS risk variants and 5 HLA MS susceptibility markers in 1,691 patients and 2,194 controls from continental Italy, and 2,861 patients and 3,034 controls from Sardinia. We then assessed differences between populations using Nagelkerke's R2 and the area under the ROC curves. As expected, the genetic burden (mean wGRS value) was significantly higher in MS patients than in controls, in both populations (p<10-45 for all wGRSs). Of note, the burden was remarkably higher in Sardinians (p<10-20 for all wGRSs), and this difference was not attributable to 14 non-HLA variants showing different allele frequencies in continental Italians (Fst>0. 01). Conversely, the proportion of variability explained and the predictive power of the assessed variants were significantly higher in continental Italians (AUC 0. 725 versus 0. 681 in Sardinians, p=4x10-5). This genetic risk score is not meaningful in clinical settings, but the observed difference between populations suggests that either the SNPs identified through large general populations are capturing the causal variants less efficiently in Sardinians and/or additional risk variants remain to be detected in this population. Furthermore, Sardinians showed another peculiar feature, with a notably higher burden of non-HLA variants in patients who do not carry HLA risk alleles (p=7x10-4). No similar trend was seen in controls. This suggests a counter-balancing aggregation effect of non-HLA loci versus HLA markers, which could be explained by selective pressure and/or interaction with environmental factors. The observed differences in the MS genetic burden between these two Mediterranean populations highlight the need for more genetic studies in these and other South Europeans to further expand the knowledge of genetics of MS.

Identification of pleiotropic loci involved in the comorbidity of addiction with major depression and anxiety using randomly ascertained extended pedigrees. *K. Hodgson[1], L. Almasy[2], E. E. M. Knowles[1], J. W. Kent Jr. [3], S. R. Mathias[1], N. Yao[1], J. E. Curran[2], T. D. Dyer[2], H. H H Göring[2], R. L. Olvera[4], R. Duggirala[2], P. T. Fox[5,6], J. Blangero[2], D. C. Glahn[1,7].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) South Texas Diabetes and Obesity Institute, University of Texas Health Science Center at San Antonio & University of Texas of the Rio Grande Valley, Brownsville, TX; 3) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 4) Department of Psychiatry, University of Texas Health Science Center at San Antonio, San Antonio, TX; 5) Research Imaging Institute, University of Texas Health Science Center at San Antonio, San Antonio, TX; 6) South Texas Veterans Health System, 7400 Merton Minter, San Antonio, TX; 7) Olin Neuropsychiatric Research Center, Institute of Living, Hartford Hospital, Hartford, CT.

Comorbidity is common in addiction, with patients frequently having additional diagnoses of major depression and anxiety disorders. The genetic architecture of these comorbidities remains unclear, but could provide an important insight into the underlying etiology of these disorders. To investigate these genetic relationships, we used a randomly ascertained sample of Mexican-American extended pedigrees. Variance decomposition methods were used to explore the role of genetics in addiction phenotypes, depression and anxiety disorders. Genome-wide univariate and bivariate linkage scans were conducted to localize the chromosomal regions influencing these traits and the high rates of comorbidity observed between them. In the univariate analyses, quantitative trait loci were identified for substance dependence (14q13. 2-q21. 2, LOD=3. 322), cocaine use (7q34, LOD=3. 211), anxiety (12q24. 32-q24. 33, LOD=2. 918) and depression (22q11. 1-q11. 21, LOD=3. 144). Considering the overlap of addiction with depression and anxiety, significant genetic correlations were observed and bivariate linkage analyses were used to identify loci with pleiotropic effects on these correlated traits. Bivariate quantitative trait loci were found for alcohol dependence-anxiety (9q33. 1-q33. 2, LOD=3. 054), substance dependence-anxiety (18p11. 23-p11. 22, LOD=3. 425) and cannabis use-major depression (11q23. 1-q23. 2, LOD=3. 229). This study confirms the shared genetic underpinnings of addiction with depression and anxiety and identifies a number of genomic loci involved in the etiology of these comorbid disorders. These quantitative trait loci show convergence with previous literature in the field, but also implicate novel regions of the genome in addiction genetics.

1064W

Genome-wide association study for facet-level traits of neuroticism in a health study cohort of Korean adults. *S. Kim[1], H. Kim[1], H. Shin[2], J. Cho[2], M. J. Kwon[2], Y. Chang[2], S. Ryu[2], H. L. Kim[1].* 1) Ewha Womens University, Seoul, South Korea; 2) School of Medicine, Sungkyunkwan University, Seoul, South Korea.

Neuroticism is a personality trait closely linked to psychological distress and a risk ofmood disorders. Converging evidence indicates that neuroticism shared genetic and biological components of psychiatric disorders. The revised NEO Personality Inventory (NEO-PI-R) measures neuroticism which consists of six facets of traits : anxiety (N1), angry hostility (N2), depression (N3), self-consciousness (N4), impulsivity (N5), vulnerability (N6). In the present study, we conducted the genome wide association study (GWAS)for neuroticism in the lower-order levels. The analysisincluded 2,064 individuals aged 19-69 years. Anxiety (N1) was associated with rs76982298 (1. 54x10-6) located in MAPK10 (mitogen-activated protein kinase 10) gene. MAPK signaling was previously known to affect anxiety and depressive-like behavior in mouse model. Depression (N3) was associated with rs8088304 (P=9. 96x10-6) located withMBP (myelin basic protein) gene. Reduced mRNA transcription of MBP was found in schizophrenia in the previous report. Self-consciousness (N4)was linked to rs4557199 (2. 53x10-7)located near ROBO2 (roundabout, axon guidance receptor homolog 2) gene. The current findings usingGWAS of neuroticism in facet level showed suggestive loci related with genetic susceptibility of mental disorders. In addition, the present study might produce insights into the biological pathways of psychological factors associated with various psychiatric disorders.

1065T

Genetic loci in periodic hypersomnia/Kleine-Levin syndrome type. *E. Mignot[1], R. Hillary[1], HM. Ollila[1], J. Faraco[1], L. Lin[1], I. Arnulf[2].* 1) Stanford University, Palo Alto, CA. USA; 2) Sleep Disorder Unit, Pitie-Salpetriere Hospital, Assistance Publique - Hôpitaux de Paris, 75013 Paris, France.

Background:Kleine-Levin syndrome (KLS) is a rare sleep disorder that affects ~ 1 person in a million and has been suggested to be more frequent in Ashkenazi Jewish. The disorder typically strikes adolescent males but improve with age, often resolving by age 30. In KLS, patients have recurrent episodes lasting several weeks when they sleep nearly 24 hours per day. When awake, patients during episodes experience apathy, cognitive disturbances and occasionally hyperphagia and hypersexuality. Between episodes, patients are totally normal. Aim: Our aim was to identify genetic variants that contribute to KLS predisposition. Methods: As a part of an international collaboration we performed GWAS in 650 KLS cases and 30, 000 controls. The sample comprised KLS cases and matched controls from United States, Europe and Asia and additional controls from the GERA consortium. Genotyping was done using Affy 6. 0 and Affymetrix Axiom World Array with ethnicity specific platforms that were imputed to 1000 genomes. Analyses were controlled for population stratification and ethnicity (Caucasian, Ashkenazi Jewish, Asians, other) . Results: Genome-wide significant loci were found near TRANK1 and ATXN1. Most interestingly, the leading TRANK1 variant is same as reported in other GWAS for schizophrenia and Bipolar disorder. Conclusions: The findings give the first biological evidence for disease mechanisms in KLS. Importantly, these results suggest a partially overlapping genetic composition for schizophrenia and KLS. The fact these patients are not primarily depressed or psychotic during episodes, completely reverse to normality between episodes could suggest important pathophysiological clues linking sleep and episodic psychiatric conditions.

1066F

An international, collaborative genome-wide association study of Tourette Syndrome in 13,000 individuals identifies a non-coding RNA expressed early in human brain development as a TS susceptibility gene. *J. M. Scharf[1,2] on behalf of the TSAICG, GGRI and TIC Genetics consortia.* 1) Mass General Hospital/Harvard Medical School, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA.

Tourette Syndrome (TS) is a childhood-onset developmental disorder with one of the highest heritabilities among neuropsychiatric diseases with non-Mendelian inheritance. TS is more common than previously recognized, and is now believed to be present in 0. 3-0. 8% of children, many of whom have additional, co-occurring neuropsychiatric disorders, such as OCD, ADHD, or autism-spectrum disorder (ASD). We previously demonstrated that TS is highly polygenic and that the majority of TS heritability can be captured by SNP arrays. However, to date the sample size of TS genetic studies has been too small to identify genome-wide significant loci. Here, we present results from the largest TS genome-wide association study (GWAS) to date and a mega-analysis of all existing TS GWAS data, totaling 4,232 European ancestry cases and 8,919 ancestry-matched controls. After standard QC procedures, the final analysis had a lambdaGC=1. 065 (lambda1000=1. 014) including SNPs with MAF>1% imputed to 1000 Genomes. One SNP, rs2708146, on chromosome 2p16. 1, achieved genome-wide significance (p=2. 8x10-8). This SNP lies within a 1Mb haplotype spanning an uncharacterized long, intergenic, non-coding RNA (lincRNA), *LINC01122,* that is expressed primarily in mid-fetal human brain development (15-16 pcw), with strongest expression in developing cerebral cortex. Pairwise correlational analysis of 22,731 genes from the Brainspan project expressed across 7 human pre-natal time points and 16 brain regions demonstrated the highest co-expression with *BCL11A*, a gene 1 Mb centromeric to *LINC01122* that has been found previously to harbor recurrent *de novo* loss-of-function mutations in ASD samples. Subsequent analyses have integrated multiple sources of epigenomic data from human brain tissue and *in vitro* human stem cell models of developing cortical neurons, including 1) H3K27Ac peaks to mark active gene enhancers, 2) developmental time-point-specific gene expression to identify regional genes that correlate with enhancer activity, and 3) biophysical models to predict changes in transcription factor binding site affinity caused by candidate causal GWAS SNPs lying within these active enhancers. These data, combined with functional *in vitro* expression studies and *in vivo* mouse experiments are in progress to characterize this regulatory locus further and its potential role in the development of cortico-striatal-thalamic-cortical circuits that have been hypothesized to be abnormal in TS patients.

1067W

ADHD risk loci identified by genome-wide association meta-analysis. *D. Demontis, the iPSYCH-SSI-Broad/MGH ADHD Workgroup and the Psychiatric Genomics Consortium: ADHD Subgroup.* Biomedicine, Aarhus University, Aarhus, Århus, Denmark.

Attention-deficit hyperactivity disorder (ADHD) is a highly heritable common childhood behavioural disorder affecting 3-6% of school-age children and ~4% of adults around the world. Several moderately sized genome-wide association studies (GWASs) have been performed, but until now no single markers have passed the threshold for genome-wide significance. The SNP heritability of ADHD has been estimated to 0. 28, indicating that common SNPs contribute substantially to ADHD susceptibility and that increasing GWAS sample sizes is likely to produce significant results. Here we present the meta-analysis of GWASs of ADHD, which is a large-scale collaboration, between the Danish *i*PSYCH (Lundbeck Foundation Initiative for Integrative Psychiatric Research) program, the Broad Institute and the Psychiatric Genomics Consortium (PGC). The study, which represents the latest ADHD freeze, includes ten ADHD PCG samples, in total consisting of ~6000 cases and ~14500 controls and the iPSYCH sample in total comprising ~8700 cases and ~11300 controls. Standard quality control procedures and genome-wide association analyses are performed on each dataset individually and subsequently a meta-analysis is conducted across datasets. A 23andMe self-reported ADHD dataset is used as replication sample in order to follow-up on the strongest independent signals from the GWAS meta-analysis. Results from the primary GWAS meta-analysis and the combined analysis of the PGC samples, the iPSYCH sample and the 23andMe replication sample will be presented. The results will reveal the first genome-wide significantly associated loci with ADHD. SNP heritability estimates for evaluating to what extent, common genetic variants explain the heritability will also be presented. Risk score profiles will be calculated and subsequently odds ratios will be estimated in order to evaluate the increased risk of ADHD for individuals belonging to the group with the highest burden of risk alleles. Additionally enrichment analyses will be presented elucidating e. g. potential enrichment of SNPs located in brain specific enhancer regions among the most associated markers. The results presented here include the identification of the first genome-wide significant loci in ADHD. Identification of specific risk loci as well as the enrichment analyses and heritability estimates presented represent an important step towards a better understanding of the genetic architecture of ADHD.

