Autism spectrum disorders (ASD) are a group of neuropsychiatric disorders characterized by deficits in social communication, as well as presence of restricted interests, stereotyped and repetitive behaviors. The genes associated with ASD remain largely unknown mostly because of the clinical and genetic heterogeneity of this complex syndrome. Here, we studied the genetic architecture of 349 individuals from the Faroe Islands including 33 patients with ASD, 105 relatives and 210 controls using genome-wide genotyping of >5 millions SNPs and whole-exome sequencing. The Faroe Islands are located between the Norwegian Sea and the North Atlantic Ocean, approximately at half distance from Norway and Iceland. As expected, we first observed a higher number of runs of homozygosity (ROH) compared to other populations (P<0. 0001). Interestingly, within the Faroe population, patients with ASD had inbreeding coefficient compared with controls (F(ASD)=0. 007 vs. F(controls)=-0. 0045; P=0. 0002), suggesting that, in a subset of patients, recessive mutations could contribute to the risk of ASD. We then analyzed the contribution of *de novo* mutations (CNVs, SNVs and indels) in families with both parents DNA available (12 for SNVs and 17 for CNVs). For 3 patients, we identified *de novo* mutations in loci previously associated with ASD: 1 deletion of 22q11, 1 deletion of *NRXN1*, and 1 damaging missense mutation of *MECP2*. We also identified inherited rare CNVs altering exons of genes previously associated with ASD (*ADNP*, *BCL9*, *IMMP2L*, *TBL1X*, *TBL1XR1* and *ACACA*). We then observed a significant enrichment of rare inherited loss of function (LoF) mutations in the Ephrin receptor *EPHA1* (P=0. 01) and in the sodium channel *SCN3A* (P=0. 04), which could represent risk factors for ASD. Finally, our analysis also revealed inherited duplications of *IQSEC3* and a *de novo* stop mutation of *RIMS4*, two genes playing a role in the establishment of neuronal connectivity. In summary, based on the results from this pilot study, it seems that the genetic architecture of ASD in the Faroe Islands is not dramatically different from other populations. We were able to identify a genetic cause of ASD in at least 10% the individuals (20% of those actually examined). Further analyses are currently in progress, with a view to better understanding the interplay between common and rare variants in the susceptibility and severity of ASD in these patients.

1103W

Whole exome sequencing of parent-proband trios to identify genes implicated in hyperserotonemia and autism spectrum disorder. *R. Chen[1], J. Sutcliffe[1], S. Guter[2], L. Davis[3], N. Cox[1], B. Li[1], E. Cook[2].* 1) Department of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Department of Psychiatry, University of Illinois at Chicago, Chicago, IL; 3) Department of Medicine, University of Chicago, Chicago, IL.

Autism spectrum disorder (ASD) is a highly heritable neuropsychiatric disorder with heterogeneous genetic etiology. Numerous lines of evidence have linked serotonergic dysfunction to this disorder, including that (1) significant elevation of platelet serotonin (5-HT) was observed in ~35% of ASD cases, termed hyperserotonemia; (2) selective serotonin reuptake inhibitors can efficiently relieve some symptoms including ameliorating anxiety and irritability related to insistence on sameness and other rigid-compulsive behaviors. This link suggests the possibility of a serotonergic pathway-related mechanism contributing to the complex etiology of ASD. Serotonin itself is highly heritable, but the genetic basis of 5-HT and its relationship to ASD are largely unknown. Given that we observe elevation of serotonin in ASD probands relative to their parents, we hypothesize that *de novo* mutations (DNMs) and rare variants with recessive inheritance may play an important role in the predisposition to hyperserotonemia in ASD probands, and propose to use these observations to identify genes and pathways contributing to hyperserotonemia and ASD. In this study, we carried out whole exome sequencing of 118 ASD parent-proband trios with 5-HT measurements. We followed best-practice procedures for data processing and variant calling. In particular, we experimentally validated all functional DNM candidates and obtained 125 functional DNMs in 124 genes. We used the phase-by-transmission algorithm to construct haplotypes and achieved almost certain phasing for infrequent-to-rare variants (allele frequency < 0. 05), enabling accurate identification of compound heterozygotes (CH; 2-hit) to investigate the recessive model. We dichotomized the probands into high and low groups and identified 149 (AF<0. 05) and 49 (AF<0. 01) CH genes enriched in the high group. Gene-set enrichment analysis showed that these CH genes overlap significantly with the TADA gene lists reported previously as ASD-associated genes; the significance was obtained empirically to control a gene-length bias by sampling random gene sets matching the gene length distribution. Analysis of DNMs showed genes harboring functional DNMs significantly overlap with genes involved in ASD such as FMRP targets, chromosome remodeling genes and synapse-related genes. We are applying network analysis of DNMs and CH genes in the high vs. the low group to further elucidate the pathways encoding serotonergic function dysregulated in ASD.

Assessing the impact of inherited and *de novo* CNVs in Autism Spectrum Disorder in high-risk infant siblings using high-resolution microarrays. *L. D'Abate[1,2], S. Walker[1], R. K. C. Yuen[1], K. Tammimies[1,3], M. J. Gazzellone[1], B. Thiruvahindrapuram[1], J. Howe[1], J. Brian[4], S. Bryson[5], K. Dobkins[6], R. Landa[7], D. Messinger[8], S. Ozonoff[9], I. Smith[5], W. Stone[10], Z. Warren[11], G. Young[9], L. Zwaigenbaum[12], S. W. Scherer[1,2].* 1) The Centre for Applied Genomics, Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 3) Center of Neurodevelopmental Disorders (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden; 4) Autism Research Centre, Bloorview Research Institute, Toronto, Ontario, Canada; 5) IWK Health Centre, Dalhousie University, Halifax, Nova Scotia, Canada; 6) Department of Psychology, UC San Diego, La Jolla, California, USA; 7) Hugo Moser Research Institute, Kennedy Krieger Institute, Baltimore, Maryland, USA; 8) Department of Psychology, University of Miami, Coral Gables, Florida, USA; 9) MIND Institute, UC Davis, Davis, California, USA; 10) Autism Centre, University of Washington, Seattle, Washington, USA; 11) Vanderbilt Kennedy Center Treatment and Research Institute for Autism Spectrum Disorders, Vanderbilt Kennedy Centre, Nashville, Tennessee, USA; 12) Autism Research Centre, University of Alberta, Edmonton, Alberta, Canada.

Background: Studies conducted on trios and quartet families have implicated rare *de novo* and inherited copy number variants (CNVs) in the complex etiology of Autism Spectrum Disorder (ASD). The Baby Siblings Research Consortium (BSRC), spanning 21 sites world-wide, is a unique sibling cohort with comprehensive data on the development and therapeutic outcomes of infant siblings of children with ASD. As clinical microarrays are commonly used to identify the genetic contributors of ASD, we are investigating whether genetic testing in young children can inform of ASD status prior to the typical age of onset of symptoms. Here, we correlated our genetic findings with the clinical data available on infant siblings, allowing us to assess the predictive value of early genetic testing. **Methods:** A total of 473 individuals (239 probands, 78 siblings with ASD, 156 unaffected siblings) were genotyped on the high-resolution Affymetrix CytoScan HD platform. All infant siblings were clinically assessed periodically and given an ASD diagnosis if appropriate at 3 yrs. of age. High-confidence CNVs were detected using a combination of four algorithms, with rare CNVs being identified by comparing with 873 platform-matched controls from the Ontario Population Genomics Platform. **Results:** From the first 200 families analyzed, we observed a *de novo* CNV rate of 5. 5% in affected individuals. This included a 610 kb deletion in the 16p11. 2 locus, corresponding to the region affected by the microdeletion syndrome. A *de novo* rate of 1. 5% was observed in unaffected siblings, which is comparable to the rate observed in population controls. Likely pathogenic rare CNVs were found in 7. 2% of affected individuals and 2. 9% of unaffected siblings. Examples include a 57 kb deletion in *MBD5* in two affected male siblings and a 200 kb deletion in *NRXN1* in a male proband and his female unaffected sibling. A 90 kb deletion affecting the third exon of *PTCHD1-AS1* was observed in a male proband and his male sibling of unknown status. Some unaffected siblings harbouring potentially pathogenic variants displayed ASD-like symptoms later in development and are currently being clinically reassessed. **Conclusions:** Although analysis of the cohort is ongoing, initial findings show that identification of potentially pathogenic variants can inform on an ASD phenotype in early childhood.

Identification of *de novo* and rare inherited mutations in autism spectrum disorder by whole genome sequencing. *H. El-Shanti[1], M. Kambouris[1], Y. Al-Sarraj[1], X. Jin[2], M. Wang[2], R. K. C Yuen[3], V. Chini[1], Y. Begaoui[1], K. Errafii[1], R. Z. Taha[1], H. Boulos[4], N. Khattab[1], H. Shaath[1], X. Wu[2], J. Ju[2], M. Al-Mutawa[1], W. Habbab[1], I. R. Thompson[1], H. Abu Al-Khair[5], M. Abdel Gani[5], F. Alshaaban[1], K. Shalaby[1], G. Wang[2], Z. Wang[2], N. Chen[2], A. Shih[6], G. Dawson[6], Y. Jiang[7], S. Scherer[3], A. Farooq[8].* 1) QBRI Medical Genetics Center, Doha, Qatar; 2) BGI-Shenzhen, Bei Shan Road, Yantian, Shenzhen, China; 3) The Centre for Applied Genomics, Hospital for Sick Children and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada; 4) Human Genetics Department, University of Chicago, Chicago, IL, USA; 5) Shafallah Center for Children with Special Needs, Doha, Qatar; 6) Autism Speaks, New York, NY, USA; 7) Duke University, Durham, NC, USA; 8) Department of Biochemistry and Molecular Biology, Leonard Miller School of Medicine, University of Miami, Miami, FL, USA.

Autism Spectrum Disorder (ASD) is a lifelong neurodevelopmental disorder characterized by deficits in social communication and interaction, repetitive and restrictive behavior, extensive clinical and etiologic heterogeneity, as well as, a remarkably rising global prevalence rate. It is currently believed that ASD has an underlying genetic basis, ranging from effects of single genes to that of multiple genes and chromosomal regions, hallmarking the multifactorial and complex etiology. While a genetic etiology is identifiable in about one quarter of the cases, in the remaining three quarters it remains elusive. Recently, whole genome sequencing (WGS) emerged as a powerful tool for variant discovery due to its comprehensive and uniform coverage. We used WGS to examine a cohort of 20 trios with a child diagnosed with ASD by, at least, an ADI-R (Autism Diagnostic Interview-revised), for *de novo* or rare inherited genetic variants. Due to the nature of the ascertainment source, all probands had associated intellectual impairment. In all probands known causes of ASD were excluded, fragile X syndrome, Rett syndrome (for females) and Copy Number Variations (CNV) by SNP genotyping on an Illumina 1M-Duo SNP array. Autosomal recessive ASD alleles were inspected by WGS coupled with homozygosity mapping. The cohort is comprised of 16 male and 4 female probands and their parents. Twelve of the parent pairs were consanguineous (60%) with cumulative homozygosity intervals ranging from 37 Mb to 583 Mb. One *de novo* mutation in a known gene (*ADNP*) was identified in one family (5%) , but 5 other potentially pathogenic de novo mutations in putative genes were identified in 5 families (25%). Rare inherited X-linked mutations in two known ASD risk genes (*UPF3B*, *KDM5C*) were identified in two families (10%), but potentially pathogenic mutations in putative genes were identified in 3 other families (15%). We did not identify any rare inherited autosomal dominant mutations in the known ASD genes. One of the values of studying inbred populations is the evaluation of identical by descent variants in genes that can be further examined for compound heterozygosity in disease-specific databases. We identified rare putative inherited autosomal recessive homozygous variants in 3 families (15%). We conclude that WGS is a powerful tool for studying the genetic causes of ASD. We also conclude that consanguineous families can provide clues to autosmal recessive ASD risk genes.

1106W

No Evidence That Differences In Cortical DNA Methylation Contribute to Autism. *S. Ellis[1], S. Gupta[1], A. Moes[1], D. Absher[2], A. B. West[3], D. E. Arking[1].* 1) Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 3) Neurology, University of Alabama School of Medicine, Birmingham, Alabama.

Autism spectrum disorder (ASD) develops in early childhood and continues as a lifelong neurodevelopmental disorder that affects approximately one in 100 individuals worldwide. To date, GWAS and gene expression studies have implicated more than 100 loci contributing to the disorder; however, the majority of risk remains unexplained. Given prenatal brain development's critical role in the progression of ASD and a period sensitive to alterations in epigenetic pathways, researchers have begun to investigate the role of DNA methylation (DNAm) in ASD to uncover more of this unexplained risk. Microarray studies have looked for DNAm differences between ASD cases and controls but have been limited by small sample sizes, the digital nature of methylation arrays, and the use of material other than the brain – the primary affected tissue in ASD. To further test the hypothesis that DNAm plays a role in ASD, we measured CpG DNAm in a set of cortical brain samples (BA19) by two independent technologies, using both next-generation methylation sequencing (reduced representation bisulfite sequencing (RRBS), N=63) and methylation microarrays (Illumina Infinium HumanMethylation27 BeadChip, N=79). Samples comprised of controls and individuals with autism – a subset of ASD – all of whom were diagnosed using ADOS and ADI-R (among other exclusions). To assess the validity of the data generated, detection of previously reported brain meQTLs (26% at $p<0.05$) and age prediction based on DNAm ($R2=0.70$) were carried out in the RRBS and microarray data, respectively. Additionally, in a direct comparison of DNAm at overlapping sites between the two technologies, mean methylation values were highly correlated ($R2=0.92$). Taken together, these results suggest that DNAm was accurately captured by both technologies allowing for meaningful downstream analyses. Given our confidence in these DNAm measurements, we tested for global, regional, and individual CpG site DNAm differences between cases and controls, while accounting for both known and unknown covariates. No significant differences in DNAm were found in either the RRBS or the microarray data after bootstrapping. Further, when we focused on six previously reported regions of differential methylation, we were unable to replicate previous findings, despite our increased sample size and use of the primary affected tissue in ASD. Together, these data offer no evidence that cortical CpG DNAm contributes to differences in autism brains.

1107T

Distinct biomolecular modules group and distinguish autism genes. *F. Hormozdiari[1], O. Penn[1], E. Borenstein[1,2], EE. Eichler[1,3].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Department of Computer Science and Engineering, University of Washington, Seattle, WA; 3) Howard Hughes Medical Institute, Seattle, WA.

There is compelling evidence that the large number of genes recently associated with *de novo* mutation in autism spectrum disorder (ASD) map to a smaller set of biological pathways and modules. Using co-expression and protein interaction data, we have enhanced our computational method named MAGI (http://eichlerlab. gs. washington. edu/MAGI/) to now incorporate private inherited mutations, in addition to *de novo* mutations for improved module discovery with better objective function. We denoted this extended method as MAGI+. We applied MAGI+ to ~10,000 exomes from 2500 simplex autism families from the SSC (Simons Simplex Collection). We group patient mutations into five biological networks with distinct biological properties. These modules in total include less than 2% of all the genes in protein interaction network yet cover over 22% of truncating mutations observed in probands. These include the WNT pathway (15. 4x, p<1. 4E-8), which is highly enriched in genes that regulate transcription (8. 8x, p<4. 6e-9), chromatin modification (especially the SWI/SNF complex) significantly enriched in cell cycle and proliferation (14. 2x, p<1. 5E-4) and long-term potentiation (33x, p<6. 1e-8) with the highest expression shown in postnatal brain. Two new modules emerge from these expanded data. This includes a module related to the neurotrophin pathway (14. 9x, 2. 4e-2) that promotes neuron survival and growth with the highest expression in fetal brain cortex. A fifth module is significantly enriched with the RIG-I-like receptor pathway (22. 4x, p<1. 5e-3) associated with the innate immune system and shows the highest expression in epithelium cells. We are currently incorporating data from an additional 3000 patients from publically accessible ASC (Autism Sequencing Consortium) and DDD (Deciphering Developmental Disorders) datasets and will present this expanded set as well as the relationship of these modules with associated phenotypes (e. g. , macrocephaly, microcephaly, intellectual disability, seizures, etc.). In addition to discovering and prioritizing novel autism genes, this network strategy provides a molecular approach to subtype autism patients for future and more effective therapeutic intervention.

1108F

Utilizing whole-exome sequencing in a multiplex family with autism spectrum disorder. *E. Koparir[1], M. C. Tarakcioglu[2], Z. Gormez[3], A. Sarac[4], M. S. Sagiroglu[3], B. Yuksel[4], A. Yuksel[5], M. Ozen[5].* 1) Medical Genetics, Kanuni Sultan Suleyman Training and Research Hospital, Istanbul, Turkey; 2) Child and Adolescent Psychiatry, Kanuni Sultan Suleyman Training and Research Hospital, Istanbul, Turkey; 3) Advanced Genomics and Bioinformatics Research Center, The Scientific and Technological Research Council of Turkey (TUBITAK-BILGEM), Kocaeli, Turkey; 4) Genetic Engineering and Biotechnology Institute, The Scientific and Technological Research Council of Turkey (TUBITAK-MAM), Kocaeli, Turkey; 5) Medical Genetics, Biruni University, Istanbul, Turkey.

Autism spectrum disorders (ASD) are childhood neurodevelopmental disorders characterized by impairments in social interaction, communication, and by restricted, repetitive, and stereotyped patterns of behavior. The prevalence of ASD is estimated to be around 0. 6%, making it one of the most prevalent disorders in childhood; however, the prevalence of multiplex families with autism spectrum disorder is very rare. Family and twin studies have provided strong evidence that genetic factors have a major role in the etiology of ASD. Although in recent years several high-throughput genetic studies have identified novel ASD genes in idiopathic autism, the vast majority of the underlying genetic factors remain still unknown. Several studies have been published to examine the role of whole-exome sequencing (WES) to identify genetic risk factors for ASD. In the current study, we utilized WES in a multiplex ASD Turkish family with three affected siblings to screen all disease related and candidate genes to find out the molecular etiology of the ASD. The mother and father were first-degree cousins. Two of the siblings were diagnosed with ASD; however one was diagnosed with non-syndromic mental retardation. In conclusion, we were able to identify two candidate genes in our informative family. Confirmation of the variants and segregation analysis are in progress.

1109W

One in three *de novo* variants seen in Autism Spectrum Disorder probands are present as standing variation in a cohort of more than 60,000 non-ASD individuals. *J. A. Kosmicki[1,2,3], K. E. Samocha[1,2,3], M. Lek[2,3], D. G. MacArthur[2,3], D. P. Wall[4], E. B. Robinson[2,3], M. J. Daly[1,2,3].* 1) Harvard Medical School, Boston, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Broad Institute of Harvard and MIT, Cambridge, MA; 4) Stanford University, Palo Alto, CA.

One of the fundamental challenges of human disease genetics is differentiating risk-conferring variants from the overwhelming amount of neutral variation in the genome. Given limited sample sizes, clear interpretations of variant impact are often restricted to those variants with large effect sizes. By leveraging the power of 60,706 reference exomes in the Exome Aggregation Consortium (ExAC), we highlight classes of risk-conferring *de novo* and inherited variation in Autism Spectrum Disorder (ASD) data sets. Previous studies of *de novo* variation commonly assumed that the vast majority of *de novo* variants are novel and heavily selected against. We examined 6192 (4,256 ASD, 1,936 control) coding *de novo* variants from 6,103 trios, and found that 32. 3% are present as standing variation in non-ASD exomes from ExAC (herein referred to as recurrent *de novo* variants). [rR1]The recurrent *de novo* variants, independent of their functional impact, are enriched for CpG sites (p<10-137) and many are present at allele frequencies above 1% in non-European populations. The non-recurrent *de novo* variants are more strongly associated with neurodevelopmental risk than those present in standing variation. This is evidenced through stronger average associations between those variants and ASD (synonymous: p=0. 6, OR=1; missense: p<10-4, OR=1. 7; nonsense: p<10-5, OR=2. 8) and low IQ in ASD cases (p<10-4) as compared to previous work (Robinson et al. , 2014; de Rubeis et al. , 2014). In contrast, recurrent *de novo* variants do not exhibit the expected patterns of enrichment in ASD (synonymous: p=0. 92, OR=1; missense: p=0. 05, OR=1. 1; nonsense: p=0. 13, OR=0. 7), low-IQ (p=0. 89) or female (p=0. 69) individuals. We also examined inherited rare variants for presence in ExAC. As with the *de novo* variants, ASD individuals are enriched for inherited, singleton, loss-of-function (LoF) variants not present in ExAC (p<10-5; OR=1. 8). Additionally, several *de novo* variants not observed in ExAC were transmitted to ASD case individuals in other trio cohorts, notably a nonsense variant in *ANK2* and a probably-damaging missense variant in *RGL1*. In a separate case control cohort (1445 cases and 4424 controls), we found that ASD cases are also enriched for rare LoF variants not seen in ExAC (p<10-25; OR=2. 35). [rR1].

1110T

Investigating Somatic Mosaicism in Simplex Autism Spectrum Disorder. *D. Krupp[1], Y. Duffourd[2], S. Evans[1], R. Bernier[3], E. Fombonne[4], S. J. Webb[3], J. B. Rivière[2], B. J. O'Roak[1].* 1) Molecular and Medical Genetics, OHSU, Portland, OR; 2) Génétique des Anomalies du Developpement, Université de Bourgogne, Dijon, France; 3) Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 4) Psychiatry, OHSU, Portland, OR.

Autism spectrum disorder (ASD) is strongly genetic with complex architecture. Somatic mosaicism has been implicated in several neurodevelopmental disorders including epilepsy, cortical malformations, and overgrowth syndromes (Poduri et al. 2013). Pathways underlying these syndromes, i. e. mTOR/AKT/PI3K, are also implicated in syndromic and nonsyndromic ASD. Moreover, in a previous ASD exome study we found 5% of *de novo* events were consistent with mosaicism (O'Roak et al. 2012). We are systematically evaluating somatic mosaicism in exomes of ~2,500 families from the Simons Simplex Collection (SSC), including parents, proband, and an unaffected sibling. Our goals are to determine rates of mutations in affected and unaffected children, overlap with ASD genes/pathways, transgenerational risk, and to infer when in development these events might occur. We began by examining presumed *de novo* germline calls from the SSC (Iossifov et al. 2014, Krumm et al. 2015). We replicated previous observations, finding 4% of sites consistent with somatic events (binomial p<0. 001). We found 25 variants in genes recurrently mutated in ASD, including *SYNGAP1*. To identify variants with reduced allele fractions (that would have been missed previously), we developed an integrated calling and validation strategy. We are applying three somatic callers, VarScan 2. 3. 2, LoFreq 2. 1. 1, and our own caller. We are then validating these sites using molecular inversion probes (MIPs), enabling massive multiplexing of target sites and samples. Each MIP incorporates a unique molecular tag, allowing us to achieve statistical accuracy and correct sequencing errors. With this approach, we have been able to detect somatic mosaicism with 2-27% allele fractions in exome and resequencing data. For further analysis development and evaluation, we are leveraging 24 deeply sequenced (median ~200x) families. We have identified 9 high-confidence putative mosaic sites in probands and 8 in siblings, and are also examining parental mosaic variants transmitted to children. Using these data, we are refining the analysis process and applying it to 400 families. This systematic evaluation of mosaicism in ASD families will help elucidate how frequently somatic events occur during development and their contributions to pathogenesis of neurodevelopmental disorders. Moreover, the methods and tools developed here will allow for detailed analyses of specific tissues, i. e. brain, in future studies.

1111F

CNV Burden in ASD and its Association with Developmental and Behavioral Impairment. *J. M. Lee[1], A. J. Griswold[1, 2], J. R. Gilbert[1,2], M. A. Pericak-Vance[1,2], M. L. Cuccaro[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL.

Autism Spectrum Disorder (ASD) is a highly prevalent neurodevelopmental disorder. Copy number variations (CNVs) contribute to genetic risk for ASD and are more likely in individuals with ASD who have developmental impairments (DI). A common feature among individuals with DI is behavioral impairment (BI). For this study, we examined CNV burden in individuals with DI and BI. We hypothesized that CNV burden will be greatest in individuals with both developmental and behavioral impairments vs a single impairment. To test this hypothesis we investigated CNV burden in an ASD dataset (N=527 European ancestry) which was divided into four groups based on DI and BI values. DI scores were based on an adaptive behavior scale while BI scores were based on a behavior problem checklist. Using these scores we constructed four ASD groups: DI only (N=166), BI only (N=56), BI+DI (N=116), and no BI or DI (N=189). A genome-wide SNP array was utilized for CNV detection using QuantiSNP and PennCNV algorithms. To test for group differences in CNV burden we compared the groups on mean number of deletions and duplications using standard univariate tests. For our ASD dataset, 46. 95 (sd 22. 6) deletions and 20. 38 duplications (sd=11. 5) were detected per individual. When analyzed by DI (+/-), neither mean number of deletions (p=. 08) or duplications (. 38) differed between the DI and no DI groups. When analyzed by BI (+/-), neither mean number of deletions (p=. 61) or duplications (. 63) differed between the BI and no DI groups. Analyzing DI and BI jointly, the mean number of deletions was highest in the BI+DI group (49. 52, sd=26. 7) while the BI only group had the lowest number of deletions per individual (43. 30, sd=17. 7). The mean number of deletions across the four groups did not significantly differ (p=0. 29). Mean number of duplications was highest in the BI only group (22. 37, sd=13. 8) while the BI+DI had the lowest mean number of duplications (19. 92, sd=12. 2). The mean number of duplications across the four groups did not significantly differ (p=0. 56). Comparisons of mean deletion and duplication values by group and sex revealed no differences. In our dataset, the co-occurrence of developmental and behavioral impairments is not associated with increased CNV burden as we did not see excessive CNVs in any group. This is surprising given prior studies. Future studies should further examine the contributions of severity in associated phenotypes in dissecting genetic risk for ASD.

1112W

Genetic analysis for circadian rhythm abnormality in autism spectrum disorder. *A. Matsumoto[1], Y. Inaguma[2], Z. Yang[1], Y. Nakano[1], M. Goto[1], K. Nakayama[3], E. F. Jimbo[1], H. Osaka[1], S. Iwamoto[3], K. Nagata[2], T. Yamagata[1].* 1) Pediatrics, Jichi Medical University, Shimotsuke, Japan; 2) Department of Molecular Neurobiology, Institute for Developmental Research, Aichi Human Service Center, Kasugai, Japan; 3) Division of Human Genetics, Center for Molecular Medicine, Jichi Medical University, Shimotsuke, Japan.

(Background) About 44-83% of children with autism spectrum disorder (ASD) are suffering from sleep problems. Some circadian-relevant genes, *MTNR1A*, *MTNR1B*, and *PER1* etc. have been reported to associate with ASD. Therefore we screened for mutation of circadian-relevant genes in ASD patients, to elucidate the relation between ASD and circadian rhythm. (Methods) We screened 18 circadian-related genes, *ARNTL, CLOCK*, *PER1,2,3*, *CRY1,2*, *NR1D1*, and *TIMELESS* etc. , in 14 ASD with sleep disturbance, in 14 ASD without sleep disturbance, as well as in 23 controls. ASD was diagnosed according to the Diagnostic and Statistical Manual of Mental Disorders, 5 (DSM-5). Their DNA was extracted from lymphocytes after obtaining informed consent from their parents. We captured the all exons of circadian-relevant genes for subjects DNA and sequenced by next-generation sequencer (454 GS Junior, Roche). The detected mutations were verified by direct sequencing analysis. Some of the interesting genes were analyzed for their function. This study was approved by the Bioethics Committee for Human Gene Analysis of Jichi Medical University. (Result) Non-synonymous mutations detected only in each group were 6 out of 14 ASD with sleep disturbance group, 7 out of 14 ASD without sleep disturbance group, and 1 out of 23 controls. In all of ASD (P=0. 001), non-synonymous mutations were significantly frequently detected than control group. We detected p. F498S of Timeless in a patient with ASD and circadian rhythm disorder. He was short stature (-3. 4SD). He presented mild disturbance of sociability, repeated patterns of behavior, and mild ID. He fell into sleep in the morning around 5-7 o'clock since his infancy. The peak of the Melatonin of this patient and mother was 8-11 o'clock, which was 5 hours difference from normal pattern. Light therapy didn't change the circadian rhythm, backward nor forward. Timeless p. F498S mutation affected the neuronal function in utero electroporation analysis. (Discussion) Mutations in circadian-relevant genes were more frequent in patients with ASD than in controls. Circadian-relevant genes may be involved in the psychopathology of ASD. *TIMELESS* has a role of DNA replication and checkpoint. It was reported that *Timeless* knockdown mouse arrested the development. Melatonin profile and abnormal neuronal migration indicated that *TIMELESS* may contribute to ASD and circadian rhythm disorder. We will further analyze the function using TIMELESS knockout mouse.

1113T

Rare loss-of-function mutations in ASD individuals. *D. P. Moreira, E. S. Moreira, N. C. V Lourenço, I. M. W. Silva, T. F. Almeida, V. L. R. Tavares, M. Zatz, M. R. Passos-Bueno.* Dept of Genetics and Evolutionary Biology, Institute of Biosciences - University of Sao Paulo, São Paulo, Brazil.

Autism Spectrum Disorder (ASD), a neurocognitive condition, has a strong genetic component with heritability estimated between 50-60%. Most recently, exome/genome sequencing has shown that rare truncating variants, *de novo* or inherited, strongly contribute to ASD etiology. These alterations are enriched in ASD affected probands as compared to unaffected siblings. However, it is still a challenge to define which of these variants are indeed causative of the phenotype, especially because some of them are inherited, being associated with non-penetrance of the phenotype. Thus, we have been investigating rare truncating variants shared among ASD related individuals with the aim of identifying those that contribute to the phenotype. We performed exome sequencing of 26 ASD-affected individuals belonging to 12 families. Rare variants (MAF < 0. 01 in international databases and in a Brazilian genomic database) were initially selected for further analysis. Of these, we selected as potentially pathogenic variants those that are truncating alterations (premature stop codon variants or frameshift variants) located in genes that are expressed in central nervous system. We identified 13 truncating variants in 7 out of 12 families, which were shared between the affected individuals within a family. *In silico* functional analysis of these genes revealed that six out of the 12 genes are related with post-transcriptional and post-translational modifications, which are biological functions strongly associated with ASD. In most of these families we could not define if there is a major mutation associated with the phenotype. However, in one family, two affected sibs have a loss-of-function mutation in *TBCK*, inherited from a non-affected father, and an intragenic deletion involving just one exon of this same gene, maternally inherited. Our results suggest that homozygous loss-of-function mutations in *TBCK* leads to ASD, confirming the relevance of mutations in this gene for neurodevelopmental disorders. Although our sample is small, our preliminary data suggest that a proportion of ASD cases might be explained by Mendelian autosomal recessive model of inheritance. FAPESP/CEPID, CNPq.

Mitochondrial Variants in Autism Spectrum Disorder through off target exome read analysis. *A. Patowary, R. Nesbitt, M. Archer, Z. Brkanac.* University of Washington, Seattle, WA.

Autism spectrum disorder (ASD) is a severe neuropsychiatric disorder with complex genetics. Recent large-scale exome sequencing studies have identified a large number of genes where it is likely that *de-novo* variants are contributory, indicating substantial heterogeneity. Thus far, large-scale exome sequencing studies have concentrated on the nuclear genome, leaving the putative role of mitochondrial DNA (mtDNA) mainly unexplored. MtDNA mutations are causal for multiple early onset disorders that also have autistic features as part of the phenotype and thus mtDNA is intriguing as a candidate for mutation responsible for ASD. The mitochondrial genome (NC_012920) is circular and double stranded, and contains16,569 nucleotides coding for 37 genes. Recently, analytical tools have been developed to extract mitochondrial DNA reads from unmapped reads in whole-exome capture sequence data. Off-target sequence reads can be used to derive the mtDNA sequence with a high degree of accuracy. We have analyzed the mitochondrial DNA sequence derived from off-target exome reads from eight unrelated ASD probands from families with multiple affected cases. The mitochondrial genomes for all the samples were sequenced to an average depth of >25X. With a minimum heteroplasmy limit of 0. 8, we have identified 81 variants in eight mitochondrial genomes, including 16 non-synonymous variants. We will be extending our analysis of mtDNA to additional affected family members in the original eight families as well as cases from 15 additional families. Detailed findings will be presented.

1115W

A 1. 5Mb terminal deletion of 12p associated with autism spectrum disorder. *S. Raskin[1,2], I. M. Silva[1], J. A Rosenfeld[3,4], S. A. Antoniuk[5], V. S. Sotomaior[1].* 1) Group for Advanced Molecular Investigation (NIMA), School of Health and Biosciences, Pontifícia Universidade Católica do Paraná (PUCPR), Curitiba, Paraná, Brazil; 2) GENETIKA - Centro de Aconselhamento e Laboratorio de Genetica, Curitiba, Paraná, Brazil; 3) Signature Genomics, PerkinElmer, Inc. , Spokane, WA, USA; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX. USA; 5) Pediatrics Department, Universidade Federal do Paraná, Curitiba, Paraná, Brazil.

Autism spectrum disorder ischaracterized by delayed and/or unusual language, problems with social interactions, repetitive and stereotyped patterns of behavior and restricted interests and activities. The causes of autism have not all been clearly defined. However, there is a genetic basis, demonstrated by the high concordance between monozygotic twins, which can be as high as 90%. Although hundreds of potential autism susceptibility loci were identified in the last years, genes on 12p13. 33 have not been previously associated with Autism. We report here a 7-year-old boy with a “de novo” 1. 5-Mb terminal deletion within 12p13. 33 associated with autism. This deletion, detected by microarray-based comparative genomic hybridization, encompasses 13 genes (*B4GALNT3, CCDC77*, *ERC1*, *FBXL14*, *IQSEC3, KDM5A, LOC100292680, LOC574538, NINJ2*, *RAD52*, *SLC6A12, SLC6A13* and *WNK1)*. Furthermore, a maternaly inherited ~350kb Xp22. 31 duplication wasalso present, but wepresumed that this small, inherited aberration from the healthy mother do not contribute to the patient phenotype. There have been few previous reports about 12p13. 33 deletions, with all cases showing variable phenotypesbut none showing a clear diagnosis of Autism. The smallest region of overlap among our patient and the previously reported individuals is within the *ERC1 gene. W*e suggest that *ERC1* can be considered as a new possible candidate contributing to the autism phenotype as well as neurodevelopmental delay present in all patients. The wide range of phenotypic severity, from learning difficulties and speech delay in early childhood to autism, can be better explained by variable expressivity, as all showed, at least, learning disability during childhood. *ERC1* encodes two different protein isoforms, ERC1a that is expressed as a cytosolic protein outside of brain and does not bind to RIM proteins, wich are present in the presynaptic active zone, and ERC1b that is a brain-specific isoform and binds RIM proteins. RIMs are putative effectors for Rab3, a synaptic vesicle protein, which regulates neurotransmitter release. In conclusion we describe the first patient with an autism diagnosis associated with a 12p13. 33 deletion. While there are no others new reports of partial monosomy of distal 12p13. 33 and new information about the genes within this region, we suggest that *ERC1* is the best candidate for the neurodevelopmental delay present with variable severity in all reported patients.

Autism gene discovery in rare female-enriched multiplex families (FEMFs). *J. M. Tilghman[1,4], C. R. Stevens[2], M. J. Daly[2,3], A. Chakravarti[4].* 1) Predoctoral Training Program in Human Genetics, Johns Hopkins School of Medicine, Baltimore, MD; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Center for Complex Disease Genomics, Johns Hopkins University School of Medicine, Baltimore, MD.

Autism has a profound male sex bias and a higher recurrence risk for siblings of affected females compared to siblings of affected males. These observations are explained by multifactorial inheritance with a higher affection threshold for females than males (“Carter effect”). We hypothesize that affected females meet their higher threshold through a higher frequency, severity, or different biological function of pathogenic alleles. To test these hypotheses and enhance autism gene discovery, we are examining coding variation in female enriched multiplex families (FEMFs) containing 2 or more severely affected (ADIR+ and ADOS+) girls. Enrichment for more severe variants in these families should allow for the detection of autism genes within even a modest number of families. A pilot study using only 13 such families led to the identification of delta-catenin (*CTNND2*) as a definitive autism gene, and the suggestion of *CYFIP1*, showing the utility of this approach. To extend this analysis, we performed whole exome capture (Agilent 44Mb) and Illumina sequencing (>80% coverage at 20x depth) on 420 individuals from 101 FEMFs. These analyses are underway. As a start, we used data from a set of 70 probands to test for enrichment in 38 high-confidence autism genes identified primarily through recurrent loss-of-function (LoF) mutations in autism. We searched for rare (<0. 1% MAF) pathogenic variants (LoF, ±2 bp consensus splice variants and missense variants with PolyPhen2 score >0. 8). These individuals harbored a total of 5 LoF variants in 5 genes (*CHD2, CHD8, DYRK1A, SCN2A, WDFY3*) and 19 damaging variants in 17 genes (*ANK2, DIP2A, CHD2, CHD8, GRIN2B, RIMS1, DLG1, PTEN, WDFY3, KDM5B, SCN2A, SHANK3, MECP2, DSCAM, DYRK1A, SYNGAP1, TNRC6B*). Both sets of LoF and damaging variants were significantly enriched over expectations (P=0. 0031 and 0. 021 for variant counts; P<0. 0001 and 0. 0033 for gene counts), determined by sampling 10,000 replicates of 70 samples from 475 European Ancestry controls and counting rare pathogenic variants (as defined above). The observed enrichment of these variants confirms that known autism genes contribute to autism pathogenesis in FEMFs as well as low-risk families.

Autism Spectrum Disorders (ASD) are heterogeneous neurodevelopmental disorders diagnosed in more than 1% of the population and characterized by impaired social communication and restricted or stereotyped interests. Thanks to whole exome sequencing technology, several ASD-risk genes were identified. Here, we analysed 99 whole exome sequencing data from 27 families (23 ASD families and 4 control families) to identify inherited and *de novo* variants associated with ASD. We found 28 damaging *de novo* mutations in 15 of 27 (55. 6%) families for an average of 0. 62 *de novo* damaging mutations per individual. Among these genes, 6 were already reported as ASD-risk genes. In three families, the identified mutations in *SCN2A* [MIM182390], *GRIN2B* [MIM138252] and *SHANK3* [MIM606230]) most likely contribute to the diagnosis of ASD. In two families with more than one affected child, the *de novo* ASD risk variants —*MECP2* [MIM300005] and *CNTN6* [MIM607220] —were not shared by the affected siblings. We also identified a *de novo* stopgain mutation in the *POGZ* gene [MIM614787], known as one of the major gene for ASD, in a control child. Finally, we identified *de novo* damaging mutations in 2 new candidate genes for ASD: *ACTL6B* (also known as *BAF53b*) [MIM612458] and *KIF1A* [MIM601255]. *ACTL6B* is a subunit of nBAF complex involved in the neuron-specific chromatin remodelling and has been reported in neurodevelopmental and intellectual disability (ID) disorders. *KIF1A* is involved in the transport of synaptic vesicles along axons and has already been reported as being involved in individual cases of nonsyndromic ID. Our results confirm the contribution of *de novo* mutations in ASD, but also highlight the crucial need of including unaffected siblings and healthy controls to better interpret the data. Our pilot study has only analysed the submerged part of the genetic iceberg of ASD. The integration of polygenic dimension, including the burden of inherited rare mutations and the accumulation of a high load of low-risk alleles, will allow us to better understand the complex genetic landscape of ASD.

A case of Autism Spectrum Disorder with a novel *SRCAP* mutation. *S. Walker[1], K. Tammimies[2], R. K. C. Yuen[1], B. Thiruvahindrapuram[1], G. Kaur[1], M. T. Carter[3], N. Hoang[3], R. Weksberg[3], B. A. Fernandez[4,5], P. Szatmari[6], S. W. Scherer[1,7].* 1) Genetics and Genome Biology, Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Center of Neurodevelopmental Disorders at Karolinska Institutet (KIND), Pediatric Neuropsychiatry Unit, Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden; 3) Department of Pediatrics, Division of Clinical and Metabolic Genetics, Hospital for Sick Children, Toronto, Ontario, Canada; 4) Disciplines of Genetics and Medicine, Memorial University of Newfoundland, St Johns Newfoundland Canada; 5) Provincial Medical Genetic Program, Eastern Health, St. Johns Newfoundland, Canada; 6) Centre for Addiction and Mental Health, University of Toronto, Toronto, Ontario, Canada; 7) McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

Autism Spectrum Disorder (ASD) is highly heterogeneous neurological condition characterised by limited communication skills, impaired social interaction and repetitive behaviours. There is a strong but complex genetic etiology with many contributing risk loci. Exome sequencing has been conducted on a cohort of 1400 Canadian individuals, including 825 affected cases. Sequencing was carried out using Life Technologies SOLiD5500xl and IonProton platforms. This cohort presents a useful resource to the field of ASD genetics. From these data, a single case has been discovered with a novel loss of function mutation in *SRCAP,* a gene implicated in ASD risk by rare copy number variant analysis. The mutation is a four base pair deletion in exon 27, leading to a premature stop codon which arose *de novo* (not present in the parents or three unaffected siblings). *SRCAP* functions in chromatin remodeling and transcriptional regulation. Loss of function mutations within exons 33 and 34 are known to cause Floating Harbor Syndrome (FHS) which is characterized by language delay, short stature and distinctive facial features; however, the phenotypic impact of mutations outside of this critical region is not known. The proband is male and presented with high functioning ASD. He had café au lait spots but did not meet criteria for a diagnosis of neurofibromatosis. At 8 years, his height and weight were at the 25th percentile and head circumference at the 98% percentile. He also had large ears and small eyes. Further investigation using additional genomic data and detailed phenotypic examination is required to determine whether this case is an atypical form of FHS or if other ASD cases with mutations at this locus may have similar features. Given the high levels of genetic and phenotypic variability in ASD, coupling genomic analyses with deep phenotyping will facilitate better understanding of highly penetrant mutations underlying ASD found in very rare cases.

1119T

Identification of rare disruptive variants in voltage-gated channel genes (*CACNA1C, CACNA1D, CACNA1S, CACNA1I*) in Japanese samples of schizophrenia and autism spectrum disorder using Ion Torrent PGM platform. *C. Wang, H. Kimura, J. Xing, K. Ishizuka, I. Kushima, Y. Arioka, A. Yoshimi, Y. Nakamura, Y. Shiino, Y. Oya, Y. Takasaki, Y. Uno, T. Okada, T. Iidaka, B. Aleksic, D. Mori, N. Ozaki.* Department of Psychiatry, Nagoya University, Nagoya, Aichi, Japan.

Several large-scale whole exome sequencing studies in schizophrenia (SCZ) and autism spectrum disorder (ASD) identified rare variants with modest or strong effect size as genetic risk factors. Dysregulation of cellular calcium homeostasis might be involved in SCZ and ASD pathogenesis, and genes coding for L-type voltage-gated calcium channel (VDCC) subunits Cav1. 1 (CACNA1S), Cav1. 2 (CACNA1C), Cav1. 3 (CACNA1D) and T-type VDCC subunit Cav3. 3 (CACNA1I) were recently identified as risk loci for psychiatric disorders. We investigated rare mutations with possibly damaging effects in those genes in Japanese sample of SCZ and ASD. We prioritized four candidate genes (CACNA1C, CACNA1D, CACNA1S, CACNA1I) for psychiatric disorders in subset of VDCC genes based on genome-wide association studies, exome sequencing and functional genomic studies. Then, mutation screening of exon regions of those 4 genes using Ion Torrent Personal Genome Machine (PGM) was performed in a Japanese sample of 370 SCZ patients and 192 ASD patients. Our AmpliSeq custom panel allowed us to cover 96. 84% of the targeted sequences. Average coverage of depth in the target region was ~200, and ~80% of sequenced region was covered over 100x coverage. Variant call and annotation were performed with Torrent Suite 4. 4 and Ingenuity Variant Analysis. Variant filtering were applied to identify those that were not registered in dbSNP database or have a minor allele frequency of less than 1% in East-Asian samples from the exome sequencing project (ESP) and 1000 Genomes, and are damaging non-synonymous, splicing site single nucleotide variants (SNVs) or small insertion and deletion predicted by in-silico analyses. All of those filtered mutations were confirmed by Sanger method. If parental samples were available, segregation analysis were employed for measuring the inheritance pattern. Under our filter, we discovered 1 nonsense SNV (p. C1471* in CACNA1D), 1 in-frame deletion (p. E1675del in CACNA1D), 2 de novo SNVs (p. A36V in CACNA1C, p. V947I in CACNA1S), 22 missense SNVs (list in poster) that are categorized as damaging by at least two different in-silico tools. Our analysis investigated several rare and possibly damaging variants on the risk for SCZ and ASD in VDCC genes, especially within L-type VDCC genes. Ongoing work includes (1) genotyping of selected rare variants in additional cohorts and rare-variant association analysis (2) further functional assessment of possible disease-causing variants.

1120F

Rare bi-allelic mutations in autism spectrum disorder illuminate gender differences and highlight novel genes. *T. W. Yu[1], R. N. Doan[1], E. T. Lim[1], S. De Rubeis[2], C. Betancur[3], D. J. Cutler[4], C. S. Poultney[2], A. G. Chiocchetti[5], C. M. Freitag[5], S. Goetze[1], M. H. Chahrour[6], E. H. Cook[7], J. S. Sutcliffe[8], M. E. Zwick[4], A. P. Goldberg[2], B. Devlin[9], K. Systematic large scale sequencing studies of patients with autism spectrum disorder (ASD) are beginning to reveal insights into the pathogenesis of this complex disorder, with evidence of clustering of genes implicated by rare inherited and *de novo* CNVs and SNVs in pathways for synapse development and chromatin remodeling. Human gene knockouts, caused by biallelic mutations disrupting both copies of a gene, provide another potential avenue to illuminating disease-relevant biological processes. Here we report the largest analysis to date of rare, inherited, biallelic mutations in whole exome data from over 3,000 cases and 6,000 controls assembled by the Autism Sequencing Consortium. Rare (AF<1%) compound heterozygous or homozygous loss of function mutations are observed in 1 in ~32 unaffected individuals in the ASC overall, but are found significantly more often in affected individuals (1 in ~23, a 37% elevation in rate vs. unaffecteds, p=0. 008). The observed biallelic excess is not explained by differences in underlying heterozygous mutation rates. Affected females exhibit the most pronounced excess (67% elevation over baseline, p=0. 02), consistent with a female protective effect similar to that previously observed for *de novo* SNVs and CNVs. Genes potentially implicated by biallelic inactivation in this analysis include those previously known to cause recessive intellectual disability/ASD as well as interesting novel candidates with diverse neurobiological roles.

Autism spectrum disorder (ASD) is a collection of neurodevelopmental conditions characterized by deficits of social interaction and communication, and presence of restricted and repetitive behaviors. *De novo* mutations (DNMs) play an important role in the etiology of ASD, but analyses so far have focused mainly on the protein coding regions of DNA, which account for only ~1% of the genome. To characterize genome-wide DNMs, we performed whole genome sequencing (WGS) on 200 ASD simplex trios with a depth of ~30x per genome using the Illumina HiSeq technology (part of the MSSNG WGS project). Using our improved variant detection pipeline, we identified 55. 4 *de novo* single nucleotide variants (SNVs), 4. 2 *de novo* insertion/deletions (indels) and 0. 12 *de novo* copy number variation per genome. Consistent with previous reports, we found that the father contributes the majority of the DNMs (72% of *de novo* SNVs and 70% of *de novo* indels), and that they are positively correlated with the paternal age ($p<0.0001$). Despite the different sensitivity on *de novo* mutation detection, we found that sequence context of DNMs is similar between ASD cases and population controls (based on 258 Dutch genomes). For the genic DNMs, we found a significant enrichment of predicted damaging DNMs in the ASD cases compare to the controls (OR: 1. 98; $p<0.0001$), of which 6. 5% are intronic splicing variants (half of them located over 10bp away from the exons). We found particularly high burden in genes (i) with medium to high expression in brain (OR: 2. 56; $p=0.0011$), (ii) targets of FMRP (OR: 5. 08; $p=0.0033$), (iii) with a functional role in human nervous system development (OR: 2. 82; $p=0.02$), (iv) implicated in mouse nervous system abnormal phenotypes (OR: 2. 55; $p=0.017$). Beyond the genic region, we also found a higher DNM rate of sites predicted to reduce transcription factor binding affinity (OR 1. 25; $p=0.018$). Our results revealed a substantial contribution of non-coding variants to the etiology of ASD and emphasized the importance of using WGS for comprehensive genetic analyses.

Wang[1], Alzheimer's Disease Sequencing Project Data Flow Work Group.* 1) Department of Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA; 2) School of Public Health, Boston University, Boston, MA; 3) Department of Medical and Molecular Genetics, Indiana University, Indianapolis, Indiana; 4) National Center for Biotechnology Information, National Institutes of health, Bethesda MD; 5) Broad Institute of Harvard and MIT, Cambridge, MA; 6) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 7) The Genome Institute, Washington Univ. , St. Louis, MO; 8) Cardiovascular Health Research Unit, University of Washington, Seattle, WA; 9) Taub Institute for Research on Alzheimer's Disease, Columbia University, New York; 10) Department of Neurology, Boston University School of Medicine, Boston, MA.

Statement of purpose. The Alzheimer's Disease Sequencing Project (ADSP) was established in February 2012 as a Presidential Initiative to fight Alzheimer's Disease (AD). Developed jointly by National Institute on Aging (NIA) and the National Human Genome Research Institute (NHGRI), the specific aims of the ADSP are to: 1) identify protective genomic variants in older adults at risk for AD, 2) identify new risk variants among AD cases, and 3) examine these factors in multi-ethnic populations to identify therapeutic targets for disease prevention. **Methods used.** The ADSP Data Flow Work Group and the NIA Genetics of Alzheimer's Disease Data Storage Site (NIAGADS) were charged with supporting ADSP data production, sharing and management, and facilitating data access by the general research community. Samples and phenotypes were contributed by the Alzheimer's Disease Genetics Consortium (ADGC) and Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) consortium. Sample plating and shipping was coordinated by the National Cell Repository for Alzheimer's Disease (NCRAD). Whole-exome and whole-genome sequencing data were generated by the three NHGRI Large Scale Sequencing Analysis Centers (LSACs). The Data Flow Work Group maintains the ADSP web site to provide study design, cohort information, news releases, and instructions to apply for access to ADSP data. The ADSP Data Portal was designed through collaboration with the Database of Genotypes and Phenotypes (dbGaP), Sequence Read Archive (SRA), and NIAGADS. The portal allows users to explore the ADSP project data archived at dbGaP with NIH iTrust user authentication. Approved investigators can then identify samples and download files using a customizable filtering system and check-out cart function. **Summary.** The ADSP has completed sequencing the exomes of 10,939 unrelated cases and controls and the whole genomes of 578 members of 111 AD families. Accompanying each sample is GWAS data and a set of phenotypes that were harmonized according to protocols generated by the ADSP. With the completion of sequencing for the Discovery phase, this work group provides support to all work groups for data related issues, coordinates with dbGaP for data transfers, and reviews, posts, and notifies ADSP members of new results generated by other work groups. More information can be found at the ADSP website (www. niagads. org/adsp) or at dbGaP (study ID: phs000572).