1068T

A novel oligogenetic framework identifies age of onset modifying mutations in Alzheimer's disease. *J. I. Vélez[1,2], C. A. Mastronardi[1], H. R Patel[1], A. S. Johar[1], F. Lopera[2], M. Arcos-Burgos[1,2].* 1) John Curtin School of Medical Research, The Australian National University, Canberra, ACT, Australia; 2) Neuroscience Research Group, University of Antioquia, Medellín, Colombia.

The identification of modifier genes (MGs) in complex traits, including Alzheimer's disease (AD), is of great interest in genetic research. Modifier genes can alter the expression of another gene, consequently affecting the natural history of complex traits. For example, MGs can affect penetrance, dominance, expressivity and pleiotropy, and are responsible for changes in the age of onset (AOO) and disease progression. Here we present a novel oligogenetic framework for the identification of MGs that combines the use of genetic isolates, high-throughput sequencing, extreme phenotype sampling, and advanced data mining tools. We applied this framework to patients from the Paisa genetic isolate in Antioquia, Colombia, who belong to the world's largest known pedigree segregating early-onset familial AD caused by the p. Glu280Ala (E280A) fully penetrant mutation in the *PSEN1* gene. Whole-exome genotypes from 71 mutation carriers with AD from this pedigree were analyzed using linear mixed-effects models. Four AOO protective variants harbored in the *APOE* (rs7412, *P*FDR = 2. 13x10-30), *GPR20* (rs36092215, *P*FDR = 6. 58x10-22), *FCRL5* (rs16838748, *P*FDR = 8. 61x10-10), *RC3H1* (rs10798302, *P*FDR = 1. 86x10-4) genes with AOO delaying effects of up to 17 years above the average AOO in this pedigree (of ~48 years), were identified. Similarly, five harmful variants in the *TRIM22* (rs12364019, *P*FDR = 1. 15x10-14), *AOAH* (rs12701506, *P*FDR = 5. 69x10-8), *PINLYP* (rs2682585, *P*FDR = 1. 67x10-6), *IFI16* (rs62621173, *P*FDR = 8. 63x10-6) and *DFNA5* (rs754554, *P*FDR = 3. 62x10-2) genes resulted in an AOO that is up to 12 years ealier than average. Genes harboring these variants play an important role in cell proliferation, protein degradation, apoptotic and immune dysregulation processes, and could be important as eventual therapeutical targets. Data mining techniques were used to construct a model with some of these genetic variants to predict the development of early- or late-onset AD in E280A mutation carriers. The results of this study provide the foundation for better management of these patients and enhanced assessment, highlighting the potential of this oligogenetic model in the clinical setting.

1069F

Genome wide association in families identifieds a genetic basis for two components of speech, phonological processing and articulation. *H. Voss-Hoynes[1], C. Stein[1], B. Truitt[1], J. Tag[2], L. Freebarin[2], B. Lewis[2], S. K. Iyengar[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Psychological Sciences, Case Western Reserve University, Cleveland, OH.

Speech sound disorders (SSD) are communication disorders occurring in 16% of 3 year olds. These disorders can affect phonological processes—sound patterning—or articulation—sound making. One phonological process, syllable sequencing, can be measured with multisyllabic word repetition tasks (MSW) while accuracy in articulation of consonant sounds is commonly measured with the Goldman-Fristoe Test of Articulation (GFTA). Using 1. 5 million markers on the Omni 2. 5 Exome chip, we performed a separate quantitative trait genome wide association analysis in PLINK on the Z-scores of MSW and GFTA scores. While no SNPs reached the multiple testing threshold of 3. 5x10-8, analysis of 545 Caucasian individuals (147 families) identified interesting loci. The 50 most significant SNPs (p=1x10-6 - 1. 1x10-5) for each phenotype did not overlap. The top SNPsfor MSW (rs73075822 and rs56260247, p=1x10-6) are intronic and located in CREB5 which is a transcription factor on chromosome 7. Another SNP of interest (rs116882098 p= 6x10-6) is located in GRIK2, a gene previously associated with intellectual disability, epilepsy, and behavioral disorder. While there does not seem to be an overt pattern for MSW genes, for GFTA, the top SNPs tend to be found in genes associated with growth and development. The top three SNPs are located in DAB1 (rs78728168 p=1x10-6), SH3B4 (rs74789325 p=1x10-6), and SLIT3 (rs35506927 p=1x10-6). DAB1 encodes a regulator of the reelin pathway, necessary for cell positioning in the brain; SH3B4 is thought to indirectly regulate cell growth and proliferation and has been associated with peripheral neuropathies; and SLIT3 encodes a slit protein which prevents developing neurons from crossing the midline. These findings indicate that despite phenotypic correlation, the genetic basis of phonological processing and articulation may have some distinct features. While the exact variants we identified are unique, there are similarities with GWAS of endophenotypes associated with language and reading. Like to the association between GRIK2 and behavioral disorder, ZNF385D has been associated with language impairment and ADHD. Additionally the neural-growth control function if SLIT3 is similar to a gene associated with dyslexia, NODAL, which maintains neural asymmetry. Future work will determine if the unique gene sets for each component of speech, language, and reading participate in the same networks. Acknowledgements: DC00528, DC012380, T32-HL007567.

1070W

Genome-wide linkage and family-based association in the Western Australian Family Study of Schizophrenia (WAFSS). *N. S. McCarthy[1], P. E. Melton[1], J. C. Badcock[2], M. Dragovic[2], B. Morar[2], V. A. Morgan[2], E. K. Moses[1], A. Jablensky[2].* 1) Centre for the Genetic Origins of Health and Disease, The University of Western Australia, Perth, Western Australia, Australia; 2) Centre for Clinical Research in Neuropsychiatry, University of Western Australia, Perth, Western Australia, Australia.

Background: Family studies provide some advantages over unrelated cohorts in the potential identification of the 'missing heritability' for SZ and other complex diseases. Pedigrees are potentially enriched for rare variants, and are less susceptible to the problem of population stratification. In addition, families are ideal for the detection of pleiotropy, an important consideration in a known heterogeneous disorder like SZ. In the present study, we conducted a genome-wide linkage and association analyses in the Western Australian Family Study of Schizophrenia (WAFSS) to identify genomic regions associated with increased SZ risk. **Methods:** Our WAFSS study sample included 336 individuals of European descent from 64 families with multiple cases of SZ or spectrum disorder. Clinical assessment included a standardised diagnostic interview and best-estimate diagnosis (ICD-10 and DSM-IV), both established by two senior clinicians. Clinical symptoms were comprehensively assessed with the Diagnostic Interview for Psychosis. Genotyping was performed on the *Illumina HumanCoreExome Beadchip*, which assays approximately 250,000 common tag single nucleotide polymorphisms and 250,000 moderately rare, exonic variants. Standard quality control filters were applied using *Plink*. For linkage analysis, variants were thinned based on linkage disequilibrium (r2 = 0. 8). Non-parametric linkage (NPL) and family-based association analyses were performed separately adjusting for age and sex using *Merlin*, and logarithm of the odds (LOD) scores calculated. **Results**: For the family-based association, the most significant genetic signal was located downstream of the glutamate receptor gene (*GRIN3A)* on chromosome 9 (rs1022749, LOD 4. 1, *P*=1. 4x10-5). In the NPL analyses the most significant genetic signal was located upstream of the RNA-binding protein *CUGBP2* on chromosome 10 (rs2398243, LOD 3. 1, *P*=7. 6x10-5). **Discussion:** Comparison of these genome-wide linkage and association results demonstrate the complementary nature of these two methods and implicate different genomic regions. The role of the NMDA-receptors is well described in SZ, and other variants in *GRIN3A* have previously been associated with SZ. In contrast, little is known about the potential role of *CUGBP2* in SZ. Additional work will include gene-centric burden testing using rare, exonic variants and prioritizing genomic regions implicated in this study for whole genome sequence data analysis in the WAFSS cohort.

P. Hall[2], UK BiLEVE consortium.* 1) Department of Health Sciences, University of Leicester, Leicester, United Kingdom; 2) Division of Respiratory Medicine, University of Nottingham, Queen's Medical Centre, Nottingham, United Kingdom; 3) Department of Biostatistics, University of Liverpool, Liverpool, United Kingdom; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 5) Department of Statistics, University of Oxford, Oxford, United Kingdom; 6) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 7) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University London, London, United Kingdom; 8) Faculty of Medicine, School of Public Health, Imperial College London, London, United Kingdom; 9) Faculty of Medicine and Health Sciences, School of Medicine, University of Nottingham, Nottingham, United Kingdom; 10) Respiratory Medicine, University of Oxford, Oxford, United Kingdom; 11) Institute of Infection, Immunity & Inflammation, University of Glasgow, United Kingdom; 12) Population Health Research Institute, St George's University of London, London, United Kingdom; 13) National Institute for Health Research (NIHR) Leicester Respiratory Biomedical Research Unit, Glenfield Hospital, Leicester, United Kingdom.

UK Biobank recruited 502,682 UK individuals aged 40-69 years (95% European ancestry), collecting detailed health and lifestyle information, DNA, and physical measures, including spirometry and smoking behaviour. In the UK Biobank Lung Exome Variant Evaluation (UK BiLEVE) we genotyped 50,000 samples from the extremes and middle of the lung function distribution amongst 25,000 heavy smokers (mean 35 pack years) and 25,000 never smokers in order to study the genetics of lung function and smoking behaviour. Genome-wide genotyping was undertaken using a custom designed Affymetrix array that included 130K rare missense and loss of function variants (selected to be polymorphic in UK populations based on currently available "exome chip" data), 642K variants selected for optimal imputation of common variation and improved imputation of low frequency variation (MAF 1-5%). A case-control analysis between the heavy and never smokers was undertaken across 28. 5 million genotyped and imputed variants. We discovered five new genome-wide significant (P<5x10-8) signals for smoking behaviour at 1p21. 3 (*LPPR5*), 2q22. 3, 6p21. 2 (*DNAH8*), 11q23. 2 (*NCAM1*) and 20q11. 21 (*NOL4L*), and confirmed two previously reported loci at 15q25 and 7p14. Two of our novel signals separately implicate *NCAM1* (neural cell adhesion molecule 1): one SNP is located within an intron of *NCAM1*; a second variant on a different chromosome (2q22. 3) and has a *trans* effect on expression of *NCAM1* in brain tissue. The 2q22. 3 variant is also a *trans* eQTL in substantia nigra (brain) tissue for *WDR61,* which is 300kb from the known 15q25 locus containing the nicotine-receptor genes *CHRNA3* and *CHRNA5*. Another novel signal in *NOL4L* is near to, but independent of, a SNP in *C20orf203* previously implicated in nicotine dependence. By conditioning on the primary signals, we identified secondary independent signals, which did not reach genome-wide significance, at 3 of the loci associated with smoking behaviour including a novel rare (MAF=0. 09%) intergenic SNP near *NCAM1*. A further 8 loci with suggestive evidence of association with smoking behaviour (5x10-8<P<5x10-7) include a variant in *CHRNA4* (20q13. 33), a gene previously implicated in smoking behaviour. The genotype data for the UK BiLEVE study has been made available to the scientific community via UK Biobank, as has subsequent data from a similar array in additional UK Biobank participants. This research has been conducted using the UK Biobank Resource.

Investigation into the Genetics Underlying Receptive Vocabulary Processing. *A. K. Adams[1], J. D. Eicher[1], N. R. Powers[1,2], N. T. Truong[2], J. R. Gruen[1,2,3].* 1) Department of Genetics, Yale University, New Haven, CT; 2) Department of Pediatrics, Yale University, New Haven, CT; 3) Department of Investigative Medicine, Yale University, New Haven, CT.

Receptive vocabulary processing is a complex neurobehavioral process requiring the integration of many different pieces of information for proper language comprehension. Receptive vocabulary processing is a genetically complex trait, which has only recently come under study from a genomic perspective. Developmental language impairment (despite normal intelligence) has been shown to be heritable, with twin studies revealing heritability estimates of greater than 50%. Studies have also shown a prevalence of 7. 4% in 5-year-old Midwestern children (Tomblin et al. , 1997). Using results from the Peabody Picture Vocabulary Test (PPVT) for receptive vocabulary, and a 550,000 marker genetic panel, an age-corrected genome wide association study (GWAS) was undertaken on 440 normally developing children of European ancestry from the Pediatric Imaging, Neurocognition, and Genetics (PING) cohort. This study revealed a single genome wide association with rs11918964 in the gene *MAGI-1* (p=3. 66 x 10 -8) as well as suggestive associations with other SNPs in both *MAGI-1* and the gene *BMP7*. *MAGI-1* is a scaffold protein that has previously been linked to neural disorders including schizophrenia, while *BMP7* is a gene affiliated with neural development. As a follow-up study to further investigate these results, both candidate SNP and full genome wide studies have been undertaken using the Hispanic American population (n=856) genotyped on a 2. 5 million marker array in the Genes, Reading, and Dyslexia (GRaD) cohort. These studies are ongoing and results are forthcoming.

1073W

Cross disorder analyses in attention deficit hyperactivity disorder and autism spectrum disorder - an update. *M. Mattheisen[1,2], The iPSYCH-SSI-Broad/MGH, the PGC ADHD, and the PGC ASD working groups.* 1) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 2) Lundbeck Initiative for Integrative Psychiatric Research (iPSYCH).

The recent success in GWAS for schizophrenia (SCZ) has helped to create a momentum in psychiatric genetics that now also spreads into other mental disorders. One of the positive developments is a substantial increase in available samples for genetic studies. Especially in childhood onset disorders, such as ADHD and ASD, contributions from private foundations and philanthropy helped to achieve an at least 2-3 fold increase in sample size for these disorders when compared to their state 1 year ago. Here, we will present our cross-disorder analyses for the two largest ADHD and ASD GWAS data sets currently available worldwide (each comprising of approx. 15k cases) with the aim to study their shared genetic risk architecture at multiple levels. The datasets used in this study stem from the individual disorder working groups in the PGC as well as a large scale collaborative project between iPSYCH, the Statens Serum Institut (SSI), and the Broad/MGH. The latter dataset is a population-based sample comprised of individuals born in Denmark after 1991 that have been diagnosed with either ADHD or ASD (a total of approx. 15k cases). We will report results from analyses that use LD score regression (LDSC), GCTA, and polygenic risk scores to study SNP heritability and genetic correlation (rG) of three sub-groups comprised of individuals diagnosed with (1) ADHD only, (2) ASD only, and (3) ADHD and ASD. For these sub-groups we will also report rG with SCZ and other adulthood onset disorders, as well as related quantitative traits (e. g. brain imaging phenotypes and cognitive traits). Furthermore, results will be presented for a full meta-analysis of all cases diagnosed with either ADHD and ASD and the respective controls. Finally, we will employ a multivariate GWAS approach in a large subset of our data (iPSYCH-SSI-Broad/MGH data) for which we have multiple psychiatric and somatic phenotypes available. Preliminary analyses based on 85% of our final dataset suggest four genome-wide significant regions for the meta-analysis of ADHD and ASD. This includes a region on chromosome 5 that harbors miR-9 and showed the strongest evidence for association in our analyses. An analysis of the final dataset is needed to provide further evidence for the importance of our preliminary findings in ADHD and ASD etiology.

1074T

A polymorphism in *CRAT* is associated with *HLA-DQB1*06:02* negative essential hypersomnia. *T. Miyagawa[1], SS. Khor[1], H. Toyoda[1], H. Kojima[2], T. Futagami[2], M. Yamasaki[1], H. Saji[2], K. Mishima[3], Y. Honda[4], M. Honda[4, 5], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) HLA Foundation Laboratory, Kyoto, Japan; 3) Department of Psychophysiology, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan; 5) Sleep Disorders Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan.

Essential hypersomnia (EHS) is a lifelong sleep disorder characterized by excessive daytime sleepiness but no cataplexy, can be divided into two broad classes based on the presence or absence of *HLA* (human leukocyte antigen)-*DQB1*06:02* allele. *HLA-DQB1*06:02* positive EHS and narcolepsy are associated with the same susceptibility genes. However, there are fewer studies of *HLA-DQB1*06:02* negative EHS. We hypothesized that *HLA-DQB1*06:02* negative EHS has a different etiological pathway from that of narcolepsy and *DQB1*06:02* positive EHS. Therefore, in order to identify susceptibility genes associated with *HLA-DQB1*06:02* negative EHS, we performed a genome-wide association study of 476,446 SNPs in 119 Japanese patients with *HLA-DQB1*06:02* negative EHS and 1,582 Japanese healthy individuals. A replication study was also conducted on 191 Japanese patients with *HLA-DQB1*06:02* negative EHS and 433 Japanese healthy individuals. SNP rs10988217 located in *CRAT* (carnitine acetyltransferase) was found to be significantly associated with *HLA-DQB1*06:02* negative EHS ($P < 5\times10\text{-}8$, odds ratio = 2. 8). An eQTL analysis showed that SNP rs10988217 was significantly correlated with expression levels of *CRAT* in various tissues or cell types, including brain tissues ($P < 0. 05$). *CRAT* gene encodes the carnitine acetyltransferase protein, which is a key enzyme for metabolic pathways involved with the control of the acyl-CoA/CoA ratio in mitochondria, peroxisomes and endoplasmic reticulum. The Metabolomics GWAS Server (Shin SY et al. , Nat Genet. doi: 10. 1038/ng. 2982.) showed that rs10988217 affected succinylcarnitine levels in blood ($P < 10\text{-}17$). The results suggest that *HLA-DQB1*06:02* negative EHS may have an underlying dysfunction in fatty acid oxidation pathway.

Search for new susceptibility genetic factor associated with panic disorder-pathway analyses based on genome-wide association study-. *M. Shimada-Sugimoto[1], T. Otowa[2], T. Miyagawa[1], S. Khor[1], K. Kashiwase[3], N. Sugaya[4], Y. Kawamura[5], T. Umekage[6], H. Kojima[7], T. Futagami[7], H. Saji[7], A. Miyashita[8], R. Kuwano[8], H. Kaiya[9], K. Kasai[2], H. Tanii[10], Y. Okazaki[11], K. Tokunaga[1], T. Sasaki[12].* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Japanese Red Cross Kanto-Koshinetsu Block Blood Center, Tokyo, Japan; 4) Department of Epidemiology and Public Health, Graduate School of Medicine, Yokohama City University, Kanagawa, Japan; 5) Department of Psychiatry, Sakae Seijinkai Hospital, Kanagawa, Japan; 6) Division for Environment, Health and Safety, The University of Tokyo, Tokyo, Japan; 7) HLA Foundation Laboratory, Kyoto, Japan; 8) Department of Molecular Genetics, Center for Bioresources, Brain Research Institute, Niigata University, Niigata, Japan; 9) Panic Disorder Research Center, Warakukai Med. Corp. , Tokyo, Japan; 10) Department of Psychiatry, Institute of Medical Life Science, Graduate School of Medicine, Mie University, Mie, Japan; 11) Tokyo Metropolitan Matsuzawa Hospital, Tokyo, Japan; 12) Department of Physical and Health Education, Graduate School of Education, The University of Tokyo, Tokyo, Japan.

Panic disorder (PD) is one of anxiety disorders characterized by panic attacks and anticipatory anxiety. Both genetic and environmental factors have been thought to trigger PD onset, but little is known about the pathogenesis of PD. To date, *TMEM132D*, which was found to be associated with PD in European genome-wide association study (GWAS), is the only genetic factor that was replicated in several studies. We previously performed GWAS with Japanese PD samples and found some genes with marginal associations with PD. However, there seems to be other genetic factors which remain to be elucidated by the analysis just focusing on SNPs with low P values. In this study, we performed pathway analyses and aimed to identify new genetic factors, considering the possibility that functional combinations of SNPs would affect PD pathogenesis. We performed three different types of pathway analyses. Each analysis indicated that immune-related pathways showed the strongest association with PD (DAVID, P = 2. 08 ×10-6, i-GSEA4GWAS, P < 10-3; ICSNPathway, P < 10-3) and that human leucocyte antigen (HLA) had the potential of contributing to the immune-related association. We then re-examined the previous GWAS findings, focusing on the *HLA* region, and found that several SNPs in this region showed suggestive associations with PD, even though these associations were not significant at the genome-wide level. Based on these results, we examined *HLA-DRB1* and *HLA-B* regions as susceptibility locus for PD in 744 subjects with PD and 1418 control subjects. Patients with PD were found to be significantly more likely to carry *HLA-DRB1*13:02* (P = 2. 50×10-4, odds ratio = 1. 54). We then performed subgroup analyses of GWAS, dividing subjects with and without *HLA-DRB1*1302*. Several SNPs in *TMEM132D* gene showed suggestive or marginal associations with PD in the subgroup without *HLA-DRB1*1302*. Our study provides initial evidence that *HLA-DRB1*13:02* and genes involved in immune-related pathways are associated with PD. Moreover, the result of subgroup analyses suggests that an immunopathogenesis is more likely to play a role in PD patients with *HLA-DRB1*13:02*. To the contrary, *TMEM132D* might affect disease states in subjects without *HLA-DRB1*13:02*. Further studies are needed to confirm these results and clarify the underlying mechanisms causing PD.

1076W

Genome-Wide Association Study Implicates Protein Kinase N2 as a Risk Factor in Persistent Drug Abuse in Intravenous Drug Users. *SC. Wang[1], G. Kirk[2], S. Mehta[2], B. Maher[1].* 1) Johns Hopkins Bloomberg School of Public Health, Department of Mental Health; 2) Johns Hopkins Bloomberg School of Public Health, Department of Epidemiology.

Background: We performed a genome-wide association study (GWAS) to identify risk variants for continuously defined intravenous drug use in a prospective cohort ascertained for drug injection. **Methods:**The sample comprised 1228 individuals from the AIDS Linked to the Intravenous Experience (ALIVE) cohort with available genome-wide SNP data (Affymetrix 6. 0). Using the semi-annual report from the ALIVE participants over thirteen years, we used latent class growth models to divide the population into two groups: persistent drug use and cessation. The median number of follow up visit is nineteen. Prior to GWAS, we performed several procedures for quality control. We removed individuals with low genotyping rate (less than 10%). We excluded SNPs with minor allele frequency (MAF) less than 0. 08 and with more than 10% missing genotyping rate or Hardy-Weinberg test p-value less than 0. 0001. Population stratification was accounted for by Multidimensional Scaling (MDS). After frequency and genotyping pruning, 712,405 SNPs remained. Latent class growth model was performed using Mplus. After filtering, there were 700 cases and 482 controls. Genome-Wide Association Study was performed using PLINK and Haploview. **Results:** Three associations were found with p-value < 1x10-6. Two are on chromosome 2 (rs6749634, Odds ratio [OR] =0. 53, *p*= 1. 755e-7; rs12711921, OR =0. 58, *p*= 4. 858e-7) and one is on chromosome 10 (rs11255655, OR =0. 51, *p*= 7. 367e-7). The above three loci are not located in any gene. In addition, significant associations were also found on chromosome 1 (rs7522512, OR =1. 629, *p*= 9. 737e-6; rs6684950, OR =1. 666, *p*=9. 858e-6) mapped to the protein kinase N2 (PKN2), chromosome 5 (rs7731348, OR =0. 60, *p*= 5. 264e-6) mapped to the G protein-coupled receptor 98 (GPR98), and chromosome 13 (rs2793763, OR =0. 52, *p*=86. 223e-6) mapped to the citrate lyase beta like (CLYBL). (Figure 1)**Conclusions:** According to past research, no phenotype associations with the above SNPs (rs6749634, rs12711921, and rs11255655) or the above genes (PKN2, GRP98, and CLYBL) have been reported to our knowledge; moreover, these genes' in vivo function is yet unknown. Further research is needed confirm associations between these SNPs and intravenous drug use.