Background: Essential tremor (ET) is one of the most common causes of tremor in humans. Despite its high heritability and prevalence, few susceptibility genes for ET have been identified. **Methods:** To identify genes for ET, we enrolled probands (affected with ET) and relatives in a family study of ET at Columbia University, New York (2011 – 2014). The study was approved by the Institutional Review Board at Columbia University and written informed consent was obtained from all enrollees. Whole exome sequencing was performed on at least two most distantly related affected (definite, probable or possible ET diagnosis) individuals from each of 37 total families. Sequence alignment to the human reference genome (UCSC hg19) was performed using the Burrows-Wheeler Aligner (BWA) algorithm, and variant calling was performed using the genome analysis toolkit (GATK; Broad Institute). The software tool pVAAST (Pedigree Variant Annotation, Analysis and Search Tool) was used to analyze the whole exome data from ET families using a dominant model and the maximum number of permutations of 1,000,000). **Results:** We identified candidate genes in independent ET families that were ranked by pVAAST and that reached genome wide significance. In two independent families, we identified likely pathogenic mutations in the same gene that co-segregated with disease. Both mutations result in amino acid substitutions of highly conserved amino acid residues that are predicted to be deleterious and damaging by *in silico* analysis. Likely pathogenic mutations in three other genes were also identified in three independent families. These genes are highly expressed in the cerebellum and Purkinje cells, and in several different ways, influence function of the GABA-ergic system. **Conclusions:** Candidate genes identified in this study are in concordance with recent evidence that the pathophysiological process in ET is associated with cerebellar degeneration, a reduction in Purkinje cells, and a decrease in GABAergic tone. Future functional studies are needed to evaluate the pathogenicity of the variants identified in these candidate genes.

1124W

Rare susceptibility variants for familial bipolar disorder: a role for G protein-coupled receptors. *C. Cruceanu[1, 2], J. F. Schmouth[2], J. P. Lopez[1], D. Spiegelman[2], D. Rochefort[2], P. Hince[2], P. A. Dion[2], M. Alda[3], G. Turecki[1], G. A. Rouleau[2].* 1) McGill University, Montreal, Quebec, Canada; 2) Montreal Neurological Institute, Montreal, Quebec, Canada; 3) Department of Psychiatry, Dalhousie University, Halifax, Nova Scotia, Canada.

Bipolar disorder (BD) is a complex psychiatric condition characterized by both manic and depressive episodes. Previous studies strongly support the role of genetics in BD, but likely due to genetic and phenotypic heterogeneity, few loci have been replicated across different studies and cohorts. We hypothesize that BD is caused by highly penetrant rare variants in many different genes across the population, which can be unveiled by through massively-parallel sequencing in well-characterized multiplex families. Thus, we re-sequenced the exomes of all affected individuals from 40 multi-generational families (3-8 individuals per family across 2-4 generations). To identify relevant BD susceptibility genes we prioritized rare variants segregating with affected status. In each family we prioritized potentially highly penetrant (e. g. protein-truncating, missense, or frameshift) or functionally relevant (e. g. 3'UTR, 5'UTR, splicing) variants. The variants that emerged from this analysis are in genes involved in brain development and neurogenesis, inflammation, and epigenetic regulation – all processes that have been suggested to be dysregulated in mood disorders including BD. The most interesting finding that emerged was an enrichment of putatively causal variants in genes belonging to the G protein-coupled receptor family, which are important drug targets and have previously been connected to psychiatric pathology. Furthermore, we followed up on the functional implications of some of the most deleterious mutations and showed targeted downstream GPCR dysregulation that could explain pathology. By focusing on rare variants in a familial cohort we have explained part of the missing BD heritability. In addition, we have narrowed in on some of the key biochemical pathways that are implicated in this complex condition.

1125T

Exome sequencing in multiplex synaesthesia families identifies rare coding variants in genes within candidate linkage regions. *K. S. Kucera[1], S. A. Graham[1], A. Vino[1], J. E. Asher[2], S. Baron-Cohen[2], S. E. Fisher[1,3].* 1) Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands; 2) Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, UK; 3) Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen, Nijmegen, The Netherlands.

Synaesthesia is a rare neurodevelopmental non-disease condition estimated to affect <2% of the human population. People with synaesthesia experience cross-modal perceptions, such as visual images triggered by sounds, words that elicit tastes, or involuntary and stable associations of letters and/or numbers with colours. It has been hypothesized that synaesthesia is a consequence of relative hyperconnectivity in the brain. The well-documented familial clustering of synaesthesia suggests that genes play a significant role. However, results of previous linkage studies indicate that synaesthesia is likely to be genetically heterogeneous; thus, a similar phenotype may result from different combinations of contributing genes and their alleles in different cases. In the current study, we used next-generation sequencing to investigate families in which multiple relatives have synaesthesia. We sequenced exomes of people with and without synaesthesia in three such families (13 synaesthetes and 4 non-synaesthetes in total), to detect rare genetic variants that segregate with the trait. We thereby identified 77 rare (MAF<0. 05) nonsynonymous protein-coding variants that segregate with the phenotype in those families. Of the 77 variants, 10 were located within previously reported suggestive linkage regions on chromosomes 2q13 and 4q28. 3. Future investigations will use data from gene expression and protein function in cells and tissues to determine which of these candidate variants are most likely to have roles in aetiology. Furthermore, common variation in the same candidate genes can be tested for association in independent case-control datasets, to complement the family-based studies described here. Identification of genes implicated in synaesthesia will not only shed light on how this intriguing trait arises, but also promises novel insight into the molecular bases of neural connectivity in the human developing brain.

1126F

***PCDH19*-related Epileptic Encephalopathy: An unusual case of an affected male with mosaic *de novo* truncating variant in *PCDH19* gene.** *I. Thiffault[1,2,4], L. Smith[1,4,5], J. Lowry[3,4,5], L. Zellmer[1], E. Farrow[1], B. Black[5], C. Baldwin[5], N. Miller[1], S. Soden[1,4,5], C. Saunders[1,2,4].* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO; 2) Department of Pathology and Laboratory Medicine, Children's Mercy Hospitals, Kansas City, MO; 3) Department of Pediatrics, Children's Mercy Hospitals, Kansas City, MO; 4) University of Missouri-Kansas City School of Medicine, Kansas City, MO; 5) Individualized Pediatric Therapeutic Medicine Clinic, Children's Mercy Hospital, Kansas City, MO.

PCDH19 encodes protocadherin 19 and is located on the X chromosome. Heterozygous variants in *PCDH19* are associated with early infantile epileptic encephalopathy-9 (EIEE), also known as epilepsy and mental retardation restricted to females. Although autosomal dominant inheritance was tentatively suggested in several familial reports, *de novo* variants in *PCDH19*, were shown to be a frequent cause of sporadic EIEE in female. The syndrome is characterized by early normal development followed by febrile and temperature-induced seizures that tend to occur in clusters and may resemble Dravet syndrome. Hemizygous males are usually unaffected except for psychiatric/behavioral abnormalities. **Case presentation:** Our patient, CMH980, is a 6 year old male with focal epilepsy of unknown etiology that began at 9 months of age. In addition to seizures, by 3 years of age he developed behavioral challenges including irritability, aggression, rigidity, and poor sleep. Response to psychotropic medications has been inconsistent. His seizure frequency has decreased with age, and he is on stable doses of zonisamide and pyridoxine. Dysmorphic features noted included plagiocephaly in occipital/parietal area, agouti hair coloring, long posterior hair swirl, normal set ears but cupping of bilateral ears, intra digital webbing of phalanges, stereotypic movements of bilateral hands. Previous negative workup included *SCN1A*, karyotype, CGH-array, brain MRI and metabolic studies. Exome sequencing was performed on CMH980 and his healthy mother. CMH980 appeared to be heterozygous in *PCDH19* for a novel pathogenic nonsense variant, c. 605C>A (p. Ser202*), inconsistent with expectations for a male. This observation is confined to this single variant, ruling out an X chromosome dosage abnormality. This child's mother is negative for the variant; father was unavailable for testing. **Conclusion:** This is the second male reported with somatic mosaicism for *PCDH19*-deficency, the first being a large deletion detected by CGH-array. In mosaic males, as in affected female, some cells express PCDH19 and others do not. The loss of function at the cellular level results in a gain of function at the tissue level because of the abnormal interactions between cells expressing PCDH19 and cells lacking PCDH19. These observations further support cellular interference as the pathogenic mechanism for this condition, which leads to this unusual mode of inheritance in which females are more frequently affected than males.

1127W

Young Northern Finnish founder population reveals enrichment of rare recessive and dominant gene variants in neurodevelopmental disorders. *M. I. Kurki[1,2], O. Pietiläinen[3], E. Saarentaus[4], E. Hämäläinen[4], J. S. Moilanen[5], O. Kuismin[5], M. Daly[6], A. Palotie[1,2,4], Sequencing Initiative Suomi consortium.* 1) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Stanley Center, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Department of Stem Cell and Regenerative Biology, University of Harvard, Cambridge, Massachusetts, USA; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 5) Department of Clinical Genetics, Oulu University Hospital, Medical Research Center Oulu and PEDEGO Research Group, University of Oulu, Oulu, Finland; 6) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA.

Genetic variants with strong reproductive disadvantages are evolutionary constrained and remain generally rare in population. However, these variants can still exist at higher frequencies in young populations, such as Finns, when the negative selection hasn't had time to counteract the effect of genetic drift on rare alleles. Thus, population isolates provide a valuable study design to explore the role of rare genetic variants in complex traits. In Finland, the youngest settlement is in the north and east parts of the country dating back to a small number of founder families only few centuries ago. In addition this region has higher prevalence of schizophrenia and intellectual disability (ID). We exploited this hypothesis by producing whole exome sequence (WES) and GWAS data from 352 patients from Northern Finland with ICD-10 diagnosis of ID of unknown etiology, and their 293 family members (97 trios, 109 duos and 146 index cases). The Northern Finland Intellectual Disability Project (NFID) exomes were combined with 8000 Finnish exomes sequenced in the Sequencing Intitative Suomi project (SISu, http://sisuproject. fi/). As expected, we observed comparable amount of large CNVs and *de novo* mutations as reported in similar patient collections, both of these categories being enriched in the NFID patients. Given the genetic origin of NFID, we expected to observe variants enriched in Finland that are 1) strong acting recessive variants that seem Mendelian but account for ~1% of a 1% phenotype rather than all of a 1/10000 phenotype and 2) dominant alleles with odds ratios in the range of 2-5. As per our hypothesis we discovered a Finnish-specific recessive cause of ID in 4 cases, homozygosity of a variant in CRADD (p=4e-8). The variant is not observed in homozygous state in 61 000 individuals worldwide (http://exac. broadinstitute. org/) or in 8000 Finnish individuals. We also observed Finnish enriched dominant missense variants in multiple genes (OR range 3-6) including a gene encoding for *TUBA1A1* (OR 5. 2, p:4e-8). Significant and promising variants are replicated by sequencing additional Northern Finnish ID cases and their family members (n=315; 150 cases; 51 trios). In conclusion, we demonstrate young founder populations as a powerful resource to study rare variants. Specifically, we show that an enrichment of deleterious alleles increases power to detect causal and disease associated variants that would require very large sample sizes in more diverse populations.

1128T

Exome and genome sequencing in Irish multiplex schizophrenia families. *B. P. Riley[1,2], B. T. Webb[1], B. Verrelli[3], S. A. Bacanu[1], M. Fromer[4], P. F. Sullivan[5,6], A. P. Corvin[7], K. S. Kendler[1,2], Irish Schizophrenia Genomics Consortium.* 1) Department of Psychiatry, Virginia Commonwealth University, Richmond, VA; 2) Department of Human and Molecular Genetics, Virginia Commonwealth University, Richmond, VA; 3) Department of Biology , Virginia Commonwealth University, Richmond, VA; 4) Department of Psychiatry, Icahn School of Medicine at Mt Sinai, New York, NY; 5) Department of Medical Epidemiology and Biostatistics, Karolinska Institute, Stockholm, Sweden; 6) Departments of Genetics and Psychiatry, University of North Carolina, Chapel Hill, NC; 7) Department of Psychiatry, Trinity College Dublin, Dublin, Ireland.

Affected members of multiplex schizophrenia (SCH) pedigrees have elevated recurrence risk compared to singleton cases, but mean polygenic risk scores between familial and singleton cases in our Irish samples do not differ. This suggess that higher familial recurrence risk is due in part to rare, higher impact variation. We are undertaking sequencing studies to identify such variation based on 3 hypotheses: 1) The study of multiplex pedigrees enriches the data for SCH risk variants; variants identified IBD in multiple families and those substantially more frequent in the families compared to population controls are of special interest. 2) Because of the population specificity of rare alleles, power is improved by studying familial and singleton SCH cases and controls from the same population; we have assembled 270 multiplex pedigrees, 3000 singleton cases and 3000 controls from Ireland, and 3781 additional UK controls. 3) We can include genomic information in analysis to improve signal detection, particularly important outside the exome; we annotate the genome with empirically-defined weights from GCTA based on data from GENCODE, ENCODE, base conservation and other sources to account for the differential prior probability that variation at a genomic position has functional consequence. In 76 pilot exomes, we identified a total of 106 variants in 65 unique genes with weights>1. Calcium channel (35-fold), cholinergic receptor (14-fold) and autism de novo variant (3. 4-fold) genes were all enriched for weighted variants. Most notably, the D112G missense change (rs137861662) in the N(alpha)-acetyltransferase 16 (*NAA16*) gene (site of de novo CNV in SCH) is predicted to be deleterious and is 19 times as frequent in familial cases as in controls. Further evolutionary analysis shows that conservation at this site is significant across >400 My of divergence (phyloP scores, 100-vertebrate: 8. 45; 46-vertebrate: 4. 49; mammalian: 2. 06; primate: 0. 52). A single ~20Kbp window centered on rs137861662 also exhibits significant phylogenetic conservation (p<0. 01). Haplotype-based modeling of this region in HapMap3 populations shows low haplotype diversity and an enrichment of rare alleles consistent with strong purifying selection seen in our deep time analyses. We are now applying this design to genome sequencing in order to identify additional variants for direct assessment in Irish singleton cases, Irish controls and UK controls.

1129F

The Diverse Landscape of Structural Variation Contributing to Autism. *R. L. Collins[1], H. Brand[1,2], C. Hanscom[1], J. T. Glessner[1,2], A. Stortchevoi[1], M. R. Stone[1], C. E. Redin[1,2], S. Eggert[1], V. Pillalamarri[1], S. Erdin[1], A. Ragavendran[1], C. W. Seabra[1,3], F. Kelley[4], T. Mason[4], L. Margolin[4], M. E. Talkowski[1,2,4].* 1) Center for Human Genetic Research, Massachussets General Hospital, Boston, MA; 2) Department of Neurology, Harvard Medical School, Boston, MA; 3) GABBA Program, University of Porto, Porto, Portugal; 4) Program in Medical and Population Genetics and Genomics Platform, Broad Institute, Cambridge, MA.

The genetic etiology of autism spectrum disorder (ASD) is complex. Recent studies suggest that alterations in gene dosage from *de novo* loss-of-function (dnLoF) mutations are among the most penetrant mutations, however these studies have only considered single nucleotide coding changes, indels, and large copy number variants. To date, the contribution of balanced and complex structural variation (SV) to ASD is largely unknown as these variants are cryptic to whole-exome sequencing (WES) and chromosomal microarray (CMA). To explore the landscape of cryptic SVs in ASD, We performed large-insert whole-genome sequencing (liWGS) of SV to deep physical coverage of mapped inserts (median = 97x) on 400 idiopathic ASD cases from the Simons Simplex Collection. Based on completed analyses (235 probands), we observed an average of 8. 26 Mb of the genome to be rearranged, representing at least 32 predicted LoF mutations per proband at the resolution of liWGS (~5 kb). We uncovered a diverse spectrum of SV, including complex variants such as germline chromothripsis involving 11 breakpoints and six chromosomes, as well as a new class of surprisingly common SV (8. 1% frequency in cohort) involving an inversion flanked by 'paired-duplications,' which we dub "dupINVdup. " Based on analyses to date, we estimate that at least 10. 6% of probands harbor a *de novo* SV that perturbs a locus of potential relevance to ASD, or approximately double the yield of CMA analyses alone in this cohort. Notably, we discovered dnLoF mutations that were cryptic to CMA and disrupted known ASD loci such as *NRXN1* and *IL1RAPL1*, as well as genes from which WES identified a single dnLoF in this cohort, which we now confirm via SV studies. We also identified putative novel ASD loci, such as a *de novo* 23 Mb inversion that disrupted *RPTOR*, a gene under strong evolutionary constraint that is associated with the mTOR pathway. Conversely, we observe probands with LoF SV inherited from a healthy parent that disrupt genes previously annotated as ASD associated loci based on multiple dnLoF from WES, suggesting that LoF mutations in these genes are likely to be incompletely penetrant. These results suggest that the yield of significant SVs in the SSC is likely to be about two-fold higher than is predictable by CMA alone, suggesting that cryptic and complex SVs represent an important and currently uncharacterized component of ASD etiology, with likely implications for other psychiatric disorders.

1130W

Structural variation in 111 families at risk for Alzheimer's disease from heterogenous whole-genome sequencing data. *N. Zhang[1], W. Salerno[2], J. Farrell[3], J. Malamon[1], L. Xia[4], A. Destefano[3], A. Naj[1], B. Vardarajan[5], A. Partch[1], D. Kobolt[6], D. Larson[6], W. Wang[1], L. Wang[1], K. Worley[2], L. Farrer[3], G. Schellenberg[1], Alzheimer's Disease Sequencing Project Structural Variant Work Group.* 1) University of Pennsylvania; 2) Baylor College of Medicine; 3) Boston University; 4) Stanford University; 5) Columbia University; 6) Washington University at St. Louis.

Determining the genetic foundations of common complex disease will increasingly depend on our ability to provide comprehensive analysis of genomic data pooled from multiple sources. As part of the Alzheimer's Disease Sequencing Project, we have characterized the structural variation in 111 families (67 Hispanic, 41 Caucasian, 1 African American and 2 Dutch Isolate) comprising 578 individuals diagnosed with or at risk for Alzheimer's Disease. Deep whole-genome sequencing (~30x) of these individuals was performed at three U. S. Sequencing and Analysis Centers and then analyzed via a unified structural variant (SV) workflow for quality control, discovery, genotyping, and annotation. Our Phase I SVs comprise a high-confidence set of prioritized deletions, insertions, and complex variants larger than 20 base pairs genotyped across all 578 individuals. These variants are prioritized based on overlap with linkage regions calculated from extended pedigrees, and compared with known structural events associated with Alzheimer's disease and linked to other common complex diseases. SV detection across the three sequencing centers requires rigorous statistical procedures for comparing and aggregating call sets across heterogeneous insert libraries and mapping pipelines. We developed a statistical framework that leverages pedigree information to assess and optimize call accuracy. While typically genotypes are used to check pedigree relationships with the kinship coefficient, we reversed the process and used the kinship coefficient to check SV genotyping. For SV programs that generate discovery sites and not genotypes, we developed the D-score which is an outgroup-based measure of sib-sharing. These two metrics take advantage of pedigree information to permit the accurate assessment of the strength of SV callers to detect structural variants of varying size ranges and types. We also developed an in silico procedure to spike-in SV of varying purity into real sequenced libraries, accommodating multi-library designs, and applied it to 3 samples that were sequenced at all three centers. This comprehensive QC process allowed us to benchmark mainstream SV callers across widely differing libraries, and to combine these callers in a library-specific way for improved specificity and sensitivity. Finally, we refine the candidate SV regions detected by an ensemble of SV callers with local assembly to provide precise breakpoints for follow-up genotyping.

1131T

Exome-based analysis of cardiac arrhythmia, respiratory control and epilepsy genes in sudden unexpected death in epilepsy. *R. D. Bagnall[1, 2], D. E. Crompton[3, 4], S. Petrovski[4, 5], L. Lam[1], C. Cutmore[1], S. I. Garry[4], L. G. Sadlier[6], L. M. Dibbens[7], A. Cairns[8], Z. Afawi[9], B. M. Regan[4], J. Duflou[2, 10], S. F. Berkovic[4], I. E. Scheffer[4, 11, 12, 13], C. Semsarian[1, 2, 14].* 1) Agnes Ginges Centre for Molecular Cardiology, Centenary Institute, Sydney, NSW, Australia; 2) Sydney Medical School, University of Sydney, Sydney, Australia; 3) Neurology Department, Northern Health, Melbourne, Australia; 4) Epilepsy Research Centre, Department of Medicine, University of Melbourne, Austin Health, Melbourne, Australia; 5) Institute for Genomic Medicine, Columbia University, New York, United States of America; 6) Department of Paediatrics and Child Health, School of Medicine and Health Sciences, University of Otago, Wellington, New Zealand; 7) Epilepsy Research Program, School of Pharmacy and Medical Sciences, University of South Australia, Adelaide, SA, Australia; 8) Neurosciences Department, Lady Cilento Children's Hospital, Brisbane, Australia; 9) Tel-Aviv Sourasky Medical Center, Tel Aviv, Israel; 10) Department of Forensic Medicine, Sydney, Australia; 11) Department of Neurology, The Royal Children's Hospital, Parkville, Melbourne, Victoria, Australia; 12) Florey Institute of Neurosciences and Mental Health, Melbourne, Australia; 13) Department of Paediatrics, University of Melbourne, Royal Children's Hospital, Melbourne, Australia; 14) Department of Cardiology, Royal Prince Alfred Hospital, Sydney, Australia.

The leading cause of epilepsy-related premature mortality is sudden unexpected death in epilepsy (SUDEP). The cause of SUDEP remains unknown. We performed an exome-based analysis of rare variants to search for genetic risk factors in SUDEP cases, including a focused analysis of cardiac arrhythmia, respiratory control, and epilepsy genes. Demographic and clinical information of 62 SUDEP cases were collected. Exome sequencing and rare variant collapsing analysis with 2,936 control exomes were performed to test for genes enriched with damaging variants. Cardiac arrhythmia, respiratory control and epilepsy genes were screened for variants with a general population frequency of <0. 1% and predicted to be pathogenic with multiple *in silico* tools. The 62 SUDEP cases were categorized as 'definite SUDEP' (n=55), 'probable SUDEP' (n=5), and 'definite SUDEP plus' (n=2). The mean age at epilepsy onset was 10. 5 ± 8. 2 years (range 0-34 years) and the mean age at SUDEP was 28 ± 11. 9 years (range 1-53 years). SUDEP occurred in bed in 41 (66%) cases, with the position noted as prone in 27 and supine in two. We identified *de novo* mutations, previously reported pathogenic mutations, or candidate pathogenic variants in 29/62 (47%) cases. Six SUDEP cases (10%) had mutations in common genes responsible for the inherited cardiac arrhythmia disease, long QT syndrome (LQTS). Eight cases (13%) had candidate pathogenic variants in dominant cardiac arrhythmia genes. Fifteen cases (24%) had six mutations and ten candidate pathogenic variants in epilepsy genes associated with dominant disorders. No gene reached genome-wide significance with rare variant collapsing analysis; however, among the top 30 genes, genome-wide, were *DEPDC5* (p=0. 00016), which causes the focal epilepsy with variable foci syndrome, *KCNH2* (p=0. 0039), which causes LQTS type 2, and *NOS1AP* (p=0. 00023), which has common variants that are associated with sudden cardiac death. A sizeable proportion of SUDEP cases have clinically relevant mutations in cardiac arrhythmia and epilepsy genes. SUDEP may occur due to a predictable and preventable cause in cases with a LQTS gene mutation. These findings have relevance to understanding the causes of SUDEP, and raise the question whether specific cardiac arrhythmia or epilepsy genes confer an increased SUDEP risk. Understanding the genetic basis of SUDEP may inform cascade testing of at-risk family members.

1132F

***LGI2* heterozygous variant identified in a Japanese family with autosomal dominant cryptogenic West syndrome.** *N. Ishihara[1,2], Y. Azuma[2,3], T. Nakata[2,3], T. Takeuchi[2,3], T. Okuno[3], K. Ohno[3], J. Natsume[2].* 1) Dept Pediatrics, Fujita Health University School of Medicine, Toyoake, Japan; 2) Dept Pediatrics, Nagoya University Graduate School of Medicine, Nagoya, Japan; 3) Division of Neurogenetics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan.

The purpose of this study was to identify the causal gene of familial West syndrome. West syndrome is an epileptic encephalopathy characterized by infantile onset epileptic spasms in cluster, developmental regression, and hypsarhythmia in interictal EEG. Some of the patients have no neurological deficit before onset of the epileptic seizure. In this study, we performed genetic analysis of a familial case of West syndrome which has no neurological deficit before the onset of the seizures, and no sequela after the treatment. Subjects: Proband is a 4-year-old girl who had epileptic spasms in cluster at the age of 4 months. She did not have any neurological complication before the onset of the seizure. Her brain MRI showed no abnormal findings, and blood test had no evidence of congenital metabolic disorder. Her interictal EEG showed hypsarhythmia, therefore she was diagnosed as cryptogenic West syndrome. She received ACTH therapy, and epileptic spasms were resolved in 3 days after starting the therapy. Her mother was also suffered from West syndrome during her infantile period, which resolved with ACTH therapy. Both the proband and her mother had no major neurological sequela, except cognitive function of the proband revealed subnormal. Methods: Whole exome sequence of the proband and her family was performed. We analysed mutations in common between the proband and her mother. Results: Analysis led to the identification of five candidate genes, and we found one of these genes had reported as causal for familial epilepsy in childhood with dogs. Leucine-rich gene glioma-inactivated 2 (*LGI2*) consisted of 545-amino acid protein contains an N-terminal signal peptide, a putative transmembrane region, and 1 partial and 4 complete leucine-rich repeats. Conclusions: There is no previous report of *LGI2* in human epilepsy syndromes, however we suggest that it may be one of the causal genes of familial West syndrome.

1133W

Evaluation of variants from epilepsy patients referred for genetic screening. *K. A. McCarty, C. da Silva, J. J. Alexander, M. Hegde, A. Escayg.* Dept of Human Genetics, Emory University, Atlanta, GA.

Epilepsy is a neurological disorder characterized by recurrent, unprovoked seizures caused by neuronal synchrony and hyperexcitability. More than a hundred genes causative of epilepsy have been identified to date. Despite this progress, a significant fraction of the genetics underlying epilepsy remains uncharacterized, and the mechanisms by which identified mutations lead to seizure generation remain elusive. Additionally, the time and financial costs associated with patient recruitment and genetic testing still create a barrier to epilepsy gene discovery. The Emory Genetics Laboratory (EGL) has developed a targeted sequencing library comprising 109 known and candidate epilepsy genes referred to as the 'epilepsy and seizure disorder panel' (ESDP). The ESDP is pulled from a larger mendeliome library of evidence-based disease genes, making this a valuable resource for identifying putative disease-causing alleles as well as new disease associations. Individuals are clinically referred to the EGL for genetic testing and are typically affected with severe childhood epilepsy. When testing is ordered, the coding exons of the 109 genes are sequenced and examined for the presence of variants; however, clinical laboratories identify variants which they are unable to classify as pathogenic without functional studies. We are utilizing this rich source of available sequence data to identify new disease-causing variants. This information will provide insight into the importance of specific residues and domains across the encoded proteins and enable pathogenic variants to be more reliably identified in the future. From the examination of 96 cases, we identified three novel variants in the voltage-gated sodium channel *SCN8A*, which is associated with early infantile epileptic encephalopathy and intellectual disability. Two of the variants occurred *de novo*, consistent with previously published mutations, while the third was maternally inherited. Studies are underway to confirm pathogenicity and investigate the functional consequences of these variants. Missense changes at conserved positions in *SCN8A* were observed infrequently in individuals referred for genetic screening on panels other than the ESDP. In addition to the *SCN8A* variants, we identified new pathogenic or likely pathogenic variants in 15 other genes from the ESDP, including *SCN1A*, *SCN2A*, *KCNQ2*, and *HCN1*, accounting for approximately 30% of the cases screened on the ESDP.

1134T

Identification of non-coding RNAs related to familial mesial temporal lobe epilepsy by whole exome sequencing and Sanger validation. *R. Secolin[1], P. A. O. Ribeiro[1], F. R. Torres[1], M. G. Borges[1], A. C. Coan[2], M. E. Morita[2], C. V. Soler[1], M. L. Santos[1], C. V. Maurer-Morelli[1], B. S. Carvalho[1], F. Cendes[2], I. Lopes-Cendes[1].* 1) Department of Medical Genetics, University of Campinas - UNICAMP, Campinas, SP, Brazil; 2) Department of Neurology, University of Campinas, UNICAMP, Campinas, SP, Brazil.

Background: Epilepsy is a common chronic neurological disorder that affects approximately 1% of the population worldwide. Familial mesial temporal lobe epilepsy (FMTLE) is a clinically well characterized syndrome with an autosomal dominant inheritance. Previous linkage studies identified a risk haplotype on chromosome (chr.) 18p11. 31 in one family segregating MTLE. Therefore, the identification of genetic variants within the candidate region could unveil the molecular basis of FMTLE. **Objective:**To identify variants within the candidate region 18p11. 31 in the family segregating MTLE. **Methods:** We evaluated four individuals, including three patients and one unaffected relative. We perform the whole exome sequencing (WES) using Nextera Rapid Capture Expanded Exome kit and Hiseq Illumina 2500 equipment (Illumina™). Bioinformatics analysis was performed using the GATK software package. We aligned the reads by BWA algorithm, using the Genome Reference Consortium Human Build 38 (GRCh38. p2). We annotated the variants using VariantAnnotator (GATK package). We included additional variant information, such as gene location, functional consequence and global minimum allele frequency, using the Variant Effect Predictor (VEP). We refine our search on chr. 18p11. 31. Variants found were validated by Sanger sequencing in additional 21 family members, including 14 patients sharing the affected haplotype on chr. 18p11. 31. **Results:** WES revealed a total of 272955 variants. Among them, we found three variants (rs75897598, rs79570056 and rs76231122) on chr. 18p11. 31. Further Sanger sequencing validation showed that all 14 haplotype-positive individuals share the rs75897598 and rs76231122 variants. In addition, all four individuals previously sequenced by WES presented the same genotype by Sanger sequencing. **Conclusion:** Among haplotype-positive individuals, eight have the diagnoses of FMTLE, two have had only a single seizure, two have the diagnoses of generalized epilepsy and two are asymptomatic relatives. However, all of them presented hippocampal abnormalities, including hippocampal atrophy and/or abnormal shape or axis identified on magnetic resonance imaging. The two validate variants are located in two long intergenic non-protein coding RNA (*LINC00526* and *LINC00667*). The lncRNAs were recently found to be related to several neurological diseases. Therefore, these two lncRNAS could be involved in the etiology of FMTLE. Supported by CEPID-BRAINN FAPESP, São Paulo, Brazil.

SORL1 mutations and Parkinsonian features in early onset Alzheimer's disease families. *M. L. Cuccaro[1, 2], R. M. Carney[3], B. W. Kunkle[2], J. M. Vance[1,2], P. Whitehead[2], J. R. Gilbert[1,2], B. N Vardarajan[4], R. Mayeux[4], M. A. Pericak-Vance[1,2].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Psychiatry & Behavioral Sciences, University of Miami Miller School of Medicine, Miami, Fl; 4) Department of Neurology, Taub Institute of Research on Alzheimer's Disease, Columbia University Medical Center, New York, NY.

Early-onset Alzheimer's disease (EOAD; onset of Alzheimer's disease (AD) prior to age 65) affects ~200,000 individuals, representing 3. 8% of all AD cases. Mutations in *PSEN1*, *PSEN2*, and *APP* can cause EOAD. We conducted a genome-wide search to identify novel mutations in a series of families enriched for EOAD using whole-exome sequencing (WES). We hypothesized that WES would identify novel mutations in these families and that these mutations would be associated with a spectrum of neurodegenerative features. Our dataset consisted of 50 families with at least one individual with EOAD. All individuals and additional family members were characterized via comprehensive medical and research record review. WES (Agilent SureSelect) was performed on individuals of interest per family; *APOE* genotypes were available as well. WES identified variants of interest in *SORL1*, a gene which previously had been primarily associated with late-onset AD. *SORL1*missensemutations were identified in 2 families. One family contained 4 affected individuals (AOO range 59-82 years; 3 with APOE genotype 3/4, 1 with 3/3) and 2 unaffected individuals (ages 81-84, both APOE 3/3) with the novel T588I*SORL1*mutation. Two individuals with *SORL1* mutations in this family also presented with Parkinsonian features. The second family carried thepreviously reported *SORL1*mutation (T749M) with 3 affected individuals with the mutation (AOO 55-84, all APOE 3/3), 1 affected individual without the mutation (AOO 76, APOE 3/4), and 1 unaffected individual with the mutation (age 79, APOE 3/3). One affected individual with in the second family with the T749M *SORL1* mutation had neuropathologic evidence of Lewy bodies without clinical Parkinsonism. A follow-up of SORL1 mutations in a separate dataset of LOAD families (Vardarajan 2015, Annals of Neurology) corroborated the presence of Parkinsonism in 4 individuals with *SORL1* mutations (3 individuals with the common rs2298813 mutation and 1 individual with a rare mutation). This study confirms *SORL1* as a gene involved in risk for EOAD. Equally compelling is our finding of Parkinson-related features and Lewy bodies without clinical Parkinsonism in association with these *SORL1* mutations. This is the first study to suggest a relationship between *SORL1*, EOAD, and Parkinsonism.

1136W

Analysis of linkage and whole exome sequencing to identify novel alcohol dependence-associated variants in extended European and African American families. *M. Kapoor[1], S. Bertelsen[1], L. Wetherill[2], JN. McClintick[2], J. Wang[1], H. Edenberg[2], T. Foroud[2], A. Goate[1], COGA Collaborators.* 1) Icahn School of Medicine at Mount Sinai, New York, NY, 10029, USA; 2) Indiana University School of Medicine, Indianapolis, IN, USA.

Genes implicated in alcohol dependence (AD) risk via linkage, candidate gene and GWAS account for only a small fraction of the overall risk, with effects varying across populations. To identify rare, high penetrance risk alleles we employed whole exome sequencing in systematically ascertained and deeply phenotyped extended families from the Collaborative Study on the Genetics of Alcoholism (COGA). We performed non-parametric linkage analysis in 2322 subjects from 118 extended European American (EA) families and observed strong linkage (lod = 2. 7) for AD symptom count on chromosome 3q24-26. Further, linkage analysis in each pedigree identified 4 families, contributing largely to the chromosome 3-linkage signal with a combined lod score of 5. 5. Twelve subjects (founder parent child trio) from these 4 families were selected for whole exome sequencing. Identity By Descent (IBD) estimates for non-sequenced subjects were generated through dense genome-wide SNP data available for each subject in the family. Sequencing and IBD based variant filtering around 3q24-26, identified 11 genes where novel functional variants segregated with AD in at least two families. We further examined the identified genes in exome array data from nearly 3000 independent EA samples and validated association for 4/11 genes, exhibiting significantly enrichment for rare variants. The most-significant association with AD was observed for WD repeat domain 52 (*WDR52*) gene (P = 8 x 10-4). Further, an improved association signal was observed (P = 3. 34 x 10-4) in meta-analysis of exome array data from EAs and nearly 1000 African American subjects. Linkage analysis in African American families in COGA resulted in a lod score of 2. 7 in the same region of chromosome 3, with AD symptom count. We obtained whole exome sequence for 40 subjects from these 10 AA families contributing to this lod score. We performed the segregation analysis using the pVAAST and prioritize several genes with functional variants. Two genes (*PPP2R3A* and *SLC41A3*) prioritized in the current analysis also overlapped with the top signals from the European American analysis. The *PPP2R3A* gene was also found to be significantly enriched for low frequency variants in the AD subjects in exome array analysis. Our initial findings suggest that multiple rare/novel variants in the same or different genes under the chromosome 3, linkage peak might be associated with AD.

1137T

Genomic analysis identifies candidate pathogenic variants in 9 of 18 patients with unexplained West syndrome. *A. Kikuchi[1], N. Hino-Fukuyo[1,2], N. Arai-Ichinoi[1], T. Niihori[2], R. Sato[1], T. Suzuki[1], H. Kudo[1], Y. Sato[1], T. Nakayama[1], Y. Kakisaka[1,3], Y. Kubota[1], T. Kobayashi[1,4], R. Funayama[5], K. Nakayama[5], M. Uematsu[1], Y. Aoki[2], K. Haginoya[6], S. Kure[1].* 1) Department of Pediatrics, Tohoku University School of Medicine, Sendai, Japan; 2) Department of Medical Genetics, Tohoku University School of Medicine, Sendai, Japan; 3) Department of Epileptology, Tohoku University School of Medicine, Sendai, Japan; 4) Division of Genomic Medicine Support and Genetic Counseling, Department of Education and Training, Tohoku Medical Megabank Organization (ToMMo), Tohoku University, Sendai, Japan; 5) Division of Cell Proliferation, United Centers for Advanced Research and Translational Medicine, Tohoku University Graduate School of Medicine, Sendai, Japan; 6) Department of Pediatric Neurology, Takuto Rehabilitation Center for Children, Sendai, Japan.

West syndrome, which is narrowly defined as infantile spasms that occur in clusters and hypsarrhythmia on EEG, is the most common early-onset epileptic encephalopathy (EOEE). Patients with West syndrome may have clear etiologies, including perinatal events, infections, gross chromosomal abnormalities, or cases followed by other EOEEs. However, the genetic etiology of most cases of West syndrome remains unexplained. DNA from 18 patients with unexplained West syndrome was subjected to microarray-based comparative genomic hybridization (array CGH), followed by trio-based whole-exome sequencing in 14 unsolved families. We identified candidate pathogenic variants in 50% of the patients (n = 9/18). The array CGH revealed candidate pathogenic copy number variations in four cases (22%, 4/18), including an Xq28 duplication, a 16p11. 2 deletion, a 16p13. 1 deletion and a 19p13. 2 deletion disrupting *CACNA1A*. Whole-exome sequencing identified candidate mutations in known epilepsy genes in five cases (36%, 5/14). Three candidate de novo mutations were identified in three cases, with two mutations occurring in two new candidate genes (*NR2F1* and *CACNA2D1*) (21%, 3/14). Hemizygous candidate mutations in *ALG13* and *BRWD3* were identified in the other two cases (14%, 2/14). Evaluating a panel of 67 known EOEE genes failed to identify significant mutations. Despite the heterogeneity of unexplained West syndrome, the combination of array CGH and whole-exome sequencing is an effective means of evaluating the genetic background in unexplained West syndrome. We provide additional evidence for *NR2F1* as a causative gene and for *CACNA2D1* and *BRWD3* as candidate genes for West syndrome.

1138F

Identification of rare variants associated with age-related macular degeneration by whole exome sequencing in 41 extended families. *R. Priya[1], M. Geerlings[2], E. De Jong[2], J. Corominas Galbany[2], L. Fritsche[3], K. Branham[4], N. Saksens[2], S. Perez[1], V. Chaitankar[1], M. Othman[4], D. Ferrington[5], E. Chew[1], G. Abecasis[3], C. Hoyng[2], A. Swaroop[1], A. den Hollander[2].* 1) 1National Eye Institute, National Institutes of Health, Bethesda, MD, USA; 2) Department of Ophthalmology, Radboud University Medical Center, Nijmegen, The Netherlands; 3) Departments of Biostatistics, University of Michigan, Ann Arbor, MI, USA; 4) Departments of Ophthalmology, University of Michigan, Ann Arbor, MI, USA; 5) Departments of Ophthalmology & Neurosciences, University of Minnesota Twin Cities, Minneapolis, MN, USA.

Age-related macular degeneration (AMD) is a common cause of visual impairment in the elderly. Genome-wide association studies have identified more than 20 susceptibility loci with common variants that explain almost half of the AMD heritability. More recently, targeted sequencing has revealed high-risk, rare coding variants at four known AMD loci. To further explain the missing hereditability, we undertook whole exome sequencing (WES) of 41 extended AMD families with multiple affected individuals. Exomes were captured using SureSelect Human All Exon kit (Agilent), and data were generated on Illumina sequencer. Reads were aligned to the human reference genome (NCBI build 37. 3, hg19) using Burrows-Wheeler Aligner, variants were called by GATK, and variants were annotatated with ANNOVAR. We identified 26 genes carrying rare, non-synonymous coding or splice variants that were shared among affected members from more than one family. Gene enrichment analysis using database for annotation, visualization and integrated discovery (DAVID) recognized genes in extracellular matrix, transmembrane transporter activity, voltage gated channel activity and non-membrane organelle cytoskeletons among the top annotation clusters. To validate their role, we have performed a gene-based burden test of the candidates using exome chip data from a large AMD case-control cohort. We have also examined human retina transcriptome data using weighted co-expression network analysis (WGCNA) to identify discrete modules of co-expressed genes that are enriched for AMD candidate genes. In conclusion, using WES, we have identified putatively family-specific AMD risk variants in genes that have not been previously associated with AMD. Our analysis highlights that family-based WES in extended AMD families may provide novel insights into the disease etiology.

1139W

Aggregated analysis of developmental disorders reveals novel risk genes and improves genetic diagnosis. *K. Retterer[1], J. Scuffins[1], D. Copenheaver[1], J. Juusola[1], W. K. Chung[2], Y. Shen[3].* 1) GeneDx, Gaithersburg, MD; 2) Departments of Pediatrics and Medicine, Columbia University Medical Center; 3) Departments of Systems Biology and Biomedical Informatics, Columbia University Medical Center.

Recent studies in developmental disorders (NDD) indicate that rare, undiagnosed developmental disorders often share risk genes or pathways with defined NDD phenotypes, such as autism and intellectual disability (ID), and aggregated analysis of *de novo* mutations can identify novel risk genes and improve the diagnostic yield of genetic analysis. We applied this strategy to a consecutive series of 1984 patients with undiagnosed developmental disorders for which we conducted whole exome sequencing of parents-proband trios. We identified *de novo* rare variants from exome data using a set of stringent empirical filters, annotated them by ANNOVAR, and predicted damaging missense (Dmis) mutations *in silico* by Meta-SVM. Using a gene-specific background *de novo* mutation rate, we identified candidate risk genes based on statistical significance of genes with at least two likely gene disrupting (LGD) or missense mutations. We identified 94 candidate risk genes with a false discovery rate (FDR) less than 0. 1. We then compiled publicly available *de novo* mutation data from ~ 5500 NDD published cases with autism, ID, epilepsy, and developmental delay, and reprocessed the mutation data using the same annotation approaches. We found that the majority (88%) of candidate risk genes have supportive evidence in the publicly available data set. There are several potentially novel genes, such as *HDAC2* and *HNRNPH2*, with plausible mechanisms in histone modification or pre-mRNA processing. We then inferred candidate risk genes in the combined data set (Meta-DD) and identified 135 genes with FDR < 0. 1, of which 60 genes are not candidates based on our cases only. Among our 358 cases carrying at least one LGD or Dmis rare variants in the Meta-DD candidate risk genes, 155 had no genetic diagnosis identified with the original clinical testing. This result represents an upper bound of a 7. 8% increase in diagnosis rate (from 25. 5% to 33. 3%). Interestingly, we also found there was an elevated rate of *de novo* damaging mutations in cases with more than one NDD phenotype. Specifically, the patients with all three major NDD phenotypes (autism, ID, epilepsy) are about twice as likely to carry damaging *de novo* rare variants in these candidate risk genes than autism patients without ID or epilepsy. This is consistent with recent findings that the *de novo* mutation burden in autism is concentrated in patients with lower IQ, and that these risk genes with *de novo* mutations are often pleiotropic.

1140T

Identification of a Nonsense Mutation in PIDD in Pakistani Families with Non-Syndromic Autosomal Recessive Intellectual Disability Using Exome Sequencing. *J. B. Vincent[1], A. mikhailov[1], T. Sheikh[1], A. Mir[2], M. Ayub[3], N. Vasli[1].* 1) Neurogenetics Sect, R30, Ctr Add/Mental Hlth,Clarke Div, Toronto, ON, Canada; 2) International Islamic University, Islamabad, Pakistan; 3) Department of Psychiatry, Queen's University, Kingston, ON, Canada.

Intellectual disability (ID) is a genetically heterogeneous neurodevelopmental disorder affecting 1-3% of the general population. It is characterized by deficits in memory skills and language development with difficulty in learning and problem solving. Today, more than 50 genes were detected in patients with ID. In an effort to identify the disease-causing mutations in patients with non-syndromic autosomal recessive ID (NS-ARID) using homozygosity mapping following by exome sequencing, we detected a homozygous nonsense mutation, c. 2587C>T, p. Gln863*, in the gene *PIDD* in two large consanguineous Pakistani families. Sanger sequencing analysis showed complete segregation within the two families with multiple affected individuals. Analysis of cryptic relatedness was performed on a set of 73,306 independent autosomal markers in PLINK version 1. 07. The pair-wise PI_HAT values between members of two families were less than 0. 10 indicating that these two families were not closely related. P53-Induced Death Domain Protein (PIDD) is a Leucine-rich repeat and death domain-containing protein expressing in brain, with a key role in DNA damage/stress response. It acts as a cell-fate switch through interacting with a prosurvivalmolecule, RIP1 and activation of NF-kB signaling to repair and survive the lesions, or via interacting with a pro-death factor, RAIDD and activation of caspase-2 and apoptotic cell death. The p. Gln863*mutation was in the death domain (DD), through which PIDD interacts with other DD proteins such as RIP1 or RAIDD. Functional studies are ongoing to establish the mechanism of pathogenicity of the variant detected. Our finding suggests the involvement of new pathways, i. e. PIDD-related pathways, in the etiology of intellectual disability.

1141F

Whole genome sequencing of autism spectrum disorder extended families reveals risk genes and variants missed by exome sequencing. *A. J. Griswold[1], H. N. Cukier[1], D. Van Booven[1], P. L. Whitehead[1], N. K. Hofmann[1], J. M. Lee[1], E. R. Martin[1,2], M. L. Cuccaro[1,2], J. R. Gilbert[1,2], J. P. Hussman[3], M. A. Pericak-Vance[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL, USA; 3) Hussman Institute for Autism, Baltimore, MD, USA.

Autism spectrum disorder (ASD) is a neurodevelopmental condition affecting 1 in every 68 individuals in the United States. A strong, but heterogeneous, genetic etiology of ASD has been demonstrated by genome-wide association studies (GWAS), copy number variation (CNV) screens, and, most recently, massively parallel sequencing. We previously reported a whole exome sequencing (WES) study of families with multiple, distantly related, ASD affected individuals and identified shared, inherited variants in ASD candidate genes previously implicated in a range of neurodevelopmental and neuropsychiatric diseases (Cukier, et al, 2014). However, in a minority of families, WES failed to reveal obvious putative risk variants based on our filtering criteria. Because WES evaluates only ~2% of the total genome coding for protein, misses certain coding exons, and is limited in detecting structural variations (SVs), we hypothesize that there are additional shared ASD risk variants in these families undetectable by WES. We have performed whole genome sequencing (WGS) on 15 affected ASD individuals across 6 of these extended families (2 or 3 individuals per family) to a depth of ~40X on the Illumina HiSeq2500. Of the ~4M single nucleotide variants (SNVs) identified per individual, 98% are noncoding and are currently being assessed for potential functional impact using bioinformatic tools such as GWAVA, CADD, and FATHHM-MKL. Among coding SNVs initially identified by WES, WGS calls are ~93% concordant across all individuals. To enrich for shared familial risk variants, we used the family structure and existing GWAS data to find variants in identical by descent (IBD) regions in each family. Depending on the family structure, the total size of the IBD regions in the six families range from 1. 5 to 500Mb. We identify 1,295 – 869,126 total SNVs within these regions per family with 15 – 6,946 in coding exons. WGS identifies ~25% more shared coding SNVs than WES per family. Furthermore, WGS reveals 0 - 300 SVs >1kb shared across individuals in each family disrupting 1-40 genes. Among these SVs is a ~1Mb deletion of the synaptic gene *SYN2* which has been implicated as an ASD candidate gene in genetic and animal model studies. Therefore, WGS is an essential tool to identify functional noncoding SNVs, SNVs not captured by WES, and SVs that might be conferring ASD risk in these unique pedigrees and were missed by other genomic technologies.

1142W

Comprehensive genomic analysis and quantitative functional assays in model systems provides evidence for the "two-hit" model in genomic disorders. *L. Pizzo[1], A. Polyak[1], J. Iyer[1], Y. Wang[1], A. Kubina[1], S. Girirajan[1,2].* 1) Department of Biochemistry and Molecular Biology. The Pennsylvania State University, University Park, PA; 2) Department of Anthropology. The Pennsylvania State University, University Park, PA.

Genomic disorders are associated with extensive phenotypic heterogeneity with individuals carrying the same genetic mutations manifesting varying levels of severity. This has led to challenges in genetic diagnosis, counseling and management. We recently described a two-hit model to explain the phenotypic variability associated with a 520-kbp deletion on chromosome 16p12. 1. A majority of these deletions were inherited from a parent and >20% of affected probands carried another large CNV elsewhere in the genome. We performed detailed phenotypic analysis of 50 probands with the deletion and identified variable frequency of neurodevelopmental features, including developmental delay (>90%), cardiac malformations (24%), epilepsy (21%), and behavioral problems (50%). Using de Vries scoring, we found that the severity of phenotypes increased through generations with carrier parents and grandparents showing subtle neuropsychiatric features such as depression and cognitive problems. We also performed exome sequencing experiments on 27 families and found an increased burden of rare inherited mutations in probands compared to parents. Several *de novo* and inherited single nucleotide variants were identified within known disease genes (such as *SETD5*, *DMD* and *LAMC3*) that potentially act in concert with the 16p12. 1 deletion genes in an additive or synergistic manner. To further assess the functional effect of the deletion itself and to validate genetic interactions, we performed phenotypic analysis by knocking down conserved genes in *Drosophila melanogaster*. We took advantage of the tissue-specific expression system conferred by UAS-Gal4 and used RNA interference to obtain the desired knockdown of putative genes in flies. We combined data from multiple phenotypic paradigms from different fly RNAi lines for the four conserved genes (*UQCRC2*, *C16ORF52*, *POLR3E*, and *CDR2*) and correlated the effect of gene dosage alteration to severity. For example, we found increased head sizes for reduced expression of *CDR2* (14. 74 SD), *UQCRC2* (9. 7 SD) and *POLR3E* (12. 37 SD) and a severe neuronal phenotype, for *POLR3E* (p<0. 0001). Using multiple quantitative tools, we also identified several enhancers and suppressors of the phenotypes due to knockdown of conserved genes within 16p12. 2. Our integrative analysis using copy-number variation and exome sequencing analysis along with quantitative functional analysis provides further evidence for the proposed two-hit model.

1143T

Meta-analysis of rare exome chip variants in 12,493 individuals identifies novel genes for white matter hyperintensities. *X. Jian[1], A. V. Smith[2], A. Teumer[3], J. C. Bis[4], E. Hofer[5], S. Hagenaars[6], L. Yanek[7], T. H. Mosley[8], M. A. Ikram[9], S. Seshadri[10], M. Fornage[1] for the neuroCHARGE Working Group.* 1) The University of Texas Health Science Center at Houston, Houston, TX; 2) Icelandic Heart Association, Kópavogur, Iceland; 3) University of Greifswald, Greifswald, Germany; 4) University of Washington, Seattle, WA; 5) Medical University of Graz, Graz, Austria; 6) The University of Edinburgh, Edinburgh, United Kingdom; 7) Johns Hopkins Medicine, Baltimore, MD; 8) The University of Mississippi Medical Center, Jackson, MS; 9) Erasmus University Medical Center, Rotterdam, Netherlands; 10) Boston University, Boston, MA.