1077T

Genetic risk variants converge in NMDAR interactome underlying schizophrenia. *Z. Wei[1], X. Chang[2], L. Lima[2], T. Wang[2], A. Cederquist[2], E. Ryan[2], J. Garifallou[2], M. Khan[2], Y. Liu[2], J. Li[2], P. Sleiman[2,3,4], H. Hakonarson[2,3,4].* 1) New Jersey Institute of Technology, Newark, New Jersey, 07102, USA; 2) The Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, 19104, USA; 3) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, 19104, USA; 4) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania, 19104, USA.

Hundreds of genomic loci have been identified with the recent advances of schizophrenia researches in genome-wide association studies (GWAS) and sequencing studies. However, the functional interactions among those genes remain largely unknown. We developed a network-based approach to integrate multiple genetic risk factors, which lead to the discovery of new susceptibility genes and casual sub-networks or pathways in schizophrenia. We applied the method on two large GWA studies. One is the largest GWAS conducted by Schizophrenia Psychiatric Genome-Wide Association Study Consortium (PGC), which recruited 36,989 cases and 113,075 controls (PGC phase 2). The other one is our previous GWAS on schizophrenia and bipolar disease with 12,362 schizophrenia and 1,032 bipolar cases and 34,676 controls. We identified significantly and consistently over-represented pathways, which are highly relevant to synaptic plasticity, neural development and signaling transduction, such as long-term potentiation, neurotrophin signaling pathway and the ERBB signaling pathway. We also demonstrated that genes targeted by common SNPs are more likely to interact with genes harboring de novo mutations (DNMs) in the protein-protein interaction (PPI) network, suggesting a mutual interplay of both common and rare genetic variants in schizophrenia. We further developed an edge-based search algorithm to identify the top-ranked gene modules associated with schizophrenia risk. Besides the genome-wide significant gene GRIN2A, multiple genes involved in the NMDAR interactome exhibited strong association with schizophrenia risk, such as DLG2 (rs12294291, P = 4. 90 α10-7), GRIN2B (rs11757887, P = 8. 81 α10-7), ATP2B2 (rs9879311, P = 2. 77 α10-6) and NOS1 (rs2293052, P = 1. 24 α 10-6). Taken together, our results demonstrate that the N-methyl-D-aspartate receptor (NMDAR) is highly targeted by multiple types of genetic risk factors, suggesting that the NMDAR interactome plays a leading role in the pathology of schizophrenia.

1078F

Population-level identity-by-descent haplotype sharing provides insight into demographic history and autism spectrum disorder. *A. R. Martin[1,2], M. Bertalan[3], A. Rosengren[3], A. Buil[3], J. H. Thygesen[3], W. Thompson[3], T. H. Sparsø[3], T. Als[4], D. P. Howrigan[1,2], J. Grove[4], C. Pedersen[4], P. B. Mortensen[4], B. M. Neale[1,2], T. Werge[3], M. J. Daly[1,2], iPSYCH-SSI-Broad collaboration.* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Mental Health Centre, Sct. Hans and Institute of Biological Psychiatry, Psychiatric Center Sct. Hans, Roskilde, Denmark; 4) National Centre for Register-Based Research, Åarhus University, Åarhus, Denmark.

Regions of the genome shared via identity-by-descent (IBD) provide insight into the fine-scale recent demographic history within and between populations, which can be inferred from genotype data at a fraction of the cost of whole-genome sequencing. Enrichments of IBD sharing among disease cases compared to controls therefore provide insight into regions of the genome containing rare risk-conferring mutations as well as the ages of their risk-conferring haplotypes. IBD mapping has been shown to be especially powerful compared to standard GWAS approaches for weakly selected regions of the genome with an accumulation of recently-arisen deleterious alleles, as is expected for example in fecundity-reducing psychiatric diseases. Here, as part of the iPSYCH program, we investigate high-resolution population structure across >34,000 genotyped Danish blood spot samples, including >7,900 ADHD and >8,900 autism cases. We leverage pairwise IBD sharing to assess effective population sizes through time on the scale of 10s-100s of generations across birth regions in Denmark. We also investigate runs of homozygosity, a special case of IBD, across subpopulations in Denmark and identify a marked increase in individuals of Middle Eastern and South Asian descent. On average, unrelated pairs of Danish individuals share 52. 4 ± 11. 8 cM of their genome in 32. 7 ± 6. 7 IBD segments ≥ 1 cM in size. We develop an IBD association framework that takes into account haplotype cluster size, haplotype length, and low complexity regions of the genome, and we apply this framework to discover rare autism risk haplotypes likely carrying recent, stronger acting variation than would be discovered via single-point GWAS analysis.

1079W

Cross-disorder analysis of 23 brain diseases and 200,000 patients using shared heritability methods reveals novel patterns in the genetic susceptibility to brain diseases. *V. Anttila[1,2,3], B. Many neurological and psychiatric diseases have considerable co-morbidity (e. g. Bipolar Disorder-Migraine, Autism-Epilepsy). In the Brainstorm project, we set out to quantify the extent of the shared genetic basis of these diseases by integrating the most recent available genome-wide association results from both neurological and psychiatric diseases, representing over 200,000 cases and 700,000 controls across 23 brain diseases. The broad and continuous nature of psychiatric phenotypic spectra has been clinically recognized for a long time. ,Recent work in psychiatric genetics has already demonstrated strong genetic correlations across mental illnesses, with the most well-known example being schizophrenia and bipolar disorder. We have recently developed an approach to estimate heritability and genetic correlation (LDSC) in order to evaluate the extent of shared genetic risk across neurological and psychiatric disease. We found that in general, psychiatric diseases as a set have considerable shared common variant genetic risk factors. Notably schizophrenia shows significant genetic correlations with most of the studied psychiatric phenotypes. In contrast, current shared genetic analyses of neurological diseases show greater specificity. Notably, a few diseases - Parkinson's, Alzheimer's and multiple sclerosis - show little or no overlap with other neurological phenotypes. Furthermore, neurological and psychiatric phenotypes tend to show little common variant genetic overlap. However, significant positive genetic correlation is observed between migraine and attention deficit hyperactivity disorder as well as depression. In this study, we set out to integrate the best available neurological and psychiatric genome-wide association results, and to use them to explore the patterns surrounding the common genetic risk factors for psychiatric diseases, to suggest directions for future cross-disorder studies. We report a number of novel, significant genetic overlaps both within and between classical disease categories suggesting new avenues for future studies in brain diseases.

ABSTRACT

Background. While more than two dozen loci that contribute to late-onset Alzheimer disease (LOAD) have been identified, few high penetrance mutations (e. g. , APP mutations) that explain risk in families heavily burdened with LOAD have been found. Linkage analyses in large multiplex pedigrees heavily affected with LOAD could point to genomic regions harboring these rare risk variants. Thus, we performed genome-wide parametric multipoint linkage analyses on 41 Non-Hispanic White (NHW) families exhibiting a pattern of dominantly inherited LOAD, free of known AD mutations and not clustering for the APOEe4 allele. Methods. Genome-wide genotyping of 385 individuals from these 41 families was used to perform a parametric multipoint affecteds-only analysis in MERLIN. The 41 NHW families selected met three criteria: 1) exhibiting dominant inheritance of LOAD; 2) no mutations at known familial AD loci; and 3) low occurrence of the APOEϵ4 allele. All were among families who had available genome-wide genotyping of common variants on either the Illumina HumanHap 550 or 1M arrays.

Results. A locus at 1p13. 2 produced a genome-wide significant linkage HLOD score of 3. 33 (significance defined by *LOD=>3. 3). This region encompasses approximately 1. 23 Mb and contains 23 genes or gene features (e. g. miRNA). Several of these are interesting functional AD candidates: WNT2B is differentially expressed in AD brains, MOV10 is a protein integral to synaptic strength and plasticity, RHOC's expression is down-regulated by beta-amyloid, leading to decreased migration of neural stem/progenitor cells, and LRIG-2 is a BACE1 substrate. Suggestive linkage (defined as *LOD>=2. 2) was observed at 2p22. 1 (HLOD=2. 42) and we confirmed our previously reported non-parametric multipoint result at 14q32. 2 (HLOD=4. 36). Regions previously identified in AD linkage scans (PSEN1, PSEN2, APP, MAPT, APOE) showed no evidence of linkage in these analyses. Conclusions. Parametric multipoint linkage analysis of 41 multiplex NHW families identified several loci of significant interest in an initial analysis of LOAD families undergoing whole-genome sequencing. Analyses of these prioritized regions using WGS data may help determine the causative variants for these loci.

Identification of chromosomal regions interacting with susceptibility loci for Alzheimer's disease. *M. Kikuchi[1], N. Hara[2], M. Hasegawa[3], A. Miyashita[2], R. Kuwano[4], T. Ikeuchi[2], A. Nakaya[1].* 1) Department of Genome Informatics, Graduate School of Medicine, Osaka University; 2) Department of Molecular Genetics, Brain Research Institute, Niigata University; 3) Division of Molecular Biology, Research Institute for Biomedical Sciences (RIBS), Tokyo University of Science; 4) Asahigawaso Research Institute.

The most common cause of dementia is late-onset Alzheimer's disease (AD), which occurs in individuals aged >65 years and leads to neuronal death. The pathogenesis of AD is strongly correlated with genetic factors. To identify single nucleotide polymorphisms (SNPs) associated with AD, genome-wide association studies (GWAS) have been performed across some cohorts and ethnic groups. At present, 334 susceptibility loci for AD are registered in the GWAS catalog database. However, 292 (87. 4%) of these loci are located within introns and intergenic regions. The contribution of AD-associated SNPs to the onset of AD remains unknown. In this study, we explored whether AD-associated SNPs are in functional non-coding regions such as enhancers and silencers. Given that enhancers and silencers participate in long-range interactions via chromatin loops, we determined these interactions for AD-associated SNPs in candidate regions of enhancers/silencers and searched for genes in the neighborhood of AD-associated SNPs. We collected 334 AD-associated SNPs from the GWAS catalog database. We explored AD-associated SNPs in regulatory elements using RegulomeDB, a database that annotates SNPs with regulatory elements (eQTL, transcription factor binding motifs, DNase-peaks, etc.). To identify long-range chromatin interactions for AD-associated SNPs, we performed tethered conformation capture (TCC) in the human neuroblastoma SK-N-SH and human astrocytoma U-251 MG cell lines. We found that 107 (36. 6%) out of 292 AD-associated SNPs lying in non-coding regions were related to one or more regulatory elements, suggesting that some AD-associated SNPs work as enhancers/silencers and influence the transcription of distant genes. For instance, eight SNPs in the *APOE* gene cluster, which includes *APOE*, a strong risk factor for AD, were localized in transcription factor binding regions. Furthermore, analysis of the chromatin structure by TCC revealed that the *APOE* gene cluster conformationally interacted with some genes involved in AD pathology. The chromatin interactions of the *APOE* gene cluster were observed only in the SK-N-SH cell line. Taken together, our study suggests that some AD-associated SNPs affect the transcriptional regulation of genes at distinct genomic regions through chromatin higher-order structure.