Purpose: Cerebral white matter hyperintensities (WMH) detected on magnetic resonance imaging are common in the aging population and are part of the spectrum of vascular and neurodegenerative disease associated with brain aging. Though WMH are highly heritable, common variants identified by genome-wide association studies (GWASs) explain a small proportion of WMH variance. Functional low-frequency and rare variants within coding regions of the genome may contribute to WMH variance but have not been explored. **Methods:** Study subjects were stroke/dementia-free adults from six population-based cohorts within the CHARGE Consortium. We genotyped approximately 250,000 mostly coding variants in 11,192 European Americans (EAs) and 1,301 African Americans (AAs) using Infinium HumanExome BeadChip. Within each cohort, we used the seqMeta R package to compute race-specific score statistics for each variant and genotypic covariance matrices within predefined gene regions. These were then combined by meta-analysis to generate single-variant and gene-based tests of association. In gene-based tests, different grouping criteria were applied according to whether the variants were annotated as 'functional', 'damaging', or 'loss-of-function' by dbNSFP. **Results:** Single-variant tests replicated two GWAS significant or suggestive loci: 17q25 (rs3760128 in *TRIM65* with p = 2. 1×10−6 in EA+AA and 2. 6×10−6 in EA) and 2q33. 2 (rs2351524 in *NBEAL1* with p = 4. 66×10−7 in EA+AA and 6. 87×10−7 in EA). Gene-based tests identified two novel genes: *CNTNAP1* on 17q21 (p = 3. 76×10−6 by collapsing 10 functional variants with minor allele frequency (MAF) < 5% in EA+AA sample) is predominately expressed in brain tissue and has been suggested to have a role in the signaling between axons and myelinating glial cells; *APBB2* on 4p13 (p = 7. 49×10−7 by collapsing six damaging variants with MAF < 1% in EA sample) may modulate the internalization of beta-amyloid precursor protein and has been associated with Alzheimer's disease. **Conclusion:** We have replicated two GWAS loci and identified two novel genes harboring functional rare variants that may influence WMH. Our results suggest that both common and rare variants have an effect on this complex trait and choice of criteria for grouping rare variants may help eliminate noise and unveil novel association signals. Future replication studies are warranted to confirm our findings.

1144F

Allelic diversity of human disease genes in a large multigenerational Old Order Amish pedigree. *R. L. Kember[1], Y. Park[1], L. Hou[2], X. Ji[1], D. C. Craig[3], J. R. O'Connell[4], A. R. Shuldiner[4], D. J. Rader[1], C. D. Brown[1], F. J. McMahon[2], M. Bucan[1].* 1) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 2) Human Genetics Branch, National Institute of Mental Health Intramural Research Program, National Institutes of Health, Bethesda, MD; 3) The Translational Genomics Research Institute, Phoenix, AZ; 4) University of Maryland School of Medicine, Baltimore, MD.

Dissecting genetic components of complex diseases such as bipolar disorder (BP) can often be complicated by the presence of other medical co-morbidities. In such cases, family-based studies reduce confounding effects resulting from non-genetic components, however teasing out genetic associations to BP risk is still challenging. Recent studies suggest that variants in Mendelian disease genes can contribute to complex disease risk. Our previous work in the extended multigenerational Old Order Amish pedigree (ASMAD) revealed multiple linkage regions (in different subpedigrees) with BP risk-alleles, supporting a high degree of locus and allelic heterogeneity. This may in part be due to the co-morbid disease loci within this family that segregate in different subpedigrees. To study BP-specific genetic risk factors and reduce the genetic heterogeneity attributable to medical comorbidities, we utilize a combination of high throughput DNA and RNA sequencing and dense SNP chip genotypes. Genotype data from 394 family members were phased and imputed in reference to the whole genome sequence (WGS) for 80 family members (30 parent-child trios) and 1000 Genomes Project Phase 3 haplotype panel. Long-range phased haplotypes estimated using an extended pedigree allow us to explore the possible pleiotropy of Mendelian disease genes in relation to BP and the co-segregation between bipolar risk factors and Mendelian loci. We conducted carrier screening for all disease causing mutations in the Human Genome Mutation Database (HGMD-DM), and identified known and novel alleles in 3017 disease genes in both the heterozygous and homozygous state, many that are private to the ASMAD population. We created a complete catalog of all variants (both CNVs and SNPs) in disease genes, and compared allele frequencies between 1000 Genomes, an Amish control population, and the ASMAD sample. We can capture the distribution of these variants and follow them across multiple generations by utilizing the rich pedigree data. Strikingly, we find that burden of all variants in HGMD-DM genes is nominally elevated in individuals with BP, both in SNP and CNV analysis. Moreover, RNA-seq data for a subset of family members demonstrates the expression changes associated with these variants. These results reinforce the hypothesis of a complex genetic architecture underlying BP, and suggest that studies will benefit from investigating the role of variants in disease genes in BP and co-morbid conditions.

1145W

Combining autism and intellectual disability exome data yields insight into both disorders. *K. Roeder[1,2], A. E. Cicek[2], B. Devlin[3], J. D. Buxbaum[4], Autism Sequencing Consortium.* 1) Dept Statistics, Carnegie Mellon Univ, Pittsburgh, PA; 2) Computational Biology Dept, Carnegie Mellon Univ, Pittsburgh, PA; 3) Dept of Psychiatry, Univ of Pittsburgh School of Medicine, Pittsburgh, PA; 4) Seaver Autism Center, Icahn School of Medicine at Mount Sinai, NY, NY.

Identifying the large number of genes underlying neurodevelopmental disorders such as autism spectrum disorder (ASD) and intellectual disability (ID) is a major challenge, and interpreting how these genes contribute to risk is another. DNA from several thousand ASD and ID subjects and their parents have now been exome sequenced, from whom analysis of *de novo* mutations has proven a powerful tool for identifying risk genes. Moreover, such analyses suggest these disorders have many risk genes in common. We exploit this overlap to enhance power to discover risk genes for both disorders. Furthermore, we investigate the nature of the overlap of risk genes with respect to gene networks built for two critical spatio-temporal developmental periods in the brain. The analysis relies on recently developed statistical tools for the identification of risk genes using de novo mutations (TADA) and gene expression networks (DAWN). We apply community detection methods to DAWN networks to identify clusters of risk genes working in concert at key developmental periods. Combining ASD and ID exome data reveals 16 additional neurodevelopmental risk genes (FDR < 05), compared to earlier whole exome analyses, largely because the ASD and ID risk genes strongly overlap. Combining the risk genes identified for ASD with gene expression networks yields further insights. In the prefrontal cortex during fetal development we identify two functional clusters, one enriched for chromatin modification and another for regulation of synaptic transmission. In the mediodorsal nucleus of the thalamus and cerebellar cortex, assessed during infancy and early childhood, we identify three functional clusters enriched for chromatin modification, synaptic transmission/calmodulin binding and neuron-neuron synaptic transmission/GABA-A receptor activity. Moreover, ID genes are more strongly represented in three of the five functional ASD clusters. Thus, while ID and ASD share many risk genes, ID genes are predominantly found in a subset of the functional ASD risk gene communities, lending insight into the biological mechanisms underlying typical and atypical CNS development.

1146T

Mitochondrial genome sequence variation, mutation accumulation, heteroplasmy, and haplogroups associated with Alzheimer's Disease. *X. Wang[1,2,5], M. A. Florez[1], L. Jiang[1,2], M. Teferra[1], J. D. Mahnken[3,5], R. A. Honea[4,5], J. Burns[4,5], R. Swerdlow[4,5], M. L. Michaelis[1,2,5], E. K. Michaelis[1,2,5].* 1) Higuchi Biosciences Center, The University of Kansas, Lawrence, KS; 2) Department of Pharmacology and Toxicology, The University of Kansas, Lawrence, KS; 3) Department of Biostatistics, The University of Kansas Medical Center, Kansas City, KS; 4) Department of Neurology, The University of Kansas Medical Center, Kansas City, KS; 5) Alzheimer's Disease Center, The University of Kansas Medical Center, Kansas City, KS.

Alzheimer's Disease (AD) is the most common form of dementia, affecting one in nine people aged 65 and older, and one in three after reaching 85. Mitochondrial dysfunction has been proposed to play an important role in the etiology of AD. While the nuclear genome codes for a large number of proteins in this organelle, the mitochondrial genome codes for 37 genes, 13 of which code for protein components that are essential for bioenergetics. Because almost all current AD genetics/genomics studies are conducted on the nuclear genome, how the mitochondrial genome might be involved in AD pathogenesis is still largely unknown. To study how sequence variation and the accumulation of mutations in the mitochondrial genome might be associated with AD, we have applied Illumina HiSeq next-generation sequencing (NGS) to identify mitochondrial DNA (mtDNA) variants that are significantly associated with AD. Furthermore, the accumulation of mutations in the mitochondrial genome, especially the distribution pattern of mutations and the resultant sequence heterogeneity (i. e. , heteroplasmy), have been examined. As an extension of this analysis, mtDNA-based haplogroups have also been studied for their association with the disease. The study cohort contains over 400 AD cases and age-matched healthy controls and was recruited to the University of Kansas Alzheimer's Disease Center. Because of the small size of the mitochondrial genome, we are able to conduct highly multiplexed sequencing with 96 or more samples being sequenced in a single lane. As a result, we have identified new mtDNA polymorphic sites that are significantly associated with AD. The accumulation of mutations in mtDNA has been shown to be extensive and affect many sites in the mitochondrial genome. The incidence of AD is found to be significantly less common in certain haplogroups. The high-throughput and cost effectiveness of our NGS approach afford unprecedented opportunities for the study of AD and other diseases, including many psychiatric and neurological diseases, characterized by mitochondrial deficits.

Using zebrafish to model the role of *GEMIN5* in neurological disease. *K. Schaffer[1,2], E. Burke[1,3], A. Adomako-Ankomah[2], J. Fohtung[2], W. Bone[1], R. Sood[2], B. Carrington[2], K. Bishop[2], W. A. Gahl[3], S. Burgess[2].* 1) NIH Undiagnosed Diseases Program Translational Laboratory, Bethesda, MD; 2) Translational and Functional Genomics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Section on Human Biochemical Genetics, Medical Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD.

As a participant in the NIH Undiagnosed Diseases Network (UDN), a 21-year-old male patient was seen and demonstrated signs of upper motor neuron dysfunction, deafness, and seizures, and has since declined into a state of paralysis. After SNP and exome analysis of the patient and his family, *Gem associated protein 5* (*GEMIN5*) was identified as a strong candidate disease allele. *GEMIN5* is the snRNA-binding component of the survival of motor neuron (SMN) complex. The SMN complex plays an important role in mRNA splicing by cytoplasmic assembly of spliceosomal small nuclear ribonucleoproteins that subsequently catalyze the splicing reaction. While *GEMIN5* is not currently associated with a human disease, the gene *SMN1* (and the related *SMN2*), the core protein of the SMN complex, is associated with spinal muscular atrophy (SMA) types 1-4. Reduction of *SMN1* is also associated with severe motor neuron degeneration. Therefore, due to the known interaction of the SMN complex and *GEMIN5*, we hypothesize the missense mutation found in one copy of *GEMIN5* is contributing to this patient's disease. We tested the function of *GEMIN5* in zebrafish by targeted inactivation using CRISPR-Cas9. We observed fatality between 7-21 dpf in fish homozygous for frame shifting deletions in *GEMIN5*. We tested the mutant fishes' ability to repair neural damage by performing a hair cell regeneration assay after copper exposure. The mutant animals had no regenerative response despite their developmentally normal appearance. We have created a transgenic line ubiquitously expressing wild-type human *GEMIN5* or the variant found in the patient to rescue the zebrafish mutant phenotypes. We examined the mutants' motor neuron development by sensory motor neuron staining using Znp-1 antibody. These results confirm a role for *GEMIN5* in survival and reinforce our interest in testing the association between the identified variants in the patient and the manifestation of the disease.

Mutation analysis of the *WNT7A* and interaction study with the *DISC1* in schizophrenia. *M. Cheng[1], A. Chuang[1], C. Chen[2], S. Hsu[1], H. Tsai[1].* 1) Department of Psychiatry, Yuli Branch, Taipei Veterans General Hospital, Hualien Country, Taiwan; 2) Department of Psychiatry, Chang Gung Memorial Hospital at Linkou and Chang Gung University School of Medicine, Taoyuan, Taiwan.

Schizophrenia is a devastating chronic mental illness that affects about 1 percent of general population worldwide. Family, twin and adoption studies have provided substantial evidence to support a strong genetic basis underlying the pathogenesis of schizophrenia. Several reports show that Wnts mediate the neuron synaptic function and brain development, suggesting that aberrant Wnt signaling involves the pathophysiology of schizophrenia. This study aimed to investigate whether the *WNT7A*, a member of the WNT gene family, is associated with schizophrenia. We resequenced putative promoter region and all the exons of the *WNT7A* in 570 patients with schizophrenia and 563 non-psychotic controls from Taiwan and conducted a case-control association study. We further evaluated the intergenic interaction between the SNPs of the *WNT7A* and the Ser704Cys of the *DISC1* and their relationship with schizophrenia. We totally identified 14 genetic variants of the *WNT7A* in this sample, including 5 SNPs (rs73151669, rs3749319, rs12639607, rs3762719, and c. 777G>A) and 9 rare mutations (minor allele frequency <5%). However, SNP- and haplotype-based analyses showed no association of these SNPs with schizophrenia. However, we identified several rare mutations that were predicted to have pathological effect on the WNT7A protein function or disrupt microRNAs binding sites located at 3'UTR of the *WNT7A* in the schizophrenic patients. For the epistatic interaction between the *WNT7A* and the *DISC* in schizophrenia, the A allele (A/A+C/A) at the *WNT7A* rs73151669 increased risk for schizophrenia in the context of a *DISC1* SerSer background (odds ratio = 1. 48, p value = 0. 01), but was not significant in patients carrying Cys allele (odds ratio = 0. 91, p value = 0. 7). Our results suggest that multiple rare variants of the *WNT7A* might contribute to the pathogenesis of schizophrenia in some patients and there is a genetic association of the *WNT7A* in epistasis with the *DISC1* and the risk of schizophrenia.

The Alzheimer's Disease Sequencing Project Discovery Phase: Case-Control Study Design, Progress, and Preliminary Results. *J. C. Bis[1], A. C. Naj[2], G. W. Beecham[3], J. Dupuis[4], J. E. Below[5], K. L. Hamilton-Nelson[3], H. Lin[4], Y. Ma[4], N. Gupta[6], W. Salerno[7], Y. Chen[4], V. Chouraki[4], L. A. Cupples[4], C. Cruchaga[8], G. Jun[4], B. Kunkle[3], A. Partch[2], R. Koester[4], M. Schmidt[3], B. Vardarajan[9], E. Wijsman[1], A. Goate[10], J. Haines[11], S. J. van der Lee[12], C. van Duijn[12], S. Seshadri[4], A. DeStefano[4], E. Martin[3], M. Fornage[5], L. Farrer[4] on behalf of the Alzheimer's Disease Sequencing Project Case-Control Work Group.* 1) University of Washington, Seattle, WA, USA; 2) University of Pennsylvania, Philadelphia, PA, USA; 3) University of Miami, Miami, FL, USA; 4) Boston University, Boston, MA, USA; 5) The University of Texas Health Science Center at Houston, Houston, TX, USA; 6) The Broad Institute, Cambridge, MA, USA; 7) Baylor College of Medicine, Houston, TX, USA; 8) Washington University in St. Louis, St. Louis, MO, USA; 9) Columbia University, New York, NY, USA; 10) Icahn School of Medicine at Mount Sinai, New York, NY, USA; 11) Case Western Reserve University, Cleveland, OH, USA; 12) Erasmus University Medical Center, Rotterdam, the Netherlands.

Responding to a 2012 Presidential Initiative to fight Alzheimer's disease (AD) and a request from the Director of the National Institutes of Health, the National Institute on Aging and National Human Genome Research Institute (NHGRI) jointly developed a project to analyze the genomes of a large number of well-characterized individuals with or without AD using $25M in funding already committed to the NHGRI's Large-scale genome Sequencing and Analysis Centers (LSACs). The overarching goals of this effort, **the Alzheimer's Disease Sequencing Project (ADSP)**, include identifying new (1) genes involved in AD, (2) genomic variation contributing to AD risk or protection, (3) insights as to why some individuals with risk factor genes escape AD, and (4) potential avenues for therapies and AD prevention. The ADSP Discovery Phase includes two components: the **Family Study** conducted whole genome sequencing on multiplex AD families and the **Case-Control Study** sequenced whole exomes of unrelated participants from the Alzheimer's Disease Genetics Consortium (ADGC) and Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium. Here, we describe the design, progress, results, and public data availability for the Case-Control Study. On the basis of *a priori* risk – determined by age, sex, *APOE*, and pathology – we selected **5,107 low-AD-risk cases** and **4,976 high-AD-risk controls** (who had 'escaped' the disease). To enrich the risk profile and diversity of the study, we also sequenced unrelated cases from AD families (N=512) as well as Dominican-Hispanic cases (N=173) and controls (N=171). Sequencing has recently been completed by three LSACs (Baylor College of Medicine, Washington University-St. Louis, and the Broad Institute); BAM files have been deposited in dbGaP/SRA; novel QC methods have integrated genotype calls from two algorithms (*GATK*, *ATLAS*); and we have performed sequence-based principal components ancestry analyses. Our ongoing analyses focus on both individual common variants (minor allele count > 10) using Score tests and Firth bias-corrected regression as well as rare functional variants (including Loss-of-Function), aggregated within genes using burden tests and SKAT. In addition to identifying important coding variant associations in known AD genes, we anticipate that our analyses will also reveal promising new loci for AD risk and protection. We expect to present preliminary findings and plans for the next phase of ADSP.

1150F

Novel ABCC1 variant associated with frontotemporal dementia. *M. De Both, A. Siniard, R. Richholt, K. Ramsey, MJ. Huentelman.* Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ.

Frontotemporal dementia (FTD) is among the most common forms of primary dementia, second only to Alzheimer's disease in early-onset cases. It is characterized by the degeneration of neurons in the frontal and temporal lobes of the brain, which can manifest as severe changes to personality, decreased social awareness, and impaired ability to comprehend words. While it often presents in families, heritable causes of the disease are not fully understood. FTD can be grouped into three general categories: behavioral variant, primary progressive aphasia (PPA), and movement disorder type. Here, we studied a familial case of PPA. In ten siblings, 6 females were diagnosed with this form of FTD while 1 female and 3 males were not. Exome sequencing (Illumina TruSeq 62Mb Exome Enrichment Kit, sequenced on Illumina HiSeq 2000) was conducted on all surviving members (3 affected females, 1 unaffected female, 1 unaffected male) with 75 million paired reads per sample, from which we identified a novel, putatively dominant acting variant in ABCC1 (chr16:16216007 A>G, CADD = 14. 32, unobserved in ExAC) common to all 3 cases and not present in the 2 unaffected individuals. As ABCC1 has previously been found to facilitate the clearing of amyloid-b across the blood-brain barrier and into the bloodstream, we suspect our FTD cases to present with increased levels of amyloid-b in the brain, a phenotype not typically observed with FTD. However, we have not as of yet been able to examine the amyloid load in any of the cases in our study family. While amyloid-b accumulation of the brain is indicative of Alzheimer's disease, it is generally not strongly observed in cases of FTD. Treatment with thiethylperazine, already FDA-approved to relieve nausea, has been shown to reduce amyloid-b accumulation in mouse models expressing ABCC1 but exhibits no effect in knockout mice lacking ABCC1, suggesting the drug functions by inducing ABCC1 expression or by facilitating its biochemical actions. Such amyloid-b pathology could represent a novel mechanism for FTD and a therapeutic target in ABCC1. Studies are currently under way to examine the role of this newly identified ABCC1 variant on amyloid production in vitro and in vivo.

1151W

Rare Loss of Function Variants from Immune System Genes and Brain Over-expressed Genes are Enriched in Alzheimer's Disease Patients Compared to Centenarians. *Y. Freudenberg-Hua[1,5], W. Li[2], V. Vacic[3], A. V. Abhyankar[3], D. Ben-Avraham[4], E. Christen[1], J. Koppel[1], B. Greenwald[5], N. Barzilai[4], S. Germer[3], R. B. Darnell[3], J. Freudenberg[2,6], G. Atzmon[4], P. Davies[1].* 1) Litwin-Zucker Research Center for the Study of Alzheimer's Disease, The Feinstein Institute for Medical Research, North Shore-LIJ, Manhasset, NY; 2) Robert S. Boas Center for Genomics and Human Genetics, The Feinstein Institute for Medical Research, North Shore-LIJ, Manhasset, NY; 3) New York Genome Center, New York, NY; 4) Institute for Aging Research Departments of Medicine and Genetics, Albert Einstein College of Medicine, Bronx, NY; 5) Division of Geriatric Psychiatry, Zucker Hillside Hospital, North Shore-LIJ, Glen Oaks, NY; 6) Translational Genetics, Regeneron Genetics Center, Tarrytown, NY.

We sequenced the whole genomes of 45 patients with Alzheimer's diseases (AD) and 53 cognitively healthy centenarians of Ashkenazi Jewish ancestry. Variants were quality filtered and annotated based on RefSeq transcripts. Despite the relatively small sample size, we replicated associations of the known AD variants *APOE4* (OR=8. 3, P=3. 6e-08) and p. Arg47His in *TREM2* (OR=7. 6, P=0. 048), indicating the power of our approach to compare AD cases with centenarian super-controls. We restricted our subsequent analysis to rare single-nucleotide and indel variants not present in the 1000 Genomes database and with a minor allele frequency below 2% in our Ashkenazi sample. We compared the burden of predicted loss-of-function variants (LoFs, defined as nonsense, frame shift, initiation codon (INIT) and splice site variants) and protein altering variants (PAVs, defined as LoFs plus missense, in frame indels, stop-loss) between cases and controls, as normalized by the level of rare synonymous variants. Notably, for the 895 rare LoFs, we found an increased burden among AD cases (OR=1. 2, Fisher's exact P=0. 004). No enrichment was observed for the 11,845 rare PAVs (OR=1. 01, P=0. 662). To probe the role of the immune system in AD, we next limited the analysis to 4,723 immune response genes. We found a moderately increased burden among AD cases for the 2,617 PAVs (OR=1. 13, P=0. 027) as well as the 190 LoFs (OR=1. 32, P=0. 038). The largest burden was found for INIT variants (OR=2, P=0. 040 overall; OR=3. 23, P=0. 076 among immune genes). Immune function genes with INIT mutations exclusive to AD patients are *DLC1, NR1H3, DAPK2* and *BPI*. We furthermore observed enrichment among cases for the 73 LoFs located in genes over-expressed in the human brain (OR=1. 49, P=0. 043), and this enrichment appears to be stronger when restricted to orthologs of mouse essential genes (OR=3. 23, P=0. 021). In contrast, we observed no enrichment for the 185 LoFs from genes being annotated as neither essential nor over-expressed in the brain (OR=1. 02, P=0. 897). Essential brain over-expressed genes that are mutated exclusively in our AD patients are *CTNNA2, TCF7L2, CC2D1A, ZGPAT, PNPLA8, PPM1B, CLCN7, AVIL*, and *CNTNAP1*. In conclusion, we found the burden of rare LoFs to be increased among AD patients, with significant contributions coming from immune system genes as well as brain over-expressed genes. Our findings support a role of rare variants from immune and brain over-expressed genes in the etiology of AD.

1152T

Exome sequencing identifies novel genes associated with Multiple System Atrophy. *A. Siniard, I. Schrauwen, J. Corneveaux, K. Ramsey, M. Huentelman.* Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ.

Multiple System Atrophy (MSA) is a rare aggressive neurodegenerative disorder with adult onset. It can be characterized by a mixture of autonomic failure, ataxia, and parkinsonism. The two main disease subtypes can be distinguished clinically as "MSA-P" (predominant parkinsonism) or "MSA-C" (dominant cerebellar features). Both are associated with significant decline in dopamine transporter levels during disease progression. The cardinal pathology of MSA is glial inclusions enriched for alpha-synuclein protein. The cause of MSA is unknown but is likely due to the combination of heritable and environmental factors. To investigate the heritable risk factors associated with MSA we studied nuclear families with one affected individual using exome sequencing with Illumina's TruSeq Exome Kit. By using a selective filtering and variant prioritization approach, we attempted to identify variants that met following criteria: (1) family specific variants or ones present at a very low frequency in the population (ExAC MAF <0. 05), (2) variants predicted to have a damaging effect on the protein (CADD >11), and (3) familial segregation consistent with a digenic heterozygous inheritance model. In two families, variants were found in *LRRK2* and *SLC6A3* (aka DAT, dopamine transporter) or *LRRK2* and *SLC6A2* (aka NET, norepinephrine transporter). Mutations in *LRRK2* have previously been associated with Parkinson's disease (PD) risk. Additionally, LRRK2 is known to regulate synaptogenesis and dopamine receptor activation. In the third family, we identified two variants in different voltage-gated calcium channel subunits, CAV1. 3 and CAV2. 1. *CACNA1D,* encoding CAV1. 3, has been reported to be involved in neurodegenerative mechanisms associated with the development of PD. *CACNA1A,* encoding CAV2. 1*, w*as previously associated with spinocerebellar ataxia type 6, which shares several clinical features with MSA-C. This study is the first report of a nuclear family analysis of MSA in a Caucasian cohort. While small, our findings suggest the presence of rare variants with significant heterogeneity as a possible mechanism of disease. Interestingly, although each family studied had a different combination of variants they coalesce on a common biological theme related to dopamine processing in the brain, a previously hypothesized disease mechanism. Future work is necessary to further generalize these findings but also to investigate the functional ramification of these newly identified variants.

1153F

Rare coding mutations identified by sequencing of Alzheimer's disease GWAS loci. *B. N. Vardarajan[1,2,3,5], M. Ghani[8], A. Kahn[3], S. Sheikh[1,3], C. Sato[8], S. Barral[1,2,3], J. L. Lee[1,2,6], R. Cheng[2,3], C. Reitz[1,2,3], R. Lantigua[3,7], D. Reyes-Dumeyer[2,3], M. Medrano[10], I. Z. Jimenez-Velazquez[11], E. Rogaeva[8], P. St George Hyslop[8,9], R. Mayeux[1,2,3,4,6].* 1) Neurology, Columbia University, New York, NY; 2) The Taub Institute for Research on Alzheimer's Disease and the Aging Brain, Columbia University, New York, NY; 3) The Gertrude H. Sergievsky Center, Columbia University, New York, NY; 4) Psychiatry, Columbia University, New York, NY; 5) Systems Biology, Columbia University, New York, NY; 6) Epidemiology, Mailman School of Public Health, Columbia University, New York, NY; 7) Medicine, Columbia University, New York, NY; 8) Tanz Centre for Research in Neurodegenerative Diseases, Deparment of Medicine,Toronto, Canada; 9) Cambridge Institute for Medical Research, Department of Clinical Neurosciences, University of Cambridge, Cambridge, UK; 10) Medicine, Pontificia Universidad Catolica Madre y Maestra, Santiago, Dominican Republic; 11) Medicine, Geriatrics Program, School of Medicine, University of Puerto Rico, San Juan, Puerto Rico.

Objective: To detect rare coding variants underlying loci detected by genome-wide association studies (GWASs) of late-onset Alzheimer's disease (LOAD). **Methods**: We conducted targeted sequencing of *ABCA7, BIN1, CD2AP, CLU, CR1, EPHA1, MS4A4A/MS4A6A* and *PICALM* in three independent LOAD cohorts: 176 patients from 124 Caribbean Hispanics families, 120 patients and 33 unaffected individuals from the 129 NIA-LOAD Family Study; and 263 unrelated Canadian individuals of European ancestry (210 sporadic patients and 53 controls). Rare coding variants found in at least two datasets were genotyped in independent groups of ancestry matched controls. Additionally, the Exome Aggregation Consortium (ExAC) was used as a reference dataset for population-based allele frequencies. **Results:** Overall we detected a statistically significant 3. 1-fold enrichment of the non-synonymous mutations in the Caucasian LOAD cases compared with controls (p=0. 002) and no difference in synonymous variants. A stopgain mutation in *ABCA7* (E1769X) and missense mutation in *CD2AP* (T374A) were highly significant (p=5. 3e-04 and 5. 3e-08 respectively) in Caucasian LOAD cases, and mutation in *EPHA1* (P460L) was significantly associated in Caribbean Hispanics (p=8. 64e-05), with LOAD. P460L in EPHA was also nominally significant in the Caucasians (p=0. 03). The *EPHA1* variant segregated completely in an extended Caribbean Hispanic family and was also nominally significant in the Caucasians. Additionally, in *BIN1* K358R segregated in two of the six families where the mutations were discovered. **Interpretation:** Targeted sequencing of confirmed GWAS loci revealed an excess burden of deleterious coding mutations in LOAD with the greatest burden observed in *ABCA7* and *BIN1*. Identifying coding variants in LOAD will facilitate the creation of tractable models for investigation of disease related mechanisms and potential therapies.

1154W

The percentage of sporadic amyotrophic lateral sclerosis patients with a known genetic etiology of disease is less than previously described. *J. M. Downie[1], S. B. Gibson[2], K. P. Figueroa[2], M. B. Bromberg[2], S. M. Pulst[2], L. B. Jorde[1].* 1) Department of Human Genetics, University of Utah School of Medicine, 15 North 2030 East Room 5100, Salt Lake City, UT 84112; 2) Department of Neurology, University of Utah School of Medicine, 175 North Medical Drive East, Salt Lake City, UT 84132.

Amyotrophic lateral sclerosis (ALS) is a fatal disease in which upper and lower motor neurons degenerate, leading to eventual paralysis. More than 16 genes have now been implicated in ALS pathogenesis. 90% of ALS cases occur with no previous family history and are termed sporadic ALS (SALS). However, twin studies have yielded an SALS heritability estimate of 61%. There is substantial disagreement about the proportion of SALS cases caused by mutations in known ALS genes, with estimates ranging between 11% and 28%. These estimates are largely derived from studies calculating the proportion of SALS patients with a rare, protein-altering mutation in a designated panel of genes. However, these studies relied on rarity as an indicator of deleteriousness instead of considering the likelihood that these variants affect normal protein function. Defining the degree to which ALS genes contribute to SALS pathogenesis will help to determine how much heritability remains to be explainedand will allow for a better understanding of SALS pathogenesis. To this end, we incorporated *in-silico* predictions of variant deleteriousness in 96 SALS patients who were exome sequenced using the Illumina HiSeq platform. Reads were aligned to GRCh37 using BWA, and variants were called using GATK (v3. 3). *ATXN2* and *C9orf72* repeat expansions were detected via PCR. Predictions of variant deleteriousness were obtained using 11 different algorithms contained in dbNSFP v2. 9. To prevent population stratification effects, we focused our study specifically on Europeans with ALS. Nine non-Europeans, who were identified using principal components analysis, were removed from further analysis. We calculated the proportion of SALS patients who had at least one rare (European MAF < 0. 01; 1000 Genomes + ESP6500), deleterious (based on *in-silico* predictions) amino-acid altering variant in any of fourteen ALS genes (*ANG*, *DAO*, *DCTN1*, *EWSR1*, *FIG4*, *FUS*, *OPTN*, *SETX*, *SOD1*, *SQSTM1*, *TAF15*, *TARDBP*, *VAPB*, *VCP*) or possessed a pathogenic repeat expansion in either *ATXN2* or *C9orf72*. We found that across the 11 *in-silico* algorithms that 14. 6%, on average (SD = 0. 0277), of SALS patients had at least one rare, deleterious variant or a pathogenic repeat expansion in one of these genes. Our estimate, which is based on both variant rarity and deleteriousness, is lower and likely more accurate than previous frequency-based estimates.

1155T

Identification of SPG11/*KIAA1840* mutations in patients with autosomal recessive axonal Charcot-Marie-Tooth disease. *L. Pedace[1], C. Montecchiani[1], T. Lo Giudice[1,2], A. Casella[1], M. Mearini[1], F. Gaudiello[1], C. Terracciano[2], J. L. Pedroso[3], R. Massa[2], O. G. P. Barsottini[3], P. H. St George-Hyslop[4,5,6], T. Kawarai[7], A. Orlacchio[1,2].* 1) Laboratorio di Neurogenetica, CERC - IRCCS , Rome, Italy; 2) Dipartimento di Medicina dei Sistemi, Université di Roma "Tor Vergata", Rome, Italy; 3) Department of Neurology, Universidade Federal de São Paulo, Brazil; 4) Centre for Research in Neurodegenerative Diseases, University of Toronto, Toronto, Ontario, Canada; 5) Department of Medicine, University of Toronto, Toronto, Ontario, Canada; 6) Department of Clinical Neurosciences, University of Cambridge, Cambridge, United Kingdom; 7) Department of Clinical Neuroscience, Institute of Biomedical Sciences, Tokushima University Graduate School, Tokushima, Japan.

Background: Mutations in the SPG11/*KIAA1840* gene are common cause of autosomal recessive hereditary spastic paraplegia with *thin corpus callosum* and peripheral axonal neuropathy and accounts for about 40% of autosomal recessive juvenile amyotrophic lateral sclerosis. The overlap between axonal Charcot-Marie-Tooth disease and both these diseases, as well as the common autosomal recessive inherited findings of *thin corpus callosum* and axonal Charcot-Marie-Tooth in three related patients, prompted us to sequence the SPG11/*KIAA1840* gene in affected individuals with autosomal recessive axonal Charcot-Marie-Tooth disease. **Methods:** The study focused on 28 unrelated pedigrees with autosomal recessive Charcot-Marie-Tooth type 2 and without genetic assessment, originated in Italy, Brazil, Canada, England, Iran, and Japan. The diagnosis was based on clinical findings and familiar history. Clinical and instrumental functional analysis consist of neurological assessment, diagnostic imaging, electroneurographic assay, and sural nerve biopsy. Molecular studies include linkage analysis, Sanger sequencing, RFLP analysis and bioinformatics. **Results:** Linkage study of all families showed homozygous haplotypes and produced positive logarithm of odds score in all affected subjects. Sanger sequencing identified 15 SPG11/*KIAA1840* mutations in 12 families. Two sequence changes were never reported before and *in silico* analysis predicted their pathogenetic effect. All mutations seemed to be pathogenic since they co-segregated with the disease in all pedigree and were absent in controls. All known axonal Charcot-Marie-Tooth autosomal recessive loci (CMT1F/*CMT2E/NEFL,* CMT2A/CMT2B1/*LMNA,* CMT2A2/*MFN2,* CMT2B2/*MED25,* CMT2F/*HSPB1*/*HSP27,* CMT2K/*GDAP1,* CMT2P/*LRSAM1,* CMT4C/*KIAA1985,* CMTRID/*COX6A1,* NMAN/*HINT*), genes causing autosomal recessive hereditary spastic paraplegia with *thin corpus callosum* and axonal peripheral neuropathy (*SPG7, SPG15*, and *SPG21*), as well as the causative gene of peripheral neuropathy with or without agenesis of the corpus callosum (*SLC12A6*) were screened out. An additional locus for autosomal recessive Charcot-Marie-Tooth disease type 2H on chromosome 8q13-21. 1 was excluded by linkage analysis. **Conclusions:** Our results indicate that SPG11/*KIAA1840* is the causative gene of a wide spectrum of clinical features, including autosomal recessive axonal Charcot-Marie-Tooth disease.

1156F

Uniparental disomy causing hereditary spastic paraplegia: Paternal disomy in FA2H causing homozygous SPG35 in two non-consanguine families. *A. S. Soehn[1], T. W. Rattay[2,3], S. Beck-Woedl[1], K. Karle[2,3], S. Wiethoff[2,3], J. Reichbauer[2,3], U. Gaiser[4], M. Doebler-Neumann[4], P. Bauer[1], S. Zuechner[5], R. Schuele[2,3,5], L. Schoels[2,3].* 1) Institute of Medical Genetics and Applied Genomics, University of Tuebingen, Tuebingen, Germany; 2) Center for Neurology, Department of Neurodegenerative Diseases, Hertie-Institute for Clinical Brain Research, University of Tuebingen, Tuebingen, Germany; 3) German Center of Neurodegenerative Diseases (DZNE), Tuebingen, Germany; 4) Department of Neuropediatrics, Tuebingen University School of Medicine, Tuebingen, Germany; 5) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL, USA.

Hereditary spastic paraplegias (HSPs) are degenerative diseases of upper motor neurons characterized by a progressive spastic gait disorder. They are genetically highly heterogenous. SPG35 is an autosomal-recessive (AR) HSP caused by mutations in the fatty acid 2-hydroxylase (*FA2H*), which is essential for maintenance of the neuronal myelin sheath. Thus far approx. 20 mutations have been described in 13 SPG35 families with 36 affected patients. Here we describe two novel homozygous *FA2H* mutations in two non-related non-consanguine families detected by whole exome sequencing or a HaloPlex assay providing high coverage of all known HSP genes ("HSP panel"), respectively. Segregation analysis revealed both fathers being heterozygous mutation carriers whereas both mothers did not carry *FA2H* mutations. A macro deletion within SPG35, that could have caused a hemizygous genotype, was excluded by MLPA. Finally, a microsatellite array revealed paternal disomy in both families leading to homozygous SPG35 mutations. UPD has rare been described as causative mechanism in neurodegenerative diseases. This is the first report of UPD as a cause for HSP. Interestingly, we identified this rare mode of inheritance in two families with the rare genotype SPG35. We are not aware of any mechanism how SPG35 mutations may trigger UPD. Since UPD seems to be a relevant factor in AR HSP we recommend segregation analysis especially in non-consanguine homozygous index cases to unravel further UPD cases in this field.

1157W

A study on the Association of monoamine and glutamate gene polymorphisms with alcohol dependence in patients from North India. *R. Gupta[1], R. Singh[1], S. Sahni[1], T. Grover[1], A. Ambekar[2], M. Vaswani[2], A. Sharma[1].* 1) Department of Anatomy, AIIMS, New Delhi, Delhi, Indi; 2) Department of Psychiatry, AIIMS, New Delhi, Delhi, India.

Alcohol dependence (AD) is a complex disorder influenced by monoamine and glutamate pathways which play a role in normal brain functions. Disturbances in these pathways are implicated in many psychiatric disorders including alcohol dependence and polymorphisms present in these pathway genes are reported to increase the risk of developing alcohol dependence. **Aim:** To identify polymorphisms in the Monoamine and Glutamate pathway genes and correlate their presence with alcohol dependence. **Method:** The study conformed to declaration of Helsinki and was approved by the Institute ethics committee. Total of 200 AD patients (DSM IV criteria) from outpatient department of Psychiatry and 200 healthy volunteers from the general population were recruited. Genomic DNA from blood samples was screened for polymorphisms in the DRD4 120bp duplication, DRD3 Ser9Gly, DRD2 Taq1A, COMT rs4680, -287A>G, HT1B G861C, 5-HTTLPR, STin2 genes of monoamine and GRIN2A rs11866328, rs1071502, rs1375067, rs1530669 of glutamate pathway. Difference in genotype frequencies was assessed through chi-square test and results were correlated with duration of alcohol use and dependence, age at onset of dependence, quantity of alcohol consumed, WHO ASSIST score and liver function tests of SGPT, SGOT, GGT. **Result:** Age at first use of alcohol was 21. 84±0. 4711, WHO ASSIST score was 42. 34±0. 7103, SGOT, SGPT, GGT were 84. 94±5. 426, 68. 98±4. 529 and 208. 5±28. 43 respectively. COMT rs4680, GRIN2A rs11866328 and rs1071502 showed a significant difference between patients and controls ($p < 0.05$). Higher frequency of HT1B (G861C) C allele and GRIN2A rs1375067 was observed in cases but the difference was not significant. The remaining markers did not show any change between cases and controls. The COMT rs4680 GG genotype showed association with amount of alcohol consumed (95. 53±13. 49 gms/day) as compared to GA (89. 55±6. 99 gms/day) and AA (61. 73±7. 33 gms/day) genotypes. The 5-HTTLPR short allele SS was significantly associated with increased alcohol intake, WHO ASSIST score and duration of dependence. GRIN2A markers rs11866328 (A allele) and rs1071502 (C allele) showed significant correlation with raised levels of SGOT (77. 63±11. 16; 103. 5±22. 51) and GGT (215±49. 78; 219. 3±55. 04) respectively. **Conclusion:** This is the first report on association of COMT and GRIN2A with alcohol dependence from India. Significantly higher frequency of the markers in patients seems to confer risk for severity of AD in them.

1158T

Identification of ADHD candidate genes in large pedigrees combining linkage analysis and whole-exome sequencing. *J. Corominas-Galbany[1], M. Klein[1], T. Zayats[2], S. Gross-Lesch[3], A. Henkes[1], C. Jacob[3], A. Reif[4], M. Romanos[5], A. Arias Vasquez[1,2,6], K. P. Lesch[3], B. Franke[1,7], IMpACT consortium.* 1) Department of Human Genetics, Radboud university medical center, Nijmegen, The Netherlands; 2) Department of Biomedicine, Bergen University, Bergen, Norway; 3) Department of Psychiatry, Psychosomatics and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany; 4) Department of Psychiatry, Psychosomatics and Psychotherapy, University of Frankfurt am Main, Frankfurt, Germany; 5) Department of Child Psychiatry, Psychosomatics and Psychotherapy, University of Wuerzburg, Wuerzburg, Germany; 6) Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud university medical center, Nijmegen, The Netherlands; 7) Department of Psychiatry, Donders Institute for Brain, Cognition and Behaviour, Radboud university medical center, Nijmegen, The Netherlands.

Attention-Deficit/Hyperactivity Disorder (ADHD) is a common neuro-psychiatric and multifactorial disorder characterized by inattention, and/or motor hyperactivity and impulsivity. This disorder has a complex genetic background hampering the identification of underlying genetic risk factors. The study of multi-generation pedigrees with multiple affected individuals can point towards novel ADHD-related genes. By combining haplotype analysis and whole exome sequencing (WES), we aim to identify genes carrying rare and/or common variants that contribute to ADHD etiology. Three German pedigrees with multiple (adult) ADHD-affected members were used in this study, in which linkage analysis was carried out on the major part of the individuals and WES data from two or more patients were obtained to detect shared genetic variants. Genotyping was performed on Affymetrix Genome-Wide Human SNP Array 6. 0 and SNP data was used to identify haplotype blocks segregating with disease. WES was carried out using Agilent SureSelect All Exon 50Mb Target Enrichment kit and single-end sequencing on the 5500xl SOLiDTM System. Linkage analyses were performed using a Multi-Point analysis implemented in Superlink online SNP 1. 1, for each family independently and by combining them. All regions with a maximum LOD score higher than 2 were selected as a candidate regions. Genes in these regions containing rare and common genetic variants shared among all sequenced individuals were selected as candidate genes. A common problem in multifactorial diseases is that the effect of individual markers is too weak to be detected; consequently, multiple genetic markers may be simultaneously analyzed to increase explained variance. Therefore, gene-set analyses were performed in an independent exome-chip genotyping dataset from 1846 adults with ADHD and 7519 controls (IMpACT consortium). The gene-set from one of the three families indeed showed a significant association with adult ADHD. As no individual gene/variant caused this finding, this suggests that the variants in several of the genes might act together in increasing ADHD risk in the pedigree and the population. The analysis strategy followed here might provide new knowledge for a better understanding of ADHD's genetic basis.

1159F

Novel L1 retrotransposon discovery in schizophrenia exomes. *C. E. Krebs[1], L. Olde Loohuis[2], R. S. Kahn[3], S. de Jong[2,4], R. A. Ophoff[1,2,3].* 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, UCLA, Los Angeles, CA; 3) Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK.

Despite being a highly heritable disease, much of the genetic architecture of schizophrenia remains unknown. In line with a growing body of evidence that neuron-specific LINE-1 (L1) retrotransposition exists in brain and is increased in schizophrenia subjects relative to controls, we utilized an exome sequencing set of 19 schizophrenia pedigrees (n = 78 subjects) to look for novel *de novo* L1 retrotransposon insertions. Using the transposable element discovery tool Retroseq we were able to detect novel L1s within whole-blood exomes of the schizophrenia pedigrees (total = 2862, mean = 29. 8 per subject). The ability to call novel L1s directly depends on the depth of sequencing around the insertion site and indeed L1 count and overall average exome coverage were highly correlated (Kendall's rank correlation, p = 1. 202x10-5). Therefore, in order to properly compare L1 counts across subjects, we subsampled the aligned reads from each subject to normalize coverage at 60x. After repeating the Retroseq analysis on the normalized data, we found no difference between the novel L1 count of probands and unaffected siblings (Wilcoxon rank sum, p = 0. 337). As has been previously reported, L1 insertion sites were biased towards 3' UTRs and depleted in coding exons (χ^2, p = 2. 2x10-16), suggesting negative selection against highly disruptive insertions. Interestingly, as many as half of all novel L1s discovered may be shared between at least two different samples, with some occurring in as many as 78% of all samples, suggesting that there are many L1s that are common in the population but not present in the reference human genome. Future studies with larger sample sizes and more relevant tissue types will be needed to determine if indeed novel L1 retrotransposition plays a role in schizophrenia etiology.

1160W

Exome Sequencing Points to Roles of *De Novo* and Rare Transmitted Mutations in Bipolar Disorder. *N. Matoba[1,2], M. Kataoka[1,3], A. Kazuno[1], K. Fujii[1,4], K. Matsuo[5], JC. Roach[6], A. Takata[1], T. Kato[1].* 1) Lab. for Molecular Dynamics of Mental Disorder, RIKEN BSI, Wako, Saitama, Japan; 2) Dept. of Computational Biology and Medical Sciences, Graduate School of Frontier Sciences, The University of Tokyo, Chiba, Japan; 3) Dept. of Child Neuropsychiatry, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 4) Dept. of Psychiatry, Dokkyo Medical University School of Medicine, Tochigi, Japan; 5) Div. of Neuropsychiatry, Department of Neuroscience, Yamaguchi University of Graduate School of Medicine, Ube, Japan; 6) Institute for Systems Biology, Seattle, Washington, USA.

Although numerous genetic studies have been conducted for bipolar disorder (BD), thegenetic architecture of BD remains elusive. Here we performed a trio-based exomesequencing study for BD to investigate the potential roles of *de novo* and transmittedmutations in the disease etiology. We identified 71 de novo point mutations in 79 BDprobands with a trend toward excess of protein-altering mutations when compared tocontrol subjects in published studies. We also suggest the roles of calcium signaling-relatedgenes from the analysis of variants transmitted to BD probands. We will further discussproperties of genes hit by *de novo* and rare transmitted mutations and potential rolesof these mutations in the pathophysiology of BD.

1161T

Contactin genes *CNTN5* and *CNTN6* code for neuronal cell-adhesion molecules that promote neurite outgrowth in the sensory-motor neuronal pathway. Deleterious mutations of *CNTN5* and *CNTN6* have previously been reported in individuals with autism spectrum disorder (ASD), but their role in the disorder remains unknown. In this study, we screened a cohort of patients with ASD and controls for the presence of deleterious variants in *CNTN5* and *CNTN6* genes. The patients showed enrichment of *CNTN6* deletions (6/1534 ASD vs. 1/8936 controls; P=6x10-5) and private *CNTN6* coding-sequence variants (9/212 ASD vs. 2/217 controls; P= 0. 03). Two *CNTN6* deletions were transmitted from fathers with ASD and one CNTN6P770L variant was *de novo*. *CNTN5* deleterious variants were also identified including a patient carrying five copies of *CNTN5*, but not significantly enriched in ASD. Using a co-culture cellular assay and protein structure modeling, we found that several CNTN5 and CNTN6 variants either decreased or increased neurite length and branching compared with wild-type proteins, and could induce changes in the local structure of the protein. Clinical investigation of the patients carrying CNTN5/6 variants showed that they suffer from hypersensitivity to sounds (hyperacusis) and display with subtle changes in wave latency within the auditory pathway. These results reinforce the hypothesis of abnormal neurite outgrowth in the pathophysiology of ASD and shed new light on the genetic susceptibility to abnormal sensory perception in ASD.

1162F

Identification of five obsessive-compulsive disorder genes utilizing animal models, evolutionary constraints and regulatory information. *H. Noh[1], R. Tang[1,2], E. Karlsson[1,3], R. Swofford[1], J. Genome-wide association studies (GWAS) have identified many risk loci for mental disorders, yet the heritability is largely unexplained. It is now evident that numerous variants contribute to the susceptibility, hampering the identification of all the risk genes by typical GWAS and with attainable sample sizes. Here, we employ a systematic model-driven approach that reduces the genetic search space for obsessive-compulsive disorder (OCD). OCD manifests in repetitive behaviors and intrusive thoughts, affecting 1-3% of humans. It is highly heritable (h2=0. 45-0. 65), yet no genes have been confidently found. Natural canine OCD is an ideal model for human OCD. As in humans, canine OCD is multigenic, and manifests in repetition of normal behaviors, e. g. tail chasing and flank sucking derived from predation and suckling, respectively. Drug response and onset age are also equivalent. Moreover, the limited genetic background within breeds aids gene mapping, allowing us to identify GWAS loci using <100 cases. Murine models are less similar as it is monogenic. Still, neurological examination consistently implicates the cortico-striatal-thalamo-cortical (CSTC) circuit in compulsive grooming. We sequenced coding and noncoding regions of 608 genes from canine OCD GWAS and the CSTC circuit in ~600 DSM-IV OCD and ~600 healthy individuals of European ancestry. We performed gene-based tests of all, coding and regulatory variants separately, and found five significantly associated genes for OCD. We found *NRXN1* and *HTR2A* with excess coding variants, *CTTNBP2* and *REEP3* with excess regulatory variants, and *LIPH* with overall excess variants, suggesting different genes harbor different types of OCD variation. Overall, we found a burden of variants in synaptic adhesion and maintenance pathways for OCD. Gel shift assays on candidate variants in *CTTNBP2* and *REEP3* identified six that alter DNA-protein binding in neuroblasts. We are now validating the associations for 90 SNPs in an independent cohort. Our method utilizing evolutionary and regulatory information is being assessed on the whole genome sequence (WGS) from other disorders for broader application. In conclusion, coding and noncoding variants are both critical to OCD, but may affect different genes. Our work provides a powerful framework for coding and noncoding variant analysis that is vital to WGS data. Lastly, our comparative approach, guided by natural and artificial models, identified novel genes and pathways for OCD.

1163W

Exome Sequencing in Multiplex Families with Bipolar Disorder Reveals Circadian Signaling Pathways. *S. Ramdas[1], A. B. Ozel[2], K. W. Walker[2], M. Burmeister[2], J. Z. Li[2].* 1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Bipolar disorder (BPD) is a psychiatric disease characterized by alternating manic and depressive episodes. Twin and family studies have shown that BPD is highly heritable, with a heritability estimate of greater than 0. 7. However, extensive genetic and phenotypic complexity remains a major barrier to identifying its genetic basis. We hypothesize that multiplex BPD families manifest a highly penetrant subset of bipolar cases and may transmit one or more high-impact coding variants that alter the function of key neurodevelopmental or neural signaling genes. In this study we focus on 34 multi-generational multiplex families in the NIMH repository with BPD Type I. We have genotyped all available members in these families, and performed exome sequencing in 90 affected individuals representing first cousins or more distant relatives, aiming to identify functional variants that are rare in the general population but are shared by affected relatives. In the event of locus heterogeneity, linkage analysis has reduced power due to ineffective accrual of positional signals across families. However we test the hypothesis that there are shared functional perturbations across families and that such evidence accumulates quickly even in the presence of locus heterogeneity. We first filter variants by population frequency, functional annotation, frequency in control databases, and segregation in each family to obtain a list of 302 putative genes, or an average of 9 genes per family. We then analyze recurrence patterns of genes across families and find some previously implicated genes mutated across multiple families, including PCNT and TNXB. Pathway analysis of the 302 genes reveals enrichment of the circadian rhythm signaling pathway, which has been previously implicated in BPD. We also analyze publicly available brain expression data to identify co-expressed pairs of genes in different brain regions at different stages of development. Among our 302 genes, we find a suggestive enrichment of co-expressed gene pairs in infancy. Our results point to a functional convergence in the genetic signal across families, though further studies are needed to narrow in on the causal genes in each family.

1164T

Unique Psychiatric and Non-Psychiatric Phenotypic Characterizations in relation to Copy Number Variants (CNVs) in a Schizophrenia Cohort. *V. Sriretnakumar[1, 2], C. Zai[1, 4], M. Maciukiewicz[1, 4], J. So[1, 2, 3], J. Kennedy[1, 4].* 1) Neurogenetics Lab, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada; 3) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network and Mount Sinai Hospital, Toronto, Ontario, Canada; 4) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada.

Increasing evidence supports the significance of copy number variants (CNVs) in the genetic contribution to psychiatric illnesses, particularly schizophrenia (SCZ). This study utilizes a robust approach to uncovering genetic variants within the heterogeneity of SCZ by delineating correlations between CNV data and extensive phenotypic data in SCZ patients. Phenotypic and CNV data of 348 SCZ patients were collected from medical history records and Affymetrix SNP Array 6. 0 assay, respectively. The number of autosomal, X-linked and total CNV counts were plotted against phenotypic characteristics in probands and proband's family history. Independent t-tests, Fischer's exact test, Pearson/Spearman correlations, and Bonferroni multiple testing corrections were performed among the various categories to identify significant associations.

The presence of head injury in probands is associated with the number of autosomal CNV duplications (p=0. 0449) and deletions (p=0. 0490). Suicide attempt in probands was also associated with the number of autosomal CNV duplications (p=0. 0088), deletions (p=0. 0450), the total number of CNVs (p=0. 0274). Genetic associations of head injury and suicide attempt in probands did not reach statistical significance after correction for multiple testing. However, there are significant associations between suicide attempt in proband's family history and the number of autosomal CNV duplications (p=0. 0017), deletions (p= 0. 0016), and the total number of CNVs (p=0. 0130). Trends were also seen between X-linked CNVs and age of onset of SCZ in probands; history of substance abuse in proband's family history; and digestive system disorders in probands. All X-linked associations did not survive sex correction.

These results suggest a strong association between CNV burden and specific phenotypic presentations in the SCZ patient population. This is compatible with the ever-increasing number of microdeletions and microduplications found to be associated with neurodevelopmental disorders, and our findings may contribute to expanding the neuropsychiatric phenotypes associated with these genetic variants. Sample size and power will be increased by genotyping the remaining individuals in this cohort to detect smaller effect sizes. Further analyses will be undertaken to define specific CNVs and genes contained within the implicated CNV regions to better characterize potential genetic effects on the phenotypic presentation of SCZ patients.

1165F

Using exome sequencing to identify rare, *de novo* mutations in Tourette Syndrome families. *D. Yu[1,2], A. Huang[3], K. Samocha[1,2], V. Ramensky[3], M. Lek[1,2], L. K. Davis[4], D. MacArthur[1,2], N. J. Cox[6], N. B. Freimer[3], C. A. Mathews[5], B. M. Neale[1,2], G. Coppola[3], J. M. Scharf[1,2], Tourette Syndrome International Consortium for Genomics.* 1) Massachusetts General Hospital, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Semel Institute, University of California at Los Angeles, Los Angeles, CA; 4) University of Chicago, Chicago, IL; 5) Langley Porter Psychiatric Institute, University of California at San Francisco, San Francisco, CA; 6) Vanderbilt University, Nashville, TN.

Tourette Syndrome (TS) is a highly-heritable, childhood-onset neuropsychiatric disorder characterized both by neurological and psychiatric symptoms. Despite its strong familiality, identification of definitive TS susceptibility genes has been challenging. We and others have previously demonstrated that a subset of individuals with TS can harbor large, rare *de novo* deletions or duplications in regions of the genome previously associated with recurrent, pathogenic copy number variation in neurodevelopmental disorders that overlap phenotypically with TS, including ADHD and autism-spectrum disorder (ASD). Here, we examine the role of *de novo* coding variation in TS pathogenesis using exome sequencing in 180 TS parent-proband trios. Exome sequencing libraries were generated using the Agilent SureSelect Broad v1. 1 targeted capture kit for 149 parent-proband trios at the Broad Institute and Nimblegen EZ-Cap v3. 0 for 37 trios at UCLA. Paired-end sequencing was conducted using the Illumina HiSeq at both institutions to a minimal read depth of 90% at 10x. Sequence processing for all samples was conducted at the Broad Institute using Picard, and joint calling of all 558 samples was performed using GATK 3. 1. After removing poor quality samples, 180 trios remained for analysis. *De novo* variants were identified and evaluated using a probability of de novo (Prob_dn) metric based on allele balance, allele frequency, read depth, Phred score, and expected *de novo* rate in the generation population. Subsequent QC filters were applied on proband allele balance (AD>0. 2 and <0. 8), allele count (AC<2 if AD<0. 3 or AD>0. 7), andProb_dn (>0. 5). Nineteen *de novo* loss of function (LoF) mutations were identified after QC, including 8 SNV and 11 indel *de novo* LoFs which were validated by Sanger sequencing; this *de novo* rate was not significantly higher than expectation (0. 106 per trio vs. 0. 087 per trio, p=0. 24). 122 missense *de novo* variants (120 SNVs and 2 indels) and 51 synonymous SNV *de novo* variants were called, and no enrichment above expectation was found. Enrichment of *de novo* LoF and missense variants from the 180 TS trios was examined for 107 previously reported ASD genes, FMRP interacting genes, genes enriched at the post-synaptic density, and genes under high evolutionary constraint, with no significant enrichment observed. Combined analysis with a parallel sample of 216 independent TS trio exomes sequenced at Yale University will be presented.

1166W

Novel gene identification in familial Alzheimer's disease. *J. Rehker[1], R. Nesbitt[1], A. Patowary[1], B. K. Martin[2], E. A. Boyle[2], J. Shendure[2], Z. Brkanac[1].* 1) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA.

Alzheimer's disease (AD) is the most common cause of dementia in US, affecting approximately 5% of individuals older than the age of 70. In addition to highly penetrant rare variants in APP, PSEN1 and PSEN2, rare variants in TREM2, PLD3 and ABCA7 have recently been recognized as contributing to AD. The ApoE4 allele, which is relatively common, is a significant contributor to AD. Whole genome association studies have identified approximately a dozen common low-risk genes associated with the disease that collectively have impact smaller than APOE4. It is likely that additional rare variants contributing to AD remain to be found. To identify additional rare variants contributing to AD, our approach was focused on 14 families from NIA and NIMH AD collections with 3 or more affected individuals. For each family, one or more of the affected subjects were second-degree relatives. Our analytical approach was tiered, with the aim to evaluate private variants first, followed by analysis of rare variants. As a consequence of this approach we obtained exome sequence on the most distantly related cases in each family and genomewide genotyping for all cases. We previously reported the analysis of private variants shared among cases (J. Rehker et all. , Rare highly penetrant variants of late onset Alzheimers disease; Program #295. ASHG annual meeting, October 25 2013, Boston, MA). In order to expand our analysis to rare variants of 1% or less, we employed linkage analysis to narrow regions shared by all affected cases. We have focused on protein changing variants (missense, frameshift, stop, and splice). For genotyping in families we used Illumina Human Exome arrays that include a backbone of linkage markers. The linkage analysis and haplotyping were performed using MERLIN and HAPLOPAINTER. We have used a tiered approach to identify candidate variants. If all affected subjects did not share any rare variants, we excluded subjects with APOE4/4 genotype and subjects without pathology confirmation of AD diagnosis. This resulted in the identification of 10 novel candidate genes. In order to provide a statistical support for involvement of the identified candidate genes with AD, we are performing targeted sequencing and gene based association analysis of 980 familial cases and elderly controls. The results of our linkage and association analyses will be presented at the conference.

1167T

Mutations in *PTRH2* cause infantile-onset multisystem neurologic, endocrine, and pancreatic disease (IMNEPD). *C. Hu[1,2], M. Matter[3], L. Issa-Jahns[4], S. Picker-Minh[4], M. Jijiwa[3], N. We characterized a consanguineous family of Yazidian-Turkish descent with IMNEPD. The two affected children suffer from intellectual disability, postnatal microcephaly, growth retardation, progressive ataxia, distal muscle weakness, peripheral demyelinating sensorimotor neuropathy, sensorineural deafness, exocrine pancreas insufficiency, hypothyroidism, and show signs of liver fibrosis. We performed whole-exome sequencing followed by bioinformatic analysis and Sanger sequencing on affected and unaffected family members. We identified a homozygous frameshift mutation in the previously not disease-associated peptidyl-tRNA hydrolase 2 (*PTRH2*) gene. *PTRH2* encodes a primarily mitochondrial protein involved in integrin-mediated cell survival and apoptosis signaling. We show that *PTRH2* is highly expressed in the developing brain and is a key determinant in maintaining cell survival during human tissue development. Moreover, we link *PTRH2* to the mTOR pathway and thus the control of cell size. The pathology suggested by the human phenotype and neuroimaging studies is supported by analysis of mutant mice and patient fibroblasts. The diagnosis of this family was recently substantiated by another three cases with similar manifestations and molecular etiology.

Modeling the association between loss-of-function *GBA1* mutations and synucleinopathies with *in vivo* mouse models. *N. Tayebi[1], A. Gonzalez[1], B. Giasson[2], B. Berhe[1], M. Brooks[2], N. Trivedi[3], A. Elkahloun[4], R. Petralia[5], E. Sidransky[1].* 1) Molecular neurogenetics section/MGB/NHGRI, National Institutes of health, Bethesda, MD; 2) Department of Neuroscience, Center for Translational Research in Neurodegenerative Diseases, University of Florida, Gainesville, FL, 32610, USA; 3) Computational and Statistical Genomics Branch, National Human Genome Research Institute, NIH, Bethesda, Maryland, USA; 4) Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, NIH, Bethesda, Maryland, USA; 5) Advanced Imaging Core, National Institute on Deafness and Other Communication Disorders, NIH, Bethesda, Maryland, USA.

Gaucher disease (GD), the recessively inherited deficiency of glucocerebrosidase (GCase) is caused by mutant *GBA1.* Missense and loss-of-function mutations in *GBA1* are common genetic risk factors for Parkinson disease (PD). To model this association, we crossed transgenic mice hemizygous (hemi) or homozygous (homo) for human mutant A53T α-synuclein (A53Tα-syn) with mice carrying a loss-of-function null *gba* allele (wt/χMGC). The resulting wt/χMGC//A53Tα-syn mice overexpressing A53Tα-syn and carrying a null *gba* allele, were compared to control groups (wt/wt, wt/A53Tα-syn and wt/χMGC) to elucidate the effect of GCase deficiency on the progression of neurological impairment in PD. Mice were followed for up to 2 years and were euthanized with their respective controls when symptomatic**.** Weight loss was the initial sign of illness, followed by arching of the back, impaired axial rotation, and limb paralysis. Survival analysis of 84 mice showed that wt/χMGC//A53Tα-syn hemi and homo mice exhibit symptoms on average 9. 76 weeks and 4. 04 weeks earlier than A53Tα-syn hemi and homo controls, respectively (p-values 0. 023, 0. 0030). Further, the wt /χMGC//A53Tα-syn mice had a more rapid disease progression than A53Tα-syn mice (p-value <0. 0001). Quantification of α-syn aggregates in the pons of 17 mice showed no significant effect of carrying the χMGC allele. GCase protein levels and activity in wt/χMGC//A53Tα-syn mice reflected haploinsufficiency of *gba,* but no added effect due to A53Tα-syn was seen and α-syn levels in A53Tα-syn mice with and without χMGC were similar. To identify other genes involved in this association, a whole transcriptome array was performed on brains of the crossed lines, revealing differences in PRNP (p-value: 3. 22*10-12; fold change: 3. 6), SERPINA3 (1. 71*10-6; 4. 7), and MMRN1 (1. 53*10-7; 4. 7), confirmed by real-time PCR. Interestingly, H2-T10 (3. 37*10-12; 6. 98) was up-regulated in only wt/χMGC//A53Tα-syn mice, suggesting its contribution to the earlier and more severe phenotypes observed. This gene is homologous to *MHC-1* in humans. Evaluation of LIMP-2, PSAP, P62 and Cathepsin-D RNA expression showed no differences. Ultrastructural and immunohistochemical evaluations of striatum, substantia nigra and midbrain indicate more microgila activation and astrogliosis in wt/χMGC//A53Tα-syn mice. These data suggest that haploinsufficiency of GCase impacts disease onset and severity in the A53Tα-syn model, and may be related to acute brain inflammation.

Transcriptomic analysis reveals convergent molecular pathways during the development of neurons derived from patients with idiopathic autism. *B. A. DeRosa[1,2,3], K. C. Belle[1,2,3], C. Garcia-Serje[1,3], H. N. Cukier[1,3], J. M. Lee[1,3], M. L. Cuccaro[1,2,3], J. P. Hussman[4], J. M. Vance[1,2,3], M. A. Pericak-Vance[1, 2, 3], D. M. Dykxhoorn[1,2,3].* 1) John P. Hussman Institute for Human Genomics; 2) Dr. John T. MacDonald Foundation Department of Human Genetics; 3) University of Miami Miller School of Medicine, Miami, FL; 4) Hussman Institute for Autism, Baltimore, MD.

Recent studies have shown that genes harboring autism spectrum disorder (ASD) risk loci are highly enriched in sets of genes expressed during early neocortical development and genes encoding proteins that function in specific biological pathways involving regulation of transcription, chromatin remodeling, cell adhesion, signaling complexes, and synapse function. These findings raise the possibility that common molecular etiologies underlie pathogenesis in subsets of individuals with idiopathic autism. Patient-specific induced pluripotent stem cells (iPSCs) present a unique opportunity to examine the hypothesis that heterogeneous ASD loci converge on specific molecular pathways during early neuronal development. Therefore, we generated patient-specific iPSC lines from 6 unrelated ASD individuals with rare variants identified through exome sequencing in extended multiplex families. The patient-specific iPSCs, in addition to iPSCs derived from unrelated control individuals, were differentiated into cortical neurons and transcriptome analysis using RNA-seq was performed on the neurons at three time points over a 135 day time course of their *in vitro* development. Pathway and gene ontology (GO) analysis was performed on the set of differentially expressed (DE) genes identified in the transcriptome data. Our results implicate disturbances in the regulation of transcription, WNT signaling, chromatin remodeling, cell adhesion and migration, and synapse development across all time points analyzed. Interesting patterns emerge from the differences in expression between analyzed time points. To highlight some of these findings, specific pathways enriched in early neurons (day 35 *in vitro*) include those involving WNT/MET signaling ($p = 4.95\times10\text{-}36$), and collagen catabolism ($p = 7.41\times10\text{-}09$). DE genes in midpoint neurons (day 85 *in vitro*) map to pathways involving cell migration ($p = 1.34\times10\text{-}06$) and GABAergic neuron signaling transmission ($p = 2.86\times10\text{-}09$). In later time point neurons (day 135 *in vitro*), DE genes are enriched in pathways involving WNT-mediated axon guidance ($p = 4.71\times10\text{-}05$), calcium signaling ($p = 8.92\times10\text{-}20$), and chromatin remodeling ($p = 1.49\times10\text{-}24$). These results provide functional evidence that common molecular etiology underlies pathogenesis in ASD and suggest a temporal order to the disturbance of cellular functions during neuronal development.

Dynamic regulation of RNA-editing in human brain development. *T. Hwang[1,2], J. H. Shin[2], D. R. Weinberger[2].* 1) Johns Hopkins University, Baltimore, MD; 2) Lieber Institute for Brain Devleopment, Baltimore, MD.

RNA-editing is the co-transcriptional process perturbing RNA sequences. In humans, the most prevalent form of RNA-editing is the single nucleotide change of adenosine to inosine ("A-to-I editing"), which is known to play a critical role in ion channel genes such as GRIA2 (GluR2) and HTR2C (5-HT2CR). In this study, we pursued comprehensive RNA editing profiles in human brain, the tissue with the most active RNA-editing activity, by applying next generation sequencing technologies to post-mortem tissues spanning from fetus to adult life. We have also developed robust computational tools to identify RNA-editing events. More than 50,000 reliable RNA editing events were identified and random examples were validated with both of DNA and RNA sequencing, including known and novel RNA-editing in protein-coding sequences and untranslated regions of mRNA. The genome-wide landscape of RNA-editing also reveals dynamic regulation of RNA-editing, which consists of three patterns: consistently high-edited, consistently low- edited and increasingly-edited across cortical development. Surprisingly, the dynamic pattern is brain-specific and accompanies temporally the growth and elaboration of cortical circuitry. The secondary structures of RNA and the temporal pattern of A-to-I RNA editing enzyme, ADAR (adenosine deaminase acting on RNA) expression determine cis- and trans- regulatory mechanisms of RNA-editing patterns, respectively. Finally, we confirm that developmentally-regulated RNA-editing is specifically involved in the development of cortical layers through glutamate signaling and vesicle/organelle membrane genes. Overall, our findings provide new insight into the understanding of RNA-editing, one of mechanisms expanding sequence diversity, in human brain development.

1171F

Longitudinal RNA-seq analysis of Parkinson's disease patient-derived dopaminergic neurons. *K. C. Belle[1 2 3], A. Mehta[1], K. Nuytemans[1 3], B. A. DeRosa[1 2 3], J. M. Vance[1 2 3], D. M. Dykxhoorn[1 2 3].* 1) Human Genetics and Genomics, Univeristy of Miami, Miami, FL; 2) Dr. John T. MacDonald Foundation Department of Human Genetics; 3) University of Miami Miller School of Medicine, Miami, FL 33136, United States.

Parkinson's disease (PD) is a progressive neurodegenerative disease characterized by the loss of dopaminergic neurons in the substantia nigra. While disease symptoms present themselves later in life, and progress in severity, it remains an open question when the antecedent dysfunction that leads to cell death and loss of motor function takes place. To initiate our investigation of this question, we differentiated induced pluripotent stem cells (iPSCs) derived from two Parkinson's patients (α-synuclein triplication and idiopathic patient) and two aged-matched controls, into midbrain dopaminergic neurons (mDAns) and performed RNA sequencing at different time points. *W*e hypothesized that as the differentiation of these lines progresses, a convergence on to common pathways and networks that drive the pathogenesis of PD phenotypes would be observed. RNA from differentiated cultures was harvested at three time points: 20 days (d20), 45 days (d45), and 120 days (d120) post-differentiation. RNA sequencing data was analyzed on a case vs control basis at each time point generating a list of differentially expressed genes that was then analyzed for enrichment in biological pathways or functions through gene set enrichment analysis *(GSEA).* GSEA of the d20 time point sequence noted differential expression between cases and controls in the neuronal developmental pathways, including Sonic Hedgehog, Notch, and TGF-b, all of which are involved in the differentiation of mDAns. In our next time point, d45, we observed similar differences in developmental pathways with the addition of the cytokine-cytokine interaction pathway. Initial pathway analysis of the differentially expressed genes between cases and controls at time point d120 revealed the involvement of multiple disease-related pathways with nominal significance; including mitochondrial protein targeting, mitochondria signaling of apoptosis, cell structure disassembly during apoptosis, and caspase cascade in apoptosis. These results suggest that next generation sequencing of RNA from iPS neuronal cultures has the potential to help understand how genetic variation associated with PD affects function and leads to disease. Additional samples and investigation of older iPS culture times are currently underway.

1172W

Disruptions to the miRNA regulatory pathway may cause an increased rate of schizophrenia in individuals with 22q11. 2 DS. *W. Manley[1], S. Siecinski[1], S. Ryan[1], V. Coulibaly[1], S. Buyske[1,2], L. M. Brzustowicz[1].* 1) Department of Genetics, Rutgers University, Piscataway , NJ; 2) Department of Statistics & Biostatistics, Rutgers University, Piscataway, New Jersey.

Schizophrenia is a complex and poorly understood disease caused by the interplay of many environmental and genetic factors. The 22q11. 2 deletion syndrome (DS) is a disorder that is caused by the microdeletion of part of chromosome 22 leading to a 25-fold greater chance of developing schizophrenia in affected individuals versus the general population. The missing 22q11. 2 region contains DGCR8, which is required for the initial step of miRNA biogenesis. However, the 22q11. 2 deletion itself is not directly the cause of schizophrenia, since 75% of individuals with this deletion do not develop the disease. We hypothesize that the 22q11. 2 deletion increases the risk of schizophrenia through alterations in miRNA regulatory networks via depletion of several miRNAs. This may serve as a protective buffer against the accumulation of deleterious mutations at other schizophrenia risk loci. We have derived human neural stem cells (NSCs) from individuals with the 22q11. 2 deletion and schizophrenia. The NSCs were generated from iPSCs using Neural Induction Media (Life Technologies). In order to ensure the presence of the 22q11. 2 deletion, a FISHprobe for 22q11. 2 (TUPLE) was used (Cell Line Genetics). Also, the levels of DGCR8 gene expression were quantified using the 7900HT Fast Real-Time PCR System (Applied Biosystems) along with Taqman Gene Expression Assays and Copy Number Assays to ensure DGCR8 reduction in 22q11. 2 DS NSCs relative to otherwise healthy control NSCs. We have characterized disruptions to the miRNA regulatory network in the NSC lines using Taqman Array Human Microarray Cards Version 3. 0. Here we will present the miRNAs that we have identified to be differentially expressed in otherwise healthy control NSCs versus NSCs with 22q11. 2 DS and schizophrenia. Our data shows that of the 377 tested miRNAs, nearly 30% have at least a 2 fold expression change in deletion samples. We predict that these miRNAs could be involved in the elevated risk of developing schizophrenia in individuals with 22q11. 2 deletion syndrome versus the general population. Future studies will focus on determining the biological targets of these miRNAs using miRNA target prediction software.

1173T

Neurodevelopmental disorders linked to damages in ARX-KDM5C path. *A. Padula[1], L. Poeta[1], A. Ranieri[1], C. Shoubridge[2], C. Trimarco[1], J. Gecz[2], J. Dupont[3], C. Schwartz[4], H. vanBokhoven[5], M. G. Miano[1].* 1) Institute of Genetics and Biophysics, CNR, Naples, Naples, Italy; 2) Department of Paediatrics, University of Adelaide, South Australia 5006, Australia; 3) Hospital de Santa Maria, Lisbon 1649-035, Portugal; 4) Greenwood Genetic Center, Greenwood, South Carolina, 29646, USA; 5) Radboud University Nijmegen Medical Centre, 6500 HB, Nijmegen, The Netherlands.

Studying molecular convergence in neurodevelopmental disorders caused by mutations in specific disease-related genes permits us to define druggable molecular pathways. The purpose of our study is to assess the degree of damage associated with the ARX-KDM5C interaction and to establish a correlation between similar phenotypes and same cellular functions. Mutations in Aristaless-related homeobox gene (*ARX*), a homeotic transcription factor with a key role in interneuron maturation, have been found in a spectrum of X-chromosome phenotypes including cortical malformations, chronic Epilepsy and X-Linked Intellectual Disabilities (XLID). About Lysine-specific demethylase 5C (*KDM5C*), its mutations have been reported as an important cause of XLID. Its protein is a histone demethylase acting as transcriptional repressor during brain development. Here we summarize *in vitro* functional analysis of two classes of ARX mutations by studying the impact on the stimulation of *KDM5C*, already reported by us as an ARX disease-target gene: 1. PolyAlanine elongations affecting the first and the second PolyA tracts, frequently found in patients with Epilepsy or XLID; and 2. Missense mutations clustered in the paired-type homeodomain (HD) found in patients with Lissencephaly with abnormal genitalia (XLAG). We have proven that PolyAlanine elongations are partial loss-of-function mutations that impair the activation of *KDM5C* transcription; while HD missense mutants are loss-of function alterations, which abolish the transcriptional activity attributable to the WT protein. Moreover, in patient-derived LCLs mutated in the ARX-KDM5C path, we have found a KDM5C reduction in coupling with a global increase of H3K4me3 signalling, potentially due to a compromised KDM5C activity. Since H3K4me3 is the hallmark of open chromatin, ARX-dependent KDM5C defects could compromise chromatin remodelling. Taken in consideration these results, we propose a *"fault-disease model"* showing that the degree of spectrum of KDM5C defects correlate with the severity of the neurophenotypes associated with ARX mutations. Starting from these data, we reason that modelling ARX and KDM5C defects in the identical stem cell line might allow us to assess the degree of molecular convergence caused by altered dosage of these two disease-related genes and the validation of potential drugs that could compensate KDM5C-H3K4me3 deregulation.

1174F

Human neuronal stem cell line validated as *in vitro* genomic model for studying neurodevelopmental disorders. *A. P. S. Ori[1], M. H. M. Bot[1], R. T. Molenhuis[2], R. A. Ophoff[1,3].* 1) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, California, USA; 2) Department of Translational Neuroscience, Brain Center Rudolf Magnus, University Medical Center Utrecht, The Netherlands; 3) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California, USA.

Large-scale genetic studies of neuropsychiatric disorders have identified hundreds of susceptibility alleles. The functional characterization and elucidation of pathways underlying these diseases present a major next challenge, especially for neurodevelopmental disorders such as schizophrenia and autism spectrum disorder. Therefore in order to address this, we established and examined an *in vitro* model to study neurodevelopment that allows for standardized gene manipulation and functional characterization using genomic approaches. We differentiated H9 human neuronal stem cells towards mature neurons over a period of 30 days and collected gene expression profiles at seven time points in triplicates. Using a machine learning approach we demonstrate that the observed *in vitro* gene expression profiles significantly match *in vivo* human neurodevelopmental stages and cellular laminae of human cortical regions. Using an empirical Bayes approach, we identified 25% of genes to be significantly differentially expressed during the 30 days of development. By subsequent fuzzy c-means clustering with bootstrapping, 10 high confidence clusters of genes with distinct expression patterns were distinguished. Biological annotation of these clusters highlight specific pathways and mechanisms important for neuronal differentiation. As expected, clusters representing neuronal processes show a clear increasing expression pattern over time while cell cycle and DNA replication processes show the opposite. Additional clusters with distinctive patterns are enriched for transcription factors, DNA binding proteins, and immune and defense response processes. The latter cluster highlights potential limitations of known pathway databases as genes can have multiple functions depending on time and location of expression and unknown functions cannot be annotated. Finally, genes differentially expressed over time are significantly enriched for genes associated to psychiatric neurodevelopmental disorders, such as schizophrenia (by permutation, P = 0. 048). Taken together, our results validate *in vitro* modeling of human *in vivo* neurodevelopment and identify key biological pathways and overall emphasize its relevance to study disease mechanisms.

1175W

BRAINCODE: How does the Human Genome Function in Specific Brain Neurons? *X. Dong[1], Z. Liao[1], D. Gritsch[1], B. Guennewig[2], Y. Hadzhiev[3], Y. Bai[1], G. Liu[1], B. Zheng[1], C. Blauwendraat[4], Q. Hu[1], C. H. Adler[5], J. C. Hedreen[6], M. P. Frosch[7], R. Faull[8], P. T. Nelson[9], J. Locascio[1], C. Vanderburg[7], P. Rizzu[4], A. A. Cooper[2], P. Heutink[4], T. G. Beach[10], F. Mueller[3], J. S. Mattick[2], C. R. Scherzer[1].* 1) Harvard Medical School and Brigham & Women's Hospital, USA; 2) Garvan Institute of Medical Research, Australia; 3) University of Birmingham, UK; 4) German Center for Neurodegenerative Diseases, Germany; 5) Mayo Clinic, USA; 6) McLean Hospital, USA; 7) Massachusetts General Hospital, USA; 8) University of Auckland, New Zealand; 9) University of Kentucky, USA; 10) Banner Sun Health Research Institute, USA.

The human brain comprises ~86 billion neurons whose function is central to human biology. How does the human genome program high performing neurons and neural networks in response to experience? What subprograms does the genome express in physiologically and morphologically distinct brain cells? The goal of the **BRAIN C**ell encycl**O**pe**D**ia of transcribed **E**lements Consortium (**BRAINCODE**) is to provide a comprehensive map of actively transcribed elements, both protein-coding and non-coding, from specific cell types, not in culture, but directly isolated from human brains. Going beyond traditional mRNA sequencing, *all* polyadenylated *and* non-polyadenylated transcripts over 50bp were ultra deeply sequenced using ribo-depleted total RNA from 50,000 neurons laser-captured from more than 130 human post-mortem brains yielding 23 terabytes of reads. Three prototypical neuron types, dopamine neurons, pyramidal neurons, and Betz cells, were prioritized because of their key biological roles and differential vulnerability to important neurodegenerative diseases such as Parkinson's or Alzheimer's disease. Genetic variation between individuals was examined for correlation with differences in transcribed sequences to identify genomic regions that influence whether, how, and how much a transcript is expressed in specific cell types in human brains. Initial results indicate a vast universe of annotated and novel non-coding RNAs expressed in brain cells and suggest a more diverse and much more complex transcriptional architecture than previously imagined. Support: NINDS U01 NS082157; U. S. Department of Defense; Michael J. Fox Foundation; U24 NS072026; P30 AG19610; P30 AG028383; NHMRC 631668.

The expression of long non-coding RNA *ANRIL* do not affected by Vitamin D treatment in Multiple Sclerosis patients. *M. Pahlevan Kakhki, M. Behmanesh.* Tarbiat Modares University, Tehran, Tehran, Iran.

Multiple sclerosis (MS [MIM 126200]) is an inflammatory disease in the central nervous system (CNS) which cause some disabilities in the young adults. Many family and twin studies showed that environmental and genetics factors are involved in the pathogenesis of MS. Antisense noncoding RNA in the *INK4* locus (*ANRIL*[MIM 613149]) gene is located at chromosome 9p21 which its product is a functional RNA molecule that interacts with polycomb repressive complex-1 (PRC1) and -2 (PRC2), leading to epigenetic silencing of other genes. This region is a significant genetic susceptibility locus for cardiovascular disease, and has also been linked to a number of other pathologies, including several cancers, intracranial aneurysm, type-2 diabetes, periodontitis, Alzheimer's disease, endometriosis, frailty in the elderly, and glaucoma. Here we are tried to assess the expression level of *ANRIL* in RRMS patients after 8 weeks treatment with vitamin D. 30 Iranian RRMS patients were clinically diagnosed according to McDonald's criteria. Also, we selected 30 age and gender matched controls. All patients received 50,000 IU vitamin D3 every week as an intra-muscular injection for 8 weeks. The vitamin D levels were estimated by 25-hydroxyvitamin detection kits of ELISA before and after supplementation. Five ml whole blood were obtained and PBMCs harvested using Ficoll solution, RNA extracted by Trizol reagent, and real time PCR was performed by Step One ABI system using specific primers. ΔΔct method was used for the analysis of gene expression results. The investigation was performed in keeping with the Helsinki declaration on research with human participant. Also, this trial was approved by the institutional ethical committee and was registered with Iranian Registry of Clinical Trials (ID: IRCT2014011216181N1) and medical ethics committee of Tarbiat Modares University. Our data showed that the expression level of *ANRIL* does not affected by the treatment of vitamin D after 8 weeks (p=0. 9). Moreover, we don't find any differences in the expression level of *ANRIL* gene in RRMS patients before and after vitamin D treatment (p=0. 217 & p= 0. 226 respectively) in comparison with healthy controls. In conclusion, based on our best knowledge, this is the first report which evaluate the expression level of long non coding RNAs specially *ANRIL* in multiple sclerosis patients under vitamin D treatment which is under elaborate investigation in our laboratory.

1177F

Oligogenic inheritance in families with amyotrophic lateral sclerosis and frontotemporal dementia. *S. M. K. Farhan[1], M. J. Strong[2], R. A. Hegele[1].* 1) Biochemistry, Robarts Research Institute, Western University, London, Ontario, Canada; 2) Department of Clinical Neurological Sciences, Western University, London, Ontario, Canada.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease that currently affects ~3,500 people in Canada and has a global prevalence of >500,000 cases. Although ALS is classified as a rare disease, it is the most common motor neuron disease in adults and is characterized by degeneration of motor neurons, which often leads to progressive weakening of limb, bulbar, and respiratory muscles and is ultimately fatal, typically within 3-5 years of onset. There are two forms of ALS: familial and sporadic, which differ in their etiology but are clinically indistinguishable. Approximately, 5-10% of ALS cases are familial however, this number seems to be growing as more pedigrees are studied. We have independently ascertained four large, unique families with familial ALS and FTD across five generations. In one family, affected individuals present with primarily ALS while in the others, ALS is accompanied with FTD and in some individuals, severe psychiatric anomalies such as agitation, hypersexuality, and psychosis. In one family, five distinct phenotypes are observed: ALS, FTD, Parkinson's disease, Alzheimer's disease, and myelopathy with degenerative disc disease. A full family history, blood and when available, brain and spinal cord samples were collected. All participating individuals were assessed using a screening neurological examination and the Montreal Cognitive Assessment. Because next-generation sequencing (NGS) allows for efficient genetic variant detection, we have used a NGS based assay enriched for neurodegenerative disease genes to identify variants contributing to the phenotypes observed in these families. We have identified several, distinct mutations in these families that may explain the spectrum of neurodegenerative phenotypes observed. We are currently investigating whether these genetic variants work synergistically to give rise to the phenotype or modify large-effect mutations consistent with an oligogenic inheritance disease model. Finally, we plan to study some of the genetic variants in biological systems to recapitulate aspects of the disease providing further evidence for gene based disease expression. We present one of the first examples of an oligogenic inheritance disease model in familial ALS and FTD using a targeted NGS method. These approaches allow us to explain the complex inter-and intrafamilial variability in familial ALS and FTD and other overlapping neurodegenerative diseases.

Duplication of 1q21. 3-q22 in a child with developmental delay, dysmorphic features and obesity. *I. O. Focsa[1], A. Tutulan-Cunita[1], S. M. Papuc[1], M. Budisteanu[1,2], D. Le Tessier[3], A. Lebbar[3], J. -M. Dupont[3,4], A. Arghir[1].* 1) Medical Genetics Laboratory, Victor Babes National Institute of Pathology, Bucharest, Romania; 2) Prof. Dr. Alex. Obregia Clinical Hospital of Psychiatry, Bucharest, Romania; 3) APHP Hôpitaux Universitaires Paris Centre - Cochin, Paris, France; 4) Université Paris Descartes, Faculté de Médecine, Paris, France.

Objective: Array-based comparative genomic hybridization (aCGH) stands as the first tier genetic investigation in a wide range of human conditions including neurodevelopmental delay associated with dysmorphic features. Here, we describe the genetic anomalies identified in a 7 years-old female patient with global developmental delay, dysmorphic features and obesity. Material and methods: The patient is the only child of healthy, non-consanguineous parents, born at term. At presentation she exhibited: obesity - weight of 30 kg (>Pc 97), height - 109 cm (Pc 3), OFC - 48. 5 cm (Pc 3); dysmorphic features (low-set, malformed ears, hypotelorism, strabismus, thick eyebrows, short nose, hypoplastic ala nasi, long philtrum, thin upper lip, high palatal arch, micrognathia) global developmental delay, IQ 48; attention deficit; behavior problems with hyperphagia, hyperkinesia. Cranial CT was normal. aCGH was performed on Agilent platforms, according to manufacturer' recommendations. Results: The genomic profile obtained by aCGH (105K platform) revealed a duplication of ~3. 1 Mb at 1q21. 3-q22. The results were confirmed by a higher resolution aCGH (180K Agilent platform) and by FISH, with genomic boundaries at 153,099,623-156,258,645 (hg 19). The duplicated region contains over 150 genes, among which several OMIM genes associated with neurodevelopment: *GATAD2B* (OMIM 614998) is a transcriptional repressor with a high expression in brain; its heterozygous loss-of-function mutations were associated with autosomal dominant developmental delay. *EFNA1* (OMIM 191164), *EFNA3* (OMIM 601381), and *EFNA4* (OMIM 601380) are members of the ephrin (EPH) family that mediate development-related events, especially in the nervous system. *KCNN3* (OMIM 602983) gene encodes a membrane voltage-independent calcium-activated channel thought to regulate neuronal excitability. Conclusion: Few genomic imbalances of this region associated with cognitive impairment and dysmorphic features were reported till now. A similar duplication (2. 49 Mb) was reported previously by Gunn et al. (2011) in a patient with growth retardation and developmental delay; approximately 15 patients with similar size duplications that partially overlap the region detected in our patient, were reported in DECIPHER database. Our patient brings new evidence regarding 1q21. 3-q22 duplication and its impact upon neurodevelopment. AcknowledgementsThe present work was supported by the National Research Project PN 09. 33. 02. 03.

1179T

Targeted analysis of whole exome sequencing in early onset epilepsy. *I. Guella[1], M. K. Demos[2], S. E. Buerki[2], E. Toyota[2], S. Adam[3], M. Van Allen[3], G. Sinclair[4], G. Horvath[4], C. D. Van Karnebeek[4], P. Eydoux[5], D. Evans[1], M. McKenzie[1], A. Datta[2], C. Boelman[2], L. Huh[2], A. Michoulas[2], B. Bjornson[2], T. N. Nelson[6], M. Connolly[4], M. J. Farrer[1].* 1) Centre for Applied Neurogenetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Division of Neurology, Department of Pediatrics, University of British Columbia and BC Children's Hospital, Vancouver, BC, Canada; 3) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 4) Division of Biochemical Diseases, Department of Pediatrics, University of British Columbia and BC Children's Hospital, Vancouver, BC, Canada; 5) Department of Pathology and Laboratory Medicine, University of British Columbia and British Columbia Children's Hospital, Vancouver, British Columbia, Canada; 6) Department of Pathology and Laboratory Medicine, Children's and Women's Health Center of British Columbia, Vancouver, British Columbia, Canada.

Advances in genomic technologies, including targeted next generation sequencing and whole exome sequencing (WES), enables identification of pathogenic variants in 10–78 % of patients with unexplained epilepsy. The clinical impact is significant including earlier diagnosis and specific treatment interventions. Here, we report the results of WES on 50 patients with early onset epilepsy (≤ 5 years) of unknown cause, evaluating diagnostic yield and time to diagnosis. Between December 2014 - June 2015 WES was performed in 43 retrospective (epilepsy > 6 months) and 7 prospective (epilepsy < 6 months) patients. Detailed clinical data was abstracted in a REDCap database. WES was performed using Ion Proton™ System within 2 weeks of receiving samples. Average coverage was >80x across all samples. Reporting was restricted to 557 genes previously implicated in epilepsy. Putative causative mutations were validated by Sanger sequencing and by parental testing. A definite diagnosis was made in 13 patients (26%: 5 prospective; 8 retrospective). This included known pathogenic and novel variants in *SCN1A, ATP1A2, ALG13, STXBP1, POLG, SCN1B, KCNQ2 x 3, PAFAH1B1, TUBB2B, GABRA1* and *CACNA1H*. A possible diagnosis was identified in 5 additional retrospective patients for whom supporting evidence is pending (*GABRB3, ARHGEF9, CHD2, KCNQ2, SCN3A*). An additional retrospective patient was identified to have a diagnosis which did not fully explain her phenotype (2 variants in *BTD* recognized to cause partial biotinidase deficiency, with biochemical support of low biotinidase). Eight patients (16%: 2 prospective, 6 retrospective) had a diagnosis with possible treatment implications (*ATP1A2, SCN1A, SCN1B, BTD, KCNQ2* x 3, *POLG*). The patient with compound heterozygous mutations in *POLG* was on valproic acid which was stopped due to study results. Her liver enzymes were increasing at time of diagnosis and normalized with valproic acid removal. The clinical utility of using WES in this cohort is supported by timely potential diagnoses in 19/50 patients (38%: 5 prospective; 14 retrospective) within a mean time of 48 days (21–105 days). WES also facilitated multi-locus variant identification that may further impact the phenotype. Within the 557 gene set, sequence kernel association testing will now explore the contribution of additional genetic variants to disease. Genome-wide WES from patients/families with no genetic diagnosis will also be analyzed to implicate novel genes in epilepsy.

1180F

The NINDS Repository collection of patient-derived biospecimens available for neurological disorders research. *C. A. Pérez[1], K. Reeves[1], J. Santana[1], S. Heil[1], A. Green[1], A. Amberson[1], D. Huber[1], R. Zhang[2].* 1) NINDS Repository, Coriell Institute for Medical Research, Camden, NJ; 2) National Institute of Neurological Disorders and Stroke, Bethesda, MD.

Neurological disorders are a major public healthcare concern and their pathophysiology remains largely unknown. The limited availability of reliable disease models hinders progress in identifying reliable genetic and molecular biomarkers for disease onset, diagnosis, progression and therapeutic response. The National Institute of Neurological Disorders and Stroke (NINDS) Repository was established in 2002 with the mission of facilitating research in neurological diseases by providing high quality biospecimens. The NINDS Repository collects biospecimens and de-identified clinical data from patients with neurological disorders as well as neurologically normal controls. The NINDS Repository features collections of patient-derived DNA, fibroblasts and induced pluripotent stem cells (iPSCs) and long term longitudinal collections of biofluids such as plasma, serum, cerebrospinal fluid, saliva and urine. Many samples are annotated with well-defined mutations. Since the NINDS Repository inception, biomaterials from more than 46,000 individuals with cerebrovascular diseases, Parkinsonism, motor neuron diseases, epilepsy, Tourette syndrome, dystonia, Huntington's disease, frontotemporal degeneration and neurologically-normal controls have been banked and are available at through its online catalog at http://catalog. coriell. org/1/NINDS The NINDS Repository has established validated standard operating procedures and rigorous quality control assessments that span the life cycle of all biospecimens collected to provide premium samples. The NINDS Repository aims to ensure and implement standardization for collecting and processing across all samples while protecting patient safety and privacy. In addition, the NINDS Repository utilizes secure and integrated laboratory information management systems to monitor inventory, sample processing, storage, and distribution of biospecimens, to collect , store and share de-identified clinical data associated to those samples and to facilitate sample-data association by cross-referring with other NIH resources such as dbGaP, DMR, etc. The development of such a centralized collection of human biospecimens and their associated de-identified clinical data allows the NINDS Repository to provide a vital resource for research designed to discover and validate genetic and molecular biomarkers relevant for the study and treatment of neurological disorders prevalent in our society.

1181W

The alternative expression of GAD1 in human prefrontal cortex. *R. Tao[1], K. Davis[1,6], C. Li[1], Y. Gao[1], J. Shin[1], M. Gondré-lewis[6], D. Weinberger[1,2,3,4,5], J. Kleinman[1], T. Hyde[1,2,3].* 1) Lieber Institute for Brain Development, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Neurology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD; 5) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Department of Anatomy, Howard University College of Medicine, Washington, D. C.

γ-Aminobutyric acid (GABA), the major inhibitory neurotransmitter in mammalian brain, has been implicated in both schizophrenia and normal brain development by postmortem and genetic studies. GABA levels and signaling in part are regulated by glutamic acid decarboxylase (GAD), the rate-limiting enzyme in GABA synthesis. Previous association studies suggested the *GAD1* promoter variants might play a role in schizophrenia and bipolar disorder. Genetic variation in *GAD1* has been associated with GAD67 expression. The decrease of GAD67 mRNA is one of the most replicated findings in the multiple brain regions of patients with schizophrenia. Schizophrenia is a highly heritable disorder. Many schizophrenia risk genes have particular transcripts that are highly expressed during fetal development. Moreover, some of the allelic variants derived from clinical association studies are associated with abnormal expression of some of these fetal-predominant transcripts. With respect to *GAD1*, during rodent embryonic development, two exclusive cassette exons are dominant in the brain, leading to two enzymatically inactive proteins (GAD25 and GAD44) derived from *GAD1*. These two truncated transcripts are highly expressed during fetal brain development, with a rapid decline after birth. In contrast, the full length transcript, GAD67, is expressed at low levels in fetal brain and dramatically rises after birth. To better understand how *GAD1* may be involved in the pathology of schizophrenia, we conducted a series of experiments to characterize the alternative splicing of *GAD1* in human prefrontal cortex. Our microarray and RNA sequencing data both suggest there are multiple splicing events of *GAD1* in human prefrontal cortex. Using PCR, we have identified 8 novel transcripts for *GAD1* in the human brain. There are another two novel exclusive cassette exons for *GAD1* beside I80 and I86. The *GAD1* transcripts produced by those four exclusive cassette exons are all highly expressed in human fetal prefrontal cortex. Our Western protein results showed that these four transcripts produce 3 truncated *GAD1* proteins with a truncation at the C-terminal and 1 truncation of the N-terminal. Further experiments are needed to characterize the sub-cellular locations of these proteins, and potential genetic regulatory components for these 4 fetal dominant transcripts. Our results provide further clues regarding the molecular mechanisms underlying schizophrenia during early brain development.

Functional impact of *SNX14* mutations that cause cerebellar atrophy and intellectual disability. *D. T. Bryant[1], C. Demetriou[1], E. Peskett[1], M. Ishida[1], D. Jenkins[1], A. Thomas[1], G. Anderson[2], R. Robertson[2], R. Scott[1,2], M. Bitner-Glinzicz[1,2], S. Sousa[3], G. E. Moore[1], P. Stanier[1].* 1) Genetics and Genomic Medicine, University College London, Institute of Child Health, London, United Kingdom; 2) Great Ormond Street Hospital, London, United Kingdom; 3) Medical Genetics Unit, Hospital Pediátrico, Centro Hospitalar e Universitério de Coimbra, Portugal.

A large number of conditions have been described where severe intellectual disability and ataxia are found in patients with cerebellar hypotrophy. Individually, most types are rare and without known molecular pathology. Mutations in *SNX14* have recently been reported to cause a distinct autosomal-recessive cerebellar ataxia with moderate to severe intellectual disability, early-onset cerebellar atrophy, sensorineural hearing loss and coarsened facial features. Patient-derived fibroblasts were acquired from individuals of three unrelated consanguineous families in Turkey and Portugal. These cell lines have mutations that result in either truncation or loss of the SNX14 protein as evidenced by western blot. The SNX14 protein contains a Phox (PX) domain and a regulator of G protein signalling (RGS) domain. In one patient, loss of a single exon (containing the PX-domain) alone was sufficient to result in the associated pathology. This suggests that the PX domain is critical for normal SNX14 function. While the precise function of SNX14 remains unknown, accumulation of vesicular inclusions in the patient cells suggest a disturbance in protein metabolism and/or vesicle mediated transport. Therefore, we are currently investigating these processes in order to identify the precise role of SNX14 and how mutations may lead to the neurological deficit.

1183F

Use of mutant mice to explore a hypothesis of neuronal/synaptic carnitine deficiency as a cause of autism. *J. Ge[1], E. Y. Kim[1], B. L. Zhang[1], J. R. Seavitt[1], F. M. Vaz[2], A. L. Beaudet[1].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Laboratory of Genetic Metabolic Disorders, Academic Medical Center, Amsterdam, The Netherlands.

The discovery that *TMLHE* deficiency leads to inability to synthetize carnitine in 1 in 350 healthy adult males and is a risk factor for autism has led us to propose a neuronal/synaptic carnitine deficiency hypothesis as a cause of autism especially in males with a normal physical exam and normal structural brain imaging. We have initiated studies in mutant mice to analyze the role of carnitine metabolism in neuronal and synaptic development to explore the hypothesis that carnitine deficiency in the brain disturbs synaptic development. Mitochondria are abundant at the synapse. The intent is to obtain null mutants for all four steps in carnitine biosynthesis and in numerous carnitine-related transporters and enzymes. Null mutations in *Bbox1* and *Aldh9a1*, both putative carnitine biosynthesis enzymes, and in X-linked *Slc6a14*, a putative blood-brain barrier carnitine transporter, were obtained from the Knockout Mouse Project (KOMP). Studies are most advanced for the *Bbox1* mice, and some data are available for the *Bbox1*/*Slc6a14* double null and for the *Aldh9a1* null mice. When fed with commonly used mouse chow which has extremely low carnitine content, *Bbox1*-/- mice are subviable with ~50% of homozygotes dying prior to weaning, but the reduced viability is corrected by supplementation with 0. 2% carnitine in the drinking water. The *Bbox1*-/- mice have 5-10% of normal levels of carnitine in plasma, liver, and brain. While the *Bbox1*-/- mice have no easily observable phenotype other than the subviability, studies including learning and social behavior and seizure susceptibility are in progress. Hemizygous *Slc6a14* -/Y male mice and female -/- mice are viable and fertile and show no obvious phenotype. The double null *Bbox1*/*Slc6a14*mice are available, and the level of carnitine in the brain compared to *Bbox1* null mice should determine whether the already very low levels of carnitine in the brain are further lowered in the double null mice. These studies should determine whether there is physiologically significant evidence that *Slc6a14* is indeed a blood-brain barrier transporter of carnitine in living mice.

1184W

Glutamate receptor interacting proteins modulate AMPA receptor phosphorylation and social behaviors in mice. *M. Han[1], R. Mejías Estévez[1], R. Rose[1], S. Chiu[2], A. Adamczyk[1], R. Huganir[2], T. Wang[1].* 1) Institute of Genetic Medicine, School of Medicine, Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, School of Medicine, Johns Hopkins University, Baltimore, MD.

Severe deficits in social interactions are a key feature for several neuropsychiatric disorders including autism and schizophrenia. Neural mechanisms that modulate social behaviors are poorly understood. Glutamate receptor interacting protein 1 and 2 (GRIP1/2) neural-enriched scaffolding proteins that bind the c-terminal of AMPA glutamate receptors 2/3 (GluA2/3) and play an important role in the regulation of GluA2/3 trafficking and neural plasticity. Gain-of-function mutations of GRIP1 were shown to correlate with increased deficits in the reciprocal social interactions in patients with autism. To study the role of GRIP1/2 in the regulation of social behaviors, we produced neuron-specific *Grip1/2* double knockout (DKO) mice by crossing *Grip2* conventional KO mice with *Grip1* conditional (neuron-specific deletion via nestin-cre expression) KO mice. Compared to wild type (WT) control mice matched for age, sex, and strain background, DKO mice show a significant increase in sociability, preference for social novelty, and dyadic male-male social interactions. Loss of GRIP1/2 expression results in decelerated GluA2 recycling while autism-associated gain-of-function GRIP1 mutations result in an accelerated GluA2 recycling in neurons. We performed immunoblot of key neural signaling proteins including AMPAR, mGluR, mTOR, and GABA and identified a significant increase in the phosphorylated GluA2 at serine 880 in brain cortex and cerebellum but not striatum. Phosphorylation at S880 is known to affect GluA2 interactions with several neural scaffolding proteins including GRIP1 and PICK1 and alter receptor recycling and AMPA synaptic strength. These data suggest that AMPA-glutamate signaling play a role in modulating social behaviors in mice and disturbance of this signaling pathway contribute to autism-related social deficits.

1185T

Functional Analysis of the Autism and Intellectual Disability Gene *PTCHD1* Reveals Hedgehog Receptor-Like Functions and PDZ-Binding Domain-Specific Regulation of *CNTNAP1* and *NLGN1*. *K. Mittal, B. Degagne, T. Sheikh, J. Vincent.* Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health, Toronto, Ontario, Canada.

This study is focused on investigating the complex functional aspects of a recently identified gene -- PTCHD1, and how its disruption leads to Autism Spectrum Disorder and/or Intellectual Disability. Sonic hedgehog (Shh) signaling plays a pivotal role in the pattern formation of many embryonic tissues and also in homeostasis and regeneration of adult tissues. PTCHD1 shows sequence homology to the Shh receptors PTCH1 and PTCH2, and has previously shown similar Gli repression activity to PTCH1 and 2. To establish the involvement of PTCHD1 in Hedgehog (Hh) pathway, transcription analysis was performed with Hh pathway genes and putative PTCHD1 partners. We also tested for a truncated construct lacking the C-terminal four amino acids, Ile-Thr-Thr-Val (ITTV) of PTCHD1, which is predicted to interact with the PDZ domains of proteins. PTCHD1 over-expression revealed increased levels of NLGN1 and CNTNAP1 mRNA, which suggests that interaction with proteins at the synapse (NLGN1) or at nodes of Ranvier or axo-glial junctions (CNTNAP1) may have a regulatory effect on these genes. The transcript levels were reduced with the PTCHD1 truncated construct, reversing the effect of PTCHD1 over-expression. These results suggest either a regulatory or a downstream effect on NLGN1 and CNTNAP1 genes via a PDZ-domain containing protein. As DLG4 (PSD-95) interacts with K+-voltage-gated channels KCNA1 and KCNA2 (both known interactors with CNTNAP1), and interacts with NLGN1, we hypothesize that PTCHD1 may have a synaptic role mediated by PSD-95. Alternatively, DLG3 (MPP3), SHANK1 or SHANK3 may mediate regulation of NLGN1. We showed high levels of *Shh*, and its putative receptor, *Ptchd1*, a well as *Smoothened* (*Smo*) transcripts in mouse brains between E12 and P2. To assess the expression pattern of PTCHD1 and Smo in post mitotic neurons, we immunolabeled PTCHD1 and Smo in cultured hippocampal neurons- a model system that has been widely used to study signaling pathways in neuronal growth. Positive PTCHD1 immunolabeling was visible in the hippocampal neurons, and Smo immunolabeling was bright and intense in the distal sections of dendrites. We hypothesize that PTCHD1 localization to hippocampal neurons could inhibit the Hh pathway by excluding Smoothened and also allows cilia to function as chemo sensors for the detection of extracellular Shh, similar to PTCH1, during neuronal development and synapse formation. Preliminary results also suggest localization of PTCHD1 in cilia.