1082W

A variant in Sarcolemma Associated Protein (*SLMAP)* achieves genome-wide significance in African Americans with Alzheimer's disease using informed conditioning on clinical covariates. *J. Mez[1], J. Chung[2], J. Kriegel[1], K. L. Lunetta[4], J. Haines[12], R. P. Mayeux[9, 10, 11], M. A. Pericak-Vance[7, 8], G. D. Schellenberg[6], L. A. Farrer[1,2,3,4,5], Alzheimer's Disease Genetic Consortium.* 1) Neurology, Boston University School of Medicine, Boston, MA; 2) Medicine, Boston University School of Medicine, Boston, MA; 3) Ophthalmology, Boston University School of Medicine, Boston, MA; 4) Biostatistics, Boston University School of Public Health, Boston, MA; 5) Epidemiology, Boston University School of Public Health, Boston, MA; 6) Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 7) The John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 8) Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 9) Taub Institute on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 10) Gertrude H. Sergievsky Center, Columbia University, New York, NY; 11) Neurology, Columbia University, New York, NY; 12) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

Late onset Alzheimer's disease (LOAD [MIM104300]) risk is influenced by multiple known genetic, clinical and environmental factors. Including these factors as covariates in traditional genetic analyses of subjects ascertained in a case-control design may decrease power to detect an association. However, an informed conditioning approach, based on a liability threshold model with parameters informed by external prevalence data, can be used to extract risk information from known genetic and non-genetic factors without a reduction in power. A previous genome wide association study (GWAS) by the Alzheimer's Disease Genetic Consortium (ADGC) found that, in addition to the *APOEϵ4* allele, a variant in the *ABCA7* gene (rs115550680) was significantly associated with LOAD at the genome-wide level in African Americans (AAs). In the current study, we conducted a GWAS in AAs employing informed conditioning that included these genetic factors and clinical and environmental factors associated with LOAD. Subjects included 1,910 well-characterized African American AD cases and 3,829 cognitively normal AA controls from 9 ADGC datasets. First, we used LTSOFT software to derive a posterior liability conditioned on age, sex, diabetes status, smoking history, education level and AD status. Next, we evaluated association of the posterior liability with a genome-wide set of 6 million imputed markers using linear regression that included principal components of population substructure and *APOEϵ4* and rs115550680. We meta-analyzed results across datasets. We obtained genome-wide significant evidence of association (p=2. 75x10-8) between the posterior liability and rs115317194 (minor allele frequency=0. 07), a single nucleotide polymorphism (SNP) in the Sarcolemma Associated Protein (*SLMAP*) gene that is unique to African ancestry. *SLMAP* is expressed in brain and its protein product binds the protein phosphatase 2A-containing striatin-interacting phosphatase and kinase complex that regulates tau phosphorylation. In the ADGC's previous African American GWAS of AD that used a traditional case-control design, the same *SLMAP* SNP reached a p-value of 3. 39x10-5 which is three orders of magnitude less significant than the one yielded for the posterior liability model. Sensitivity analyses revealed that adding the clinical and environmental factors accounted for most of the change in the p-value. The current study suggests an informed conditioning approach can improve association signals in GWAS.

1083T

Novel risk variants and the genetic architecture of amyotrophic lateral sclerosis. *W. van Rheenen[1], A. Shatunov[2], A. Al-Chalabi[2], L. H. van den Berg[1], J. H. Veldink[1], Project MinE consortium.* 1) 1. Department of Neurology and Neurosurgery, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 2) 2. Department of Basic and Clinical Neuroscience, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease affecting 1 in 400 people at a median age at onset of 65 years. Genome-wide association studies have identified several risk loci in ALS. The majority of ALS heritability, however, remains unexplained. Considering our incomplete understanding of ALS, we need to expand our knowledge of the genetic basis of this disease. Furthermore, elucidating the genetic architecture of ALS is essential to design effective future genetic studies in ALS. We genotyped new cases and controls and collected existing genotype data of all previously published GWAS in ALS. Variants obtained from whole genome sequencing 1,246 ALS cases and 615 controls merged with the 1000 Genomes Project reference panel were imputed (1000GP). SNP associations were tested in a meta-analysis and using a linear mixed model (LMM). Predictions were made using polygenic risk scores and heritability was estimated across the allele frequency spectrum. In total 12,577 cases and 23,475 cases passed GWAS quality control. Imputing variants from our custom reference panel improved the imputation accuracy (r2 = 0. 63 and 0. 83 for 1000GP and custom panel respectively). The meta-analysis confirmed genome-wide significant ($p < 5 \times 10\text{-}8$) associations for the three known ALS loci. Furthermore, a rare coding variant was found in a novel locus that was subsequently replicated (joint meta-analysis $p = 1.8 \times 10\text{-}12$), and we observed an enrichment of rare coding variants in this gene (OR 2. 33, p = 0. 013). Using a LMM we found three more loci reaching genome-wide significance. Polygenic risk score predictions indicated a polygenic architecture of ALS ($R2 = 0.7\%$, $p = 2.3 \times 10\text{-}16$). Finally, we estimated the SNP-based heritability at 8. 5% (SE 0. 5%) with an important role for less common variants (1-10%). This is supported by the observation that less common to rare variants exhibit an overall risk increasing effect on ALS suggesting purifying selection against ALS risk alleles while ALS patients are perfectly fit to produce offspring. Identifying 7 genome-wide significant loci including a new ALS gene this study substantially increases our knowledge of the genetic basis of ALS. Furthermore, it highlights a polygenic architecture where less common to rare variants confer to the overall risk of this disease. These results emphasize the need for large-scale screens for rare variants in ALS and searching the cause of selection against ALS risk alleles.

Variants in *CNTN5* Associated with ADHD Susceptibility: A Meta-Analysis of Two Pediatric Cohorts. *J. J. Connolly[1], B. Almoguera[1], F. Mentch[1], L. Vazquez[1], D. J. Abrams[1], P. Sleiman[1,2], T. Lingren[3], B. Namjou[4], T. Froehlich[5], J. B. Harley[4], H. Hakonarson[1,2], The Electronic Medical Records and Genomics (eMERGE) Network.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 3) Department of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 4) Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center and US Department of Veterans Affairs Medical Center, Cincinnati, OH, USA; 5) Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA.

Attention deficit hyperactivity disorder (ADHD) is the most common neurobiological disorder in children, with a prevalence of ~6-7% that has remained stable for decades. We present results of a meta-analysis of two genome-wide association studies (GWASs) involving European American (EA) cohorts from The Children's Hospital of Philadelphia (CHOP – 762/4,907 cases/controls) and Cincinnati Children's Hospital Medical Center (CCHMC – 222/402 cases/controls). All cases and controls were defined by an electronic health record (EHR)-based algorithm, which mines health EHRs for pertinent diagnostic (i. e. ICD9 codes) and medication information. The algorithm was run and validated on the CHOP cohort of >80,000 patients, and also externally at the CCHMC, n=>6,000. Chart review of 50 cases and 50 controls at CHOP produced positive and negative predictive values of 96% and 96%. Respective values for CCHMC were 89% and 95%. All samples were genotyped on Illumina on HumanHap550 or Human610-Quad and imputation of non-observed genotypes was carried out using SHAPEIT and IMPUTE2. Association analysis was conducted using SNPtest and 10 principal components were generated using Eigenstrat 3. 0 to adjust for population stratification. Metal was used for meta-analysis of the two cohorts. Three single nucleotide polymorphisms (SNPs) at the contactin 5 (*CNTN5*) gene were nominally significant in each cohort, but statistically significant in the combined analysis (P=1. 34 x 10-8, P <2. 39 x 10-8, and 3. 88 x 10-8 respectively). *CNTN5* represents a solid ADHD candidate gene as it encodes a neuronal membrane protein, which functions as a cell adhesion molecule and mediates cell surface interactions during nervous system development. While a CNV study previously associated *CNTN5* with ADHD, this is the first time that a single nucleotide variant is observed to be associated with ADHD at a genome-wide significant level.

1085W

Identifying Genetic Modifiers of an Inherited Peripheral Neuropathy in a GWAS Design. *F. Tao[1], G. Beecham[1], N. Vasudeva[1], L. Abreu[1], R. Schüle[1,2], S. Blanton[1], D. Pareyson[3], M. Reilly[4], M. Shy[5], S. Züchner[1], Inherited Neuropathy Consortium.* 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, University of Tübingen, Tübingen, Germany; 3) Department of Clinical Neurosciences, C. Besta Neurological Institute, Milan, Italy; 4) MRC Centre for Neuromuscular Diseases, UCL Institute of Neurology, London, UK; 5) Department of Neurology, University of Iowa, Iowa City, IA, USA.

The most common subtype of inherited peripheral neuropathies is Charcot-Marie-Tooth disease type 1A (CMT1A), caused by a uniform 1. 5Mb duplication including PMP22 gene on chromosome 17. Although sharing the same genetic cause, CMT1A patients show great differences in their symptom onset and disease severity, suggesting that other factors such as genetic modifiers may play a role in modulating the phenotypic presentation. This study uses genome-wide association tests as the primary study design to identify genetic variants with modifying effects in CMT1A. We genotyped 715K SNPs in 919 CMT1A patients and performed a genome-wide association study (GWAS) to identify genetic variants that associate with the following phenotypic outcomes: difficulty in walking, difficulty in balance, decreased sensation and foot dorsiflexion. The genotypes were also utilized to confirm PMP22 duplication in each CMT1A patient. Two different association tests were performed: genome-wide association analyses with family data (GWAF) for SNP-based association test, and sequence kernel association test (SKAT) for gene-based association test. Both SNP-based GWAF and gene-based SKAT generated multiple genetic variants of interest associated with the four clinical outcomes. However, none of the candidate SNPs and genes reached genome-wide statistical significance after Bonferroni correction to adjust for multiple testing. The top SNPs identified by GWAF are: rs7196367 for difficulty in walking (raw p-value = 6. 7×10-7), rs2406176 for difficulty in balance (raw p-value = 1. 3×10-6), rs4346964 for decreased sensation (raw p-value = 3. 3×10-6), rs11212437 for foot dorsiflexion (raw p-value = 3. 7×10-6). The top genes identified by SKAT are: LOC441025 for difficulty in walking (raw p-value = 1. 4×10-4), NR5A1 for difficulty in balance (raw p-value = 3. 9×10-5), DIS3L2 for decreased sensation (raw p-value = 2. 8×10-4), PLCXD3 for foot dorsiflexion (raw p-value = 1. 9×10-5). This study, thus far, did not show a genome-wide statistically significant association of genetic modifiers with the phenotypic variability in CMT1A patients. We are currently conducting pathway-based analysis from the top 5% genes of interest, and are also complementing these studies with an extreme phenotype approach using whole genome sequencing (WGS). Meanwhile, the Inherited Neuropathy Consortium is working on expanding the sample size for GWAS to achieve higher statistical power in detecting modifier variants.

1086T

Investigating the Genetic Architecture of Major Depression and Body Mass Index in 10649 Han Chinese Women using Sparse Whole Genome Sequencing and Molecular Signatures of Stress. *R. Peterson[1], T. Bigdeli[1], N. Cai[2], A. Edwards[1], W. Kretzschmar[2], F. Yang[3], J. Marchini[2], J. Flint[2], K. Kendler[1], S. Bacanu[1], B. Webb[1], CONVERGE Consortium.* 1) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, PO Box 980126, Richmond VA, 23298, USA; 2) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford OX3 7BN, Oxfordshire, UK; 3) Shanghai Mental Health Center, Shanghai Jiao Tong University School of Medicine, No. 600 South Wanping Road, Shanghai, P. R. China.