1186F

Chromatin remodelers in autism: deciphering regulatory networks that contribute to autism risk. *R. A. Muhle[1], JL. Cotney[2], W. Niu[3], S. Abdallah[3], S. J. Sanders[4], A. J. Willsey[4], W. Liu[4], J. Yin[3], S. K. Reilly[3], A. T. Tebbenkamp[5], C. Tebbenkamp[5], M. Pletikos[5], N. Sestan[5], M. W. State[4], J. P. Noonan[3].* 1) Child Study Center, Yale University, New Haven, CT; 2) Department of Genetics & Genome Sciences, UConn Health, Farmington, CT; 3) Department of Genetics, Yale School of Medicine, New Haven, CT; 4) Department of Psychiatry, University of California, San Francisco, CA; 5) Department of Neurobiology, Yale School of Medicine, New Haven, CT.

Advances in next generation sequencing technologies have greatly enhanced the field of autism genetics. Recent gene discovery efforts in autism spectrum disorder (ASD) have identified chromatin modifiers, such as the chromodomain helicase *CHD8*, as important new contributors to ASD pathogenesis. These and additional ASD risk-associated genes are co-expressed in human midfetal cortex, suggesting that ASD risk genes may converge in regulatory networks that are perturbed in ASD. To investigate the factors shaping this regulatory network, we have undertaken studies to globally map regulatory targets of ASD risk-associated chromatin modifiers during neurodevelopment. We have found that CHD8 regulates other ASD risk genes during human neurodevelopment. We have mapped the binding sites of CHD8 in the developing human and mouse brain using chromatin immunoprecipitation (ChIP-seq), and have characterized global dysregulation of CHD8 targets following *CHD8* knockdown utilizing shRNAs followed by RNAseq. We find that CHD8 gene targets in human and mouse developing brain are significantly enriched in ASD risk genes bearing one or more *de novo* loss of function mutations, and that genes found in ASD risk-associated spatiotemporal co-expression networks during human brain development are more likely to be targeted by CHD8. Knockdown of *CHD8* expression levels by shRNA leads to significant dysregulation of ASD risk genes. CHD8 binds the ASD risk genes *CHD2*, *SUV420H1*, *ARID1B*, *POGZ*, *MLL5/KMT2E*, *ASH1L*, and *SETD2*, among others. In further studies, we will characterize the gene targets of CHD8-targeted ASD-associated chromatin modifiers using *in vivo* and *ex vivo* systems to elucidate common regulatory pathways. These studies provide an initial view of ASD-associated regulatory networks in the developing brain. We will build on these results by identifying regulatory targets of other chromatin modifiers conferring risk for ASD. Mapping regulatory targets of CHD8 and other ASD-associated chromatin modifiers in the developing brain will identify biological pathways underlying ASD etiology. This will provide the means to interpret ASD-associated coding and noncoding variatiants, and offer potential avenues for drug discovery by revealing specific mechanisms contributing to ASD.

1187W

Sonic hedgehog signaling involvement in bipolar disorder is supported by linkage disequilibrium near the EVC and HHIP genes for haplotypes of the D4S2949, D4S397 genotypes according to EVC genotypes among the Old Order Amish. *Y. E. Song[1], M. Galdzicka[2], J. A. Egeland[3], E. I. Ginns[4], R. C. Elston[1].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 2) Department of Pathology, University of Massachusetts Medical School, Shrewsbury, MA; 3) Department of Psychiatry and Behavioral Sciences, University of Miami Miller School of Medicine, Miami, FL; 4) Departments of Psychiatry and Pathology, University of Massachusetts Medical School, Shrewsbury, MA.

Our study of cosegregation of Ellis-van Creveld syndrome (EvC) and bipolar affective disorder (BPAD) in a large, multigenerational Old Order Amish pedigree led to the identification of significant association between absence of bipolar I (BPI) and presence of EvC (Ginns et al, Molecular Psychiatry 2014). This discovery suggested that the molecular change causing EvC confers protection (that is, mental health wellness) from bipolar I (BPI) cases, as well as suggesting a more general protection against the spectrum of affective disorders. The prior evidence of genetic linkage between BPAD and two loci at the opposite ends of chromosome 4, D4S2949 and D4S397, coupled with the fact that EvC is the result of disrupted sonic hedgehog (Shh) signaling, suggested the functional involvement of Shh signaling as an underlying molecular mechanism for susceptibility and protection in BPAD. The estimated percent of the total sample variance that can be attributed to EVC segregation for various clinical category contrasts provided statistical evidence that disruption of sonic hedgehog signaling in EvC confers protection from BPI and perhaps against other affective disorders. In this present study, using the same Amish sample, additional genotype data were analyzed to provide the missing link from the original article. Specifically, we examined the association between alleles at D4S2949 and D4S397 respectively near the EVC and HHIP genes, at the opposite ends of chromosome 4. By examining this association, additional corroborating evidence was obtained for sonic hedgehog involvement in BPAD, both in all subjects and in those with the EVC G/G genotype. The best contrasting clinical categories explained by this protective effect of EvC, after BPI, are those classified with BPI, BPII or other disorders in the BPAD spectrum, versus those who are definitely mentally well. The new data thus support a more general protection against the spectrum of affective disorders in these families. Understanding how disrupted Shh signaling protects against BPI could uncover variants in the Shh pathway that cause or increase risk for bipolar and related mood disorders. We conclude that studying special populations, like the Amish, may be a better strategy to detect complex disease causing genes and pathways than the pursuit of ever larger case-control samples.

1188T

Genetic ablation of the long non-coding RNA *Pantr2* affects cortical neuron migration and striatal gene expression in mice. *M. Feyder[1,2], A. Groff[3,4], M. Sauvageau[3,4], S. Lodato[3,4], D. B. Sanchez-Gomez[3,4], M. Morse[3,4], C. Gerhardinger[3,4], J. L. Rinn[3,4,5], P. Arlotta[3,4], L. A. Goff[1,2].* 1) Johns Hopkins University, Baltimore, MD; 2) Department of Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD; 3) Stem Cells and Regenerative Medicine, Harvard University, Cambridge, MA; 4) The Broad Institute of MIT and Harvard, Cambridge, MA; 5) Department of Pathology, Beth Israel Deaconess Medical Center, Boston, MA.

Long non-coding RNAs (lncRNAs) mediate a diverse number of cellular processes and can regulate cellular differentiation. These conclusions have been principally derived from cell culture systems. The physiological relevance of lncRNAs *in vivo*, however, is less known and represent a significant limitation to our current understanding because many are tissue-specific. The lncRNA *Pantr2* is highly expressed in neural stem cells and exhibits a moderate expression in the adult brain, suggesting a potential role in the development of the central nervous system. Accordingly, brain tissue from *Pantr2* knockout (KO) mice exhibits attenuated indices of proliferation in progenitor cell populations, altered gene expression associated with cellular proliferation and neuronal maturation, and abnormal cortical lamination (Sauvageau *et al.* , 2013). We extend these initial findings and report that these same KO animals also exhibit disordered cortical neuron migration and alterations in striatal gene expression. In the embryonic brain of KO mice, neurons expressing Tuj1, a neuronal-specific tubulin, are found in terminal zones, where they are normally absent. Similarly, in the adult brain, neurons immunostained for Cux1, a marker of upper cortical laminae, were present in lower cortical laminae, where they are also normally absent. Taken together, these results suggest that a loss of *Pantr2* may impair the migration of cortical neurons. Additionally, we uncovered transcriptional abnormalities in the striatum, a large subcortical nuclei of the basal ganglia that receives widespread projections from the cortex. RNA-seq of the embryonic telencephalon demonstrated that *Ppp1r1b* (*DARPP-32), Ngef* and *Pcp4L1*, all of which are highly expressed in the striatum, were increased in KO mice, consistent with the notion of precocious differentiation in *Pantr2* KO mice. An increase in striatal DARPP-32 was confirmed by immunostaining. Differentially expressed transcripts between WT and KO mice were associated with disorders of the basal ganglia, such as Huntington's disease, Parkinson's disease and dyskinesia. These data demonstrate that disruption of *Pantr2* expression perturbs both the cortex and the striatum. As corticostriatal connectivity may underlie behavioral disorders such as obsessive-compulsive disorder and autism, these data reveal an *in vivo* role for lncRNAs with potential relevance to clinical syndromes.

1189F

Role of ANK2 in autism. *J. Li, M. Wakahiro, B. Fregeau, G. Gente, E. Sherr.* Dept Neurology, Univ California, San Francisco, San Francisco, CA.

ANK2 encodes a member of the ankyrin family of proteins (Ankyrin B) that link integral membrane proteins (e. g. L1CAM) to the underlying spectrin-actin cytoskeleton. Ankyrins play key roles in activities such as cell motility, activation, proliferation, cell-cell contact and the maintenance of specialized plasma membrane domains. Mutations in ANK2 have been found to cause autosomal dominant long QT syndrome 4 and cardiac arrhythmia syndrome in humans. Recent next generation DNA sequencing projects in Autism cohorts (the Simons Simplex Collection) have revealed several heterozygous de novo ANK2 missense and nonsense mutations marking ANK2 as a 'high-confidence' autism candidate gene. Additionally, our lab has identified multiple individuals who not only have cognitive and behavioral deficits, but are also missing the corpus callosum (agenesis of the corpus callosum; ACC), which is comprised of nearly 200 million axons connecting the two cerebral hemispheres. These genetic findings highlight the importance of ANK2 in neurodevelopment, but how mutation of ANK2 leads to these brain disorders is still unknown. As a first step to address this question, we reported an expected and significant decrease in expression of ANK2 mRNA and protein in patient compared to control PBMC's. We also investigated the abundance of the neuronal adhesion protein, L1CAM. This protein has been shown to bind to ankyrin B, and the protein half-life was dependent on ankyrin B "anchoring" L1cam to the plasma membrane. Thus, we found that L1CAM protein abundance is decreased in patients with ANK2 mutations (one with a balanced chromosomal translocation through ANK2 t (4;8)(q25; q23), and in two other Autism patients with nonsense mutations in ANK2) and that L1CAM expression is rescued after transient transfection of ANK2 into a cell line from one patient carrying a nonsense mutation in ANK2. Our results suggest that disruption of the normal interaction and balance between ANK2 and L1CAM may play an important role in Autism and other neurodevelopmental disorders such as ACC. Moreover, this linkage between ACC and ASD has implications for the mechanistic overlap for these two groups of disorders.

1190W

Fine-mapping of regulatory variants in schizophrenia. *K. Farh[1], M. J. Daly[2], B. Bernstein[2].* 1) Illumina, San Diego, CA; 2) Broad Institute, Cambridge, MA.

Genome-wide association studies have now identified over a hundred risk loci for schizophrenia, over 97% of which are noncoding, indicating that the great majority of genetic risk can be attributed to differences in gene regulation between individuals. To understand the underlying molecular mechanisms, we are employing a combination of statistical and biochemical methods to identify genetic variation that disrupts *cis*-regulatory elements in disease-relevant cell types. By measuring allele-specific differences in gene regulation on the two chromosomes of heterozygous individuals, we can effectively control for effects on gene regulation due to non-genetic factors, such as age, sex, environment, and stochastic influences.

1191T

Pathway analysis of genome-wide SNP data for Gilles de la Tourette Syndrome shows enrichment in genes expressed in nervous system tissues. *F. Tsetsos[1], J. Alexander[1], D. Yu[2], J. H. Sul[3], G. Coppola[4], I. Zelaya[4], P. Drineas[5], C. Mathews[6], J. M. Scharf[2], P. Paschou[1], TSA-ICG, GGRI.* 1) Department of Molecular Biology and Genetics, Democritus University of Thrace, Alexandroupolis, Evros, Greece; 2) Psychiatric and Neurodevelopmental Genetics Unit, Center for Human Genetics Research, Departments of Neurology and Psychiatry, Massachusetts General Hospital, Boston, MA, USA; 3) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) Semel Institute for Neuroscience and Human Behavior, Departments of Neurology and Psychiatry, The David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA, USA; 5) Department of Computer Science, Rensselaer Polytechnic Institute, Troy, NY, USA; 6) Department of Psychiatry, University of California, San Francisco, CA, USA.

Gilles de la Tourette Syndrome (GTS) is a childhood-onset neuropsychiatric disorder that is characterized by a multitude of vocal and motor tics. Recent advances in the genetics of GTS are starting to shed new light on its genetic aetiology. We have recently completed a second Genome Wide Association Study (GWAS) of GTS on 2,859 cases/3,855 controls. A subsequent meta-analysis with existing GTS GWAS data (final sample size of 4645 cases and 9,750 controls) generated multiple LD-independent SNPs with p-value less than 10^{-5}. These SNPs implicate novel loci on Tourette Syndrome pathogenesis.

Here, we focused on the top scoring SNPs from the GTS GWAS meta-analysis for downstream pathway analysis. For the pathway analysis, we used DEPICT, a novel tool for the interpretation of GWAS results, and additional pathway analysis software, including INRICH, FORGE and DAPPLE. Furthermore, we also applied a set-based association approach on the Second Genome Wide Association Study case and control data. In order to perform the set-based association, we collected pathway gene sets from KEGG, REACTOME, Molecular Signatures Database, OMIM and constructed sets of SNPs located at genes present on the pathway gene sets. The set-based association was run using PLINK and 1 million permutations.

DEPICT analysis showed significant enrichment among top GTS associated SNPs in genes expressed in nervous system tissues, including the parietal lobe and the basal ganglia. INRICH analysis hints towards the involvement of neuronal transcription factor binding sites, with the top scoring being TCF3. We also report the results from the set based association analysis, which further illuminate candidate pathways for investigation, implicating a complex network of factors. Our study aims to untangle the complex interaction networks of genes implicated in GTS and points to candidate etiological pathways for further investigation in future studies.

1192F

Structural variants and neurodegenerative diseases in aging: regulatory and causality consequences. *O. Chiba-Falek[1], M. W. Lutz[1], R. Saul[2], A. D. Roses[1, 3].* 1) Department of Neurology, Duke University, Durham, NC; 2) Polymorphic DNA Technologies, Alameda, CA; 3) Zinfandel Pharmaceuticals, Chapel Hill, NC.

Over the last decade large genome-wide association studies (GWAS) identified many loci associated with neurodegenerative disease risk, however the precise causal genetic variants and the molecular mechanisms underlying those genetic associations remain largely unknown. In GWAS, SNPs have taken the spotlight in analyses of human complex diseases and expression traits (eQTL). Structural Variants (SVs) such as, short tandem repeats (STRs), homopolymers and indels, were underrepresented, mainly due to GWAS platforms that enabled high density SNP genotyping and the inability to accurately sequence long contiguous genomic sequence using current next-generation sequencing. We embarked on an effort to identify noncoding functional SVs within loci in the genome that have been associated with neurodegenerative phenotypes. We have studied the functional consequences of intronic and intragenic SVs and their role in susceptibility to a broad spectrum of dementia and Lewy body (LB) disorders. We employ bioinformatics tools including a novel software (dbSV) to annotate SV, and phased sequencing approach to discover candidate SVs and haplotypes associated with neurodegenerative diseases and pathologies and to evaluate the *cis*-effects of disease-risk SVs on gene expression and splicing in human brain tissues from disease-affected and healthy individuals. Using phylogenetic analyses based on phased sequence data, we identified a variable intronic poly-T, in the *TOMM40* gene that is associated with risk for Alzheimer's (AD) and age of onset. We demonstrated using AD-affected and normal brain tissues and a luciferase reporter system that this highly-variable poly-T site regulates the transcripts levels of both *TOMM40* and its neighboring gene, *APOE*. Previously we also discovered that Rep1, a SV associated with increased PD-risk, regulates *SNCA* transcription in human brain and confirmed our findings using luciferase reporter assay and humanized mouse model. In our new studies we have recently identified four distinct haplotypes within a highly-polymorphic-low-complexity CT-rich region with specific haplotype conferred risk to develop LBV/AD. We further demonstrated that the risk haplotype was significantly associated with elevated levels of *SNCA*-mRNA in human brain tissues and suggested that the CT-rich site acts as an enhancer element. Collectively, our research has demonstrated the importance of noncoding SVs in the etiology of sporadic neurodegenerative diseases in adulthood.

Layered genetic control of DNA methylation and gene expression: locus of multiple sclerosis in healthy individuals. *J. Shin[1,12], C. Bourdon[1,12], M. Bernard[1], M. Wilson[1], E. Reischl[2], M. Waldenberger[2], B. Ruggeri[3], G. Schumann[3], S. Desrivieres[3], A. Leemans[4], M. Abrahamowicz[5], L. Richer[6], L. Bouchard[7,8], D. Gaudet[8,9], T. Paus[10,11], Z. Pausova[1], The IMAGEN Consortium, The SYS Consortium.* 1) The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 2) Research Unit of Molecular Epidemiology, Helmholtz Zentrum Munchen, Munich, Germany; 3) MRC Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom; 4) Image Sciences Institute, University Medical Center Utrecht, Utrecht, the Netherlands; 5) Department of Epidemiology, Biostatistics and Occupational Health, McGill University, Montreal, Canada; 6) Department of Psychology, Université du Québec à Chicoutimi, Chicoutimi, Canada; 7) Department of Biochemistry, Université de Sherbrooke, Sherbrooke, Canada; 8) ECOGENE-21 and Lipid Clinic, Chicoutimi Hospital, Chicoutimi, Canada; 9) Department of Medicine, Université de Montréal, Montréal, Canada; 10) Rotman Research Institute, University of Toronto, Toronto, Canada; 11) Child Mind Institute, New York, NY, USA; 12) Authors with equal contribution.

DNA methylation may contribute to the etiology of complex genetic disorders through its impact on genome integrity and gene expression; it is modulated by DNA-sequence variants, named *methylation quantitative-trait loci* (meQTLs). Most meQTLs influence methylation of a few CpG dinucleotides within short genomic regions (<3kb). Here we identified a layered genetic control of DNA methylation at numerous CpGs across a long 300-kb genomic region. This control involved a single *long-range* meQTL and multiple *local* meQTLs. The *long-range* meQTL explained >50% of variance in methylation of CpGs located over extended areas of the 300-kb region. The meQTL was identified in four samples (p=2. 8x10-17, 3. 1x10-31, 4. 0x10-71, 5. 2x10-199), comprising a total of 2,796 individuals. The *long-range* meQTL was strongly associated not only with DNA methylation but also with mRNA expression of several genes within the 300-kb region (p=7. 1x10-18–1. 0x10-123). The associations of the meQTL with gene expression became attenuated when adjusted for DNA methylation (causal inference test: p=2. 4×10-13–7. 1×10-20), indicating coordinated regulation of DNA methylation and gene expression. Further, the *long-range* meQTL was found to be in linkage disequilibrium with the most replicated locus of multiple sclerosis, a disease affecting primarily the brain white matter. In middle-aged adults free of the disease, we observed that the risk allele was associated with subtle structural properties of the brain white matter found in multiple sclerosis (p=0. 02). In summary, we identified a *long-range* meQTL that controls methylation and expression of several genes and may be involved in increasing brain vulnerability to multiple sclerosis.

1194T

De novo BCL11A variants in neurodevelopmental disorder disrupt multiple aspects of protein function. *S. B. Estruch[1], S. A. Graham[1], P. Deriziotis[1], S. E. Fisher[1,2].* 1) Max Planck Institute for Psycholinguistics, Nijmegen, The Netherlands; 2) Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, The Netherlands.

The rare chromosome 2p16. 1-p15 deletion syndrome (MIM 612513) is characterized by intellectual disability, dysmorphic features and microcephaly. A high proportion of affected individuals have autism, behavioral problems and language deficits. Skeletal and organ abnormalities have also been reported. Comparison of the chromosomal regions deleted in different cases suggests that haploinsufficiency of the zinc finger transcription factor BCL11A (MIM 606557) may underlie the neurological features of the syndrome. Although the role of BCL11A in brain development is poorly understood, the gene is expressed in the developing cortex, hippocampus, basal ganglia and cerebellum, and has recently been reported to play a role in the specification of subcortical projection neurons by repressing expression of TBR1 (MIM 604616), a gene recurrently mutated in cases of autism. In addition to its function in the brain, BCL11A has a key role in mediating the switch from the fetal to the adult form of hemoglobin, and persistence of fetal hemoglobin has been reported in several patients with BCL11A deletions. The first disorder-associated missense variants in BCL11A have recently been identified in three unrelated infants with developmental delay. The variants in these patients cluster within the N-terminal portion of the protein, and lie outside the zinc finger DNA-binding domains, in a region of unknown function. We therefore sought to characterize the effects of these variants on protein function in order to confirm their etiological role in disorder in these three patients, and to illuminate the molecular mechanism of disorder. We found that all three variants disrupt the localization of BCL11A within the nucleus and abolish protein dimerization and transcriptional regulatory activity. Our results therefore strongly support a causal role for BCL11A variants in the developmental delay in these patients, and add to the growing evidence that BCL11A is a recurrently mutated gene in neurodevelopmental disorder. Furthermore the characterization of these variants reveals a key role for the N-terminal region of BCL11A in mediating protein dimerization and regulation of transcription.

1195F

Deciphering the genetic basis of intellectual disability using 1000 knockouts. *B. Yalcin[1,3,6], A. Mikhaleva[1], V. E. Vancollie[2], M. Kannan[3], C. Wagner[3], A. Edwards[4], H. Whitley[3], J. Estabel[2], C. J. Lelliott[2], U. K. Sanger Mouse Genetics Project[2], D. A. Keays[5], J. K. White[2], R. Ramirez-Solis[2], D. J. Adams[2], Y. Herault[3], A. Reymond[1].* 1) Center for Integrative Genomics, University of Lausanne, Switzerland; 2) Wellcome Trust Sanger Institute, Hinxton, Cambridge, CB10 1HH, UK; 3) Institute of Genetics and Molecular and Cellular Biology, Illkirch, 67404, France; 4) Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford, OX3 7BN, UK; 5) Research Institute of Molecular Pathology, 1030 Vienna, Austria; 6) Corresponding author.

Intellectual disability (ID) affects 1-3% of the general population. Genetic mutations account for about half of the currently undiagnosed cases, and it has been suggested that up to 2,000 further genes remain to be identified. To identify genes involved in brain malformation and potentially associated with ID, we are collaborating with the Sanger Mouse Genetics Project (MGP), allied to the International Mouse Phenotyping Consortium (IMPC), to systematically study the neuroanatomy of the MGP/IMPC knockout mouse strains. We are measuring a standardized set of 78 brain parameters across 22 brain regions to detect a variety of mechanisms that underlie brain disorders, such as aberrant cell proliferation, neuronal migration defects or elevated cell death rates. So far, we have assessed brain defects in 992 knockout mouse genes that are randomly distributed throughout the mouse genome. These preliminary data yielded success with the identification of 91 genes including 18 well-known ID genes such as *Aspm*, *Cdk5rap2*, *Ctcf*, *Dlg3* and *Smc3*, demonstrating the pertinence of our approach. The remaining 73 genes are novel, and examples include *Bach2*, *Cbx6*, *Daam2, Kif21b, Os9, Pik-3cb*, *Rnf10*, *Selk* and *Wdr47*. Interestingly, one fifth of these novel genes have been reported in non-recurrent forms of severe ID (Gilissen *et al* Nature 2014), thus are good candidate genes for ID. Strikingly, these novel genes showed a significant enrichment in both cellular components and molecular functions pertaining to the cytoskeleton, and were mostly affecting the formation of the commissures and the ventricles. Half of these novel genes have a global effect throughout the brain, for example *Rnf10* and *Kif21b*, while the other half have specific impact on brain structure, for example *Bach2*. Our study is the largest screen of brain morphology from the MGP/IMPC. It shows the importance of an unbiased screen as we can detect severe brain abnormalities in about 8% of knockout genes of previously unknown brain function, and that these novel genes are a rich resource for investigating brain disorders. Our resource offers a complementary approach to human genetic studies.

1196W

Disassembly of MICOS complex by *CHCHD10* mutations promotes lossof mitochondrial cristae with defectsin mitochondrial genome maintenance and apoptosis. *E. Genin[1], M. Plutino[1], S. Bannwarth[1,2], E. Villa[3], E. Cisneros-Barroso[4], M. Roy[5], B. Ortega-Vila[4], K. Fragaki[1,2], F. Lespinasse[1], E. Pinero-Martos[4], G. Augé[1,2], D. Moore[6,7], F. Burté[6,7], S. Lacas-Gervais[8], Y. Kageyama[5], P. Yu-Wai-Man[6,7], H. Sesaki[5], J. E. Ricci[3], C. Vives-Bauza[4], V. Paquis-Flucklinger[1,2].* 1) IRCAN, UMR 7284, INSERM U1081, Nice Sophia-Antipolis University, Nice, France; 2) Department of Medical Genetics, National Centre for Mitochondrial Diseases, Nice, France; 3) INSERM U1065, Centre Méditérranéen de Médecine Moléculaire (C3M), Nice Sophia-Antipolis University, Nice, France; 4) Research Health Institute of Palma (IdISPa), University Hospital, Palma de Mallorca, Spain; 5) Department of Cell Biology, Johns Hopkins University, School of Medicine, Baltimore, MD, USA; 6) Wellcome Trust Centre for Mitochondrial Research, Institute of Genetic Medicine, Newcastle University, Newcastle, UK; 7) Newcastle Eye Centre, Newcastle, UK; 8) Joint Center for Applied Electron Microscopy, Nice Sophia-Antipolis University.

Recently, we described *CHCHD10* as a novel gene responsible for mtDNA instability disorder by studying a large family with a late-onset phenotype including motor neuron disease, cognitive decline looking like frontotemporal dementia (FTD), cerebellar ataxia and mitochondrial myopathy with accumulation of multiple mtDNA deletions. Subsequently, other groups and ourselves identified *CHCHD10* mutations in cohorts of patients with frontotemporal dementia-amyotrophic lateral sclerosis (FTD-ALS), pure familial or sporadic ALS, late-onset spinal motor neuropathy (SMAJ) or Charcot Marie Tooth 2A (CMT2A).

Here, we show that CHCHD10 is a component of the "mitochondrial contact site and cristae organizing system" (MICOS) complex. The expression of *CHCHD10* mutant allele leads to MICOS complex disassembly and loss of mitochondrial cristae in patient fibroblasts. The abnormalities of the inner membrane are responsible for nucleoid disorganization leading to defect in mtDNA repair after oxidative stress, which explains the multiple mtDNA deletions found in patient muscles. Interestingly, the expression of *CHCHD10* mutant alleles inhibits apoptosis by preventing cytochrome*c* release. This result supports previous studies suggesting that, in some ALS models, motor neuron death can occur *via* caspase-independent apoptotic mechanism.

In conclusion, we show for the first time that mutations in a gene encoding a MICOS component are responsible for human disorder. Dissecting the cellular pathways disrupted by the expression of *CHCHD10* mutant alleles represents, therefore, a golden opportunity to gain powerful insight into the sequence of events that link mitochondrial dysfunction with neurodegenerative disorders.

1197T

***Polr3a* KI and KI/KO mice do not develop hypomyelinating leukodystrophy.** *K. Choquet[1,2,3], S. Durrieu[4], R. Lariviere[1], M. -J. Dicaire[1], G. Bernard[5], T. E. Kennedy[1], M. Teichmann[4], C. L. Kleinman[2,3], B. Brais[1,2].* 1) Montreal Neurological Institute, McGill University, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) Lady Davis Institute, Jewish General Hospital, Montreal, Quebec, Canada; 4) INSERM U869, Institut Europeen de Chimie et Biologie, Universite Bordeaux Segalen, Bordeaux, France; 5) Department of Pediatrics, Neurology and Neurosurgery, Division of Pediatric Neurology, Montreal Children's Hospital, McGill University Health Center, Montreal, Quebec, Canada.

Hypomyelinating leukodystrophies (HLD) are a heterogeneous group of neurodegenerative disorders characterized by impaired myelin formation in the central nervous system (CNS). Recessive mutations in the ubiquitously expressed *POLR3A* and *POLR3B* genes cause one of the most frequent forms of childhood-onset HLD: POLR3-related leukodystrophy. *POLR3A* and *POLR3B* encode the two catalytic subunits of RNA Polymerase III (POLR3), which is responsible for the transcription of transfer RNAs and a large array of other small non-coding RNAs. We hypothesized that mutations in *POLR3A* and *POLR3B* would alter POLR3's transcription efficiency, leading to a decreased expression of key transcripts for the development of CNS white matter. Comparison of the expression levels of POLR3 transcripts in control and patient-derived fibroblasts identified only one transcript decreased in a subset of patients, BC200 RNA. This lack of global deregulation of POLR3 transcripts in patients' fibroblasts suggested that the impact of *POLR3A* and *POLR3B* mutations would be restricted to CNS tissues. Therefore, we developed and characterized mouse models of POLR3-related HLD. Since homozygous *Polr3a* knock-out (KO) mice could not be conceived, we generated knock-in (KI) mice homozygous for the French Canadian founder mutation c. 2015G>A (p. Gly672Glu) in *Polr3a*, as well as compound heterozygous mice for one *Polr3a* KI and one KO allele (KI/KO). Both KI and KI/KO mice are viable, able to reproduce and do not display a grossly abnormal phenotype. To establish if they manifest a subtler motor phenotype, WT, KI and KI/KO mice (n=15 per group) were submitted to rotarod, inverted grid, beam and open field tests at 40 and 90 days old. The three groups performed comparably on all tests, indicating that the KI and KI/KO mice have normal balance, coordination, strength and general locomotion. Quantification of CNS myelin proteins in brain and cerebellum of 30 and 90 days old mice did not detect differences between the three groups, suggesting that myelination is not impaired in *Polr3a* KI and KI/KO mice. Finally, we compared the expression levels of POLR3 transcripts in the brains of KI and WT mice using RNA-Seq but no differences were uncovered. In conclusion, our results suggest that *Polr3a* KI and KI/KO mice do not recapitulate the severe childhood-onset HLD seen in humans with *POLR3A* mutations, although we cannot exclude that they may develop a later-onset phenotype.

1198F

Evaluating the expression of the long non coding RNA *lnc- IL7R* and two isoforms of *IL7RA* gene in the PBMCs of relapsing-remmiting multiple sclerosis patients. *P. Bina, M. Pahlevan Kakhki, M. Behmanesh.* Biological Sciences, Tarbiat Modares University, Tehran, Tehran, Iran.

Multiple sclerosis (MS [MIM 126200]) is an inflammatory-mediated demyelinating disease of the human central nervous system (CNS). Many studies showed that the environmental and genetics factors are involved in the pathogenesis of MS. Interleukin 7 receptor alpha (*IL7RA* [MIM 146661]) (also known as *CD127*), encoded by Interleukin 7 receptor (*IL7R* [MIM 146660]), is a member of the type I cytokine receptor family and forms a receptor complex with the common cytokine receptor gamma chain. It has been showed that rs6897932 SNP [MIM 612595] on *IL7R* affects alternative splicing of exon 6, leading to increased skipping of the entire exon 6 and corresponds to the soluble form of the ligand specific IL7RA subunit. *LncRNAs* are a group of non coding RNAs which are longer than 200 nt and play important roles in various biological processes, such as proliferation, differentiation, and development through various modes of action. *Lnc-IL7R*, is 1427 nt in length which overlaps with the 3'untranslated region (3'UTR) of the human *IL7R* gene, regulates the inflammatory responses of LPS-treated cells. The majority of lnc-IL7R existed in the nucleus. The increase in *lnc-IL7R* expression after lipopolysaccharide stimulation indicates that *lnc-IL7R* is involved in the early immune responses. RR-MS patients were selected based on some exclusion and inclusion criteria. The study was approved by the ethnics commette of Tarbiat Modares university of IRAN and informed consent were obtained from all participants. five ml of whole blood were obtained and PBMCs harvested using Ficoll solusion, RNA extracted by Trizol reagent, and real time PCR was performed by Step One ABI system using specific primers. χχct method was used for the analysis of gene expression results. Our pilot studies on LncRNAs showed interesting evidences from lncRNAs key roles in the different physiological conditions of MS. Also, we checked the expression of *Lnc-IL7R* using RT-PCR method in the diabetic chronic arthery disease (CAD+) patients which showed the significant elevated expression of this LncRNA in comparison with healthy subjects. Analysis of the expression level of this Lnc-RNA in the diabetic and MS patients are under investigation in our laboratory by RT-PCR and Real time PCR methods. We hope that, our study shed further light to the precise mechanism of gene expression regulation in MS patients. In summery, this study supports the view that *lnc-IL7R* may be involved in the pathogenesis of RR-MS.

1199W

Divergent transcription of the *BDNF* gene in human and mouse brain: relevance for schizophrenia. *G. Ursini[1,2], G. Punzi[1,2], J. H. Shin[1], K. Maynard[1], E. Radulescu[1], A. Jaffe[1], J. E. Kleinman[1], T. M. Hyde[1], Y. Jia[1], K. Martinowich[1], D. R. Weinberger[1].* 1) Lieber Institute for Brain Development, Baltimore, MD; 2) Group of Psychiatric Neuroscience, Aldo Moro University, Bari, Italy.

Background: Non-coding RNA (ncRNA) transcription by RNA polymerase II often initiates from bidirectional promoters that synthesize mRNA and ncRNA in opposite directions. These divergent ncRNAs may be particularly important in CNS function as cells of neural origin are highly transcriptionally active and show robust ncRNA expression. *BDNF* is a complex and highly regulated gene: several untranslated 5' exons can be spliced with a 3' coding exon providing bipartite or tripartite transcripts and multiple splice variants. Here we detected and analyzed previously unknown divergent transcription in this locus. Methods: PolyA enriched RNA was extracted from post-mortem human and mouse prefrontal cortex (PFC) and then purified and enriched with PCR to create a cDNA library for high throughput sequencing using the Illumina HiSeq2000. We used Race-PCR, followed by PacBio Sequencing of the PCR amplicons, in order to detect the structure of the divergent transcripts. We performed a KCl-induced depolarization experiment on cultured E14 mouse cortical neurons. A functional magnetic resonance imaging analysis of brain physiology *in vivo* was performed in 326 healthy volunteers, 56 patients with schizophrenia and 84 siblings. Results: In the human and mouse transcriptome, novel antisense divergent ncRNAs (divRs) are initiated from bidirectional promoters located in the region of *BDNF* exons I, II and III and have different 3' terminations, also located 50kb 5' of *BDNF*. Expression of these divRs is low at baseline, but increases 20-fold following induced neural activity ($p<0.01$). We found that the expression of divRs is significantly greater in patients with schizophrenia compared with controls ($F1, 200=3.8$, $p=.04$) and genetic variants associated with expression of these divRNAs ($p<0.01$) show association with schizophrenia ($p<1e-4$) and predict PFC activity measure with fMRI during working memory in patients with schizophrenia and their healthy siblings. Conclusions: We demonstrate multiple antisense divRs in the *BDNF* locus, revealing an additional complexity in the biology of *BDNF* which may be differentially regulated in schizophrenia as well as other disorders. Divergent transcription might contribute to the complex regulation of the *BDNF* gene, in human and in mouse, specifically after neuron depolarization. More in general, when mapping a phenotype to a certain genomic locus, it is necessary to consider ncRNAs and bidirectional promoters as causes for phenotypic variability.

1200T

Gene expression profiles of cultured neural progenitor cells from patients with schizophrenia provide insight into the disease. *C. Armoskus, V. Spitsyna, T. Souaiaia, C. Walker, J. Nguyen, A. Camarena, J. Herstein, K. Wang, J. A. Knowles, O. V. Evgrafov.* Zilkha Neurogenetic Institute, USC, Los Angeles, CA.

Gene expression profiling by RNA-Seq is increasingly being used to investigate a variety of mental disorders, including schizophrenia (SZ). However, most studies examine post-mortem brain, which may not be an adequate tissue for investigation of brain development, or the blood transcriptome, which may not be fully representative of neural gene expression. In this study, we investigated gene expression in cultured neural progenitor cells derived from olfactory neuroepithelium (CNON) from 82 patients with SZ and 72 controls. Cells of this type divide, migrate, and differentiate into neurons, demonstrating the same developmental processes that define the size and structure of components of the nervous system. Libraries were made using TruSeq Stranded Total RNA library preparation kits (Illumina) and sequenced on HiSeq2000 (Illumina). Reads were aligned and counted with GT-FAR against hg19/GenCode 19. Differential expression (DE) analysis using DESeq2 revealed 105 genes DE in SZ (FDR < 0. 05). Several DE genes, such as FGFR2, PPARGC1A, VAV3, NRXN3, ADRA2A, ABCA1, and PLAT have previously been implicated in SZ based on GWAS or candidate gene association studies. Other DE genes, including CCL8, CCL11, CNTNAP3, PDE8B, and TGFB2, have previously been reported as upregulated in SZ, matching our observations. HTR2B, a serotonin receptor, is over-expressed in SZ and has not been previously associated with SZ but is a functionally plausible candidate. IPA canonical pathway analysis showed enrichment for TR/RXR and PPARα/RXRα activation pathways. Notably, both pathways were found significantly enriched in a network created based on GWAS data. Enrichment for biological processes from Gene Ontology included “cell migration”, “cell adhesion”, “tissue development”, and “positive regulation of cell proliferation”, which are processes involved in neurodevelopment, and “positive regulation of MAPK cascade”. The KEGG pathway “Cytokine-cytokine receptor interaction” was also enriched, supporting the hypothesis of cytokine involvement in SZ etiology. Results of transcriptome analysis of CNON samples are strongly supported by other studies using different methods and different cellular or animal models. However, the CNON model has the advantages of allowing genetic modification or pharmaceutical treatment of individual cell lines. CNON cell lines also have the potential to be differentiated into neurons to study disease-specific changes in synaptic machinery.

1201F

Regulatory Function of Schizophrenia-Associated Variants in *CACNA1C*. *N. Eckart[1], R. Wang[1], R. Yang[2], Q. Song[3], H. Zhu[3], D. Valle[1,4], D. Avramopoulos[1, 2].* 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Psychiatry, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Pharmacology and Molecular Sciences, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD.

Schizophrenia is a chronic psychiatric disorder with 60-80% heritability. Several GWAS have repeatedly identified the SNP rs1006737, an intronic variant in the gene *CACNA1C*, to be strongly associated with disease risk. We and others have previously shown a correlation between genotype at this SNP and steady state levels of *CACNA1C* mRNA in human post mortem brains, suggesting it tags a regulatory variant at this locus. Here we report on our search among variants in high linkage disequilibrium (r2 > 0. 8) for those that may be functionally relevant. We consistently observe that the risk allele of rs4765905, a SNP tagged by rs1006737, shows significantly reduced enhancer activity (p=1. 5 *10-6) in dual luciferase reporter assays on human neuroblastoma SK-N-SH cells. The two alleles of this SNP also show different affinity for proteins or complexes extracted from SK-N-SH nuclei in electrophoretic mobility shift assays (EMSA). Using protein microarrays we show allele-specific binding for rs4765905 to a number of proteins, including transcription factors such as ZKSCAN5 and HR. This evidence suggest that rs4765905 might have regulatory function. While only rs4765905 shows differences in luciferase assays, 13 of 16 SNPs examined by EMSA show allele-specific protein binding. Based on the observed electrophoretic shift, it appears that it may be the same protein complexes that bind most of these variant sequences. Our data from the protein microarrays also show that 15 of the 4215 proteins bind 4 or more of the 9 SNPs examined thus far. These observations suggest the possibility that complex interactions involving multiple SNPs in strong LD might regulate *CACNA1C* expression. *CCAT* is an alternative *CACNA1C* transcript starting from the exon 46 and encodes a transcription factor hypothesized to negatively regulate *CACNA1C* transcription. We applied circularized chromatin conformation capture with next-generation sequencing (4C-seq) from the *CCAT* promoter and found interacting fragments approximately 20kb downstream of the transcription termination site in both HEK293 and SK-N-SH cells, but interaction evidence in the area of the schizophrenia associated SNPs was weak. We are currently interrogating the *CACNA1C* promoter by 4C-seq. Our data help elucidate the molecular mechanism by which one of the best-supported risk loci contributes to schizophrenia through regulation of the *CACNA1C*.

1202W

A human-specific isoform of AS3MT regulated by a human-unique VNTR explains susceptibility to psychiatric illness associated with the 10q24. 32 locus. *M. Li[1], R. Tao[1], A. E. Jaffe[1], J. H. Shin[1], Y. Wang[1], Q. Chen[1], C. Li[1], Y. Jia[1], K. Ohi[1], B. J. Maher[1], R. E. Straub[1], N. J. Brandon[2], A. Cross[2], J. Chenoweth[1], D. Hoeppner[1], H. Wei[1], T. M. Hyde[1], R. McKay[1], J. E. Kleinman[1], D. R. Weinberger[1].* 1) Lieber Institute for Brain Development, Baltimore, MD; 2) AstraZeneca Neuroscience iMED, Cambridge, MA, USA.

Background: Genome-wide association studies (GWAS) have reported many SNPs associated with psychiatric disorders, but knowledge is lacking regarding causative genomic sequences and specific molecular mechanisms. **Methods:** We performed deep RNA-Sequencing in the dorsolateral prefrontal cortex (DLPFC) of human brain from healthy controls and psychiatric patients (N=604). Further analyses were carried out using molecular cloning, qPCR, luciferase assays, DNA methylation analysis, protein characterization in brain and in neuroblastoma and human pluripotent stem cells. **Results:** SNPs across the 10q24. 32 locus showing GWAS association with several psychiatric disorders and spanning multiple genes are associated selectively with the expression of a previously uncharacterized human-specific truncated AS3MT isoform (AS3MTd2d3) in both Caucasian and African American samples of cases and controls (p=1. 15×10-27). These SNPs are in high linkage disequilibrium (LD) with a human unique variable number tandem repeat (VNTR) polymorphism in the first exon of AS3MT; the VNTR risk allele is associated specifically with increased expression of AS3MTd2d3 (p=1. 99x10-30), which is also more abundant in patients than controls (p<0. 0007). VNTR genotype predicts AS3MT promoter activity in luciferase assays and DNA methylation in the spliced 3rd exon (p=9. 31×10-39). AS3MTd2d3 encodes a protein lacking 102 amino acids from the methyltransferase domain, which in brain is comparably abundant to the full-length protein. AS3MTd2d3 is expressed early during human stem cell differentiation toward neuronal fates and lacks arsenic methyltransferase activity. **Conclusions:** These results provide a molecular explanation for the prominent 10q24. 32 locus association, implicating a novel and evolutionarily recent protein involved in early brain development and risk for psychiatric illness.

1203T

Comparative transcriptomic and metabolomic profiling of psychiatric disorders across three brain regions. *R. Ramaker[1,2], K. Bowling[1], B. Lassiegne[1], J. Gertz[1], K. Varley[1], N. Davis[1], P. Cartegena[4], M. Vawter[4], D. Walsh[4], B. Bunney[4], J. Barchas[5], W. Bunney[4], S. Watson[3], H. Akil[3], S. Cooper[1], R. Myers[1].* 1) Department of Genetics, University of Alabama at Birmingham, Birmingham, AL; 2) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 3) University of Michigan, Ann Arbor, MI; 4) University of California at Irvine, Irvine, CA; 5) Weill Cornell, New York, NY.

Neuropsychiatric disorders comprise 13% of the global burden of disease and account for a staggering 184 million disability-adjusted life years (DALYs) worldwide. Schizophrenia (SZ), bipolar disorder (BPD), and major depression disorder (MDD) are multigenic diseases with complex etiology that combine to account for over 50% of these mental health related DALYs. Furthermore, current therapies for these psychiatric disorders are not effective in many patients and may treat only a subset of an individual patient's symptoms. Approaches targeting the underlying molecular pathologies within and across these disorders are necessary to address the enormous psychiatric component of global disease burden and improve care for the millions of Americans diagnosed with these conditions. We performed gene expression profiling by RNA sequencing on dissected post-mortem tissues from the anterior cingulate cortex (AnCg), dorsolateral prefrontal cortex (DLPFC), and nucleus accumbens (nAcc) from four well-documented cohorts of 24 patients each with SZ, BPD, MDD and 24 matched controls (CTL). We also conducted untargeted metabolomic profiling via two-dimensional gas chromatography with mass spectrometry (2D-GCMS) in AnCg tissue from the same subjects across each disorder. The most significant gene expression signals were brain region-specific with the most robust disease differences seen in the AnCg of SZs compared to CTLs although more subtle changes were observed in the DLPFC and nACC. Our identification of overlapping RNA expression profiles between BPD and SZ suggest that a subset of patients with these disorders share a common molecular signature. Combined transcriptomic and metabolomic analyses provide evidence to further previous work demonstrating that dysregulated γ-aminobutyric acid (GABA) and glutamate metabolism are major drivers in a subset of SZ and BPD patients. Examination of transcripts previously associated with individual neuronal cell types indicates different cell populations are present between brain regions and disease groups. Moreover, we show that SNPs identified by GWAS and exome sequencing are overrepresented near genes differentially expressed in BPD and SZ. This study highlights the power of pairing transcriptomic and metabolomic profiling to better understand complex psychiatric disorders.

1204F

Identifying enhancer variants at the *POU3F2* locus associated with both cognition and neuropsychiatric disease. *S. Q. Shen, J. S. Kim-Han, J. C. Corbo.* Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO.

Expansion of the neocortex, especially of the upper layers, is thought to underlie the advanced cognitive capacities of humans, as well as their unique susceptibility to neuropsychiatric disease. Several large genome-wide association studies (GWAS's) have recently identified non-coding variants associated with both increased cognitive performance and increased risk for bipolar disorder. This region is located ~1 Mb upstream of *POU3F2*, a transcription factor important for the development of the upper layers of the cerebral cortex. We hypothesize that the causal variant at this locus exerts its effect by altering *POU3F2* expression levels. Using computational and experimental approaches, we have identified two neurodevelopmental enhancers within this region. These enhancers contain two common human variants that are in strong linkage disequilibrium with the tagging SNPs in the GWAS's, and thus may represent causal variants. These variants affect highly conserved nucleotides and have high predicted pathogenicity. We have generated transgenic reporter mice, as well as mutant CRISPR-Cas mice with germline deletions of the orthologous enhancers, for detailed *in vivo* and *in vitro* phenotyping. In this way, we hope to elucidate the mechanistic link between cognition and neuropsychiatric disease at a molecular level.

A polymorphism in human α-synuclein affects 3'UTR mRNA isoform expression. *E. S. Barrie, S. K. Handelman, J. T. Frater, M. Kataki, D. Scharre, W. Sadee.* The Ohio State University, Columbus, OH.

Aggregation of alpha-synuclein, encoded by the gene *SNCA,* is the primary structural component of Lewy bodies, the hallmark of Parkinson's disease and frequently found in Alzheimer's disease. Its physiological functions involve dopamine signaling and regulation. The purpose of this study was to identify *cis*-acting regulatory variants in the *SNCA* gene region that affect transcription and mRNA processing. To detect these variants, we use measurements of allelic mRNA ratios in human brain RNA samples. Allelic ratios deviated significantly from unity when measured at a SNP in the middle of the 3χ untranslated region (UTR), but not at its start, suggesting genetic regulation of RNA isoforms with different length 3χUTRs. Scanning of the *SNCA* gene locus in multiple brain samples identified a SNP in the 3χUTR of *SNCA* strongly associated with instances of allelic imbalance. While this SNP does not overlap a microRNA binding site, a non-coding RNA running antisense to the 3χUTR expressed in these brain samples could also play a role. To assess the clinical impact of this variant, we queried the results from multiple neurocognitive genome-wide association studies (GWAS). Although not directly implicated, this candidate regulatory SNP from our study was in linkage disequilibrium with multiple SNPs significantly associated with Parkinson's disease in GWAS, all part of a long haplotype apparently implicated in pathophysiology. Our results indicate that a variant regulates expression of *SNCA* RNA isoforms and may be implicated in disease risk.

Elucidating the molecular pathways in X-linked dystonia-parkinsonism (XDP): Expression profiling in blood and fibroblasts followed by target transcript analysis in iPSC-derived neurons. *K. Freimann[1], A. Domingo[1,2], A. Westenberger[1], D. Amar[3], L. Lee[2], R. Rosales[2], R. Jamora[2], E. dela Paz[2], R. Shamir[3], P. Seibler[1], C. Klein[1].* 1) Institute of Neurogenetics, University of Lübeck, Lübeck , Germany; 2) XDP Study Group, Manila, Philippines; 3) Edmond J. Safra Center for Bioinformatics, Tel Aviv University, Tel Aviv, Israel.

Objective: Identification of dysregulated genes that might be causative of X-linked dystonia-parkinsonism (XDP) in blood as well as fibroblasts and subsequent validation in iPSC-derived neurons. Background: Genetic studies have suggested that TAF1 (TATA-binding protein associated factor 1), a component of RNA polymerase II-based transcription, plays a critical role in the pathogenesis of XDP. Given that several gaps remain in the exact molecular mechanism of XDP pathogenesis, it is plausible that also further transcriptional differences may be causative of the clinical phenotype. Methods: RNA was extracted from blood and from cultured fibroblasts of XDP patients and controls and subjected to microarray-based genome-wide expression profiling. Fibroblasts were reprogrammed and characterized with respect to pluripotency markers. Three patient and three control iPS cell lines were differentiated into cortical neurons for 66 days. Identified dysregulated transcripts were validated in blood and fibroblasts by quantitative PCR and further analyzed in iPSC-derived neurons. Results: In contrast to blood and fibroblasts, the canonical transcript of *TAF1* was not underexpressed in iPSC-derived neurons of patients versus those of controls (fold change 1. 08). Out of the other analyzed transcripts we saw underexpression of *Synaptotagmin-Like 2* (*SYTL2*, coding for a protein that is involved in exocytosis and vesicle docking) and *Chemokine-Like Receptor 1* (*CMKLR1*, coding for a receptor involved in several signaling cascades) with fold changes of -1. 3 and -5. 7 respectively. Conclusions: In our study, we show the first transcriptional analysis of dysregulated genes in a neuronal model of XDP. Taking clues from microarray analysis in blood and fibroblasts, we found genes related to vesicular function and intracellular signaling to be downregulated in iPSC-derived neurons. Nevertheless, the comparison between the different tissues clearly indicates differential expression strengthening the fact that a cellular model, recapitulating the disease phenotype, of an otherwise inaccessible tissue is needed. Considering that neuronal transcripts of genes other than *TAF1* might be involved in the pathogenesis of XDP, this present cellular model may serve as a valuable tool for future studies.

1207F

Transcriptional networks disentangle cognitive decline from Alzheimer's neuropathology. *S. Mostafavi[1], C. Gaiteri[2], J. Xu[3], C. White[3], S. Sullivan[3], C. McCabe[4], E. Bradshaw[3], T. Young-Pearse[3], L. Yu[2], L. Chibnic[3], N. Pochet[3], J. Schneider[2], D. A. Bennett[2], P. L. De Jager[3,4].* 1) University of British Columbia, Vancouver; 2) Rush University; 3) Harvard Medical School; 4) Broad Institute.