Obesity is a major public health concern, and is often comorbid with psychiatric conditions including major depression (MD). Notably, several symptoms of MD are related to energy balance, including changes in appetite, weight, and sleep. It is conceivable that stressful life events (SLE) and dysregulation of biological systems of stress may underlie a shared liability between mental and physical health. However, despite numerous associations between obesity and various mental health outcomes there has been limited research on shared genetic and environmental liability. We sought to investigate the relationship between obesity and MD by (1) testing genetic variants previously identified as influencing body mass index (BMI) for association with BMI, MD, and depression subtypes, (2) constructing genetic risk scores (GRS) and test for cross-trait association, and (3) evaluating the moderating effects of SLEs and molecular signatures of stress. We used sparse whole-genome sequencing data from the CONVERGE (**C**hina, **O**xford a**n**d **V**CU **E**xperimental **R**esearch on **G**enetic **E**pidemiology) study of 6,000 Han Chinese women with recurrent MD and 6,000 screened controls. In aggregate, common SNPs accounted for 15. 5% of the variance in BMI (p=8. 0x10-7), 22. 6% in MD diagnosis (p<1. 0x10-16), and 16. 1% in atypical depression liability (p=0. 002). Associations with individual variants previously implicated in BMI were not robust (p*FTO*=0. 005). However in aggregate, a GRS constructed from 92 BMI-associated genetic variants was significantly associated with BMI, accounting for ~0. 75% of the variance (p<1. 0x10-16). The GRS was negatively associated with MD (effect=-0. 72, p=0. 014) but not atypical depression. Phenotypic analyses indicated significant environmental main effects of childhood sexual assault (OR=2. 9, p=2. 6x10-19), childhood physical abuse (OR=4. 6, p=4. 2x10-23), and serious childhood neglect (OR=4. 8, p=2. 5x10-51) on MD. We also observed a significant association between MD and both mtDNA levels (OR=1. 33, p=9. 0x10-42) and telomere length (OR=0. 85, p=2. 8x10-14). Analysis of SLEs and molecular signatures of stress will be applied to models of comorbidity. Initial results were suggestive of partially shared genetic risk between MD and BMI. Furthermore, results suggest genetic variation associated with BMI may only partially overlap between European and Han Chinese populations, highlighting the importance of studying genetic contributions to complex traits in diverse populations.

Background: Major depressive disorder (MDD) is one of the commonest psychiatric illnesses and a leading cause of morbidity worldwide. Although modestly heritable (30-40%), MDD is a genetically complex and etiologically heterogeneous trait, complicating efforts to identify variants conferring risk or protection. For these reasons, we investigated the genetic basis of MDD in subjects for whom known sources of phenotypic and genetic heterogeneity were minimized and known risk factors documented. **Approach**: The CONVERGE (China, Oxford and Virginia Commonwealth University Experimental Research on Genetic Epidemiology) consortium recruited 11,670 Han Chinese women through a collaboration involving 58 hospitals in 45 cities and 23 provinces of China. Whole genome sequence (WGS) was acquired to a mean depth of 1. 7X per individual from which 32,781,340 SNP sites were identified. Comparison of genotypes from the low coverage sequencing to genotypes called from 10X sequencing data indicated 98. 1% concordance (*N*=9). Following stringent quality controls, we performed a genome-wide association study (GWAS) of 5,303 cases with recurrent MDD and 5,337 controls screened to exclude MDD. **Results**: We identified and replicated in an independent Han Chinese sample (*N*=6,417) two genome-wide significant loci contributing to risk of MDD on chromosome 10: one near *SIRT1* (*P* = 2. 53x10-10) and the other in an intron of *LHPP* (*P* = 6. 45x10-12). Comparison with results from the Psychiatric Genomics Consortium (PGC) mega-analysis of European studies failed to provide robust replication for our top SNPs. However, the proportion of associations in the same direction in the two studies exceeded chance expectations (*P*< 0. 001). **Conclusions**: We have identified the first robustly associated, replicated genetic associations with MDD. We attribute our success to the recruitment of relatively homogeneous cases with severe illness, and to our having conducted the largest WGS study of a single cohort to date. Our results clearly demonstrate that obtaining low sequence coverage of a large number of individuals can be an effective way to screen the genome for association signals. We discuss relevant implications for future genetic studies, as well as emergent findings from a joint PGC-CONVERGE trans-ethnic meta-analysis of MDD.

1088W

Cross-Disorder Genome-Wide Analyses and Genetic Relationship between ASD and OCD. *W. Guo[1], JF. Samuels[2], Y. Wang[2], MA. Grados[2], MA. Riddle[2], OJ. Bienvenu[2], FS. Goes[2], B. Maher[2], AE. Pulver[2], D. Valle[3], G. Nestadt[2], YY. Shugart[1].* 1) Unit of Statistical Genetics, NIMH, Bethesda, MD; 2) Johns Hopkins University School of Medicine, Department of Psychiatry and Behavioral Sciences, Baltimore, MD 21205, USA; 3) John Hopkins University School of Medicine, Institute of Human Genetics, Baltimore, MD 21205, USA.

Obsessive-compulsive disorder (OCD) and Autism spectrum disorder (ASD) are highly heritable neurodevelopmental disorders that are thought to share genetic risk factors. However, the underlying genetic determinants are largely unknown. The authors report a combined genome-wide association study (GWAS) of ASD and OCD. The OCD dataset includes 3087 individuals in 1065 families (comprising 1406 patients with OCD and 2895 individuals in total). The ASD dataset includes 6782 individuals in 2227 trios. GWAS summary statistics were examined for enrichment of functional variants associated with gene expression levels in brain regions. Polygenic score analyses were conducted to investigate the genetic relationship within and across the two disorders. The heritability on both data were examined using genome-wide common variant data by the program Genome-wide Complex Trait Analysis (GCTA). We examined genomic architectures of ASD and OCD by chromosome and MAF bin.

1089T

Identification of novel genetic variants of DSM-5 alcohol use disorder: Exome Array analyses in NESARC-III. *J. Jung, H. Zhang, RB. Goldstein, BF. Grant.* Laboratory of Epidemiology and Biometry, National Institute on Alcohol Abuse and Alcoholism, National Institutes of Health, Rockville, MD.

DSM-5 Alcohol use disorder (AUD) is a complex psychiatric disorder that affects about 32% of European Americans (EA) and 22% of African Americans (AA). Moderate to severe DSM-5 AUD and DSM-4 alcohol dependence (AD) are similarly genetically influenced with heritability of 50-65% and genetic correlation between them of 95%. We analyzed data from the National Epidemiologic Survey on Alcohol and Related Conditions-III (NESARC-III) to perform a Exome Array study of alcohol use disorder with moderate to severe symptoms (AUD >=4). EA and AA in NESARC-III samples were genotyped by Affymetrix Axiom Exome Chip 319K and 100K additional customized SNPs. EA samples of 2114 cases and 2697 supernormal controls with no psychiatric disorders, and AA samples of 436 cases and 1448 supernormal controls were analyzed. A single SNP based analysis with common variants (minor allele frequency (MAF)>= 0. 01) was performed to test association with AUD using an additive model and a gene based analysis with rare variants (MAF<0. 05) was conducted using Sequence Kernel Association Test after controlling for sex, age, family income, marital status, education, and two population stratification scores. Based on a single SNP analysis, we identified three novel SNPs in *ST5* (rs200029552), *GRIN3A* (rs144427058), and *DEPDC5* (rs199749859), with p-value < 2e-7 in EA. In addition, we found that a SNP rs117916638 located in exon region of gene *EGLN2* (p-value=3. 74e-6) is significantly associated with AUD in EA samples, and we replicated it in AA samples (p-value=6. 2e-3). In a gene based analysis, we identified 3 novel genes (*FER1L6-AS1, FOLR2, H2BFM*) with p-value <2. 5e-6 of a gene level threshold in EA and *EGLN2* was detected in both EA (4. 2e-5) and AA (6. 2e-3). Both gene based approach and a SNP based approach confirmed that *ADH1B* (p=1. 3e-5) is associated in only EA. In addition to confirming previous findings on associations of *ADH1B, GRIN3A* and *FOLR2* with alcohol-related phenotypes, our preliminary data identify novel associations that open up promising path to improved understanding to the etiology of AUD.

1090F

Genome-wide Linkage on Chromosome 10q26 for a Dimensional Scale of Major Depression. *E. E. M. Knowles[1], J. W. Kent[2], D. R. McKay[1], E. Sprooten[3], S. R. Mathias[1], J. E. Curran[4], M. A. Carless[2], M. A. A. de Almeida[4], H. H. H. Goring[2], T. D. Dyer[4], R. L. Olvera[5], P. T. Fox[5], R. Duggirala[2], L. Almasy[5], J. Blangero[4], D. C. Glahn[1].* 1) Yale University, New Haven, CT; 2) Texas Biomedical Research Institute, San Antonio, Texas, USA; 3) Icahn School of Medicine at Mount Sinai, New York, NY; 4) The University of Texas, Rio Grande Valley, Edinburg, TX; 5) University of Texas Health Science Center, San Antonio, Texas.

Major depressive disorder (MDD) is a common and potentially life-threatening mood disorder. Identifying genetic markers for depression might provide reliable indicators of depression risk, which would, in turn, substantially improve detection, enabling earlier and more effective treatment. The aim of this study was to identify rare variants for depression, modeled as a continuous trait, using linkage and post-hoc association analysis. The sample comprised 1221 Mexican-American individuals from extended pedigrees. A single dimensional scale of MDD was derived using confirmatory factor analysis applied to all items from the Past Major Depressive Episode section of the Mini-International Neuropsychiatric Interview. Scores on this scale of depression were subjected to linkage analysis followed by QTL region-specific association analysis. Linkage analysis revealed a single genome-wide significant QTL (LOD = 3. 43) on 10q26. 13; the majority of the linkage signal originated from a large multiplex pedigree within the larger sample (LOD = 1. 84). QTL-specific association analysis conducted in the entire sample revealed a suggestive variant within an intron of the gene *LHPP* (rs11245316, p = 7. 8x10-04; LD-adjusted Bonferroni-corrected p = 8. 6x10-05). Family-specific association analysis within the multiplex MDD pedigree (from which the majority of the linkage signal originated) revealed a variant within an intron of CPXM2 (rs7913161, p = 2. 4x10-05) that met the peak-adjusted alpha. The signal for this variant in the entire sample was not significant (p = 0. 19), suggesting that the variant rs7913161 is likely marking a functional and rare variant present only in the multiplex pedigree. This region of the genome has previously been implicated in the etiology of MDD; the present study extends our understanding of the involvement of this region by highlighting a putative gene of interest (*LHPP*), and implicating the possible role of rare variation within the gene *CPXM2* in a newly identified multiplex MDD pedigree.

1091W

Bivariate linkage and association for recurrent major depression and right hippocampal volume. *S. R. Mathias[1], E. E. M. Knowles[1], J. W. Kent[2], D. R. Mckay[1], M. A. Carless[2], J. E. Curran[3], M. A. A de Almeida[3], H. H. H. Goring[2], T. D. Dyer[3], R. L. Olvera[4], P. T. Fox[4], L. Almasy[4], J. Blangero[3], D. Glahn[1].* 1) Yale University, New Haven, CT; 2) Texas Biomedical Research Institute, San Antonio, TX; 3) The University of Texas Rio Grande Valley, Edinburg, TX; 4) University of Texas Health Science Center, San Antonio, TX.

Previous work has shown that the hippocampus is smaller in the brains of individuals suffering from major depressive disorder (MDD) than in those of healthy controls. Moreover, right hippocampal volume specifically has been found to predict the probability of subsequent depressive episodes. The present study explored the utility of right hippocampal volume as an endophenotype of recurrent MDD (rMDD). We observed a significant genetic correlation between the two traits in a large sample of Mexican American individuals from extended pedigrees (ρ_g = -0. 34, s. e. = 0. 14,p = 0. 013). A bivariate linkage scan revealed a significant pleiotropic quantitative trait locus on chromosome 18p11. 31-32 (LOD score = 3. 61). Bivariate association analysis conducted under the linkage peak revealed a variant within an intron of the gene *SMCHD1* (rs12455524) met the level of LD-adjusted peak-wide significance (p = 7. 4 x 10-5). Univariate association analyses of each phenotype separately revealed that the same variant was significant for right hippocampal volume alone (p= 2. 6 x 10-5), and also revealed a suggestively significant variant within the gene *DLGAP1* for rMDD alone (p = 0. 0001). The results implicate right-hemisphere hippocampal volume as a possible endophenotype of rMDD, and in so doing highlight a potential gene of interest for rMDD risk.