Age-related cognitive decline is Alzheimer's disease (AD) is associated with multiple neuropathologies that are linked to impairment of neuronal function and eventual neuronal loss. These neuropathologies accumulate slowly during the long asymptomatic prodromal phase of AD. Only 21 variants have been associated with AD susceptibility despite large GWAS, and the genomic architecture of this disease and age-related cognitive decline remains poorly characterized. Here, we take a complementary approach and leverage RNA-sequencing data from dorso-lateral prefrontal cortex of 507 subjects from a longitudinal aging cohort, in order to resolve the transcriptional changes related to cognitive decline from those that are related to brain pathology. In particular, in order to tease apart merely correlated from likely consequential associations related to cognitive decline, we developed a probabilistic model for jointly analyzing multiple AD-related traits, confounding factors such as cell type composition, and modules of co-expressed genes. Our approach identifies co-expressed gene modules relevant to AD-pathology and cognitive decline and learns a directed Bayesian network that relates module-level gene expression to AD-related traits and cell type composition. From 47 modules observed in the human brain, this approach identifies 6 modules of co-expressed genes that are directly associated (p<1e-6) with cognitive decline or AD pathology. Inflammation-related gene modules appear to play a modest, indirect role in this network, and, using four different approaches and AD GWAS results, we find that today's limited genetic architecture of AD susceptibility does not strongly influence our network structure. Rather, it highlights the importance of Module 109, enriched for genes related to cell cycle regulation, as being proximal to cognitive decline in the sequence of molecular events leading to dementia (p<1e-8). While it has an effect on amyloid pathology, its effect on cognitive decline is largely mediated through non-amyloid processes. We replicate this finding in both an additional set of 96 subjects from our cohort (p<0. 005) and in an independent microarray dataset from frontal cortex of 300 individuals (p<1e-6). shRNA and ORF perturbation of elements of module 109 in human astrocytes supports the coherence of this module*in vitro*form a preliminary basis to characterize its effects on AD-relevant outcomes such as APP processing or synaptic function.

1208W

Transcriptome analysis of human induced pluripotent stem cells and neural progenitor cells in Tourette's Disorder. *N. Sun[1,2], RP. Hart[2,3,4], L. Deng[1,2], JC. Moore[1,2,3], JA. Tischfield[1,2,3], GA. Heiman[1,2].* 1) Genetics, Rutgers University, Piscataway, NJ; 2) Human Genetics Institute of New Jersey, Piscataway, NJ; 3) RUCDR Infinite Biologicals NIMH Stem Cell Resource, Piscataway, NJ; 4) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ.

Tourette Disorder (TD) is a heritable neurodevelopmental disorder characterized by the presence of both motor and vocal tics. Deleterious mutations in protein coding genes have been identified in subsets of TD individuals[GAH1]. However, no single gene with recurrent mutations has been reported. To better understand the genetic architecture of TD, we studied members of three multiplex families (families with multiply-affected individuals) that contain a family-specific variant co-segregating with TD. These variants are known to change the function of the gene product. Understanding how these variants alter gene expression of neurobiological pathways can help clarify the neuropathology of TD and suggest other genes involved in those pathways. To look for gene expression alterations during early neural development, we performed RNA sequencing on human induced pluripotent stem cells (iPSCs) and neural progenitors cells (NPCs) derived from individuals with and with TD from each family. By using a customized analytical pipeline comprised of publically-available bioinformatics tools, the gene expression profiles of TD and control iPSCs/NPCs were compared and differentially expressed genes (DEGs) were selected. Neurobiological pathways in which the DEGs are enriched in are identified using multiple pathway analysis and annotation approaches. 120 DEGs from NPCs of one family and 346 DEGs from iPSCs of another family were initially analyzed. We will study the functional changes of common pathways shared by the three families and further investigate cellular phenotypes in TD.

1209T

Gene expression profiling in LRRK2-G2019S purified iPSC-derived dopaminergic neuronal models of Parkinson's disease. *C. Webber[1], C. Sandor[1], P. Robertson[2], A. Heger[3], R. Wade-Martins[2].* 1) MRC Functional Genomics Unit, Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK; 2) Oxford Parkinson's Disease Centre, Department of Physiology, Anatomy and Genetics, Le Gros Clark Building, University of Oxford, Oxford, UK; 3) MRC Computational Genomics Analysis and Training Programme, MRC Functional Genomics Unit, Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, UK.

The *LRRK2* **G2019S** variant is significantly associated with both familial and sporadic forms of Parkinson's disease **(PD)**. However, the molecular pathways perturbed by this variant that predispose to the pathological loss of nigral dopaminergic neurons remain unknown. To identify these pathways, we compared the RNA-sequencing profiles of purified populations of induced pluripotent stem cell **(iPSC)-**derived dopaminergic midbrain neurons originating from three PD patients carrying *LRRK2* G2019S mutations to profiles similarly obtained from three controls. Comparison of the transcriptional profiles pre- and post-purification demonstrated that cellular heterogeneity accounts for more of the transcriptional variation than the genetic background. Amongst 53 postmortem tissue profiles reported by the Genotype-Tissue Expression **(GTEx)** project, our iPSC-derived dopaminergic midbrain neuron transcriptional profiles were most similar to the nigral tissue profile. Comparing the PD *LRRK2* G2019S line transcriptional profiles to controls identified 168 protein-coding genes that were differentially expressed (DE) between the cases and controls. Network analyses showed these 168 DE genes to be functionally-coherent with distinct clusters of functionally-related genes demonstrating concordant increases or decreases in expression. Notably, DE genes were enriched in genes whose orthologues' disruption in the mouse yields abnormal motor capabilities/coordination/movement phenotypes (**ab motor c/c/m**; FDR < 5%) and this enrichment concurringly segregates with those DE genes that demonstrate reduced expression. Of the 14 PD GWAS risk loci that included a gene expressed in these iPSC-derived neurons, 4 loci harboured a DE gene (p=0. 023) including *SYT4* (Synaptotagmin IV) which is also associated with ab motor c/c/m phenotypes. Analyses of the counteracting drug response profiles through Connectivity Map identifies several significant associations that include clioquinol, acompoundknown to rescue Parkinsonism and dementia phenotypes of the tau-knockout mouse. These results demonstrate the potential of iPSC-derived models to capture the molecular perturbations associated with a neurodegenerative disorder such PD.

1210F

The effects of perinatal Fluoxetine (FLX) exposure in the modulation of neurodevelopment using the *Shank3* $^{e4\text{-}9/+}$ mutant mouse model. *J. Murry[1], D. Engler[3], C. Ljungberg[2], I. Van den Veyver[1,2,4].* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Obstetrics & Gynecology, Baylor College of Medicine, Houston, TX; 3) Proteomics Core at Houston Methodist Research Institute, Houston, TX; 4) The Jan and Dan Neurological Research Institute at Texas Children's Hospital TX, 77030.

Autism spectrum disorder (ASD) manifests with repetitive behaviors, social and communication impairments. Early environmental exposures concurrent with genetic factors are implicated in ASD. Genes like *SHANK3,* affecting synaptic function, are causative in a subset of ASD patients and *Shank3* null mice exhibit ASD-like behavior. Perturbed serotonergic signaling has been reported in ASD and FLX, a Selective Serotonin Reuptake Inhibitor, is an increasingly common early life exposure. We hypothesized that ASD-associated risk alleles (*Shank3*) in conjunction with perinatal exposures (FLX) modulate neurodevelopment, increasing penetrance of offspring behavior disturbances. Using a *Shank3* mutant mouse model, HET dams (n=21-28) were exposed to FLX (15mg/kg) in drinking water during pregnancy (dpc0) and lactation (until PND7) and mated with HET males. FLX and its active metabolite, Norfluoxetine in plasma was within range by mass spectrometry. Adult male and female offspring (KO, HET, WT) (+/-FLX) were tested for anxiety-like, repetitive, and social behaviors. After behavior testing, brains were harvested for histological and molecular analysis. Two-way ANOVA was used to test gene-environment (GXE) interactions, with Tukey's posthoc test. Student's t-test was used to test preferences. Litter sizes of HET(+FLX) dams differed significantly from HET(-FLX) dams)(p<0. 05), with no difference in adverse pregnancy outcomes. There were minor weight differences at P28 in HET(+FLX) compared to HET(-FLX) males that equalized upon aging, but differences between KO(+FLX) and KO(-FLX) females (p<0. 05)persisted. In elevated plus maze, KO(-FLX) males had more open arm entries vs. WT and HET(-FLX) (p<0. 05) and traveled greater distance in open arm than WT(-FLX)(p<0. 001), with a significant GXE interaction (p<0. 05), but exposure resulted in a trend towards more anxiety in KO males. In open field assay, vertical locomotion was lower in KO(+FLX) males vs. HET(+FLX)(p<0. 01) with a significant GXE interaction (p<0. 01). In three-chamber test, both KO(+FLX) males and females lacked social preference (p=0. 8; 0. 4*)*. In direct social interaction test, WT and HET(+FLX) males have increased active social contact vs. WT and HET(-FLX) males (p<0. 001; 0. 05). No repetitive behavior was observed. These data suggest that chronic FLX exposure may inhibit social and anxiety-like behaviors. Ongoing experiments will address molecular and structural effects of developmental FLX exposure in these mice.

1211W

Multimodal twin research approach to identify genetic and environmental factors in neurodevelopmental disorders. *K. Tammimies[1], C. Willfors[1], M. Arora[2], B. Thiruvahindrapuram[3], V. Bölte[1,7].* 1) Women's and Children's Health, Center of Neurodeve, Karolinska Institutet, Stockholm, Sweden; 2) Department of Preventive Medicine, Icahn School of Medicine at Mount Sinai, New York, United States; 3) The Centre for Applied Genomics, Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Canada; 4) Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 5) Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden; 6) Clinical Neurochemistry Laboratory, Institute of Neuroscience and Physiology, Department of Psychiatry and Neurochemistry, The Sahlgrenska Academy, University of Gothenburg, Mölndal, Sweden; 7) Child and Adolescent Psychiatry Stockholm, Center for Psychiatry Research, Stockholm County Council, Stockholm, Sweden; 8) Department of Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden; 9) Public Health Epidemiology, Department of Public Health Sciences, Karolinska Institutet, Stockholm, Sweden; 10) Institute of Neuroscience and Physiology, the Sahlgrenska Academy at The Gothenburg University, Gothenburg, Sweden; 11) Departments of Psychiatry and Preventive Medicine, Mount Sinai School of Medicine, New York, NY, USA; 12) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

Neurodevelopmental disorders (NDDs), such as autism spectrum disorders (ASD) and attention deficit hyperactivity disorder (ADHD), are highly heterogeneous conditions with a strong genetic component. Also the contribution of environmental factors has been increasingly acknowledged. The Roots of Autism and ADHD Twin Study in Sweden (RATSS) is an ongoing project investigating monozygotic (MZ) and dizygotic twins carefully assessed for NDD phenotypes. In addition to the detailed neuropsychological profiles, we have collected medical records, brain imaging data and multilevel biological samples such as blood, cerebrospinal fluid, skin biopsies and baby teeth to enable multimodal approach to investigate the contribution of genetic and environmental factors in these disorders. To date more than 100 twin pairs have participated in RATSS. We are currently analyzing possible post-twinning somatic mutations and putative pathogenic mutations in the twins using whole exome sequencing (WES), whole genome sequencing and DNA microarrays. In parallel, the biological samples are analyzed for proteomics, metal concentrations and metabolomics to identify co-twin and global differences associated with NDDs and correlated with the genetic findings. In our pilot study, WES data was acquired for nine MZ twin pairs either primary or secondary discordant for ASD and ADHD. No early somatic mutations were found in these twin pairs, however putative pathogenic mutations were identified in three of the nine pairs. In all of these three pairs, medical records revealed that both twins have earlier exhibited symptoms in the NDD spectrum. For example, in male MZ twin pair showing differences in developmental trajectories for ASD and ADHD, a maternally inherited hemizygous splice site variant affecting *CASK* was identified. This variant resulted in two different mutant transcript (p. del389-415; p. A406fs*4). We are now analyzing neurons derived from immunopluripotent stem cells from this twin pair to identify cellular phenotypes associated with the *CASK* mutation and how the different environmental components identified in the other screens affect the splicing pattern caused by the mutation to understand the discordant phenotypes seen in the twins. Our multimodal approach and powerful co-twin design will be able to provide novel insights into penetrance and expressivity of genetic variants and explore the genetic x environment interactions to better understand the heterogeneous nature of NDDs.

1212T

An integrative disease-relevant multi-omics analysis to predict risk for stress-related psychiatric disorders. *J. Arloth[1,2], N. Møller[2], E. B. Binder[1,3].* 1) Translational Research in Psychiatry, Max Planck Institute of Psychiatry, Munich,Germany; 2) Institute of Computational Biology - Helmholtz Zentrum Müchen, Neuherberg, Germany; 3) Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, GA, USA.

Depression risk is exacerbated by genetic factors and stress exposure; however, the biological mechanisms through which these factors interact to confer depression risk are poorly understood. One putative biological mechanism implicates variability in the ability of cortisol, released in response to stress, to trigger a cascade of adaptive genomic and non-genomic processes through glucocorticoid receptor (GR) activation. We applied expression quantitative trait locus (eQTL) analysis using genome-wide gene expression data (Illumina HT12v3, v4) from GR-stimulated gene expression in peripheral blood cells of 300 individuals and genome-wide imputed SNP array data (Illumina 660W-Quad, OmniExpress) to identify genetic variants associated with GR-induced gene expression changes. Secondly, by adopting an expression quantitative trait DNA methylation (eQTM) approach using a linear regression model with an Elastic net penalty, we assessed the predictive ability of the transcriptional response to glucocorticoids and distinct methylation patterns (Illumina 450k). We show that GR-response eQTLs are more distant than SNPs that regulate the baseline gene expression as well as DNA methylation status. One possible explanation for this long-range regulation could be a chromatin interaction between the eSNP locus and the regulated transcript. Which we validated using both ChIA-PET as well as chromatin confirmation capture analysis. Moreover, we could show that such eQTL SNPs are highly enriched among SNPs associated with MDD relative to baseline eQTL SNPs as well as schizophrenia (FDRs<0. 001) and the PGC cross-disorder analysis (FDR<0. 066). The SNPs showing an association with both GR-mediated transcription and MDD cumulatively influence intermediate phenotypes for psychiatric risk such as amygdala activation to threat, as shown in an independent imaging cohort (n = 647). These cumulative GR-risk SNPs also interact with exposure to childhood adversity to predict mood and anxiety disorders in adulthood. Furthermore, network analysis suggests that the eQTL transcripts functionally interact to perform an orchestrated function. We currently explore whether epigenetic changes associated with these GR-response eQTLs could provide additional insights into disease risk mechanisms. Disease-relevant stimuli in eQTL and eQTM approaches can expand our understanding of the genetic basis of stress-related disorders, in which the GR-function plays an important pathophysiologic role.

1213F

Snus use is not associated with variation in the *CHRNA5-CHRNA3-CHRNB4* gene cluster in Sweden, Norway and Finland. *P. A. Lind[1], D. J. Benjamin[2], J. Buchwald[3], D. Cesarini[4], M. E. Gabrielsen[5], J. K. Hällfors[3], M. Johannesson[6], J. Kaprio[3], T. Korhonen[3], H. E. Krokan[7], A. M. Loukola[3], P. K. E. Magnusson[8], S. E. Medland[1], R. J. Rose[9], F. Skorpen[5], E. B. Stovner[10].* 1) Quantitative Genetics, QIMR Berghofer Medical Research Institute, Herston, Australia; 2) Center for Economic and Social Research, University of Southern California, Los Angeles, CA; 3) Department of Public Health, Faculty of Medicine, University of Helsinki, Helsinki, Finland; 4) Center for Experimental Social Science, Department of Economics, New York University, New York, NY; 5) Department of Laboratory Medicine, Children's and Women's Health, Norwegian University of Science and Technology, Trondheim, Norway; 6) Department of Economics, Stockholm School of Economics, Stockholm, Sweden; 7) Department of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Trondheim, Norway; 8) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 9) Department of Psychological and Brain Sciences, Indiana University, Bloomington, IN; 10) Department of Computer and Information Science, Norwegian University of Science and Technology, Trondheim, Norway.

Meta-analyses of genome-wide association studies have established a robust association between the number of cigarettes smoked per day (CPD) and the *CHRNA5-CHRNA3-CHRNB4* gene cluster on chromosome 15q25 which encode nicotinic acetylcholine receptor subunits. Variation in this gene cluster is also associated with nicotine dependence and a wide range of cigarette smoking behaviours. This meta-analysis examines snus use in three Scandinavian cohorts to assess whether the gene cluster is also associated with other forms of tobacco use. Three phenotypes were analysed; age of onset of snus use (AOI), ever versus never snus use (EVRSNUS) and the number of boxes of snus consumed per month (BPM). Association analyses included cigarette use (ever or regular smoking), gender, age, birth year and Principal Components as covariates. This study included a maximum of 7619 participants spanning three countries (Sweden, Norway and Finland): 1474 EVRSNUS cases and 6145 controls, 1205 subjects with AOI and 1247 subjects with BPM data. Meta-analyses were conducted in METAL using summary statistics. There was little or no evidence for association between the snus traits and 15q25 variants (non adjusted P-values > 0. 001). However, three genome-wide significant associations ($p < 5E-08$) were observed in *CHRNB4* for the cigarette-related trait CPD in the Swedish sample. These results provide evidence that the *CHRNA5-CHRNA3-CHRNB4* gene cluster does not have a significant effect on snus use and that the influence of variants in this region on tobacco use may depend on the mode of ingestion.

1214W

Toxicogenetic approach reveals strong genetic control of environmental toxicant levels and surprising relationship with autism susceptibility. *M. Traglia[1], L. A. Croen[2], K. Lyall Dodge[3], A. R Torres[4], M. Kharrazi[5], G. N DeLorenze[2], O. Zerbo[2], G. C Windham[3], L. A Weiss[1].* 1) Department of Psychiatry and Institute for Human Genetics, University of California, San Francisco, 401 Parnassus Ave, LangPorter, San Francisco, CA 94143, USA; 2) Autism Research Program, Division of Research, Kaiser Permanente, 2000 Broadway, Oakland, CA 94612, USA; 3) Division of Environmental and Occupational Disease Control,California Department of Public Health, 850 Marina Bay Pkwy, Bldg. P, Richmond, CA 94804, USA; 4) Center for Persons with Disabilities, Utah State University, 6804 Old Main Hill, Logan, UT 84322-6804, USA; 5) Genetic Disease Screening Program, California Department of Public Health, 850 Marina Bay Pkwy, Richmond, CA 94804, USA.

Maternal exposure to environmental pollution could affect fetal brain development and increase Autism Spectrum Disorder (ASD) risk due to differential genetic susceptibility. To investigate this hypothesis, we analysed genome-wide SNP data along with a set of 7 polybrominated diphenyl ethers, a class of organohalogens used as flame retardants, which accumulate in humans and could act as neurodevelopmental toxicants. Levels of the flame retardants (PBDE 28, 47, 99, 100, 153, and BB153, and their sum)were measured in mid-pregnancy blood samples as previously described (Sjodin, Anal Chem 2004) in a genome-wide genotyped population of 790 women in California (Tsang, PLoS ONE 2013). The offspring from these pregnancies are 390 ASD affected and 400 control children studied in the EMA (Early Markers of Autism) study (Croen, Autism Res 2008). Log10-transformed PBDE levels showed high estimated SNP-based heritability (h2g) accounting for 44% to 87% of variance (P<0. 05, each) in a REML model (Yang, Nat Genet 2010) adjusted for genetic population stratification, maternal education level and country of birth, offspring gender and month of birth, as well as offspring affection status. In addition, 5 out of 7 PBDEs were associated with offspring affection status (P<0. 05, each). Genome-wide association via linear regression highlighted two associated loci for PBDE levels: one locus reached Bonferroni-adjusted significance and maps between ADAMTSL1 and SH3GL2 (PBDE28; P=3x10-8). ADAMTSL1 is involved in extracellular matrix functions, SH3GL2 in synaptic vesicle endocytosis and is associated with cognitive impairment. The second locus maps to CYP2B6 (PBDE99; P=1x10-7) that encodes a lipase oxidase, recently associated with a different class of organohalogens (PCBs). Our results suggest that genetic make-up is a major determinant of circulating levels of environmental toxicants, and imply that an observation of an association between a presumed toxicant and ASD could be due to pleiotropy of pathways involved in xenobiotic metabolism. The genes near loci implicated in controlling PBDE levels include xenobiotic metabolism genes, and genes with associations or functions in neurodevelopment. We thus conclude that future studies investigating associations between environmental exposures and neurodevelopmental outcomes should consider interactions with underlying genetic background.

1215T

The role of translational control in schizophrenia. *A. Dang Do, D. Avramopoulos, D. Valle.* McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

The complex but strongly familial expression, late onset, and variable phenotype of schizophrenia suggests a mechanism where environmental factors influence genetic expression. Genome-wide association studies (GWAS) and whole exome sequencing (WES) have provided many potential genetic targets. However, the neurobiological connection between sequence variants and disease is largely uncharacterized. Regulation of mRNA translation initiation is a major mechanism for selective protein expression in response to specific environmental stressors. This modulation works in parts through the presence of upstream open reading frames (uORF) or 5' terminal oligopyrimidine tract (5'-TOP). We hypothesize that transcripts of genes associated with schizophrenia contain 5' non-coding region (NCR) sequences that are targets for translational regulation. To test this we examined the intersections between published data sets from GWAS and WES studies of individuals with schizophrenia, and from *in silico* and experimental studies of transcripts containing uORF or 5'-TOP sequences. Of transcripts from genes highly expressed in nerve tissue 1. 7% overlap with the uORF transcript set and 4. 6% with the 5'-TOP transcript set. In comparison, of the transcripts from genes associated with schizophrenia by GWAS 1. 8% (Fisher's one-tailed p = 0. 52, compared to nerve transcript set) contain uORF, and 3. 4% (p = 0. 15) contain 5'-TOP sequences. Of the transcripts from genes associated with schizophrenia by WES 1. 4% (p = 0. 30) contain uORF, and 5. 6% (p = 0. 15) contain 5'-TOP sequences. When examined at the gene level, significantly more genes identified from the schizophrenia WES study have transcripts containing 5'-TOP sequences than those from the nerve gene set (14. 3% vs 8. 3 %, respectively; p = 0. 013). Factors explaining these results may include: 1) WES studies focus on exonic variants, thus variants in the NCR that may associate with schizophrenia may be missed; 2) The enrichment of transcripts with uORF or 5'-TOP sequences contributing to the pathology of schizophrenia may be specific to certain biological pathways or processes; 3) The differential regulation of transcript translation contributing to the pathology of schizophrenia may occur through regulation of proteins in the eukaryotic initiation factor 2 or mechanistic target of rapamycin pathways and not at the sequence level. We are exploring these possibilities.

Expression Profiles of miRNA in Peripheral Blood Associated with Post-Traumatic Stress Disorder in Military Service Members. *C. Martin[1], S. Yun[2], J. Gill[1], H. Rusch[1], H. Kim[1], A. Cashion[1].* 1) National Institute of Nursing Research, Bethesda, MD; 2) Yotta Biomed, Potomac, MD.

The etiology of Post-Traumatic Stress Disorder (PTSD) likely involves the interaction of numerous genetic and environmental factors via gene expression changes, which may be potential indicators of neural processes. MicroRNA (miRNA) is a potential regulator of gene expression, and miRNAs have been identified as biomarkers for a range of medical conditions from cancer to autoimmune disorders. However, it is not yet clear how expression of miRNA affects maintenance of and recovery from symptoms in PTSD. We tested the following hypotheses: (1) detectable levels of miRNA will be present in peripheral blood of combat-exposed military service members following deployment (2) post-trauma expression levels of miRNA in peripheral blood would differ between participants based on PTSD symptomology. Ion Torrent PGM was used to sequence miRNA in peripheral blood samples from 32 military personnel (11 PTSD-maintained subjects, 11 PTSD-improved subjects, and 10 non-PTSD control subjects) following return from deployment to war zones in Iraq or Afghanistan and again at a 6 month follow-up. Whole-genome miRNA profiles were generated by trimming and aligning sequences to both hg19 and miRBase20, and expression of annotated genes were compared by ANOVA run on an in-house PERL script. Preliminary results demonstrated presence of miRNA sequences in all peripheral blood samples. Mean length of pre-trimmed reads was 40bp. They were trimmed to 25bp and aligned to the hg19 reference genome. Of these reads, 55. 5% aligned to the miRBase20 reference set, suggesting that some of the miRNA associated with PTSD may be novel sequences. Of the miRNA sequences that were mapped, differences were noted both in variety and relative abundance of sequences between tested groups. This study is ongoing and current findings are being verified with quantitative PCR. Results will also be corroborated with microarray data of mRNA expression. These findings will lead to an increased understanding of how dynamic regulation of genes associated with PTSD affects presentation of clinical symptoms, as well as identify potential biomarkers that can be useful in a military context as a diagnostic tool to inform post-deployment medical screening, and identify appropriate treatment strategies.

Lower Extremity Skeletal Muscle DNA Methylation in Chronic Stroke. *H. Xu[1], AS. Ryan[2,3,4], TG. Forrester[5], YC. Cheng[1], A. Parihar[1], K. Tanner[1], JW. Cole[6], BD. Mitchell[1,7], CE. Hafer-Macko[6,8,9], RF. Macko[2,4,6,8,10].* 1) Division of Endocrinology, Diabetes, and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 2) VA Maryland Exercise and Robotics Center of Excellence(MERCE), Baltimore, MD; 3) The Geriatric Research Education and Clinical Center (GRECC), Baltimroe Department of Veterans Affairs Medical Center,Baltimore, MD; 4) Department of Medicine, University of Maryland School of Medicine, Baltimore, MD; 5) UWI Solutions for Developing Countries, University of the West Indies, Mona Campus, Kingston 7, Jamaica; 6) Department of Neurology, University of Maryland School of Medicine, Baltimore, MD; 7) Department of Epidemiology and Preventive Medicine, University of Maryland School of Medicine, Baltimore, MD; 8) Rehabilitation Research and Development's Maryland Exercise and Robotics Center of Excellence, Baltimore VAMC, Baltimore, MD; 9) Myasthenia Gravis Center, University of Maryland School of Medicine, Baltimore, MD; 10) Department of Physical Therapy and Rehabilitation Science, University of Maryland School of Medicine, Baltimore, MD.

Stroke is the number one cause of serious long-term disability including extremity motor dysfunction in the United States. Skeletal muscle in paretic limbs switches toward fast twitch fiber-type with reduced oxidative capacity, increased intramuscular fat, inflammation, and atrophy, compared to non-paretic muscle. There are differences in muscle transcriptome profiles that relate to these specific phenotypic pathologies, which we postulate could result from post-stroke epigenetic changes. We hypothesize that hemiparetic stroke alters paretic leg skeletal muscle genomic DNA methylation profiles related to these transcriptome and phenotypic abnormalities, compared to non-paretic leg. Five males (mean age 56. 6 ±14. 5 years) with chronic (>6 months) hemiparetic gait post-stroke underwent bilateral vastus lateralis muscle biopsies. Methylation status of genomic DNA was assessed by Illumina 450K Methylation array. We identified 54 (P<0. 001) or 331 (p<0. 005) CpG loci showing differential DNA methylation status between paretic and non-paretic muscle (>1. 3 fold changes). Pathway analysis of the top 100 genes with most significant CpG loci revealed enrichment for those related to remodeling/plasticity, neuronal signaling, energy metabolism and inflammation. Methylation sites mapping to genes related to skeletal and muscle disorders (11 genes) and connective tissue disorders (10 genes) were over-represented in these top 100 genes. Consistent with our previous observation that myogenin (*MYOG*), a muscle-specific myogenesis transcription factor, has lower mRNA expression (-1. 57 fold) in paretic muscle, we show *MYOG*'s upstream transcription regulators, *SIX4* (p= 3. 0*10-3) and *HDAC4* (p= 4. 8*10-3), have reduced methylation at the 1st intron and 2nd intron in paretic vs. non-paretic muscle. Conclusion: We report that hemiparetic stroke produces a distinct profile of genomic DNA methylation alterations in paretic leg skeletal muscle that is consistent with phenotypic and transcriptome abnormalities related to energy metabolism, contractile activity, atrophy and structural remodeling. Further understanding of epigenomic mechanisms regulating skeletal muscle structure and function will facilitate the discovery of therapeutic targets for post-stroke rehabilitation and recovery.

1218T

Sp1 modulation of APP and BACE1 activity as a drug target in Alzheimer's disease. *B. L. Bayon[1], K. Nho[2], B. Maloney[3], N. Chopra[4], D. K. Lahiri[1,3,4].* 1) Department of Medical & Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 2) Department of Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN; 3) Department of Psychiatry, Institute of Psychiatric Research, Indiana University School of Medicine, Indianapolis, IN; 4) Department of Neuroscience, Indiana University School of Medicine, Indianapolis, IN.

β-site APP Cleaving Enzyme (BACE1) is the β-secretase responsible for the rate-limiting cleavage of amyloid-b precursor protein (APP) to amyloid-b (Ab), which oligomerizes and contributes to the plaque formation seen in Alzheimer's disease (AD) which generally occurs in the later stages of life. Expression levels of some transcription factors (TFs) such as Sp1 are perturbed in a latent fashion. Sp1 positively regulates APP and induces BACE1 via their respective promoters. We tested Sp1-mediated regulation of APP with an Sp1 inhibitor, Mithramycin A (MTM), and Tolfenamic acid (TA), an inducer of Sp1 degradation, and with siRNAs in mammalian cell lines (rat neuronal PC12 and human glioblastoma U373), a primary human fetal neuron culture (HFN) and mixed cultures derived from human fetal neurospheres (NSPc). Treatment of PC12 reveals minimal changes in confluence, cytotoxicity, neurite length, and neurite outgrowth after Sp1 knockdown via siRNA or treatment with Sp1 modulating drugs. Morphology and cell death tracking studies from U373 reveal increasing cytotoxicity in MTM concentrations above 10 μM after 36 hours. Treatment of HFN with TA did not affect cell viability with doses up to 5 μM. Western blotting shows a significant decrease in expression of BACE1 after MTM treatment in NSPc and U373. Treatment with TA does not significantly decrease APP or BACE1 in NSPc or U373. APP siRNA knocks down expression of APP in both of these cell types. APP expression is not altered by treatment with TA in NSPc, perhaps due to disparate mechanisms of these Sp1-inhibiting drugs. MTM reduces APP and BACE1 expression. Treatment with Sp1-inhibiting drugs or transfection with Sp1 siRNA does not affect cell viability of primary neurons or differentiated NSPc. We chose single nucleotide polymorphisms (SNPs) within the Sp1 gene from the AD Neuroimaging Initiative GWAS data, performed an association analysis with an AD-specific imaging biomarker (entorhinal cortex thickness), and identified a significant SNP (rs11170553) associated with entorhinal cortex thickness. rs11170553 was also associated with cerebral amyloid deposition. Compounds which modify Sp1 binding to sites on the BACE1 and APP promoters may provide a means to limit the production of Ab peptide and could slow the symptoms of AD. Our results show that appropriate modulation of a specific TF can be a novel drug target for AD.

1219F

Extracellular RNA sequencing to identify RNA biomarkers of head impact in college athletes. *R. Richholt[1], A. Yeri[1], R. Mccoy[2], M. Anastasi[2], S. Althoff[1], A. Allen[1], A. Siniard[1], M. DeBoth[1], I. Malenica[1], T. Beecroft[1], E. Carlson[1], L. Ghaffari[1], S. Allen[1], M. Shahbauder[1], K. Ryden[1], R. Bruhns[1], A. Janss[1], D. Vooletich[3], T. Ide[3], D. Arment[3], D. Objective

When brain injuries occur, rest is essential for recovery. Whenthese injuries go undetected, prognosis worsens and there is increased likelihood ofrepeated injuryandlasting symptoms. Rapid objectivediagnosis in easily obtainable samples is critical to reduce the impact of traumatic brain injury. To work towards that goal, we studied college-aged football players using a combination of in-helmet monitoring andbiospecimenbased RNA biomarker profiling.

Methods

Measurements of head impacts were recorded using the Riddell SRS at every contact practice and game. Urine samples were collected from Arizona State University football players weekly within 24 hours following the completion of a game. Control urine samples were collected from a group of non-contact athletes of similar age as well as from every enrolled player prior to their first full contact practice. Extracellular RNA was isolated from urine with the NORGEN Total RNAPurification Maxi Kit. 2ng of total RNA werereverse transcribed with theClontechSMARTerUniversal Low Input RNA kit, andwhole RNAtranscriptomesequencing libraries were prepared with theClontechLow Input Library Prep kit. Libraries were sequenced on theIlluminaHiSeq2500 with paired-end 83bp runs. Gene counts were computed and normalized with DESeq2. Classification of samples into case and control groups was performed using aRandomForestapproach. 25 genes providing the highest information gain were selected andthentested by classifying cases and controls.

Results

From an average urine specimen, we generated 39 million reads and identified 41 thousand transcripts. Using a Random Forest algorithm, we classified cases and controls for highest magnitude hits and highest frequency hits. 25 genes with the highest information gain were selected for classification. In a preliminary validation of 6 cases and 16 controls, high magnitude hitters were classified with 100% sensitivity and 75% specificity. High frequency hitters were classified with 100% sensitivity and specificity.

Conclusions

This is an early attempt to assess brain injury by quantitativetranscriptomeanalysis. Accurate, unbiased diagnosis of TBI is critical to prognosis of individuals with brain injury. These data suggest that extracellular RNA expression changes following head impacts can be detected in peripheralbiofluidsand serve as biomarkers of TBI.

L-type voltage-sensitive calcium channel subunit (LVSCC)-A1C is associated with increased Parkinson disease risk only when plasma vitamin D concentration is deficient. *L. Wang[1,2], L. Maldonado[1], G. W. Beecham[1,2], E. R. Martin[1,2], M. L. Evatt[3], J. C. Ritchie[4], J. L Haines[5], C. P. Zabetian[6,7], H. Payami[8,9], M. A. Pericak-Vance[1,2], J. M. Vance[1,2], W. K. Scott[1,2].* 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Neurology, Emory University, Atlanta, GA; 4) Department of Pathology, Emory University, Atlanta, GA; 5) Department of Epidemiology and Biostatistics, and Institute for Computational Biology, Case Western Reserve University, Cleveland, OH; 6) Veterans Affairs Puget Sound Health Care System, Seattle, WA; 7) Department of Neurology, University of Washington, Seattle, WA; 8) Departments of Neurology and Genetics, University of Alabama-Birmingham, Birmingham, AL; 9) HudsonAlpha Institute for Biotechnology, Huntsville, AL.

The hallmark of Parkinson disease (PD) is the loss of substantia nigra dopaminergic neurons (SNDNs), which have sustained opening of L-type voltage-sensitive calcium channels (LVSCC) for their pacemaker activity. Maintaining intracellular Ca2+ homeostasis in the face of extended Ca2+ influx puts SNDNs under substantial cellular stress making them vulnerable to cell death. *In vitro* studies show that vitamin D (vit D) promotes neuronal Ca2+ homeostasis by decreasing the expression of the A1C subunit of LVSCC, encoded by the *CACNA1C* gene. Recently, vit D deficiency has been associated with higher risk of PD. We hypothesize that the "missing heritability" in genome-wide association studies (GWAS) in PD includes gene-environment (GxE) interactions. To investigate *CACNA1C*-vit D interaction in modifying PD risk, we utilized two GWAS with vit D measurements: one with 477 cases and 430 controls genotyped on Illumina 610quad chips and one with 482 cases and 412 controls genotyped on Illumina Omni 1M chips. Vit D deficiency (plasma vit D <20 ng/ml) was associated with PD in both datasets (Odds Ratio (OR)=2. 7, *P*<0. 0001; OR=1. 9, *P*=0. 009). Genotypes in both datasets were imputed to 5. 3M SNPs (after quality control) using 1000Genomes reference panels. Joint meta-analysis (JMA) of GxE interaction was conducted by comparing a model containing vit D deficiency, SNP dosage, an interaction term, and covariates (age, sex and sampling season) to a restricted model with only vit D deficiency and covariates, in each dataset separately, and by then meta-analyzing across the two datasets. To adjust for testing multiple SNPs in *CACNA1C*, simpleM was used to estimate the effective number of independent tests (n=314) taking into account linkage disequilibrium among SNPs. The strongest evidence for interaction was found at rs34621387 (JMA *P*=7. 5x10-5, adjusted *P*=0. 02). The minor allele at rs34621387 is associated with increased risk of PD in vit D deficient individuals in both datasets (OR =2. 0, *P*=0. 002; OR=2. 1, *P*=0. 002). The SNP is not associated with PD risk in vit D non-deficient individuals (*P*>0. 8 in both datasets). Thus, risk of PD only increases in carriers of this allele who also have vit D deficiency. Our study demonstrates vit D-gene interaction in PD and suggests that GxE interactions might explain some of the "missing heritability". Importantly, our data suggest that people carrying the minor allele of rs34621387 might benefit more from vit D supplementation to lower PD risk.

1221T

Characterization of a missense variant in the fatty acid amide hydrolase gene (*FAAH*) in pharmacodynamic response to alcohol in nondependent social drinkers and alcohol-related traits in non-treatment-seeking drinkers and individuals seeking treatment for alcohol dependence. *J. Yan[1,2], B. L. Stangl[1], M. L. Schwandt[1], J. Westman[1], P. Spagnolo[1], C. Hodgkinson[3], D. Goldman[3], R. Momenan[1], V. A. Ramchandani[1].* 1) Laboratory of Clinical and Translational Studies, National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD; 2) Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, VA; 3) Laboratory of Neurogenetics, National Institute on Alcohol Abuse and Alcoholism, Rockville, MD.

The endocannabinoid system has been shown to modulate response to alcohol as well as display persistent adaptations to chronic use. A functional missense variant, rs324420 (C385A), in the gene encoding fatty acid amide hydrolase (*FAAH*) has been associated with amygdala habituation to threat, anxiety, fear extinction, stress reactivity and reward-related activity. The A allele of rs324420 confers decreased levels of the FAAH enzyme, which breaks down the endocannabinoid anandamide, and subsequent increased anandamide levels; thus, it is hypothesized to increase anandamide signaling in the brain and potentiate reward-related responses to alcohol. In an effort to investigate the pathways in which this variant plays in alcohol response, this study aimed to characterize its effect on intermediate alcohol-related phenotypes and its interaction with childhood adversity in a sample of individuals seeking treatment for alcohol dependence and non-treatment-seeking drinkers. The total sample consisted of 1170 individuals, a subset of whom participated in an intravenous alcohol self-administration (IV-ASA) study (n=82), wherein participants press a button to self-administer alcohol via IV-infusion, providing greater control over brain exposure to alcohol than oral intake. The association between rs324420 and its interaction with childhood trauma and alcohol traits was assessed using linear and logistic models with sex, age, and ancestry as covariates. Variation in rs324420 was assessed using a dominant model. Adversity was measured using the Childhood Trauma Questionnaire (CTQ), which assesses emotional, sexual, and physical abuse and emotional and physical neglect. Alcohol-related traits included alcohol consumption and problems, subjective response to alcohol, and peak and average breath alcohol concentration (BrAC) reached during the IV-ASA. The A allele was associated with increased average number of drinks consumed and number of heavy drinking days (p<0. 05). No main effects were found for alcohol self-administration in the IV-ASA sample. An interaction between rs324420 and CTQ total score was associated with subjective response following a priming dose of alcohol (p<0. 05). Individuals with the CC genotype and greater childhood trauma scores reported greater response to alcohol following priming. These results suggest differential response to alcohol and childhood trauma based on functional changes in anandamide signaling associated with this polymorphism.

1222F

Brain-derived Neurotrophic Factor genetic polymorphism Val66Met does not interact with stress in Colombian MDD individuals. *A. M. Gaviria-Manrique[1], M. Tovar-Parra[1], C. Cañizares-Escobar[2], Y. Gomez-Maquet[2], A. Arenas[3], M. C. Lattig-Matiz[1].* 1) Centro de Investigaciones Geneticas en Enfermedades humanas, Universidad de los Andes, Bogotá, Colombia; 2) Departamento de Psiquiatria, Universidad de los Andes, Bogotá, Colombia; 3) Clínica la Inmaculada, Bogotá, Colombia.

Major Depressive Disorder (MDD [MIM: 608516]) is a multifactorial disease that affects morbidity, mortality and quality of life. It has a reported heritability of approximately 35%, indicating an important genetic component. Several reports show a clear involvement of the Brain-Derived Neurotrophic Factor Gene (*BDNF*) Val66Met (rs6265) variant to MDD. Additionally, gene x environment interactions demonstrate that stressful life events and the Met variant play an important role in the development of MDD. However, most of the studies have been performed on Caucasian or Chinese populations while South American populations have not been fully studied in this regard. The interaction between early childhood abuse and Val66Met variant was related with negative affectivity in a Colombian non-clinical cohort by Perea et al. However, a meta-analysis conducted by Jiang's group (2013) including different ethnic groups found that the interaction is stronger between adulthood stress and Met genotype. Here we present a case-control study using a clinical Colombian population and match controls. A cognitive diagram of each individual was evaluated using the standard psychological tests M. I. N. I, ESV, STAI and IDER questionnaires after signing informed consent endorsed by the Ethics committee of the Universidad de los Andes; genotyping was performed using qPCR with taqman probes through Applied Biosystems 7500/7500 Fast Real time protocol, and data was analyzed using a multivariate logistic regression and interaction analysis in R software. The homozygous variant for the Val allele was the most common genotype observed in both cases and controls (59,5% and 61,8% respectively). A relevant association between abuse (physical or psychological) (OR=0. 15, p-value=0. 03) and sexual abuse (OR=0. 1, p-value=0. 007), and depression phenotype was found. Additionally, a strong correlation was noticed between the reported negative events number and MDD (OR=0. 04, p-value= 1. 39 e-5). Regarding genotype, no effect of the Val66Met variant and development of clinical depression was observed. When analysis for interaction was performed, no effect of gene x environment action was evidenced between studied variables. Even though it has been well established that *BDNF* plays an important role in the pathogenesis of MDD, this study concludes that we cannot generalize to all populations as our Colombian population may have a set of different genetic risk factors involved in the development of MDD.

1223W

The identification of novel genes in anxiety disorders: a gene x environment correlation and interaction study. *N. W. McGregor[1, 5], J. Dimatelis[2], S. M. J. Hemmings[1], K. Kinnear[3], D. Stein[4, 5], V. Russell[2], C. Lochner[1, 5].* 1) Psychiatry and Genetics, Stellenbosch University, Stellenbosch, Western Cape, South Africa; 2) Human Biology, University of Cape Town, Cape Town, Western Cape, South Africa; 3) Molecular Biology and Human Genetics, Stellenbosch University, Stellenbosch, Western Cape, South Africa; 4) Psychiatry and Mental Health, University of Cape Town, Cape Town, Western Cape, South Africa; 5) MRC, Anxiety and Stress Disorders Unit, Stellenbosch University, Tygerberg, Western Cape, South Africa.

There is clear evidence for a genetic component in anxiety disorders, and increasing focus has been placed on genetic and environmental interaction (GxE) in mediating disorder pathogenesis. Although a number of genetic studies have been conducted on anxiety disorders, no singular gene or genetic abnormality has been explicitly identified. The hypothesis is that a pre-existing genetic vulnerability (or genetic risk) interacts with the impact of adverse life events to result in the development of one or more anxiety disorder(s). Sprague Dawley rats exhibiting anxiety-like behaviours in the context of environmental stressors (maternal separation and restraint stress) were used as a model for the identification of novel susceptibility genes for anxiety disorders in humans. The striatum, previously implicated as a candidate in the brain architecture of anxiety pathogenicity, and the synaptic plasticity pathway were investigated in the rat brain using RT Profiler array assays. The human homologues of two susceptibility candidate genes (*MMP9* and *BDNF*) were screened in a human cohort of patients with obsessive-compulsive disorder (OCD), panic disorder (PD) or social anxiety disorder (SAD) (relative to controls) using probe-based genotyping arrays. Several genes were identified to be aberrantly expressed in "anxious" rats relative to controls (*Mmp9*, *Bdnf*, *Ntf4*, *Egr2*, *Egr4*, *Grm2* and *Arc*). Three single nucleotide polymorphisms (SNPs) were found to be significantly associated with these conditions (*MMP9*: rs3918242 and *BDNF*: rs6265 and rs10835210) in a case-control association fashion. Three SNPs were also found to significantly interact with the presence and severity of childhood trauma (*BDNF*: rs6265, rs10835210, rs11030107). This project yielded important findings pertaining to the aetiology of anxiety disorders. The use of a combined anxiety disorders cohort (OCD, PD and SAD) may suggest that the associations found here may hold true for anxiety disorders in general and not only for a particular clinically delineated condition. Several novel susceptibility genes, three significant SNP associations, and three significant SNP-environment interactions were contributed as candidates in the pathogenicity of anxiety disorders. Furthermore the severity of childhood trauma was confirmed as a risk factor for anxiety disorders.

1224T

The interplay between risky sexual behaviors and alcohol dependence: a genome-wide investigation. *R. Polimanti[1,2], H. Zhao[3,4], L. A. Farrer[5], H. R. Kranzler[6], J. Gelernter[1,2,4,7].* 1) Department of Psychiatry, Yale University School of Medicine, West Haven; 2) VA CT Healthcare Center, West Haven, CT; 3) Department of Biostatistics, Yale University School of Public Health, New Haven; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT; 5) Departments of Medicine (Biomedical Genetics), Neurology, Ophthalmology, Biostatistics, and Epidemiology, Boston University Schools of Medicine and Public Health, Boston, MA; 6) Department of Psychiatry, University of Pennsylvania School of Medicine and VISN 4 MIRECC, Philadelphia VAMC, Philadelphia, PA; 7) Department of Neurobiology, Yale University School of Medicine, New Haven, CT.

Alcohol dependence (AD) is associated with risky sexual behaviors (RSB), but the basis for shared biological mechanisms leading to AD and RSB is poorly understood. We conducted AD-stratified genome-wide association studies (GWAS) and genome-wide gene-by-AD (GW-GxAD) analyses of RSB (modeled as a quantitative measure of unprotected sex and multiple sexual partners) in 3,924 African-American (AA) and European-American (EA) subjects (75% with AD, 55% AAs, and 32% women). We also used information about sexually transmitted disease (STD) status to evaluate the effect of RSB-AD loci on STD risk. Considering only consistent findings between the two genome-wide approaches, we identified five independent genome-wide significant (GWS) regions ($p<5x10-8$) and a suggestive GWS region ($p<6x10-8$). The AA-EA meta-analysis identified a GWS signal in *LHPP* (Phospholysine phosphohistidine inorganic pyrophosphate phosphatase; rs34997829, p=2. 51x10-8), a gene associated with major depression. In men, we observed a GWS signal in *FAM162A* (Family with sequence similarity 162, member A; rs2002594, p=4. 96x10-8), a suggestive locus for major depression. In women, there is a suggestive GWS locus in *PLGRKT* (Plasminogen receptor, C-terminal lysine transmembrane protein; rs3824435, p=5. 52x10-8), a previously identified GWS region for "Openness to Experience" in young women. In AAs, a GWS signal was observed within *GRK5* (G protein-coupled receptor kinase 5; rs1316543, p=1. 25x10-9), a gene involved in the regulation of G protein-coupled receptors. In AA men, we observed an intergenic GWS signal (rs12898370, p=4. 49x10-8) near *LINGO1* (Leucine rich repeat and Ig domain containing 1), a gene implicated in brain signaling. In EA men, a GWS signal was present in *CCSER1* (Coiled-coil serine-rich protein 1; rs62313897; p=7. 93x10-10), a gene with unknown function previously identified by multiple GWAS of brain phenotypes. The key loci identified offer molecular insights into the interplay between AD and RSB, highlighting mechanisms related to metal illness, personality features and other brain functions. We also investigated the effect of the loci identified in STD status, observing significant interaction between *LHPP* rs34997829 and AD (p=4. 97x10-3). To our knowledge, this is the first report of genome-wide investigation of RSB, and we provided the first genetic information about the interplay between AD and RSB, also indicating new insight about the relationship between AD and STDs.

1225F

Genetic vulnerability of the 5-HTTVNTR (STin2) variant of the SLC6A4 gene in major depressive disorder and childhood stressors in a Colombian population. *M. Tovar[1], C. Cañizares[1], Y. Gómez[1], M. C. Lattig[1], A. Arenas[2].* 1) biological science, Universidad de los Andes, Bogotá, Colombia; 2) Hermanas Hospitalarias: Clinica la Inmaculada.

Major depressive disorder- MDD (MIM: 608516) affects 25% of women and 17% of men around the world. It is a heterogeneous condition resulting from the interaction among genetic, environmental and social factors. Childhood stressors are defined as negative experiences occurred in childhood or adolescence, and are known to be risk factors for MDD. Serotonin is known to play an essential role in central nervous system development; thereby genetic variants related to serotonin uptake could cause alterations in maturation of neuron circuits involved in stress responses. The serotonin transporter protein (SLC6A4) is involved in serotonin reuptake at the presynaptic cell. A variant involving variable number of tandem repeats (VNTR) located in intron 2 (5-HTTVNTR (STin2) variant, Entrez: 6532) has two common alleles (10 and 12). The 5-HTTVNTR (STin2) variant has not been widely studied; however the genotype 10/10 was previously linked with depression and suicide. We performed a case-control study evaluating a clinical MDD population from the city of Bogotá-Colombia. All individuals signed informed consent approved by the university ethics committee. The aim of the study was to evaluate if stressors (childhood sexual, psychological and physical abuse) and 5-HTTVNTR(STin2) variant act as risk factors for MDD in our population. We also evaluated interaction among stressxSTin2 and the development of MDD, as this interaction has been reported for other genetic variants regarding the SLC6A4 gene. Psychological risk was assessed using the M. I. N. I and IDER standard tests; stress response was measured using the ESV test. STin2 VNTR variant was genotyped using standard PCR protocol. Statistical analysis included a multivariate logistic regression and interaction analysis using the statistical R software. Childhood sexual abuse was found as a risk factor for MDD (OR=19. 83 p=1. 0293e-03) as well as psychological and physical childhood abuse (OR=14. 63 p=2. 6031e-06). When analyzing the 5-HTTVNTR (STin2) variant and the development of MDD no significant association was observed. Interaction among childhood abuse and the Stin2 variant was not observed. Our results demonstrate that childhood stressors are high risk factors for the development of MDD as has been demonstrated in almost all populations studied. To our knowledge this is the first report of the STin2 variant in a clinical study in Colombian population and does not seem to have a crucial role in the development of MDD.

1226W

RNA-Seq uncovers specific genetic mechanisms in the hippocampus that are associated with behavioural and cognitive amelioration after environmental enrichment in a mouse model of prenatal alcohol exposure. *A. Chokroborty Hoque.* Biology, University of Western Ontario, London, Canada.

Maternal alcohol consumption during pregnancy gives rise to a spectrum of behavioural and cognitive deficits (Fetal Alcohol Spectrum Disorders (FASDs)) and their severity is significantly affected by the postnatal environment. We are using C57BL/6 mice to study the poorly understood interaction between prenatal alcohol exposure and the postnatal environment. Alcohol exposure during synaptogenesis produces high levels of anxiety-like traits and decreased memory performance in C57BL/6 mice. Ethanol- exposed mice (and matched controls) were put in 'environmentally enriched' conditions of voluntary exercise, physical activities and cognitive stimulation to ascertain the effects of a positive postnatal environment. While environmental enrichment ameliorates anxiety-like behaviour and memory performance of ethanol-exposed mice relative to ethanol-exposed non-enriched mice, the recovery is incomplete, indicative of the permanent damage of prenatal alcohol exposure on the developing brain. RNA was obtained from dissected mouse hippocampi for RNA-Seq (Illumina pair-end sequencing with V4 chemistry) and gene-expression microarray (GeneChip® Mouse Gene 2. 0 ST Array) analysis to determine the underlying genetic mechanisms associated with behavioural and cognitive recovery. DNA was obtained from dissected mouse hippocampi for global methylation analysis. For this conference, I will present (1) behavioural data (anxiety-like behaviour, recognition memory, visuo-spatial memory) (2) molecular data obtained from RNA-Seq analysis (Tuxedo Pipeline and edgeR to determine differential gene expression and GeneMania and WebGestalt to determine gene ontologies and significantly affected pathways) and global methylation analysis (3) elucidate upon the molecular biology of behaviour and cognition in a mouse model of prenatal alcohol exposure and (4) identify key genes and pathways associated with behavioural and cognitive recovery. Initial analysis implicates an upregulation of neuroactive ligand receptor interactions and cell-adhesion processes that may be targeted when formulating rehabilitative therapies to treat behavioural and cognitive deficits characteristic of FASDs. This work provides us with a detailed picture of gene regulation in the hippocampus associated with (1) alcohol exposure during neurodevelopment of mice and (2) cognitive and behavioural amelioration exhibited by affected mice in the presence of a positive, nurturing environment.

1227T

Large causal network analysis of transcriptional specialization in the brains of humans. *M. Yang, P. Wang, M. Xiong.* University of Texas School of Public Health, Houston, TX.

Develop statistical methods for construction of brain connectivity networks that connect brain regions is a key issue in neuroscience. In the past decade, a variety of methodological approaches have developed for the estimation of brain connectivity. However, most methods for construction of brain networks explore correlation or association between imaging measurements of the neural activity of the brain subregions. The correlation analysis is difficult to reveal the causal relationships among information flow in the brain regions. The statistical methods for causal networks of brain regions have less been developed. To overcome these limitation, we develop an analytic platform and novel statistical methods for inferring brain causal connectivity network that model information flow of molecular process. An essential issue for using causal graphs to study brain neuron activities is how to accurately and efficiently estimate the structure of causal graph. Early methods for structure learning mainly focused on approximation algorithms, but such methods are unable to ensure the generation of the true causal graph. To obtain the causal graph from observation data as close to the biological causal graph as possible, "score and search"-based methods for exact learning causal graphs of brain to find the best-scoring structures for a given dataset are developed. We use Allen Human Brain Atlas dataset to evaluate the methods for the construction of the brain causal networks and whole genome- gene expression causal networks where the whole genome-wide gene expressions of each of 231 brain subregions for six samples were profiled by microarray. A causal brain network with 98 nodes and 138 edges from gene expression data is inferred. The whole-genome gene expression causal network consists of two steps: In the first step, we constructed 100 clusters of the gene expressions. For each cluster, we calculate the principal components. These principal components were used as summary statistics of the cluster and were used to construct causal networks with 76 nodes and 101 edges. In the second step, for each cluster we infer gene expression causal networks. For example, for the 64th cluster, we obtained a causal gene expression network with 62 nodes and 72 directed edges. The whole genome gene expression causal networks in this were inferred. To our knowledge, this is the first attempt to infer whole genome gene expression causal networks.

Integrative Causal Network Analysis of Imaging and Genetic Data in Schizophrenia Studies. *N. Lin[1], P. Wang[4], Y. Zhu[5], L. Luo[2], V. Calhoun[3], M. Xiong[1].* 1) University of Texas School of Public Health, Houston, TX; 2) University of New Mexico; 3) Mind Research Network; 4) Fudan University; 5) Tulane University.

Rapid advances in medical imaging and genomic technologies dramatically change the research in genetic studies of schizophrenia and other psychiatric disorders. Integrative analysis of genetic and imaging will facilitate discovery of the mechanism of the complex diseases. The popular methods for integrative image-genetic analysis are mainly based on correlation and association analysis. These methods cannot efficiently detect, distinguish and characterize the true biological, mediated and spurious pleiotropic effects. Therefore, these approaches may not provide clear biologically or clinical relevant information that allows the mechanisms of genetic effects to be discovered and understood. To overcome these limitations, we develop a new framework for inferring causal networks of genotype-images and detecting, distinguishing and characterizing the true biological pleiotropic, mediated pleiotropic and spurious pleiotropic effects of genetic variants on imaging measurements as endophenotype. We also develop a new sufficient dimension reduction methods for network classification. The proposed method for causal network analysis was applied to the MIND clinical imaging consortium's schizophrenia image-genetic study with 142 series of diffusion tensor MRI images (DTI) and 14,412 genes typed in 64 schizophrenia patients and 78 healthy controls. DTI series were segmented into 41 regions by super pixel method and the mean intensity of each region were taken as the image measurement of the brain region. The causal image-genotype networks were separately constructed for schizophrenia patient population and normal population. In cases, the brain image network consisted of 41 nodes and 54 directed edges, and in controls, the brain image network consisted of 41 nodes and 57 directed edges. There were 29 common directed edges in both the case and control brain image networks. The causa image-genotype networks were also constructed. We identified 840 genes and 238 genes that were significantly connected to the brain image region at the genome-wide significance level, respectively, in cases and controls. The developed network classification algorithms were also applied to the dataset to predict schizophrenia. Using 5 fold cross validation for evaluation, we can achieve 100% prediction accuracy in all the five training data set and the average prediction accuracy, sensitivity and specificity over 5 test data sets were 95. 1%, 96. 2% and 93. 9% respectively.

Alzheimer's disease (AD) is the most common form of dementia with a global prevalence of 24 million, predicted to quadruple by 2050. The major genetic risk factor is the Apolipoprotein E (*APOE*) locus, with large-scale GWAS meta-analyses having identified a further 19 common risk SNPs. A low frequency missense variant in *TREM2* also substantially increases AD risk. A reduction in subcortical brain volumes, observed using structural magnetic resonance images (MRI), are specific indicators of AD pathology. This is especially apparent in the hippocampus and amygdala, detectable in prodromal and early stage AD. We examined whether increased genetic risk for AD, based on *APOE* genotype, *TREM2* genotype and polygenic risk scores (PRS) combining common risk variants influences hippocampal and amygdala volumes. This was tested in AD case-control (ADNI and AddNeuroMed) and population based cohorts including elderly (the Older Australian Twin Study, the Sydney Memory and Aging Study) and young people (the Queensland Twin Imaging cohort) with a total sample size of 2141. Incidence of AD and Mild Cognitive Impairment (MCI) were taken into account in the elderly group. The PRS (excluding *APOE*) and a SNP in *TREM2* both associate with reduced hippocampal volume in the elderly, with a significant association still apparent in the healthy older group without AD or MCI. *APOE* ϵ4 associates with hippocampal and amygdala volume in those with AD and MCI, but not in the healthy older group. No associations were found in young adults (16-30 years N=467). We have shown that genetic risk for AD affects the hippocampus before the clinical symptoms of AD, reflecting a neurodegenerative effect prior to clinical manifestations in older adults. This correlation with early MRI markers of AD shows evidence for a genetic modulation of neurodegeneration and the potential for a combination of PRS and brain biomarkers to aid in the prediction of future cognitive decline and the development of AD. Future work is investigating the effect of genetic risk variants on hippocampal microstructure and subcortical thinning, which are potentially more sensitive to early changes.

1230T

Investigating the non-linear association of anxiety-depression score with right lingual surface area. *B. Couvy-Duchesne[1,2,3], L. Strike[1,2,3], P. M. Thompson[5], K. L. McMahon[3], G. I. de Zubicaray[2], N. G. Martin[6], I. B. Hickie[4], M. J. Wright[1].* 1) NeuroImaging Genetics, QIMR Berghofer Medical Research Institute, Herston, QLD, Australia; 2) School of Psychology, University of Queensland, Brisbane, QLD, Australia; 3) Centre for Advanced Imaging, University of Queensland, Brisbane, QLD, Australia; 4) Brain & Mind Research Institute, University of Sydney, Sydney, NSW, Australia; 5) Imaging Genetics Center, Keck School of Medicine, University of Southern California, Marina del Rey, CA, USA; 6) Genetic Epidemiology, QIMR Berghofer Medical Research Institute, Herston, QLD, Australia.

There is little consensus in the literature about brain changes associated with depression and anxiety. Structural markers of depression-anxiety are of importance as they could provide insight into the aetiology of depression and anxiety, as well as quantitative assessment of the depressed/anxious brain. In a population sample of young adults comprising 865 twins and siblings (63% female) we tested the association of 170 standard structural brain phenotypes (subcortical volumes, cortical surface area and thickness) with anxiety-depression from the Somatic and Psychological HEalth REport (SPHERE) (Hansell, et al. , 2012; Hickie, et al. , 2001). The only association to survive multiple testing correction was between anxiety-depression and surface area of the lingual gyrus (cubic relationship, p-value=4. 9E-5). Higher anxiety-depression score was associated with a reduction (up to~15%) in surface area, with a genetic correlation of -0. 31 [-0. 51, -0. 13], p-value=7. 0E-4. The SPHERE provides a self-reported measure of anxiety and depression computed from 18 items. Boundaries of the lingual gyrus were defined using parcellation available in Freesurfer 5. 3. Models were corrected for age at MRI, sex, time difference between scoring and scanning, mean surface area or cortical thickness. The association was observed despite the anxiety depression score being acquired on average 4 years prior to scanning, (mean age at scan was 22, sd=3. 1). In a nested case-control sample, a 3. 3% reduction of right lingual surface area was observed in recurrent MDD cases (DSM-IV definition, p-value=0. 015). We sought replication in an independent young adult clinical sample and investigated the robustness of the result using a genetically derived cortical atlas and a voxel based approach. We aimed to confirm the association of right lingual gyrus surface area with our continuous measure of anxiety-depression.

A practical grading definition for the diagnosis of autosomal recessive spastic ataxia of Charlevoix-Saguenay. *I. Coupry[1,8], J. Pilliod[1,8], S. Moutton[1,2], J. Lavie[1], E. Maurat[1], C. Hubert[1,3], N. Bellance[1], N. Houcinat[2], J. Van-Gils[2], C. M. Durand[1], C. Rooryck[1,2], D. Lacombe[1,2], R. Rossignol[1], G. Stevanin[4,5,6,7], G. Benard[1], A. Durr[4,5,6], C. Goizet[1,2].* 1) Université de Bordeaux, Laboratoire Maladies Rares: Génétique et Métabolisme, EA4576, Bordeaux, France; 2) CHU Pellegrin, Service de Génétique Médicale, Bordeaux, France; 3) Université de Bordeaux, Centre de Génomique Fonctionnelle, Bordeaux, France; 4) APHP, Hôpital de la Pitié-Salpêtrière, Service de Génétique, Paris, France; 5) Institut du Cerveau et de la Moelle, INSERM U1127, Paris, France; 6) Sorbonne Universités, UPMC Université Paris VI, Paris, France; 7) Ecole Pratique des Hautes Etudes, Laboratoire de NeuroGénétique, Paris, France; 8) These authors contributed equally to this work.

Objective: Autosomal recessive spastic ataxia of Charlevoix-Saguenay (ARSACS, [MIM 270550]) is caused by mutations in the *SACS* gene. *SACS* encodes sacsin, a protein whose function remains unknown, despite the description of numerous protein domains and the recent focus on its potential role in the regulation of mitochondrial physiology. This study aimed to identify new mutations in a large population of ataxic patients and to functionally analyze their cellular effects in the mitochondrial compartment. **Methods:** 321 index patients with spastic ataxia, selected from the SPATAX network, were analysed by direct sequencing of the *SACS* gene, and 156 patients from the ATAXIC project presenting with congenital ataxia were investigated either by targeted or whole-exome sequencing. For functional analyses, primary cultures of fibroblasts were obtained from 11 patients, carrying either mono- or bi-allelic variants, including one case harboring a large deletion encompassing the entire *SACS* gene**Results:** We identified biallelic *SACS* variants in 33 patients from SPATAX, and in 5 non-progressive ataxia patients from ATAXIC. Moreover, a drastic and recurrent alteration of the mitochondrial network was observed in 10 of the 11 patients tested. **Interpretation:** Our results permitted to extend the description of clinical and mutational spectrum of ARSACS patients. Moreover, we suggest that the observed mitochondrial network anomalies could be used as a trait biomarker for the diagnosis of ARSACS when *SACS* molecular results are difficult to interpret (i. e. , missense variants and heterozygous truncating variant). Based on our findings, we propose a grading diagnostic definition using clinical, genetic, and cellular criteria for ARSACS.

Animal model module of AutDB catalogues the effects of rescue agents on ASD phenotypes. *I. Das, M. A. Estevez, S. Banerjee-Basu.* Mindspec, Inc. , McLean, VA.

The Autism Database (AutDB) is a publicly available, manually annotated, modular database that serves as an ongoing collection of genes linked to Autism Spectrum Disorders (ASD). Here, we describe further development of the animal model module of AutDBwhich catalogues ASD-relatedrodent models. A new release of the database also includes rat models in addition to mouse models, since both of these species are widely used in current research. In addition to ASD models, the animal model module also contains rescue models based on existing parent ASD models. All data is extracted from published, peer-reviewed primary reports. The metadata is standardized in a phenotypic database (PhenoBase), which is a routinely updated comprehensive list of phenotypic terms (pheno-terms) and experimental paradigms. These pheno-terms reflect the actual research and are divided into categories that align with human ASD phenotypic features. The recently updated PhenoBase has been standardized to about 380 pheno-terms divided into 16 categories. Given the complex manifestation of ASD phenotypes, described as core and auxiliary in the human population, a wide variety of drugs and genetic manipulations are being used in the mouse models to assess their ameliorative effects on some or all of these phenotypes. We categorize these 'rescue' paradigms based on the type of agent: biological, behavioral, genetic or pharmaceutical, and have developed annotation methods to clearly represent the treatment effects on ASD phenotypes paralleled in mouse models. The scientific standardization of phenotype, their presentation in animal models and the effects of rescue, allow for data mining and bioinformatics analysis. Coupled to our large curated dataset this can be used to elucidate ASD research trends and etiology.

1233T

Phenotype-genotype associations in concordant and discordant monozygotic and dizygotic twins based on quantitative trait and case-control association analyses. *V. Hu, C. Devlin.* Biochemistry & Molecular Medicine, The George Washington University School of Medicine & Health Sciences, Washington, DC.

Autism is a highly heterogeneous and heritable neurodevelopmental disorder characterized by impaired social communication and interactions, often coupled with stereotyped behaviors and restricted interests. Although there has been much discussion regarding the magnitude of the genetic contribution to autism based on concordance rates of the diagnosed disorder in monozygotic vs. dizygotic twins, there is little information on genetic contributions to specific behaviors on which the diagnosis is based. Here, we compared the phenotypic profiles of both concordant and discordant mono- and dizygotic twins across five behavioral traits, using cumulative trait severity scores from the Autism Diagnostic Interview-Revised (ADI-R) instrument for each individual, as previously described [1]. These traits included spoken language, nonverbal communication, play skills, social behaviors, and insistence on sameness or ritualistic behaviors. The five trait profiles across the different twin populations were then used for quantitative trait association analyses using genotype data for the respective individuals. Trait-associated single nucleotide polymorphisms with a nominal p-value of 10-5 were then used for case-control association analyses. Cases included individuals in the lowest (first) and uppermost (third) quartiles of the quantitative trait distribution curves, and controls consisted of 2438 previously genotyped nonautistic individuals [2]. Results: The deep phenotypic analyses revealed that there are significant differences in trait profiles between the discordant nonautistic monozygotic and discordant nonautistic dizygotic twins, with the dizygotic twins exhibiting significantly lower severity across virtually all behaviors analyzed. By comparison, all of the twins diagnosed with autism exhibit similar behavioral severity profiles across all ADI-R items, regardless of zygosity. The combination of quantitative trait and case-control association analyses revealed Bonferroni significant genetic variants that clearly distinguish individuals in the uppermost quartile of trait severity from those in the lowest quartile. In summary, while the comparison of discordant nonautistic dizygotic vs. monozygotic twins suggests that genotype is a significant determinant of autistic traits, the similarity of trait profiles in the concordant dizygotic twins also suggests a role for environment. 1. Hu & Steinberg, Autism Res. 2:67-77, 20092. Wang *et al*. Nature 459:528-533, 2009.

Genetic involvement in progression of MS disease course. *M. F. Davis[1], B. Peaden[1], S. Sriram[2], J. L. Haines[3], J. C. Denny[4].* 1) Department of Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Department of Neurology, Vanderbilt University Medical Center, Nashville, TN; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 4) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Multiple sclerosis (MS) is a neurodegenerative autoimmune disease of the central nervous system, with over 100 known genetic loci associated with risk of development of the disease. However, disease course is incredibly varied among individuals with MS and it is unknown if disease course is also associated with genetic variation. The timed 25-foot walk (T25FW) is a quantitative clinical measure of disability progression that MS patients at the Vanderbilt University Multiple Sclerosis Clinic complete each visit. We used a validated natural language processing approach to extract 4,792 T25FW measurements over 17 years of clinic visit for 717 patients, with an average walk time of 9. 7 seconds. Patients were genotyped on the Illumina ImmunoChip and are a part of Vanderbilt's BioVU DNA database. We analyzed the data using mixed model linear regression in R, with the null model consisting of amount of time taken to walk 25 feet as a response variable, the amount of time since the first recorded T25FW and three principle components for ethnicity as fixed effects, and the amount of time since last walk and the patient as random effects. This model was tested against models that added a SNP as a fixed effect. The p-value was calculated based on the difference between the two models. Using a Bonferroni corrected p-value of 5. 7 x 10-7, three SNPs in *ABHD6* (p=8. 4 x 10-8), *ILKAP* (p=5. 7 x 10-9), and *FGF20* (p-1. 9 x 10-8) were significant. No known MS risk alleles achieved Bonferroni significance; the strongest association with known MS risk alleles was rs8070345 with p=0. 02. Of special interest is the region around *ABHD6* on chromosome 3, which has been associated with risk of development of systemic lupus erythematosus, another autoimmune disease.

1235W

Novel mutations in SPTAN1: expanding the neurological phenotype.
V. Gartner[1,2], T. Markello[2], C. J. Tifft[1,2], W. A. Gahl[1,2], P. R. Lee[1,2]. 1) Office of the Clinical Director, NHGRI/NIH, Bethesda, MD; 2) NIH Undiagnosed Diseases Program, NIH Office of Rare Diseases Research and NHGRI, Bethesda, MD.

De novo mutations in Spectrin Alpha Non-Erythrocytic 1 (SPTAN1) have previously been linked to Early Infantile Epileptic Encephalopathy 5 (EIEE5), a rare and severe neurological disorder. Defining features of EIEE5 include refractory epilepsy, hypoplasia and/or atrophy of the cerebellum and brain stem, and cerebral hypomyelination. Patients with EIEE5 additionally have hypsarrhythmia on EEG, acquired microcephaly, intellectual disability, and spastic quadriplegia. Previous reports indicate that mutations in SPTAN1 that disrupt the C-terminus domains of the alpha-II spectrin protein have a dominant negative effect that may correlate with phenotypic severity. Only one case of a *de novo* mutation in SPTAN1 causing neurological symptoms without seizures has previously been reported. The aim of our study was to provide careful phenotypic descriptions of two additional cases with observed *de novo* mutations in SPTAN1 to further expand the spectrum of this rare disease. In both cases we describe novel *de novo* mutations that were identified by whole-exome sequencing completed as part of comprehensive examinations of the patients. One patient is heterozygous for a missense mutation leading to a premature stop codon in exon 21. This patient has cerebellar and brain stem hypoplasia, cataracts, intellectual disability, and autism spectrum disorder. However, this patient does not have seizures and therefore represents only the second known case with a SPTAN1 mutation to not have a diagnosis of epilepsy. The second patient we describe is heterozygous for an intronic missense mutation leading to the insertion of 15 nucleotides before exon 50, and 5 residues added in the C-terminus of the protein. This patient suffers from severe ataxia and cerebellar and brain stem hypoplasia, and has ADHD, intellectual disability, and autism spectrum disorder. While this patient has a more severe phenotype than our first case, this patient would be the third described without seizures. The mutation loci and relative phenotypic severity of these two cases expand on prior descriptions of the disorder. Additionally, we conclude that mutations in SPTAN1 do not invariably lead to seizures or severe epileptic encephalopathy. Notably, we provide a unique example in which a mutation in the C-terminus region of the protein is correlated with greater phenotypic severity without seizures, whereas prior C-terminus mutations all had a significant epileptic component to their SPTAN1-related disease.

1236T

The Neurodevelopmental Spectrum Associated with SHANK-3 Mutations.
P. Lawson[1], O. Goker-Alpan[2], S. Lipinski[2], C. Samango-Sprouse[1,3]. 1) The Focus Foundation, Crofton, MD; 2) O and O Alpan LLC, Genetics Division, Fairfax, VA; 3) The Neurodevelopmental Diagnostic Center for Young Children, Davidsonville, MD.

Background: The *SHANK3* gene encodes a scaffolding protein in the cortex and cerebellum that has a role in synaptic signal transmission. *SHANK3* is disrupted in Phelan-McDermid Syndrome (PMS, or 22q13.3 deletion syndrome), which is characterized by variable central nervous dysfunction including autism spectrum disorder (ASD), speech, motor, and intellectual deficits with hypotonia and ataxic gait. Typically, receptive language is less impaired than expressive communication. Dysmorphic features include periorbital fullness, long eyelashes, dysplastic toenails, bushy eyebrows, and a bulbous nose. Larger deletions correlate with greater developmental dysfunction. **Case Description and Results:** We present a 4 ½ year-old girl with a history of regression, limb asymmetry, advanced bone age, and coordination difficulties. Early development was normal, however feeding disturbances and speech delay with intermittent regression of motor and speech-language skills were noted at 18 months. She had truncal hypotonia with motor difficulties, balance problems, and oculomotor apraxia (OMA), but had normal gait. She did not have ASD with GARS-2 and GADS scores below the first percentile, however, she had atypical peer social interactions with Childhood Apraxia of Speech (CAS) and misarticulations, and visual perceptual deficiencies (SS=74 on VMI). The SRS-2 revealed mildly atypical scores in social cognition and social awareness, with the four remaining scores well within normal limits. Intellectual function was normal with a Fluid Reasoning (FR) of 93, Working Memory Index (WMI) of 103, Verbal Comprehension Index (VCI) of 81, and FSIQ of 83 on the Wechsler Intelligence Tests. The expressive and receptive vocabulary scores were 97 and 103 on EOWPVT-R and ROWPVT-R, respectively. Whole Exome Sequencing identified a de novo c. 2265+3 A>T variant in intron 19 in the *SHANK3* gene. **Discussion:**This report highlights the first case where a single-point mutation in the *SHANK3* gene has resulted in a constellation of findings associated with PMS, supporting that the *SHANK3* gene is critical in PMS. While *SHANK3* is implicated in ASD, this patient shows no autistic features. This case is also unique, in that FSIQ, FR, WMI and VCI are within normal limits. This presentation thus supports higher intellectual capability than has been previously reported in patients with *SHANK3* mutations.

1237F

Phenotypic spectrum of *GNAO1* variants: epileptic encephalopathy to involuntary movements with severe developmental delay. *H. Saitsu[1], R. Fukai[1,2], B. Ben-Zeev[3,4], Y. Sakai[5], M. Mimaki[6], N. Okamoto[7], Y. Suzuki[8], Y. Monden[9], H. Saito[9], B. Tziperman[3], M. Torio[5], S. Akamine[5], N. Takahashi[6], H. Osaka[9], T. Yamagata[9], K. Nakamura[10], Y. Tsurusaki[10], M. Nakashima[10], N. Miyake[10], M. Shiina[11], K. Ogata[11], N. Matsumoto[1].* 1) Human Genetics, Yokohama City University, Yokohama, Japan; 2) Neurology and Stroke Medicine, Yokohama City University, Yokohama, Japan; 3) The Edmond and Lily Safra Children's Hospital, Sheba Medical Center, Ramat Gan, Israel; 4) Sackler school of medicine, Tel aviv University, Tel aviv, Israel; 5) Pediatrics, Kyushu University, Fukuoka, Japan; 6) Pediatrics, University of Tokyo, Tokyo, Japan; 7) Medical Genetics, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 8) Pediatric Neurology, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan; 9) Pediatrics, Jichi Medical University, Tochigi, Japan; 10) Pediatrics, Yamagata University Faculty, Yamagata, Japan; 11) Biochemistry, Yokohama City University, Yokohama, Japan.

*De novoGNAO1*variants have been found in four patients including three patients with Ohtahara syndrome and one patient with childhood epilepsy. In addition, two patients showed involuntary movements, suggesting that*GNAO1*variants can cause various neurological phenotypes. Here we report additional four patients with*de novo*missense*GNAO1*variants, one of which was identical to that of previously reported. All the three novel variants were predicted to impair Gαofunction by structural evaluation. Two patients showed early-onset epileptic encephalopathy, presenting with migrating or multifocal partial seizures in their clinical course, but remaining two patients showed no or few seizures. Together with four previously reported patients, all the eight patients showed severe intellectual disability, and motor developmental delay. In addition, involuntary movements were observed in six of eight patients, indicating that involuntary movements may be one of key features suspecting *GNAO1* variants. Progressive cerebral atrophy and thin corpus callosum were common features in brain images. Our study demonstrated that*GNAO1*variants can cause involuntary movements and severe developmental delay without/with seizures including various types of early-onset epileptic encephalopathy.

1238W

VarDB: a catalog of genetic variability in neurodegenerative disease. *D. M. Evans, M. J. Farrer.* Centre for Applied Neurogenetics, CBH, University of British Columbia, Vancouver, British Columbia, Canada.

There are several databases of whole exome or whole genome data available online based off of hundreds or thousands of individuals. However, there are very few public resources that capture genetic variability in conjunction with any available phenotype information. The Djavad Mowafaghian Centre for Brain Health has developed a publicly available database of short nucleotide variants from more than 1000 individuals with associated biographic and clinical information. Variants can be returned by searching on any subset of subject data including neurodegenerative disorder affection status, call quality, ethnic background and sequencing platform. Results include single nucleotide and short indel variant annotation with externally generated population frequencies as well as variant identifiers and resulting cDNA and amino acid changes. A subset of samples have also undergone high-density SNP genotyping, allowing for the interrogation of copy number variation data by locus. The database is available at http://vardb. can. ubc. ca.

1239T

Genome-wide Association Study of Clinical Features in the SchizophreniaPsychiatric Genomics Consortium: Confirmation of Polygenic Effect on Negative Symptoms. *A. Fanous[1,2,3], T. B. Bigdeli[3], S. Ripke[4], R. L. Amdur[1,2], P. A. Holmans[5], A. Corvin[6], P. G. C. SCZ working group[1-7], K. S. Kendler[3,7].* 1) Washington VA Medical Center, Washington, DC; 2) Department of Psychiatry, Georgetown University School of Medicine; 3) Department of Psychiatry, Virginia Commonwealth University School of Medicine; 4) Center for Human Genetic Research, Massachusetts General Hospital, Boston, Massachusetts; 5) Department of Psychological Medicine and Neurology, School of Medicine, Cardiff University, Cardiff, Wales, UK; 6) Neuropsychiatric Genetics Research Group, Trinity College Dublin, Dublin, Ireland; 7) Department of Human Genetics, Virginia Commonwealth University School of Medicine.

Objective: Schizophrenia is a clinically heterogeneous disorder. Proposed revisions in DSM-5 included dimensional measurement of different symptom domains. We sought to find common genetic variants affecting these dimensions, and confirm our previous finding that polygenic risk of schizophrenia influences Negative symptom severity. **Methods:** The Schizophrenia Psychiatric Genomics Consortium comprised 8,388 cases of European ancestry with available clinical phenotype data. Symptoms averaged over the course of illness were assessed using the OPCRIT, PANSS, LDPS, SCAN, SCID, and CASH. Factor analyses were performed to identify the Positive, Negative, Manic, and Depressive symptom dimensions. Genome-wide association studies (GWAS) of the resulting quantitative traits were performed using linear regression adjusting for ancestry, and meta-analyzed across study sites. We considered also whether each symptom factor was significantly associated with polygenic scores indexing schizophrenia risk. **Results:**We observed the strongest evidence of association for the Positive symptom factor, at rs74263251 (*P*=6. 27x10-8) in an intron of*RFX8*(2q11. 2). Polygenic scores for schizophrenia risk were significantly correlated with the Negative factor (*P*=6. 39x10-9), explaining approximately 0. 4% of the variance. These scores were not strongly associated with Positive or Manic symptoms, and were found to significantly predict Depressive symptoms only among female patients (*P*=0. 00922). **Conclusions:**While we found no definitive evidence of modifier loci for schizophrenia, associations between SNPs in*RFX8*and Positive symptoms approached genome-wide significance (*P*=5x10-8). As this may have been due to insufficient statistical power, follow-up in additional samples is warranted. Critically, we confirmed our previous finding that polygenic risk of schizophrenia explains at least some of the variance in Negative symptoms, a core illness dimension.

***C9ORF72* repeat expansions that cause frontotemporal dementia are detectable among patients with psychosis without dementia.** *V. Nimgaonkar[1], G. Coppola[2], A. Watson[3], M. Pribadi[2], K. Chowdari[3], S. Clifton[3], J. Wood[3], B. Miller[4].* 1) University of Pittsburgh, Pittsburgh, PA; 2) University of California, Los Angeles, CA; 3) Department of Psychiatry, University of Pittsburgh, School of Medicine, Pittsburgh, PA; 4) University of California, San Francisco, CA.

Background: A pathologic hexanucleotide repeat expansion in the regulatory region of *C9ORF72* causes frontotemporal dementia (FTD) or amyotrophic lateral sclerosis (ALS). In addition to features of dementia, behavioral abnormalities can be present among mutation carriers. It is uncertain whether a proportion of individuals clinically diagnosed with psychoses bear pathologic *C9ORF72* expansions in the absence of dementia. Aim: To screen for *C9ORF72* repeat expansions among individuals diagnosed with functional psychoses such as schizophrenia (SZ) / schizoaffective disorder (SZA), and to describe the clinical features of individuals with the mutation. Results: Pathogenic *C9ORF72* repeat expansions were detected in two pairs of related individuals following a survey of 740 participants in a psychiatric genetic research study. The mutation carriers included two siblings with schizophrenia, another unrelated individual with schizoaffective disorder and her non-psychotic mother. All the mutation-bearing patients with SZ/SZA had severe, florid illness, but did not provide a history suggestive of dementia or ALS. Conclusions: A small proportion of patients with SZ/SZA bear *C9ORF72* repeat expansions. The patients show atypical psychotic features without the typical cognitive features of dementia.

1241W

An open-label trial in Friedreich ataxia suggests clinical benefit with high-dose resveratrol, without effect on frataxin levels. *M. Delatycki[1, 2, 3], E. Yiu[1, 3, 4], R. Peverill[5], K. Lee[3, 6], K. Croft[7], T. Mori[7], B. Scheiber-Mojdehkar[8], B. Sturm[8], M. Praschberger[8], A. Vogel[1, 9], G. Rance[9], S. Stephenson[1, 3], J. Sarsero[10], C. Stockley[11], C. Lee[12], A. Corben[1, 3].* 1) Bruce Lefroy Ctr, MCRI, Royal Children's Hosp, Parkville, Australia; 2) Department of Clinical Genetics, Austin Health, Heidelberg, Victoria, Australia; 3) Department of Paediatrics, The University of Melbourne, Parkville, Victoria, Australia; 4) Department of Neurology, Royal Children's Hospital Melbourne, Parkville, Victoria, Australia; 5) Monash Cardiovascular Research Centre, Monash HEART and Monash University Department of Medicine, Monash Medical Centre, Clayton, Australia; 6) Clinical Epidemiology and Biostatistics Unit, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 7) School of Medicine and Pharmacology, University of Western Australia, Perth, Western Australia, Australia; 8) Department of Medical Chemistry, Medical University of Vienna, Vienna, Austria; 9) Department of Audiology and Speech Pathology, The University of Melbourne, Parkville, Victoria, Australia; 10) Cell and Gene Therapy, Murdoch Childrens Research Institute, Parkville, Victoria, Australia; 11) Australian Wine Research Institute, Adelaide, South Australia, Australia; 12) School of Biological Sciences, The University of Hong Kong, Hong Kong, China; 13) Department of Neurology, Monash Health, Clayton, Victoria, Australia; 14) Neurosciences Research, Murdoch Childrens Research Institute, Parkville, Victoria, Australia.

Friedreich ataxia (FRDA) is due to a triplet repeat expansion in *FXN*, resulting in deficiency of the mitochondrial protein frataxin. Resveratrol is a naturally occurring polyphenol, identified to increase frataxin expression in cellular and mouse models of FRDA, and has anti-oxidant properties. This open-label, non-randomized trial evaluated the effect of two different doses of resveratrol on peripheral blood mononuclear cell (PBMC) frataxin levels over a 12-week period in individuals with FRDA. Secondary outcome measures included PMBC *FXN* mRNA, oxidative stress markers, and clinical measures of disease severity. Safety and tolerability were studied. Twenty-four participants completed the study; 12 received low-dose resveratrol (1 g daily) and 12 high-dose resveratrol (5 g daily). PBMC frataxin levels did not change in either dosage group [low dose group change: 0. 08 pg/μg protein (95% CI -0. 05, 0. 21, p=0. 21); high dose group change: 0. 03 pg/μg protein (95% CI -0. 10, 0. 15, p=0. 62)]. Improvement in neurologic function was evident in the high-dose group [change in Friedreich Ataxia Rating Scale -3. 4 points, 95% CI (-6. 6, -0. 3), p=0. 036] but not the low-dose group. Significant improvements in audiologic and speech measures, and in the oxidative stress marker plasma F2-isoprostane were demonstrated in the high-dose group only. There were no improvements in cardiac measures or patient-reported outcome measures. No serious adverse events were recorded. Gastrointestinal side-effects were a common, dose-related adverse event. This open-label study shows no effect of resveratrol on frataxin levels in FRDA, but suggests that independent positive clinical and biologic effects of high-dose resveratrol may exist. Further assessment of efficacy is warranted in a randomized placebo-controlled trial.

Cell-free microRNA (miRNA) deregulation in the plasma of Friedreich's Ataxia patients. *D. Subrahamanyam[1], A. Srivastava[2], MR. Rajeswari[1].* 1) Biochemistry, All India Institute of Medical Sciences, New Delhi, India; 2) Neurology, All India Institute of medical Sciences, New Delhi, India.

Friedreich ataxia (FRDA) is a multisystem disease affecting predominately nervous system, heart and pancreas. Autosomal recessive inheritance of trinucleotide repeat (GAA) expansion in the *FXN* gene causes the abnormal phenotype in FRDA patients. Current research focused on therapeutic intervention using drugs aimed at molecular amelioration, but there are no reliable biomarkers available to monitor the efficacy of the drug. The present study investigates the alterations of plasma cell-free miRNAs (micro RNAs) in FRDA patients and attempt to find the significance in relevance with molecular pathogenesis. Clinically suspected patients for FRDA were genetically diagnosed for GAA repeat expansion using Long Range PCR (polymerase chain reaction). Total RNA was isolated from the plasma and subjected to miRNA microarray analysis using the Agilent microarray platform. Deferentially regulated miRNAs were validated by Sybr green Real Time PCR. We identified twenty-one (21) deregulated miRNAs (FDR p<0. 01, fold change ≥1. 5≤) when compared with healthy controls. Out of which 17 miRNAs were upregulated and 4 miRNAs were downregulated. The majority of the identified miRNAs reported to be highly expressed in the brain. Further validation (n= 18) through Quantitative RT-PCR found significant (p< 0. 05) upregulation in 3 miRNAs, hsa-miR-103a-3p, hsa-miR-15b-5p, hsa-miR-21-5p in comparison with healthy controls. Target and pathway analysis of these miRNAs have shown association with neurodegenerative and cardiomyopathy features. However, there was no association identified with clinicopathological features of FRDA patients. Considering progressive decline in the function of nervous and cardiac systems in FRDA individuals, we expect the present study may aid in the monitoring of effective therapeutics.

1243F

A neuronal/synaptic carnitine deficiency hypothesis for prevention of 10-20% of autism. *A. Beaudet.* Molecular & Human Genetics, Baylor Col Med, Houston, TX.

The discovery that X-linked *TMLHE* deficiency prevents endogenous biosynthesis of carnitine and is a likely risk factor for autism has led us to hypothesize that carnitine deficiency in the brain in the first three years of life may cause autism. *TMLHE* deficiency itself is found in less than 1% of autism, but we hypothesize that diet, minor illnesses, and the many known common genetic variants affecting carnitine metabolism may contribute to carnitine deficiency causing as much as 10-20% of autism. Boys with *TMLHE* deficiency typically have a normal physical exam except perhaps acquired macrocephaly and normal structural imaging of the brain. We have reported regression in association with very low plasma carnitine in one *TMLHE* deficient male with autism. The male:female ratio is particularly high in milder autism, in non-dysmorphic autism, and in Asperger syndrome. One study reported a 23 to 1 male to female ratio in autism probands with a normal physical exam and normal structural imaging of the brain. This extreme sex bias in a significant fraction of autism is the basis for proposing that this hypothesis might involve 10-20% of all autism. We also speculate that lack of X-inactivation for the *SLC6A14* putative blood-brain barrier carnitine transporter might explain the sex bias. We hypothesize that brain carnitine deficiency may be a common cause of autism in the subgroup of males with normal physical exam and brain imaging. We hypothesize that the risk of dietary deficiency would start at the time that solid foods, usually very low in carnitine, are introduced into the diet and might continue until meat and especially beef was added into the diet. There are some reports of low plasma carnitine in autism, but these are not from children in the 6 to 36 month age group that would be of greatest relevance to this hypothesis. We hypothesize that low brain carnitine levels might explain some cases of regression even in the presence of normal plasma levels of carnitine. An extensive review of the literature identifies findings for and against the neuronal/synaptic carnitine deficiency hypothesis. The effect of carnitine deficiency on synaptic development is being studied in mouse models of abnormal carnitine metabolism, and human genetic data are also being analyzed. We urge implementation of a clinical trial of carnitine supplementation in infant siblings of autism probands, where a very high recurrence risk is reported.

1244W

A Mendelian randomization investigation of the causal relationship between atopic dermatitis and psychobehavioral outcomes. *L. Paternoster, H. Sallis.* MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom.

Atopic dermatitis (AD, or eczema) is a chronic inflammatory skin condition, common in early childhood (affecting ~20% of children). AD sufferers are at increased risk of some physical, psychological and psycho-social problems, including depression and conduct problems, suggesting successful early treatment of AD may have a wider public health impact than management of the immediate symptoms alone. However, these observational associations could be influenced by confounding and might not represent causal effects. We attempted to address this issue by using Mendelian randomization (MR) analysis to determine the causal relationship between AD and pyschobehavioral outcomes. AD was classified according to data collected throughout childhood for participants enrolled in the Avon Longitudinal Study of Parents and Children (ALSPAC). Parent-reported adolescent mental health was measured using the Strengths and Difficulties Questionnaire (SDQ) completed when the child was 12 and 16 years old. Observational analyses identified associations between AD and increased hyperactivity scores at age 12 and increased conduct problems at age 16. MR uses genetic instruments to proxy a modifiable risk factor and is largely free from issues such as confounding and reverse causality, thus strengthening causal inference in the use of observational data. However, potential pleiotropic effects of the variants should be considered. We constructed two instruments for AD; 1) using mutations in the *FLG* gene (known to impact eczema through skin barrier dysfunction) (F=38. 2), and 2) using SNPs identified in a recent genome-wide association study and believed to effect AD through immune mechanisms (F=30. 4). By using multiple instruments representing different etiological pathways of AD we can investigate if pleiotropic mechanisms are at play. We found no evidence of a causal association between AD and hyperactivity scores using either instrument. However, for conduct disorder, the two genetic instruments showed contrasting effects. The immune SNPs were associated with decreased conduct problems and the *FLG* mutations were associated with increased conduct problems. We also investigated directional pleiotropy using Egger regression. Our results suggest that the causal relationship between AD and pyschobehavioral outcomes is complex. Pleiotropic mechanisms are likely to exist and it is not clear what effect early successful treatment and/or prevention of AD may have on these outcomes.

Using genetic information to predicting response to treatment in patients with epilepsy. *I. Lopes-Cendes[1], R. Secolin[1], M. S. Silva[1], B. S. Carvalho[1], E. Bilevicius[2], C. V. Maurer-Morelli[1], F. Cendes[2].* 1) Dept Med Gen, Univ Campinas - UNICAMP, Campinas, SP, Sao Paulo, Brazil; 2) Dept Neurology, Univ Campinas - UNICAMP, Campinas, SP, Sao Paulo, Brazil.

Background: Mesial temporal lobe epilepsy (MTLE) is the most common form of adult epilepsy. Currently, the only characteristic, which seems to predict poor response to clinical treatment in these patients, is the presence of hippocampal sclerosis (HS). Studies showed that single nucleotide polymorphisms (SNPs) in genes encoding drug transporter and metabolism proteins could influence response to drug therapy. **Objective:** To evaluate whether combining information from clinical variables and SNPs in candidate genes could improve the discriminatory accuracy of predicting response to drug therapy in patients with MTLE. **Methods:** We evaluated 73 patients with MTLE who were responsive to antiepileptic drug (AED) therapy and 163 patients refractory to drug therapy. We genotyped 119 SNPs within the *ABCB1*, *ABCC2*, *CYP1A1*, *CYP1A2*, *CYP1B1*, *CYP2C9*, *CYP2C19*, *CYP2D6*, *CYP2E1*, *CYP3A4*, and *CYP3A5* genes. We assessed a first scenario using only clinical variables and a second one including SNP information. We used random forests combined with leave-one-out cross-validation to identify the best predictive model in each scenario and compared their discriminatory accuracies using the area under the curve statistic, by R software. Additionally, we built a variable importance plot to present the set of most relevant predictors on the best model. **Results:** The selected best model included the presence of HS and 53 SNPs among all genes evaluated. Additionally, including SNPs in the model improved the discriminatory accuracy from 0. 5865 to 0. 8244. **Conclusion:** To the best of our knowledge, this study demonstrated for the first time that genetic information improves the prediction of response to drug treatment in patients with MTLE. This may allow patients more likely to develop resistance to AED treatment to have a timely referral for epilepsy surgery. Supported by CEPID-BRAINN FAPESP, São Paulo, Brazil.

Characterization of APOE and TOMM40 Allele Frequencies in a Japanese Population. *H. Nonomura[1], A. Nishimura[1], S. Tanaka[1], M. Yoshida[1], Y. Maruyama[2], Y. Aritomi[1], A. Saunders[3], D. Burns[2], M. Lutz[3], G. Runyan[4], E. Lai[4], K. Budur[4], A. Roses[2].* 1) Takeda Pharmaceutical Company Limited, Osaka, Japan; 2) Zinfandel Pharmaceuticals, Inc. , Durham, NC, USA; 3) Duke University School of Medicine, Durham, NC, USA; 4) Takeda Development Center Americas, Inc. , Deerfield, IL, USA.

Identification of cognitively normal individuals at high-risk for developing Alzheimer's disease (AD) symptoms may enable early medical interventions or preventive therapies. Using longitudinal cohorts of elderly Caucasian subjects, a Biomarker Risk Assignment Algorithm (BRAA), comprised of Apoliprotein E (*APOE)* genotype, Translocase of outer mitochondrial membrane 40 homolog rs10524523 (*TOMM40* '523) genotype, and age of an individual was developed to predict the risk of developing mild cognitive impairment (MCI) due to AD within the next 5 years in the 65-83 year old age group. A clinical study (TOMMORROW; registered with ClinicalTrials. gov, NCT01931566) is being conducted to qualify the BRAA and evaluate the efficacy of pioglitazone 0. 8 mg slow release (SR) to delay the onset of MCI due to AD in high-risk subjects as determined by the BRAA. However, it is unknown if the BRAA developed in Caucasians is applicable to a Japanese population. In order to develop/validate the algorithm to identify Japanese high-risk individuals for a potential delay of onset study, it is important to characterize the allele and haplotype architecture of the *TOMM40* '523 *APOE* variations in this population. We determined frequencies of *APOE* and *TOMM40* '523 genetic polymorphisms and haplotypes in a Japanese population cohort (ages 20-68, N=300, 150 males and 150 females) from whole blood samples and compared them with samples from previous findings in Caucasian, African, and African-American subjects. Point estimates show that Japanese subjects had a lower frequency of *APOE*ϵ4 than Caucasian populations and a much lower frequency of *APOE*ϵ4 than African and African-American populations. For the *TOMM40* '523 polyT allele frequency, based on point estimates, Japanese subjects had higher frequencies of the Long (L20-29 Ts) alleles and Very Long (VL>29 Ts), and lower frequencies of the Short (S<20 Ts) alleles than other ethnicities compared. For the Japanese subjects, we did not find any extra-long alleles (T40-T57), which were occasionally observed in African and African-American subjects. In addition, we observed *APOE*ϵ4/*TOMM40* '523 S haplotype, which is rarely observed in Caucasian cohorts. These findings highlight the importance of determining the genetic architecture of this region of distinct ethnic groups for assessing its contribution to AD risk.

1247W

Progression rate from intermediate to advanced age-related macular degeneration varies with the number of risk alleles at the *CFH* locus. *P. J. Persad[1], R. J. Sardell[1], S. G. Schwartz[2], J. L. Kovach[2], J. A. Fortun[2], M. A. Brantley[3], A. Agarwal[3], J. L. Haines[4], W. K. Scott[1], M. A. Pericak-Vance[1].* 1) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami, FL; 3) Ophthalmology and Visual Sciences, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH.

As a complex disease, risk of advanced age-related macular degeneration (AMD) is associated with both demographic and environmental factors, such as age, sex, smoking history, and diet, along with common and rare genetic variants at over 19 loci. However, risk is just one facet of AMD disease architecture; disease progression rate is another crucial aspect of variability among individuals. Whether genetic variants also affect progression rate from early/intermediate stages to advanced AMD is largely unknown. We tested whether genetic risk at 4 major common AMD risk-associated loci (*CFH*, *ARMS2*, *C2*, and *C3*) also predicts disease progression. We recruited AMD cases of European ancestry and monitored disease progression via regular clinical exams. Subjects were graded using the modified Age-Related Eye Disease Study (AREDS) scale. We tested whether progression rate from intermediate (grade 3) to advanced AMD (grade 4, geographic atrophy, or grade 5, choroidal neovascularization) was associated with the number of risk alleles (0, 1, or 2 risk alleles) at *CFH* (rs10737680), *ARMS2* (rs10490924), *C2* (rs429608), and *C3* (rs2230199), accounting for age at first grade 3 exam and sex. Cox proportional-hazards models were fit to allow for right censoring (some eyes had not progressed by the most recent exam), and for repeated measures (both left and right eyes may be included). Over the study period (max. 13 years), 172 (of 550) eyes from 376 individuals progressed from grade 3 to grade 4 or 5. Progression rate differed with the number of risk alleles at the *CFH* locus; individuals with 2 risk alleles progressed faster than those with 1 risk allele [hazard ratio (HR) = 1. 60, 95% CI 1. 07-2. 39, p=0. 02]. Genotype at the other 3 risk loci did not predict progression, but older subjects had higher hazard ratios in all models [HR= 1. 05, 95% CI=1. 03-1. 08, p<0. 01]. Sex was not significant in any model. These results support other studies' findings that progression rate to advanced AMD varies with the number of risk alleles at the *CFH* locus. However, since the effect of *CFH* was not strong and effects for the other 3 risk loci were not significant, additional genetic or environmental factors are likely to explain variation in AMD progression. These results warrant the need to test for association with other known AMD risk variants, novel loci, and potential environmental predictors.

1248T

Identification of IKAP responsive-genes as biomarkers for therapy of Familial Dysautonomia. *E. Morini, A. Ragavendran, M. Salani, S. Erdin, A. Stortchevoi, A. Brenner, M. Nilbratt, M. Talkowski, S. Slaugenhaupt.* Center for Human Genetic Research, Massachusetts General Hospital Research Institute/Harvard Medical School, Boston, MA.

Familial dysautonomia (FD) is a fatal, congenital sensory and autonomic neuropathy. We previously identified the genetic cause of FD, namely a "leaky" mRNA splicing defect in *IKBKAP* gene that results in reduced levels of IKAP protein. IKAP, or ELP1, is a scaffolding protein of the Elongator complex which is required for efficient transcriptional elongation. We found that kinetin can correct the *IKBKAP* splicing defect and increase the amount of normal mRNA and protein in FD cell lines and in mice following oral dosing. Our ongoing analyses are seeking to produce a new class of splicing modulators with significantly increased potency and efficacy over kinetin. If successful, such efforts could derive a therapy for FD by enhancing exon 20 inclusion and consequently increasing production of functional IKAP protein. Therefore, the identification of early disease-relevant pathways will permit the identification of biomarkers that can be used to assess the *in vivo* efficacy of therapies that alter IKAP levels. To identify IKAP-regulated pathways necessary for proper development of the sensory and autonomic nervous system, transcriptome sequencing analysis was performed in embryos expressing increasing amounts of IKAP: *Ikbkap*-/-, TgFD1/*Ikbkap*-/-, TgFD9/*Ikbkap*-/- and WT embryos. Consistent with the role of IKAP in transcriptional elongation, approximately 60% of all differentially expressed genes were down-regulated, and overall, down-regulated genes were longer than up-regulated genes. Importantly, we identified 262 genes whose expression increased strictly as a monotonic function of IKAP levels. These genes highlight pathways involved in nervous system development, including synapse formation, neuron differentiation, axon guidance, axon growth and neuronal cell adhesion. Remarkably, the IKAP dose-responsive genes show strong enrichment of genes involved in neurotrophin signaling pathway ($p < 10\text{-}4$). Many genes known to be associated with clinically similar types of hereditary sensory and autonomic neuropathy are involved in this pathway, including *NTRK1* for HSAN IV and *NGF* for HSAN V. Our findings emphasize the vital role of IKAP in embryo development and indicate that IKAP levels tightly regulate the expression of many genes involved in neurodevelopmental pathways. Further characterization of these pathways could yield robust biomarkers that will allow us to determine efficacy of promising therapeutics.

1249F

Cancer frequency among Machado-Joseph disease/Spinocerebellar Ataxia Type 3. *L. B. Jardim[1, 2, 5, 6, 7], G. N. Souza[1], N. Kersting[1], D. L. O. Pacheco[3], A. C. Krum-Santos[2], M. L. Saraiva-Pereira[4, 6], J. A. M. Saute[1, 6].* 1) Post-Graduation Program in Medical Sciences, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 2) Medicine School, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 3) Social Service School, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 4) Department of Biochemistry, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 5) Department of Internal Medicine, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil; 6) Medical Genetics Service, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 7) Instituto Nacional de Genética Médica Populacional (INAGEMP), Porto Alegre, Brazil Porto Alegre, Brazil.

Background: Former studies reported a reduced risk of cancer among polyglutamine (polyQ) disorders, suggesting that poliQ protects against cancer. This was not tested yet in Machado-Joseph disease/spinocerebellar ataxia type 3 (MJD/SCA3). **Aims**: to compare the cumulative incidence (CI) of cancer, and the proportion of cancer among causes of death of MJD/SCA3 symptomatic individuals with those found in unrelated controls, in the last 15 years. **Methods**: after consent, structured interviews were applied in individuals older than 18 years-old: unrelated controls and symptomatic SCA3/MJD cases registered at our institution in Rio Grande do Sul, Brazil, where 180 families with molecular diagnosis and 700 symptomatic individuals were living by May, 2015. Cancer occurrences were obtained. The CIs were also compared to the expected number of cancers for this population, as published by "Instituto Nacional do Cancer" (INCA), Brazil, 2014. Interviews also asked for dead affected relatives of SCA3/MJD individuals in the last 15 years. Causes of death were obtained, as well as those from two death controls of similar age and same gender, that occurred imediatelly after or before, according to death registry "Sistema de Informacao sobre Mortalidade" (SIM). **Results**: 154 SCA3/MJD cases (45±12 years-old; 44. 2% males) (41 families), and 80 unrelated controls (45±13 years-old, 32. 5% males) were interviewed between May 2014 and April 2015. The CI of cancer in the last 15 years was of 7/154 (4. 5%) in SCA3/MJD and of 5/80 (6. 25%) in unrelated controls (χ^2=0,314; p=0. 575; RR 1. 375, CI 95% 0. 451 to 4. 195). The expected CI for this population in this period, according to INCA data, was 6%. With the absolute reductions of risk (ARR) of 1. 8%, 1,938 individuals per group were needed for a study with a 80% power to detect significant differences (p<0. 05). The SCA3/MJD individuals reported 55 deaths among their affected relatives in the last 15 years. Death causes were compared to 108 deaths of controls. Cancer was a cause of death in 4/55 (7. 3%) SCA3/MJD and in 27/108 (24. 5%) non-SCA3/MJD individuals (χ^2=7. 17; p=0. 007): an ARR of 17. 2% and a relative risk of 0. 296 (CI 95%: 0. 109-0. 805) of dying from cancer were associated to SCA3/MJD. **Discussion**: the study of CI of cancer is unattainable because sample sizes needed far exceed the overall population of SCA3/MJD in our state. Notwithstanding, SCA3/MJD was associated to a significant reduction of risk of death related to cancer.