Genome-Wide Association Study of Smoking Quantity in American Populations: Identification of Novel Risk Loci in Both African- and European-Americans. *J. L. Montalvo-Ortiz[1], H. R. Kranzler[3], R. Sherva[4], L. Almasy[5], A. I. Herman[1,2], R. Koesterer[4], H. Zhao[6], L. A. Farrer[4,7], J. Gelernter[1,2].* 1) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 2) Departments of Genetics and Neurobiology, Yale University School of Medicine, New Haven, CT; 3) Department of Psychiatry, University of Pennsylvania, Philadelphia, PA; 4) Department of Medicine (Biomedical Genetics), Boston University, Boston, MA; 5) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 6) Departments Biostatistics and Genetics, Yale School of Public Health, New Haven, CT; 7) Departments of Neurology, Ophthalmology, Genetics & Genomics, Epidemiology and Biostatistics, Boston University School of Medicine, Boston, MA.

BACKGROUND: We report a genome-wide association study (GWAS) of the trait of smoking quantity, defined as the number of cigarettes smoked per day in the lifetime in European-American (EA) and African-American (AA) populations. METHODS: Our GWAS sample included the Yale-UPenn sample (2114 EA and 2602 AA) used in our previous GWAS studies, augmented by additional subjects ascertained identically. We conducted the GWAS analysis by considering smoking quantity as an ordinal trait, assessed by the Semi-Structured Assessment for Drug Dependence and Alcoholism (SSADDA), which is a polydiagnostic assessment for psychiatric traits. RESULTS: In AAs, *IRX3* SNP rs16953233 located in chromosome 16 was genome-wide significant (GWS) (p = 2. 84 × 10-8). SNP rs61040077 mapped to chromosome 6 region near *RGS17* was also nominally associated with smoking quantity (p = 3. 76 × 10-7). Although it is not genomewide significant it may be interesting since we have previously shown *RGS17* to be associated with risk for substance dependence diagnoses including alcohol, cocaine, opioid and marijuana dependence and has been also shown to be associated with smoking behaviors. In EAs, three SNPs mapping to *IQCF3* were the most significant results obtained (minimal p = 4. 65 × 10-7). Pathway analysis identified association with calmodulin and calcium signaling in both populations, which has been previously found to be involved in the effects of nicotine dependence and other substance use disorders. CONCLUSIONS: These risk variants for smoking behavior provide novel insights into potential therapeutic and prevention interventions.

Genetics of depression across adolescence. *H. M. Sallis[1,2], L. Paternoster[1], J. Evans[2], G. Davey Smith[1].* 1) MRC Integrative Epidemiology Unit, School of Social and Community Medicine, University of Bristol, Bristol, United Kingdom; 2) Centre for Academic Mental Health, School of Social and Community Medicine, University of Bristol, Bristol, UK.

Despite many attempts to understand the genetic architecture of depression, little progress has been made. The heritability of depression in adults has previously been estimated at around 0. 37 (Wray et al, 2013), while the Psychiatric Genomics Consortium used SNP-based methods to estimate a heritability (h2SNP) of 0. 21 (Lee et al, 2013). The majority of these studies have been carried out in adults and have ignored the potential influence of development. However a recent publication by Nivard et al (2014) looked at heritability of depression across the life course. This study showed a substantial genetic component to depression at earlier ages, with a distinct drop in heritability around the age of puberty. However, this finding coincided with a switch from parent to self-report measures. The Avon Longitudinal Study of Parents and Children (ALSPAC) collected consistent self-report measures of depressive symptoms between ages 10 and 18 and is uniquely placed to investigate the heritability of depression across adolescence, an important developmental period involving major biological changes and a rising incidence of depression. We used genome-wide complex trait analysis (GCTA) to investigate h2SNP of depression across adolescence, in addition to bivariate GCTA to look at the genetic correlation between depressive symptoms. We investigated the role of puberty by stratifying estimates of h2SNP according to onset at ages 10 and 13. A genome-wide association study of depressive symptoms during early and late adolescence was performed to identify genetic variants associated with depression at different stages of development. We found fluctuations in h2SNP across adolescence, with a peak at age 13 (h2SNP=0. 17, se=0. 06). A genetic correlation between depressive symptoms at ages 13 and 18 of 0. 40 was found, although the statistical evidence for this was weak. h2SNP estimates differed according to timing of pubertal onset. No genetic variants achieved genome-wide significance at ages 10 or 18, however, we found a signal on chromosome 7 at age 13. We are currently attempting to replicate this finding. In conclusion we found evidence of the heritability of depression across adolescence but no evidence to support an abrupt drop in heritability with the onset of puberty. There is evidence of partial overlap of the genetic architecture of depression between mid and late adolescence. A genetic variant on chromosome 7 may contribute to the heritability of depression at 13.

1094W

Schizophrenia Polygenic Risk Score is Strongly Associated with Bipolar 1 Disorder in a Multi-ethnic Sample. *C. Schaefer[1], L. Shen[1], K. Thai[1], E. Jorgenson[1], T. Hoffmann[2], Y. Banda[2], M. Kvale[2], N. Risch[1,2].* 1) Division of Research, Kaiser Permanente Northern California Division of Research, Oakland, CA; 2) Institute for Human Genetics, UCSF, San Francisco, CA.

Growing evidence supports a large, shared polygenic contribution of common variants to bipolar disorder (BD) and schizophrenia (SCZ). To better understand shared genetic variation of SCZ with bipolar phenotypes and with BP1 in minority race/ethnicity groups, we calculated a polygenic risk score for schizophrenia (SCZ-GRS) based on 108 genetic variants significantly associated with SCZ in a recent GWAS (PGC, Nature, 2014), using a multi-ethnic sample of 5,056 BD1 cases and 65,114 controls. BD1 cases and controls are participants in the Kaiser Permanente Research Program on Genes, Environment, and Health (RPGEH); cases were identified by multiple treatment episodes of BD1 and/or hospitalization with BD1 from electronic medical records (EMR). Persons with diagnoses of SCZ, schizoaffective disorder, or non-affective psychoses were excluded. The resulting sample was 68% female; average age at study entry was 47 years, and 25% were minority or mixed race-ethnicity. Controls were screened using EMR data to exclude those with Axis 1 disorders. Cases and controls were genotyped on the Affymetrix Axiom system imputed to 1000 Genome Project (March 2012 release). The SCZ-GRS was calculated as the weighted sum of the number of risk alleles; one-sided p-values were used due to the strong hypothesis of association of SCZ-GRS with BD. In analyses of non-Hispanic whites (3726 cases; 54620 controls), SCZ-GRS was significantly higher in cases (mean = 10. 44; s. d. = 0. 54) than controls (mean = 10. 36; s. d. = 0. 55; b=0. 270, p = 4. 31E-17). BD1 cases with psychotic symptoms (N=2418) had higher SCZ-GRS than those without (N=1307)(b=0. 204, p = 0. 0013). The SCZ-GRS was significantly associated with BD1 in each stratum of age at onset (<= 20, 21-39, >=40 years). The SCZ-GRS was associated with BD1 in East Asians (cases 298; controls 5777;b=0. 255, p = 0. 053) and Latinos (cases =732; controls = 4770;b=0. 141, p = 0. 077), but not in African Americans (cases= 300; controls=2167)(b=0. 121, p = 0. 373). These results show that genetic variation is broadly shared by BD and SCZ, including among Latinos and Asians, and specific BD1 phenotypes, such as psychotic symptoms, show increased sharing. Further examination of BD1 phenotypes, as well as gene pathways or networks may point to additional specificity in the shared variation of BD and SCZ.

Genetics of Alcohol Drinking Behaviors for Koreans: a Population with one third of Slow Metabolizers. *S. Son[1], S. Yang[1], M. Kim[2], J. Sung[1].* 1) Department of Epidemiology, Graduate School of Public Health, Seoul National University, Seoul, South Korea; 2) Shattuck-St. Mary's School, Faribault, MN.

It is well documented that individuals with Lys mutation (Glu504Lys) (=rs671 G>A) of *Aldehyde Dehydrogenase 2 (ALDH2)* gene are so-called "slow metabolizers" and less prone to alcohol abuse. In Korea and East Asian countries, about one third of population has one or two copies of the "slow" allele. Many of "slow metabolizers", however, drink as much and as frequently in Korea, and it remains unclear whether other differences in genetic constitutions explain drinking behaviors between slow and fast metabolizers. To identify genetic architecture of alcohol drinking behaviors, we performed genome wide association studies for a range of alcohol-related traits in general Korean population. We performed GWAs for 8,852 subjects from two independent cohort (3,479 from family-based, 5,373 from population-based cohort). 3,479 subjects from family-based cohort were measured for details of drinking habits and genetic markers with 3. 7 million SNP markers. After excluding 735 abstinent participants for religious reasons, we performed GWAs for self-reported facial flushing reaction with alcohol use, three domains (hazardous drinking, harmful use, and alcohol dependence) of the Alcohol Use Disorders Identification Test (AUDIT), and frequency and amount of drinking as phenotypes. All the analyses were repeated by stratifying the rs671 alleles, and SNPs interacting with the rs671 alleles on alcohol consumption behaviors were examined genome-widely. Only *ALDH2* rs671 explained facial flushing (P=3. 1×10-68). For various aspects of alcohol drinking habits, some other SNPs within the LD block of rs671 showed stronger associations, but adjusting for rs671 attenuated the significance (from P=10-68 to P=10-6). When we performed stratified analysis by fast/slow metabolizers, novel loci on the 3p14. 1 (P=6. 4×10-9) and 10p14 region(P=1. 4×10-7) showed associations with hazardous and harmful drinking domains for "fast metabolizers"; also a novel locus on the 20p12. 1 region (P=2. 2×10-7) was associated with dependence domain of AUDIT for "slow metabolizers". The same 20p12. 1 region also showed probable interaction with rs671 (P=2. 0×10-6) for dependence domain. *ALDH2* gene has a large LD block (81 kb), and it is not clear whether some other loci near rs671 also participate in the susceptibility of certain drinking habits, particularly binge drinking habits. Our findings suggest genetic susceptibility for problematic drinking behaviors might differ between fast and slow metabolizers.

Genome-wide meta-analyses identify copy number variation associated with alcohol dependence in African and European populations. *A. Sulovari[1,2], D. Li[1,3,4].* 1) Microbiology and Molecular Genetics, University of Vermont, Burlington, VT; 2) Cell, Molecular and Biomedical Sciences Graduate Program, University of Vermont, Burlington, VT; 3) Department of Computer Science, University of Vermont, Burlington, VT; 4) Neuroscience, Behavior and Health Initiative, University of Vermont, Burlington, VT.

Background: Alcohol dependence is one of the most common causes of morbidity, mortality and disability among individuals with psychiatric disorders. We report genome-wide meta-analyses between copy-number variation (CNV) and alcohol dependence (AD) in samples of European and African descent. **Methods**: We analyzed CNVs in a total of 7,467 unrelated samples from three different studies, including OZALC (Genome-wide association study of alcohol use and alcohol use disorder in Australian Twin-Families), CIDR (Collaborative Study on the Genetics of Alcoholism Case Control Study) and SAGE (Study of Addiction: Genetics and Environment). CNV detection was carried out using PennCNV and QuantiSNP. Of all samples 5,778 were of European ancestry and 1,585 of African descent. For each of the two populations we conducted a meta-analysis under the model of fixed effects (Cochran-Mantel-Haenszel, CMH) for association with AD. **Results:**In samples of European descent, CNVs in region 7p22. 3 were significantly associated with AD diagnosis (CMH OR = 3. 7,*P* =6. 82 × 10-5). In samples of African descent, CNVs in regions 14q32. 33 and 11p11. 2 were associated with AD (CMH OR = 2. 24,*P* =7. 51 × 10-6and CMH OR = 2. 36,*P* =6. 33 × 10-5, respectively). **Conclusions:** Our genome-wide meta-analyses identified three CNV risk loci that may contribute to the development of alcohol dependence in the European and African populations.

Cooperativeness Character Domain of Temperament and Character Inventory (TCI) is Associated with 15q26. 3 region in General Korean Population. *S. Yang[1], J. H. Kim[3], J. Sung[1,2].* 1) Complex Disease & Genome Epidemiology Branch, Department of Epidemiology, School of Public Health, Seoul National University, Korea; 2) Institute of Environment and Health, Seoul National University, Korea; 3) Department of Psychiatry, Samsung Medical Center, Sungkyunkwan University School of Medicine, Korea.

An individual's personality affects health by predisposing the person to a higher chance of specific health behaviors. Despite moderate heritability of 0. 3-0. 6 for most personality domains, specific genetic variants that explain personality have been elusive in studies with Caucasian samples. We conducted a genome-wide search for both TCI domains and multivariable TCI-Five-Factor Model (FFM, for sub-samples) in a population cohort of Korea, where cultural environments are different from Western populations. This study includes a total of 3342 individuals (1419 men, 691 families, 557 monozygotic twins) from the Healthy twin study of Korea with detail epidemiologic, clinical information and TCI measures; 1169 (476 men) also fulfilled the FFM. Two Platforms (Affymetrix Genome-Wide Human array 6. 0, Illumina Infinium Humancore Beadchips) were used for genotyping and the markers were imputed using 1kG Asians (n=280). For statistical analysis, we conducted a family-based univariate association test using mixed-effect variance component approach for TCI scales (MERLIN), and multiple family-based quasi-likelihood score test (MFQLS) of linear mixed model, which incorporates best linear unbiased predictor as an offset, for multivariable analysis. Univariate TCI domain analysis showed cooperativeness (CO) domain were associated with ADAMTS17 gene (on 15q26. 3, p= 9. 0e-8), but other domains did not reach significance level. When we performed a principal component analysis for both TCI and FFM domains, several latent layers of personality traits were evident. In multivariate analysis, persistence (PE-TCI) and openness (OP-FFM) (r=0. 32, RP5-897D18. 1, 20q13. 31, p= 1. 9e-7), PE-TCI and extraversion-FFM (r=0. 37, GALNT18, 11p15. 3, p= 2. 0e-7), self-transcendence-TCI and OP-FFM (r=0. 57, ADGRG7, 3q12. 2, p= 2. 6e-7) showed meaningful genetic associations. Our findings suggest that 1) some personality domains, particularly character traits might have different biological background in Koreans, 2) not a single measure but a multiple measures of personality traits might better capture the genetic architecture of personality traits. Because genetic studies on personality in Asian populations and studies which measured both TCI and FFM are scarce, we currently await collaborations to replicate our findings. This work was supported by the Post-Genome Technology Development Program (10050164, Developing Korean Reference Genome) funded by the Ministry of Trade, Industry & Energy (Korea).

1098T

Exome-wide rare variant analyses reveal NT5DC1 gene as a new candidate gene for adult ADHD. *T. Zayats, K. Jacobsen, IMPACT Consortium, J. Haavik, S. Johansson.* K. G. Jebsen Centre for Research on Neuropsychiatric Disorders, Department of Biomedicine, University of Bergen, Bergen, Norway.

Objectives: Attention-deficit/hyperactivity disorder (ADHD) is a highly heritable childhood-onset neuropsychiatric condition that often persists into adulthood. The genetic architecture of ADHD, and particularly ADHD in adults, is largely unknown. We performed an exome-wide scan of adult ADHD using Illumina HumanExome BeadChip, which allows examination of over 250,000 common and rare variants. Methods: DNA samples were collected by the International Multicenter persistent ADHD CollaboraTion (IMpACT). Statistical analyses were divided into 3 steps: (1) gene-level analysis of rare-variants (MAF<5%), (2) single marker association tests of common variants (MAF≥1%) and (3) pathway analyses. To account for multiple testing, Bonferroni correction was applied. Results: In total, 9. 365 individuals (1. 846 cases and 7. 519 controls) were analyzed. Analysis of rare variants revealed a new, genome-wide significant candidate gene for adult ADHD: NT5DC1 gene (p=3. 17E-08). The strongest signal from common variants was observed at rs9325032 in *PPP2R2B* (p=1. 61E-05). In pathway analyses, the strongest association was observed for the termination of RNA polymerase II transcription (GO:0006369 term, p=2. 48E-05), surviving Bonferroni correction for multiple testing of GO terms. Conclusion: In this largest molecular genetic study of adult ADHD performed so far, the results point to the involvement of haloacid dehalogenase superfamily of hydrolases in the etiology of adult ADHD, providing new insights into possible mechanisms underlying this condition.

1099F

RNA-sequencing identifies differentially expressed novel gene isoforms in bipolar disorder. *N. Akula, FJ. McMahon.* Human Genetics Branch, 35 Convent Drive, National Institute of Mental Health, National Institutes of Health, Bethesda, MD.

Bipolar disorder (BD) is a complex brain disorder that affects ~2% of the population. Genome-wide association studies (GWAS) have consistently identified several common variants associated with BD, but their impact on gene expression remains largely unexplored. Recent RNA sequencing (RNA-seq) studies have revealed that many of the BD GWAS-implicated genes encode thousands of alternative transcripts in the fly brain (Brown et al. 2014), suggesting that alternative splicing may be an important mechanism underlying risk for BD. To test this hypothesis, we performed deep RNA-seq (over 276 million paired-end reads/sample) in dorsolateral prefrontal cortex tissue obtained from 6 BD cases and 6 age- and sex- matched controls (Akula et al. 2014). We also identified 29 genes from the NIH GWAS Catalogue that mapped near SNPs associated with BD or related disorders at p<10-7. We analyzed alternative isoforms in these BD GWAS-implicated genes using STRINGTIE. This method identified 515 isoforms, of which 190 were apparently novel, since they have not been called by ENSEMBL, GENCODE, or other public sources. Of the 80 apparently novel isoforms that were abundant enough for testing, 22 isoforms were differentially expressed in BD at nominal p<0. 05. These apparently novel isoforms of genes implicated in BD GWAS were more likely to be differentially-expressed in BD than novel isoforms of other genes (hypergeometric p-value < 0. 0001). At the more stringent FDR<0. 05, 9 isoforms were differentially expressed, mapping to 7 of the genes implicated by BD GWAS: ADCY2, ANK3, CACNA1C, LINC00473, LMAN2L, PBRM1, and SYNE1. Most of the differentially expressed isoforms showed intron retention; the rest represented alternative 5' or 3' splicing sites or exon skipping events. While the sample size is small and experimental validation of these apparently novel isoforms is needed, these results suggest that alternative splicing events in the brain may play an important role in etiology of BD.

A search for novel causative genes for autosomal recessive hereditary spastic paraplegia based on exome sequencing of singletons from individual families. *H. Ishiura[1], J. Mitsui[1], H. Shimazaki[2], K. Koh[3], Y. Ichinose[3], Y. Takahashi[4], J. Goto[1,5], J. Yoshimura[6], K. Doi[6], S. Morishita[6], H. Sasaki[7], Y. Takiyama[3], S. Tsuji[1], JASPAC (Japan Spastic Paraplegia Research Consortium).* 1) Department of Neurology, The University of Tokyo, Tokyo, Japan; 2) Department of Neurology, Jichi Medical University, Tochigi, Japan; 3) Department of Neurology, Yamanashi University, Yamanashi, Japan; 4) Department of Neurology, National Center of Neurology and Psychiatry, Tokyo, Japan; 5) Department of Neurology, International University of Health and Welfare Mita Hospital; 6) Department of Computational Science, Graduate School of Frontier Sciences, The University of Tokyo, Chiba, Japan; 7) Department of Neurology, Hokkaido University Graduate School of Medicine, Hokkaido, Japan.

[Background]Hereditary spastic paraplegia (HSP) is a neurodegenerative disorder characterized by spasticity and pyramidal weakness of the lower limbs. The mode of inheritance of HSP can be autosomal dominant (ADHSP), autosomal recessive (ARHSP), X-linked, and mitochondrial. The causative genes for ARHSP are more heterogeneous than those of ADHSP and about 60% of ARHSP patients remain to be elucidated. In the majority of the families, affected individuals are singletons, making it difficult to efficiently narrow the candidate region with linkage analyses. We tried to identify novel causative gene for ARHSP based on exome sequencing of singletons from individual families. [Methods]One hundred and eight patients of undiagnosed HSP whose family histories were compatible with autosomal recessive mode of inheritance were enrolled. Nonsynonymous and splicing variants whose minor allele frequencies were <0. 2% were selected from exome data. We then searched for patients carrying biallelic variants, and examined if the genes with biallelic variants were shared by multiple families. [Results]We identified four families, where affected individuals shared biallelic variants in the same gene. We found two homozygous nonsense variants and one homozygous missense variants in two families. Homozygous nonsense variants strongly support loss-of-function mutations relevant to the disease. The missense variant is located in a conserved catalytic domain and the haplotypes surrounding the missense mutation were identical in the two families. The clinical presentation of these four patients are characterized by ataxia or dysarthria in addition to spastic paraplegia. Thus, the gene is considered to be causative gene for ARHSP. [Discussion]Utilizing exome data, we attempted to identify causative genes for ARHSP, focusing on genes with biallelic variants shared by multiple families. We identified a novel putative gene for ARHSP, based on the findings that 4 families have homozygous variants including two independent nonsense variants. The present study revealed that our study paradigm is efficient for identifying causative genes even though only singletons from individual families are available for the analysis. On the other hand, causative genes for ARHSP seem to be heterogeneous with each accounting for less than 1-2% of families individually. To further identify causative genes based on this strategy, it will be essential to further increase the number of families.

Characterization of the transcriptome of vestibular dysfunction associated with *SLC26A4* mutations. *Y. H. Chan[1], Y. C. Lu[1], C. W. Yu[1], I. S. Yu[2], Y. H. Lin[1,3], P. L. Chen[4,5,6,7], C. C. Wu[1,7], C. J. Hsu[1].* 1) Department of Otolaryngology, National Taiwan University Hospital,Taipei, Taiwan; 2) Transgenic Mouse Models Core, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 3) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 5) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan; 6) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 7) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan.

Recessive mutations in *SLC26A4* are responsible for non-syndromic enlarged vestibular aqueduct (EVA) and Pendred syndrome (PS), constituting a common cause of hearing impairment in children. To date, several mouse models with *Slc26a4* mutations have been established. Corresponding to the human counterpart, mice with defected *Slc26a4* revealed both auditory and vestibular dysfunction. In contrast to the phenotype of hearing loss which has been exhaustively investigated in these *Slc26a4*-defected mice, the pathogenetic mechanisms underlying the vestibular dysfunction associated with *Slc26a4* mutations remain largely unexplored. In the present study, we performed RNA-seq analyses on the inner ear extracts obtained from three groups of mice at 8 weeks: *Slc26a4*-defected mice with circling behavior (C; n=6), *Slc26a4*-defected mice without circling behavior (NC; n=6), and wild-type mice (WT; n=6). The resulting expression data were then subjected to Ingenuity Pathways Analysis (IPA), and the differentially expressed genes were validated in vivo via immunohistochemistry. We identified 90 genes differentially expressed between the C and WT groups, 8 genes differentially expressed between the NC and WT groups, and 11 genes differentially expressed between the C and NC groups. Genes considered highly correlated to vestibular dysfunction included: *Dynlt1f*, *Entpd4*, *Fam25c*, *Gm3776*, *Hbq1a*, *Hist1h2ai*, *Hist1h4m*, and *Lst1*. Among these genes, we have validated the expression of 6 genes in the inner ear using immunostaining. Canonical pathways identified by IPA included glutathione-mediated detoxification and NRF2-mediate oxidative stress response, indicating that reactive oxygen species might play a pivotal role in the development of vestibular phenotypes. Our results provide insights into the molecular pathology of vestibular dysfunction related to *SLC26A4* mutations, and may inform future studies on the potential therapeutic implications of modulating the associated genes or pathways.