1250W

Genetic aspects of sporadic spinocerebellar degeneration in the Japanese population. *Y. Takahashi, M. Kanai, S. Watanabe, M. Murata.* Dept Neurology, National Center of Neurology and Psychiatry, Kodaira, Tokyo, Japan.

[Background]Spinocerebellar degeneration (SCD) is a group of disorders characterized by progressive ataxia caused by degeneration of cerebellum or its afferent or efferent connections. By excluding multiple system atrophy, approximately 60% of SCD are familial SCD (fSCD) and the remaining sporadic SCD (sSCD). Genetic backgrounds of fSCD are highly heterogeneous: the modes of inheritance include autosomal-dominant (AD-SCD), autosomal-recessive (AR-SCD) or X-linked (X-SCD), with numerous causative genes. Meanwhile, the clinical entity of late-onset sSCD contains wide variety of diseases with diverse etiology, whereas that of early-onset sSCD presumably consists mostly of AR-SCD. [Purpose]To elucidate genetic aspects of sSCD in the Japanese population. [Subjects and Methods] Sixty patients with clinical diagnosis of sSCD excluding MSA were enrolled in this study. The ages of onset of the patients ranged from 0 to 83 years. DNA samples obtained with informed consent were subjected initially to the fragment analysis for triplet repeat expansion diseases including SCA1, 2, 3/MJD, 6, 8, 12, 17 and dentate-rubro-pallido-luysian atrophy (DRPLA), followed by fragment analysis and repeat-primed PCR for SCA31. DNA samples from 29 patients with the ages at onset below 40 were further subjected to the mutational analysis of *APTX* and *SACS* employing direct nucleotide sequencing method. This study was approved by the Institutional Review Board of National Center of Neurology and Psychiatry. [Results] Causative mutations were identified in 5 patients (8. 5%) with sSCD, consisting of 2 patients with SCA6, 2 with DRPLA, and one with SCA31. The ages at onset were 37 and 65 years old with SCA6, 19 and 57 years old with DRPLA, and 60 years old with SCA31. The expanded CAG repeat numbers were 24 and 22 in SCA6 (normal; 4~19) and 60 and 59 in DRPLA (normal; 6~36), respectively. In contrast, no homozygous or compound heterozygous pathogenic mutations were identified in *APTX* or *SACS*. [Discussion and Conclusion] Substantial proportion of patients with sSCD harbored causative mutations of AD-SCD, demonstrating that screening of AD-SCD in early-onset as well as late-onset sSCD proved to be fruitful. In contrast, screening of causative genes for AR-SCD did not establish genetic diagnosis, indicating that exome analysis would be efficient for elucidating genetic aspects of early-onset sSCD. Optimization of diagnostic algorithms is necessary for accurate clinical diagnosis of sSCD.

Huntington disease (HD) is caused by a CAG•CTG expansion in the *huntingtin (HTT)* gene. Although most HD research has focused on the downstream effects of the HTT polyGln-expansion protein, the discovery of repeat associated non-ATG (RAN) translation raises the possibility that additional HD mutant RAN proteins are expressed across the CAG•CTG expansion mutation and contribute to the disease. We now report that four novel, homopolymeric expansion proteins (polyAla, polySer, polyLeu & polyCys) accumulate in HD human brains. These sense and antisense HD-RAN proteins accumulate most abundantly in brain regions with substantial neuronal loss, microglial activation and apoptosis, including the caudate/putamen and in juvenile-onset cases, also the cerebellum. RAN protein accumulation and aggregation patterns are length-dependent. Codon substitution experiments show that HD-RAN proteins are toxic to neural cells independent of RNA effects. Taken together, these data support a pathogenic role of RAN proteins in HD and suggest that therapeutic strategies targeting both sense and antisense genes may be required for efficacy. This is the first demonstration that RAN proteins are expressed across an expansion located in an open-reading frame and suggest RAN translation may also contribute to other polyglutamine diseases.

C9orf72 repeat expansion detection using short-read whole-genome sequencing data. *M. A. Eberle[1], J. F. A. van Vugt[2], R. J. Shaw[3], W. van Rheenen[2], A. M. Dekker[2], M. A. Bekritsky[3], S. S. Ajay[1], S. Chowdhury[1], T. Hambuch[1], R. Taft[1], D. Bentley[3], L. H. van den Berg[2], J. H. Veldink[2].* 1) Department of Population and Medical Genomics, Illumina, Inc. , San Diego, CA; 2) Department of Neurology and Neurosurgery, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Illumina Cambridge Ltd. , Chesterford Research Park, Saffron Walden, Essex, CB10 1XL, UK.

The hexanucleotide repeat expansion of CCGGGG in the *C9orf72* gene has been recognized as a major cause of ALS and Frontotemporal Dementia (FTD) and been implicated in other neurodegenerative and psychiatric disorders. Approximately 30% of familial ALS cases, 20% of familial FTD cases, 6% of sporadic ALS cases and 5% of sporadic FTD cases have been attributed to the *C9orf72* repeat expansion. While the exact pathological cut-off has not yet been established, the *C9orf72* repeat is considered expanded when it counts more than 30 hexamers (>180bp). Since it is so prevalent, all genetic studies in ALS and FTD must be stratified or adjusted for *C9orf72* repeat status, requiring a continuous and separate RP-PCR analysis. Moreover, the exact length of the repeat expansion is difficult, if not impossible, to determine and currently involves a combination of RP-PCR, Southern blotting and targeted sequencing. Here, we present a sequence-based method to accurately determine the length of any 3-6 nucleotide repeat, even when they are extremely expanded, in paired-end whole-genome sequence data. Sequencing was performed on 349 individuals (including 77 with the C9orf72 expansion) on an Illumina HiSeq 2000 using 2x100bp paired reads to ~40x depth. Of the 77 *C9orf72* samples that RP-PCR identified as expanded, only 1 sample had a repeat count of less than 20 according to the sequence analysis, whereas 6 samples had a repeat count between 20 and 30 and the rest of the samples had a repeat count higher than 30. Of the 272 *C9orf72* samples that were not expanded according to RP-PCR, only 1 sample had a repeat count of 260 according to the sequence analysis, whereas 2 samples had a repeat count between 20-30 and the rest of the samples had a repeat count lower than 20. If a count of 30 is the pathological cutoff, sensitivity of the tool is 90. 9%, and specificity 99. 6%. If the true cutoff is 20, these numbers are 98,7% and 98. 9% respectively. Further validation of this tool is ongoing in independent samples and for other repeat expansions, which will be presented. Since microsatellite expansions are a common genetic risk factor in neurodegenerative diseases, accurately determining the length of a repeat at known genomic locations using NGS data and also discovering unknown repeat expansions will allow studying the impact of repeat expansion on neurodegenerative disorders.

Large-scale single-molecule sequencing of tandem repeats on the human X chromosome. *A. Zablotskaya[1,2], G. Peeters[1,2], W. I. M. Meert[2,3], H. Van Esch[2,4], K. J. Verstrepen[5], G. Froyen[2,6,7], J. R. Vermeesch[1,2].* 1) Laboratory for Cytogenetics and Genome Research, Department of Human Genetics, KU Leuven, 3000 Leuven, Belgium; 2) Center for Human Genetics, University Hospitals Leuven, KU Leuven, 3000 Leuven, Belgium; 3) Genomics Core, University Hospitals Leuven, 3000 Leuven, Belgium; 4) Laboratory for Genetics of Cognition, Department of Human Genetics, KU Leuven, 3000 Leuven, Belgium; 5) VIB Laboratory for Systems Biology & CMPG Laboratory for Genetics and Genomics, KU Leuven, 3001 Leuven, Belgium; 6) Human Genome Laboratory, Department of Human Genetics, KU Leuven, 3000 Leuven, Belgium; 7) Jessa Hospital, Laboratory for Molecular Diagnostics, Clinical Biology, 3500 Hasselt, Belgium.

Tandem repeats are short DNA sequences that are repeated head-to-tail with a propensity to be variable. They constitute a significant proportion of the human genome, also occurring within coding and regulatory regions. Variation in these repeats can alter the function and/or expression of genes allowing organisms to swiftly adapt to novel environments. Importantly, some repeat expansions have also been linked to certain diseases. Unfortunately, due to the nature of short read sequencing technologies, tandem repeats are not analyzed during whole genome or exome sequencing studies. We developed a novel capture assay for large-scale genotyping of tandem repeats (Duitama J. , Zablotskaya A. et al. , Nucl. Acids Research, 2014) and extended the assay for the identification of X linked disease-related repeats using long read (averaging 12 kb) PacBio RS II technology. For 837 (83% of all) potentially functional repeats, unique capture baits were designed, as well as for 1000 intronic and intergenic repeats. Of these, a full tandem repeat length sequence was obtained for 88-90% of the targets in male DNA samples. Sequencing read length and analysis pipeline allows to detect cases of tandem repeat expansion. We are currently implementing this assay to screen for potentially causal variation underlying X-linked disorders that are not explained following array and exome sequencing. Can rare variants account for signals from common variants? *F. Begum[1], M. A. Taub[2], I. Ruczinski[2], E. J. Leslie[3], D. C. Koboldt[4], T. H. Beaty[1], J. C. Murray[5], M. L. Marazita[3,6], Cleft Seq 1 Consortium.* 1) Department of Epidemiology, Johns Hopkins University, Baltimore, MD; 2) Department of Biostatistics, Johns Hopkins University, Baltimore, MD; 3) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) The Genome Institute,Washington University School of Medicine, St. Louis, MO; 5) Department of Pediatrics, Carver College of Medicine, University of Iowa, Iowa City, IA; 6) Department of Human Genetics, Graduate School of Public Health, and Clinical and Translational Science Institute, School of Medicine, University of Pittsburgh, Pittsburgh, PA.

While genome-wide association studies (GWAS) have successfully identified polymorphic markers associated with complex diseases, few are directly causal. High-throughput sequencing holds the promise of identifying directly causal mutations. Several statistical methods for sequencing data under case-control study designs are available, but fewer methods for family-based studies exist. Also, rare variants (RV) capable of producing deleterious gene products cannot be identified in conventional association study designs due to lack of power. We are proposing a new empirical method, which is primarily motivated by the concept of 'synthetic association' with a common marker and disease being a reflection of multiple causal RVs. Our method looks for an excess of putatively functional RVs on transmitted risk haplotypes tagged by a common marker showing significant association in the allelic transmission disequilibrium test (aTDT), compared to corresponding untransmitted risk and non-risk haplotypes. We illustrate our approach using 1,409 case-parent trios ascertained through a child with a non-syndromic oral cleft from 3 ethnic groups (Chinese, Filipino and European) sequenced on 6. 3 Mb in 13 candidate genes/regions. We used counts of putatively deleterious RVs transmitted with the common risk allele and compared them to counts of RVs on both untransmitted risk and non-risk haplotypes, and found some significant differences for selected genes. We designed permutation-based tests to assess evidence that non-random sets of RVs are transmitted to the affected child. We observed significant over-transmission of putatively deleterious RVs in the regions around *VAX1*, *IRF6*, *MAFB* and *FOXE1* (all candidate genes for oral clefts) and borderline empirical significance in other regions. We are following up our findings to identify which among these deleterious RVs could be actually casual. We will expand this approach to consider local linkage disequilibrium structure and further characterize functionality of these RVs, which may offer a viable method for resolving causal variants that could explain associations found with polymorphic markers in GWAS.

1255T

A Comparison Study of Fixed and Mixed Effect Models for Gene Level Association Studies of Complex Traits. *C. Chiu[1], J. Jung[2], D. Weeks[3], A. Wilson[4], J. Bailey-Wilson[4], C. Amos[5], M. Xiong[6], R. Fan[1].* 1) Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), National Institutes of Health (NIH); 2) National Institute on Alcohol Abuse and Alcoholism, NIH; 3) University of Pittsburgh; 4) National Human Genome Research Institute, NIH; 5) Dartmouth Medical College; 6) University of Texas - Houston.

In association studies of complex traits, fixed effect regression models are usually used to test for association between phenotypic traits and major gene loci. In recent years, variance-component tests based on mixed models were developed for region-based genetic variant association tests. In the mixed models, the association is tested by a null hypothesis of zero variance via a sequence kernel association test (SKAT) and its optimal unified test (SKAT-O). Although there are some comparison studies to evaluate the performance of mixed and fixed models, there is no systematic analysis to determine when the mixed models perform better and when the fixed models perform better. Here we evaluated, based on extensive simulations, the performance of the fixed effect and mixed model statistics, using genetic variants located in 6, 9, 12, and 15 kb simulated regions. We compared the performance of three models: (1) mixed models which lead to SKAT and SKAT-O, (2) traditional fixed effect additive effect models, and (3) fixed effect functional regression models. We performed simulation analyses for two scenarios: (1) all causal variants are rare; (2) some causal variants are rare and some are common. We found that the fixed effect tests have accurately controlled false positive rates. In most cases, either one or both of the fixed effect models performed better than or similar to the mixed models, when some causal variants are rare and some are common, or when all causal variants are rare except for the 12 and 15 kb region cases. We argue that the fixed effect models are useful in most cases. In practice, it makes sense to perform analysis by both the fixed and mixed effect models and make a comparison, and this can be readily done using our R codes and the SKAT and SKAT-O packages.

1256F

A Statistical Approach for Testing Pleiotropic Effects of Rare Variants. *M. P. Epstein[1], K. A. Broadaway[1], D. J. Cutler[1], R. Duncan[1], J. L. Moore[2], E. B. Ware[3], M. A. Jhun[3], L. F. Bielak[3], W. Zhao[3], J. A. Smith[3], P. A. Peyser[3], S. LR. Kardia[3].* 1) Department of Human Genetics, Emory University, Atlanta, GA; 2) Department of Evolution and Ecology, University of California, Davis, Davis, CA; 3) Department of Epidemiology, University of Michigan, Ann Arbor, MI.

Empirical findings suggest many trait-influencing genetic factors are associated with multiple distinct phenotypes; these associations are defined as pleiotropic or cross-phenotype associations. When cross-phenotype effects exist, association methods of multiple phenotypes that leverage pleiotropy are more powerful than univariate methods that consider each phenotype separately. While several statistical approaches exist for testing pleiotropy in genome-wide association studies, there is a lack of statistical tools for pleiotropic analysis of rare variation that aggregate information across a gene or region of interest. In order to fill this important gap, we introduce a new statistical method for gene-based pleiotropic analysis of rare variants using a nonparametric distance-covariance approach that constructs sample pairwise similarity (or dis-similarity) matrices for phenotypes and genotypes and then evaluates whether the individual elements in the two matrices are independent. The approach possesses many valuable features. The method can accommodate an arbitrary number of categorical and/or continuous phenotypes, thereby scaling easily to handle high-dimensional data, and further can adjust for covariates. Further, the resulting test is computationally efficient and scalable to genome-wide application since the test has a closed form (circumventing complicated optimization) and follows an asymptotic distribution thereby allowing analytic derivation of P-values usingDavies' exact method. We use simulated data to demonstrate that our method, which we refer to as the Gene Association with Multiple Traits (GAMuT) test, provides increased power over univariate SKAT testing of individual traits when pleiotropy exists. We also illustrate our approach using exome-chip data from the Genetic Epidemiology Network of Arteriopathy.

Functional Regression Models for Gene-based Association Studies of Complex Traits. *R. Fan[1], C. Chiu[1], Y. Wang[2], J. Jung[3], Y. Jiang[4], W. Chen[4], D. Weeks[4], H. Ren[5], C. Amos[6], A. Wilson[7], J. Bailey-Wilson[7], M. Xiong[8].* 1) Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), National Institutes of Health (NIH), Bethesda, MD; 2) Food and Drug Administration (FDA), Silver Spring, MD; 3) National Institute on Alcohol Abuse and Alcoholism, NIH, Bethesda, MD; 4) University of Pittsburgh, Pittsburgh, PA; 5) Regeneron Pharmaceuticals, Inc. , Basking Ridge, NJ; 6) Dartmouth Medical College , Lebanon, NH; 7) National Human Genome Research Institute, NIH, Bethesda, MD; 8) University of Texas - Houston, TX.

By using functional data analysis techniques, fixed effect functional regression models are developed to test associations between complex traits and genetic variants, which can be rare or common variants or a combination of the two, adjusting for covariates. By treating multiple genetic variants of an individual in a human population as a realization of an underlying stochastic process, the genome of an individual in a chromosome region is a continuum of sequence data rather than discrete observations. The genome of an individual is viewed as a stochastic function which contains both genetic position and linkage disequilibrium information of the genetic markers. Then, the genetic effect of genetic variants is assumed to be a smooth function, i. e. , a continuous genetic effect function, which can be estimated by B-spline or Fourier basis functions. The association between phenotypic traits and genetic variants is tested by testing a null hypothesis that the genetic effect function is equal to 0. In our published papers [Genetic Epidemiology 37:726-742 (2013), 38:622-637 (2015), and 39:259-275 (2015)], test statistics of the proposed functional regression models are built to test association between phenotypic traits (which can be quantitative or dichotomous) and genetic variants. Extensive simulation analysis and real data analysis were performed to demonstrate that the proposed models and tests perform better in most cases than existing popular procedure of sequence kernel association test (SKAT) and its optimal unified test (SKAT-O). In our unpublished work, we extend the functional regression approach to pedigree data to analyze quantitative or dichotomous traits. One motivation is the superior performance of the functional regression models in analyzing population data, and this merit should be useful for analyzing pedigree data. We build functional linear mixed models to model the phenotypic traits. Again, the genetic effect of genetic variants is modeled by a genetic effect function, and the relation among the family members is modeled by a variance-covariance matrix as variance component models of traditional population genetics. The performance of the model is being evaluated and the methods will be used to analyze complex traits with exome chip genotyping of pedigree data. The proposed models can be useful in whole genome and whole exome association studies of complex traits.

A heterogeneity sequence association test identified novel genes of alcohol addiction in African Americans. *W. Ouyang[1,2], HZ. Qin[1,2].* 1) Center for Bioinformatics and Genomics; 2) Department of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA.

Phenotypic variance heterogeneity is ubiquitous in systems epidemiology data from the multi-ethnic populations. It occurs via various means, such as genetic admixture, ancestral background linkage disequilibrium, genetic pleiotropy, as well as gene-by-gene and gene-by-environment interactions. Existing gene-based association methods essentially focus on valid analyses of mean effects and neglect variance effects. In this report, we proposed a heterogeneity sequence association test (HSAT) to integrate valuable marker-specific heterogeneity signals with group-wise mean effects. Under a wide range of simulation designs in major journals, the proposed HSAT appropriately controlled Type I error rate and appeared notably more powerful than several existing prominent gene-based sequence association tests, e. g. , the SKAT, SKAT-O and GEMMA. The proposed HSAT demonstrated even more noteworthy power gains over the established tests under simulated scenarios of admixture genetics. To illustrate its practical utility, we applied the HSAT to the DNA sequence and alcohol dependence data of 1265 African Americans from the SAGE. The HSAT identified *RIC3*, *IL36RN*, *RAM23, SPTBN1, PARP8* as novel significant genes that were missed by aforesaid prominent tests and were not reported in the literature. 41 out of 114 top significant genes identified by the HSAT have been reported to be associated with alcohol dependence.

1259F

Human Population Classification Based on Common and Rare Variants Using Random Forests, Artificial Neural Networks, and Support Vector Machines. *M. Rao[1], T. Mersha[2], M. Wathen[3], D. Tadesse[4].* 1) Environmental Health, Univ Cincinnati, Cincinnati, OH 45267; 2) Division of Asthma Research, Cincinnati Children's Hospital, 3333 Burnet Avenue, Cincinnati, OH 45229; 3) Division of Biostatistics and Bioinformatics, Department of Environmental Health, University of Cincinnati, OH 45267; 4) Department of Mathematical Sciences, University of Cincinnati, Cincinnati, OH 45267.

In genetic studies of common variants population structure is well-known and well-understood. Population structure in the realm of rare variants is unclear. The objective of the presentation is to analyze relationship between common and rare variants in terms of population structure by finding answers to the following questions. Is the population structure (or inferred ancestry) similar in common and rare variants? From a population classification persprctive, identify SNPs with the most inpact on classification. We perform extensive population structure analysis using common and rare variants data available from the 1000 Genomes Project for 11 populations. The data are divided into two groups including common and rare variants. Both variants are summarized across the study populations. For SNP data, each respective SNP is considered as a categorical variable with three genotypes. Three analytical approaches are compared including random forests (RF), neural network (NNET), and support vector machines (SVM) in terms of classification accuracy with respect to both rare and common variants. Performances are compared based on the models' predictive ability.

1260W

A New Method for Detecting Associations with Rare Copy-Number Variants. *J. Szatkieiwcz[1], J. Tzeng[2,3], P. Magnusson[4], P. Sullivan[1,4], The Swedish Schizophrenia Consortium.* 1) University of North Carolina, USA; 2) North Carolina State University, USA; 3) National Cheng-Kung University, Taiwan; 4) Karolinska Institutet, Stockholm, Sweden.

Copy number variants (CNVs) play an important role in the etiology of many diseases such as cancers and psychiatric disorders. Due to a modest marginal effect size or the rarity of the CNVs, collapsing rare CNVs together and collectively evaluating their effect serves as a key approach to evaluating the collective effect of rare CNVs on disease risk. While a plethora of powerful collapsing methods are available for sequence variants (e. g. , SNPs) in association analysis, these methods cannot be directly applied to rare CNVs due to the CNV-specific challenges, i. e. , the multi-faceted nature of CNV polymorphisms (e. g. , CNVs vary in size, type, dosage, and details of gene disruption), and etiological heterogeneity (e. g. , heterogeneous effects of duplications and deletions that occur within a locus or in different loci). Existing CNV collapsing analysis methods (a. k. a. the burden test) tend to have suboptimal performance due to the fact that these methods often ignore heterogeneity and evaluate only the marginal effects of a CNV feature. We introduce CCRET, a random effects test for collapsing rare CNVs when searching for disease associations. CCRET is applicable to variants measured on a multi-categorical scale, collectively modeling the effects of multiple CNV features, and is robust to etiological heterogeneity. Multiple confounders can be simultaneously corrected. To evaluate the performance of CCRET, we conducted extensive simulations and analyzed large-scale schizophrenia datasets. We show that CCRET has powerful and robust performance under multiple types of etiological heterogeneity, and has performance comparable to or better than existing methods when there is no heterogeneity.

1261T

An extended variance-component score test for association of multivariate phenotypes and gene-level rare variants. *I. Patanam[1], W. Qi[2,3], M. E. Garrett[1], B. Anderson[1], C. H. Yu[3], X. J. Qin[3], A. E. Ashley-Koch[1,2,4], Y. J. Li[2,3].* 1) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 2) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC; 3) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 4) Department of Medicine, Duke University Medical Center, Durham, NC.

In genetic studies of complex diseases, investigators often collect multiple disease-related measurements in addition to the primary dichotomous disease outcome. Multivariate analysis can increase the power for genetic association tests and detect pleiotropy, where a single gene may affect multiple traits (Williams 1957). Methods for multivariate analysis such as multivariate analysis of variance (MANOVA) and generalized estimating equation (GEE) have been well documented in classical statistics literature. There is also a robust literature on multivariate genetic association tests for common variants, including application to genome-wide association study (GWAS). Here, motivated by the increasing availability of next generation sequencing data, we extended the concept outlined in the GEE-SPU method of Zhang et al (2014) for common variants and the SKAT score test (Wu et al. 2011) for a set of rare variants to a multivariate variance-component score test for multiple phenotypes at the gene level. Assuming *t* traits of interest, we utilized GEE to estimate the parameters of covariates and rare variants in order to compute the marginal mean of *t* traits for each individual. We derived a variance component score statistic (*Q*) with form similar to that of SKAT but in *t*t* dimension for *t* traits. We, therefore, propose a multivariate variance component score test in a form of the sum of eigenvalues of the *Q* matrix, which is equivalent to the sum of *Qt* where *Qt* is the score statistic of the *tth* trait. Multiple weighting schemes for rare variants and traits were evaluated. Simulation studies are in progress to evaluate type I error and statistical power, and to compare the performance of our method to the TATES method (van der Sluis et al. 2013), which uses p-values derived from SKAT for each trait to generate a combined p-value for each gene. The new method and TATES were also applied to cranial morphologic data (as described in Markunas et al. , 2014) with targeted rare-variant data on a set of candidate genes. This new method provides a flexible solution to the analysis of rare variants as they contribute to multivariate phenotypes.

1262F

A unified powerful set-based test for sequencing dataanalysis of GxE interactions of rare variants. *Y. Su[1], U. Peters[1], S. Berndt[2], S. Bézieau[3], H. Brenner[4], P. Campbell[5], A. Chan[6], J. Chang-Claude[7], M. Lemire[8], P. Newcomb[1,9], J. Potter[1,9,10], M. Slattery[11], M. Woods[12], C. Di[1], L. Hsu[1].* 1) Public Health Science Division, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 3) Service de Génétique Médicale, CHU Nantes, Nantes, France; 4) Division of Clinical Epidemiology and Aging Research, German Cancer Research Center, Heidelberg, Germany; German Cancer Consortium (DKTK), Heidelberg, Germany; 5) Epidemiology Research Program, American Cancer Society, Atlanta, GA; 6) Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 7) Division of Cancer Epidemiology, German Cancer Research Center, Heidelberg, Germany; 8) Ontario Institute for Cancer Research, Toronto, Canada; 9) School of Public Health, University of Washington, Seattle, WA; 10) Centre for Public Health Research, Massey University, Wellington, New Zealand; 11) Department of Internal Medicine, University of Utah Health Sciences Center, Salt Lake City, UT; 12) Discipline of Genetics, Memorial University of Newfoundland, St. John's, NL, Canada.

Next generation sequencing allows researchers to study comprehensively the contributions of genetic variations, in particular rare variants, and their interaction with environmental factors in relation to risk of common complex disease such as cancer. However, analysis of gene-environment interactions (GxE) for rare variants poses considerable challenges for making statistical inferences because very few subjects carry the variants and even fewer subjects who carry the variants are exposed to risk factors. To tackle this challenge, we propose a set-based statistical modeling and testing procedure that assesses the effects of a set of rare variants (e. g. , genes or regulatory regions). Under this framework, GxE is modeled by two components: an interaction (BxE) between a burden risk score (the total number of rare-variant minor alleles carried) and the environmental factor, and a random component of the interaction effects, which follows a distribution with mean 0 and variance tau2, to account for the residual GxE that has not been accounted for by BxE. We derive score tests for both components and combine the two score tests to gain power on GxE signal detection. The concept of the proposed combination here is different from that in meta-analysis, in that the two combined components are from the same study but represent different parameters, whereas for meta-analysis the combined components are from different studies, but estimate the same parameter. We propose two new data-adaptive combination approaches and establish the asymptotic distributions, which makes the genome-wide search for GxE computationally feasible. The extensive simulation results show that the proposed approaches maintain the correct type I error and possess power comparable to existing methods such as the sequence kernel association test for interaction effects (iSKAT, Lin *et al*. 2013). We applied the proposed methods and iSKAT to an exome chip dataset from the Genetics and Epidemiology of Colorectal Cancer Consortium (GECCO) to identify potential GxE interaction effects between 7,600 genes and NSAID use. We found a novel GxE interaction effect for *TELO2* that reaches exome-wide significance using the proposed methods, but failed to identify this finding using the iSKAT approach. The novel finding may provide new insights into the role of NSAID use and its interplay with genetic variation on colorectal cancer risk.

1263W

Generalized linear Mixed Model Association Tests (GMMAT) for rare variants to control for population stratification and relatedness in sequencing studies with continuous and binary phenotypes. *H. Chen[1], C. Wang[2], S. Lee[3], S. Redline[4], X. Lin[1].* 1) Department of Biostatistics, Harvard T. H. Chan School of Public Health, Boston, MA; 2) Computational and Systems Biology, Genome Institute of Singapore, Singapore; 3) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 4) Division of Sleep and Circadian Disorders, Departments of Medicine and Neurology, Brigham and Women's Hospital, Boston, MA.

SNP-set based tests have been widely used for rare variant association analysis in sequencing studies, where a SNP set consists of a set of genetic variants in a gene, region or a pathway. Existing SNP-set based tests for binary traits such as burden tests, the sequence kernel association test (SKAT) and SKAT-O are applicable to independent samples. To control for population stratification, family and cryptic relatedness, and complex sampling designs in sequencing association studies, we propose a general framework of SNP-set based tests and meta-analysis using Generalized linear Mixed Model Association Tests (GMMAT). We show that applying linear mixed models to binary traits may lead to incorrect type I error rates in the presence of population stratification. We develop a computational efficient score based association tests by fitting generalized linear mixed models for rare variant analysis. Fitting generalized linear mixed models using GMMAT is almost two orders of magnitude faster than existing implementation in SAS PROC GLIMMIX. Simulation studies show that our tests have correct type I error rates for binary traits in the presence of population stratification and relatedness, while naïve burden tests, SKAT, SKAT-O and linear mixed model based SKAT and SKAT-O fail to control type I error rates. We compare the power of our tests in various scenarios and illustrate how they could be used to test a broad class of different scientific hypotheses. We also apply our methods to a case-control rare variant study to perform a trans-ethnic meta-analysis of both population-based and family-based studies.

1264T

Robust association testing for quantitative traits and rare variants. *P. Wei[1], Y. Cao[1], Z. Xu[2], Y. Zhang[2], J. Crosby[1], E. Boerwinkle[1], W. Pan[2].* 1) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 2) Division of Biostatistics, School of Public Health, University of Minnesota, Minneapolis, MN.

With the advance of sequencing technologies, it has become a routine practice to test for association between a quantitative trait and a set of rare variants (RVs). However, to our knowledge, there is no study yet on the robustness of association testing to the non-Normality of the observed traits, e. g. due to skewness, which is expected to be ubiquitous for quantitative traits. By extensive simulations, we demonstrate that SKAT and SKAT-O are not robust to heavily-tailed or right-skewed error (or trait) distributions with inflated Type I error rates; in contrast, some other tests, including our proposed SPU tests and their adaptive version called aSPU test, are much more robust. We further propose a robust version of the SPU and aSPU tests, denoted as SPUr and aSPUr. We conduct extensive simulations to evaluate the power of the tests, finding that in most situations the aSPU test achieves similar power to that of SKAT or SKAT-O when testing on a smaller number of RVs; on the other hand, for a larger number of RVs, the aSPU test is often more powerful than others, owing to its high data-adaptivity. As expected, the aSPUr test loses power in the absence of outliers. We also compare different tests by conducting association testing of (1) triglyceride in 1731 individuals using the NHLBI ESP whole exome sequencing data, and (2) brain imaging phenotypes in 812 individuals using the Alzheimer's Disease Neuroimaging Initiative (ADNI) whole genome sequencing data. In the former, the QQ plots for SKAT, SKAT-O and T1 tests of the untransformed triglyceride were severely inflated (lambda = 1. 89, 1. 78 and 1. 13, respectively), while those for aSPU and aSPUr behaved normally (lambda < 1. 04). The positive control gene *APOC3* [MIM: 614028] (Crosby et al, NEJM 2014) was ranked 37th by aSPUr, but was not among the top 200 genes by all other methods. When applied to Log and inverse-normal transformed triglyceride, all tests had lambdas < 1. 05, but only T1, SKAT-O, aSPU and aSPUr ranked APOC3 among the top two. In the ADNI example, SKAT could have severely inflated QQ plots even with Log or inverse-normal transformed imaging phenotypes, for which aSPU and aSPUr controlled the lambda well. Due to its relatively high robustness to outliers and high power of the aSPU test, we recommend its use complementary to SKAT and SKAT-O. If there is evidence of inflated Type I error rate from the aSPU test, we would recommend the use of the more robust (but less powerful) aSPUr test.

High-dimensional genotypes and phenotypes in rare variant association studies. *M. Pirinen[1], C. Spencer[2], M. J. Daly[3,4], M. I. McCarthy[2,5], M. A. Rivas[2,3].* 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 3) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 5) Oxford Centre for Diabetes, Endocrinology and Metabolism, Oxford, UK.

We consider assessing association between multiple rare variants and multiple phenotypes. This topic is particularly timely in the context of biobank studies where detailed genetic data can be combined with several correlated phenotypes. We propose the multiple rare variants and phenotypes (MRP) approach, a general statistical framework that is able to exploit knowledge about the correlation of genetic effects 1) across a group of genetic variants, 2) across a group of phenotypes, and 3) across a group of studies. Our implementation is efficient, making the analysis of large study designs practical; flexible and extensible making the analysis of gene-sets, pathways, and networks feasible; and includes standard univariate and multivariate gene-based tests as special cases. We work with summary statistics data permitting the joint analysis of multiple independent studies. Simulations show that on a standard laptop an exome-wide analysis of 10,000 to a million individuals can be achieved in 17 seconds to less than 3 days for the number of quantitative traits in the range 3-100. We study the method's ability to detect signal by simulations mimicking the effect of known protein truncating variants in *APOC3* on lipid levels. Results show that under many scenarios rare variant analysis across multiple variants and multiple phenotypes has a considerable advantage, measured by ROC area under the curve, over analyses that consider only a single variant or a single phenotype at a time. To support the analysis of rare variants across multiple phenotypes using summary statistics alone, as in RAREMETAL for univariate phenotypes, we extend our framework to allow for possible differences in genetic effects across ethnicities or populations. As expected, high concordance is observed ($r2 \approx 1.0$) between a joint-analysis of full phenotype and genotype data and the analysis based on the summary statistics only. Finally, we apply the framework to coding sequence data from 25 GWAS risk genes in UK residents comprising 24,892 subjects with six autoimmune disease phenotypes and 17,019 controls. We identify a potential new association of protein truncating variants at *TNFAIP3*. We envision that our method will be a valuable tool for future studies of complex traits in settings where high-dimensional genetic and phenotypic data are available.

Rare Variants Association Analysis in Large-Scale Sequencing Studies at the Single Locus Level. *J. Y. Tzeng[1,2], X. J. Jeng[1], W. Lu[1], Z. J. Daye[3].* 1) Department of Statistics, Campus Box 7566, North Carolina State University, Raleigh, NC 27695, USA; 2) Bioinformatics Research Center, Campus Box 7566, North Carolina State University, Raleigh, NC 27695, USA; 3) Department of Epidemiology and Biostatistics, University of Arizona, Tucson, AZ 85724, USA.

Genetic association analyses of rare variants in next-generation sequencing (NGS) studies are fundamentally challenging due to the presence of a very large number of candidate variants at extremely low minor allele frequencies. Recent developments often focus on pooling multiple variants to provide association analysis at the gene instead of the locus level. Nonetheless, pinpointing individual variants is a critical goal for genomic researches as such information can facilitate the precise delineation of molecular mechanisms and functions of genetic factors on diseases. Due to the extreme rarity of mutations and high-dimensionality, significances of causal variants cannot easily stand out from those of noncausal ones. Consequently, standard false positive control procedures, such as the Bonferroni and false discovery rate (FDR), are often underpowered, as a majority of the causal variants can only be identified along with a few noncausal ones. To provide informative analysis of individual variants in large-scale sequencing studies, we propose the FAlse Negative control Screening (FANS) procedure in this paper. The proposed procedure is computationally efficient and can adapt to the underlying proportion of causal variants. Extensive simulation studies across a plethora of scenarios demonstrate that the FANS is advantageous for identifying individual rare variants, whereas the Bonferroni and FDR are exceedingly over-conservative for rare variants association studies. In the analyses of the CoLaus dataset, FANS has identified individual variants most responsible for gene-level significances. Moreover, single-variant results using the FANS have been successfully applied to infer related genes with annotation information.

Evaluating Power and Sample Size Considerations for Gene Discovery in Rare Diseases. *M. H. Guo[1,2,3], J. N Hirschhorn[1,2,3].* 1) Division of Endocrinology, Boston Children's Hospital, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA.

Over the past few years, next generation sequencing has greatly facilitated gene discovery for rare genetic diseases. However, for many rare diseases, the genetic causes have not yet been found or have only been found for a subset of cases. The sample sizes needed to discover novel genetic causes from next generation sequencing are often unknown. Key considerations include genetic architecture (penetrance, locus heterogeneity) and the background rate of rare neutral variants that are difficult to distinguish from pathogenic mutations. Here, we have created an empirical simulation framework to evaluate power and sample size considerations in a typical scenario for rare disease gene discovery efforts, where unrelated probands are sequenced and a gene-based burden test is performed against suitable controls. Our simulation framework utilizes exome sequences in approximately 3000 individuals from the NHLBI Exome Sequencing Project and allele frequency data from the Exome Aggregation Consortium. Using our framework, we demonstrate how locus heterogeneity, penetrance, ability to distinguish neutral from pathogenic variants, minor allele frequency thresholds, mode of inheritance, and control population sizes each affect power. The simulation results demonstrate that, across genes, there is a wide range in the sample sizes needed to achieve a given power. We also found that increasing locus heterogeneity results in rapid increases in sample sizes needed. For example, under modest locus heterogeneity (each gene contributing to 5% of cases) and complete penetrance, approximately 300 cases are needed to achieve 90% power to detect a gene. We demonstrate the validity of our framework using existing results from several exome sequencing projects for rare diseases. Our studies provide a wide-ranging examination of power in rare disease gene discovery, with the added advantage of incorporating real sequencing data. Our studies provide useful guidance for study design for exome sequencing under a variety of genetic architectures. Broadly, our studies demonstrate that rare disease gene discovery will often require large sample sizes and necessitate international collaborations.

Rare variant association tests for pleiotropic traits in family studies. *Y. Chiu[1], L. Chien[1], F. Hsu[2], D. Brown[3].* 1) Institute of Population Health Sciences, National Health Research Institutes, Zhunan, Miaoli County 35053, Taiwan, ROC; 2) Department of Biostatistical Sciences, Wake Forest School of Medicine, Winston-Salem, North Carolina, USA; 3) Personalized Medicine Research, Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, North Carolina, USA.

Given the functional relevance of many rare variants, their identification is frequently critical for dissecting disease etiology. Functional variants are likely to be aggregated in family studies enriched with affected members, and this aggregation increases the statistical power for rare variant detection. However, methods for the analysis of rare variants for families with pleiotropic traits remain fairly limited. These methods should be capable of accounting for different sources of correlations and handling large amounts of sequencing data efficiently. To identify rare variants for pleiotropic traits in family studies, we extended the powerful pedigree-based burden and kernel association tests to genetic longitudinal studies. Generalized estimating equation (GEE) approaches were used to generalize the pedigree-based burden and kernel tests to multiple correlated phenotypes under the generalized linear model framework. Adjustments were made for the fixed effects of confounding factors. These tests accounted for the complex correlations between multiple phenotypes and between individuals within the same family. Comprehensive simulation studies were conducted to compare the proposed tests with mixed-effects models and marginal models using GEEs under various configurations. The proposed tests were applied to the Diabetes Heart Study.

Conditioning Adaptive Combination of *P*-values to Analyze Case-Parent Trios with or without Population Controls. *W. Lin, Y. Liang.* Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan.

Rare causal variants (minor allele frequency (MAF) < 1%) detection can help to uncover the etiology of complex diseases. Recruiting case-parent trios is a simple and popular study design in family-based studies. If researchers can also obtain data from population controls, utilizing unrelated controls in trios can improve the power of a statistical method. The transmission disequilibrium test (TDT) is a well-known method to analyze case-parent trio data. It has been extended to rare-variant association testing (referred to as 'rvTDT' hereafter), with the flexibility to incorporate population controls. The rvTDT method is robust to population stratification because of its conditioning approach. However, power loss may occur in the conditioning process. We here propose a 'conditioning adaptive combination of *P*-values method' (abbreviated as 'conADA'), to analyze trios with/without unrelated controls. By first truncating the variants with larger P-values, it is less vulnerable to the inclusion of neutral variants compared with other statistical approaches. Moreover, because the test statistic is developed by conditioning on parental genotypes, conADA generates valid statistical inference in the presence of population stratification. We evaluate the validity and power performance of conADA and some other methods through simulations. Furthermore, a real data analysis about hypertension is presented. The validity and power of next-generation sequencing data analyses can be affected by population stratification and the inclusion of neutral variants, respectively. We recommend the conADA method for its robustness to these two factors.

Kernel-Based Association Mapping on the X Chromosome in Samples with Complex Structure. *C. McHugh, T. Thornton.* Biostatistics, Univ Washington, Seattle, WA.

As the cost of whole-genome sequencing continues to decrease, researchers are able to generate rich datasets that include both rare and common variants. Large-scale genomic studies often include individuals who are related through documented pedigrees or are cryptically related. Furthermore, genetic studies include individuals from diverse populations with complex ancestry, such as admixed populations. In recent years, kernel-based statistical association methods have been proposed for association testing with rare (and common) variants within a gene region of interest on the autosomes. Some methods allow for family structure, but only if this structure is known. A limitation of existing methods is that they are not directly applicable to association testing of regions on the X chromosome. Here, we propose a method for **KE**rnel-based **A**ssociation **T**esting in **S**tructured samples on the **X** chromosome (KEATS-X) that is valid for samples with known and/or unknown complex structure. KEATS-X uses empirical genetic relatedness matrices and variance componentsestimated fromthe autosomes and X chromosome separately to account for sample correlation. Our approach is flexible and can include other sources of correlation, such as shared environmental effects. Fixed covariates can be included to account for population stratification or other common effects such as sex or age. In simulation studies, we demonstrate that the proposed KEATS-X method has the correct type I error for gene-based testing on the X chromosome, with both rare and common variants. We also show that existing methods applied to X chromosome genetic variants are not properly calibrated and have inflated type I error for gene-based tests on the X chromosome. We illustrate the KEATS-X method by analyzing genetic variants on the X chromosome using hematological traits measured in individuals from the Hispanic Community Health Study/Study of Latinos (HCHS/SOL).

Family-based rare variant association analysis: a fast and efficient method of multivariate phenotype association analysis. *L. Wang[1], D. Qiao[2,5], M. Cho[2,3], E. Silverman[2,3], S. Won[1,4].* 1) Interdisciplinary Program in bioinformatics, Seoul National University, Seoul, Seoul, South Korea; 2) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA 02115, USA; 4) Graduate School of Public Health, Seoul National University, Seoul, 151-742, Korea; 5) Department of Biostatistics, Harvard School of Public Health, Boston, MA 02115, USA.

Motivation: Family-based designs have been repeatedly shown to be powerful in detecting the significant rare variants associated with human disease. Furthermore, human diseases are often outcomes of multiple phenotypes, and thus we expect multivariate, family-based analyses to be efficient in detecting associations with rare variants. However, few statistical methods implementing this strategy have been developed. In this report, we describe one such implementation: the multivariate family-based rare variant association tool (*mFARVAT*). **Results:** *mFARVAT* is a quasi-likelihood-based score test for the rare variant association analysis with multiple phenotypes, and tests homogeneous and heterogeneous effects of each variant on multiple phenotypes. Simulation results show that the method is generally robust and efficient for various disease models, and we identify some promising candidate genes associated with chronic obstructive pulmonary disease. **Availability and Implementation:** The software is freely available at http://healthstat. snu. ac. kr/software/mfarvat/, implemented in C++ and supported on Linux and MS Windows.

1272W

Prevalence of Allelic Heterogeneity in Genotype-Tissue Expression (GETx) data. *F. Hormozdiari[1], A. Zhu[1], G. Kichaev[2], B. Pasaniuc[2,4], E. Eskin[1,3].* 1) Department of Computer Science, UCLA, Los Angeles, CA; 2) Inter-Departmental Program in Bioinformatics,UCLA, Los Angeles; 3) Department of Human Genetics, UCLA, Los Angeles; 4) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles.

Allelic heterogeneity (AH) is a phenomena where more than one variant in the same gene affects a phenotype. The Genotype-Tissue Expression project data provides an unprecedented opportunity to quantify the amount of allelic heterogeneity across tissues. The current approach for detecting theallelic heterogeneity is based on conditional analysis used in the context of fine-mapping. The conditional approach relies on an iterative selection of the most associated variants followed by re-computation of the statistical score for the remaining variants conditional on the already selected variants. The conditional process continues until statistical score for all the variants falls below a pre-defined significant threshold. As we show in our experiments, the conditional approach is sensitive to complex patterns of linkage disequilibrium and can often result in inaccurate predictions. In our work, we propose a novel probabilistic method to quantify allelic heterogeneity. Our method is an extension of our fine-mapping method, CAVIAR. The benefit for our method is that it provides a probability for different number of variants that affect the phenotype. Thus, we can assign probability to each gene which it harbors allelic heterogeneity and as a result we can have a confident level for our prediction ofgenes which harbors allelic heterogeneity. We assess the performance of our method using simulated and real datasets. Our simulation results show that our method has high confidence in detecting the allelic heterogeneity loci. In addition, we apply our method to GTEx datasets that consist of nine tissues, weobserve multiple allelic heterogeneity loci in different tissues. We considered genes which are detected as allelic heterogeneity for both methods. We observe both tissue-specific and cross-tissue allelic heterogeneity. The software for our method is freely available for download at http://genetics. cs. ucla. edu/caviar/.

1273T

EIGEN: A spectral approach for the integration of functional genomics annotations for both coding and noncoding sequence variants. *I. Ionita-Laza[1], K. McCallum[1], B. Xu[2], J. Buxbaum[3].* 1) Department of Biostatistics, Columbia University, New York, NY; 2) Department of Psychiatry, Columbia University, New York, NY; 3) Mount Sinai School of Medicine, New York, NY.

Over the past few years, substantial effort has been put into the functional annotation of variation in human genome sequence. Such annotations can play a critical role in identifying putatively causal variants among the abundant natural variation that occurs at a locus of interest. The main challenges in using these various annotations include their large numbers, and their diversity. We discuss an unsupervised approach (EIGEN) to derive an integrative score of these diverse annotations. The proposed method produces estimates of predictive accuracy for each functional annotation score, and subsequently uses these estimates of accuracy to derive the aggregate functional score for variants of interest as an optimal weighted linear combination of individual annotations. We show that the resulting meta-score has good discriminatory ability using disease associated and putatively benign variants from published studies (for both Mendelian and complex diseases), and is more strongly associated with the disease association status of such variants compared with the recently proposed CADD score. Furthermore, we show how the meta-score is particularly useful in prioritizing likely causal variants in a region of interest when it is combined with sequencing data in the framework of a hierarchical model.

1274F

denovolyzeR : an R package for the interpretation of *de novo* variation in human disease. *J. S. Ware[1,2,3,4], K. E. Samocha[2,3,4], J. Homsy[2,5], M. J. Daly[2,3,4].* 1) NIHR Cardiovascular Biomedical Research Unit at Royal Brompton Hospital and Imperial College London, London UK; 2) Department of Genetics, Harvard Medical School, Boston MA; 3) Broad Institute of MIT and Harvard, Cambridge MA; 4) Analytical and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston MA; 5) Cardiovascular Research Center, Massachusetts General Hospital, Boston MA.

Spontaneously arising (*de novo*) genetic variants are important in human disease, yet every individual carries many such variants, with a median of 1 *de novo* variant affecting the protein-coding portion of the genome. We recently described a mutational model that provides a powerful framework for the robust statistical evaluation of such coding variants. Here we present a new open-source software package, **denovolyzeR**, that implements this model and provides tools for the analysis of *de novo* coding sequence variants. Exome sequencing and analysis of *de novo* variants has identified genes underlying rare and genetically homogeneous Mendelian diseases. In Kabuki syndrome, for example, *de novo* missense variants were identified in *KMT2D* (*MLL2*) in 9 out of 10 unrelated individuals: an accumulation that is extremely improbable in the absence of a causal role in the disease. It is more challenging to dissect the role of *de novo* variants in conditions with high levels of locus heterogeneity, including heritable complex traits and some Mendelian conditions, where *de novo* variants may be spread across many genes, and may make a smaller overall contribution to pathogenesis. The interpretation of *de novo* variants is complicated by the background mutation rate, which varies greatly between genes. Additionally, as more individuals are sequenced, it is inevitable that multiple *de novo* variants will be observed in some genes by chance. Our statistical framework addresses these challenges. Briefly, the mutability of each gene is determined based on local sequence context, and the probability of a *de novo* event in a single generation is calculated. The consequence of each possible *de novo* SNV is computed, and *de novo* probabilities are tabulated by variant class. The probability of a small frameshifting indel is also estimated. For a given study population, observed variant numbers are compared against model-derived expectation using a Poisson framework. This permits robust significance estimates for the pileup of *de novo* variation in individual genes and gene sets, and increases the power of genome-wide analyses. **denovolyzeR** makes this statistical framework widely available. We demonstrate the application of this software to analyses in autism spectrum disorder and congenital heart disease, confirming the important role of *de novo* variation in the pathogenesis of these conditions, and identifying new genes and pathways associated with disease.

1275W

DISSECT: A new tool for analyzing extremely large genomic datasets. *O. Canela-Xandri[1], A. Law[1], A. Gray[2], J. Woolliams[1], A. Tenesa[1,3].* 1) The Roslin Institute. University of Edinburgh, Edinburgh, United Kingdom; 2) EPCC. University of Edinburgh, Edinburgh, United Kingdom; 3) MRC HGU at the MRC IGMM. University of Edinburgh, Edinburgh, United Kingdom.

Computational tools are quickly becoming the main bottleneck to analyze large-scale genomic and genetic data. This big-data problem, affecting a wide range of fields, is becoming more acute with the fast increase of data available. To address this, we developed DISSECT, a new, easy to use, and freely available software able to exploit the parallel computer architectures of supercomputers to perform a wide range of genomic and epidemiologic analyses which currently can only be carried out on reduced sample sizes or in restricted conditions. We showcased our scalable tool by addressing the challenge of predicting phenotypes from genotype data in human populations using Mixed Linear Model analysis. We analyzed simulated traits from half a million individuals genotyped for 590,004 SNPs using the combined computational power of 8,400 processor cores. We found that prediction accuracies in excess of 80% of the theoretical maximum could be achieved with large numbers of training individuals.

1276T

Cost-effective omnibus meta-analysis of massive studies. *H. Qin[1,2], W. Ouyang[1,2], SL. Cao[3], Y. Zhu[4].* 1) Center for Bioinformatics and Genomics; 2) Department of Biostatistics and Bioinformatics; 3) Department of Biomedical Engineering; 4) Department of Epidemiology,Tulane University, New Orleans, LA.

In this report, we propose a general framework for integrating massive independent pieces of evidence. Infimum omnibus statistics are constructed by integrating the *p*-values from separate studies. The proposed framework allows for both continuous and categorical traits as well as heterogeneity, population structure, and cryptic relatedness. As mathematically proven, the exact null distributions of the integrated statistics are invariant to the number of studies. Thus, the proposed framework suffers no penalty in degrees of freedom due to the increase in the number of studies involved. We have developed a high-performance computational package to accurately compute the *p*-value of the infimum omnibus statistics. Extensive numerical results demonstrated that the proposed framework has improved statistical power over conventional meta-analysis methods, especially when a large number of separate studies are involved. Our analytical results and computational tool would benefit researchers to maximize statistical power by integrating valuable pieces of information and minimize the harms caused by incautiously combining pure noises in large-scale meta-analyses.

1277F

Phasing using rare variants and large haplotype reference panels. *K. Sharp[1,3], O. Delaneau[2], J. Marchini[1,3].* 1) Department of Statistics, University of Oxford, 1 South Parks Road, Oxford OX1 3TG, UK; 2) Département de Génétique et Développement (GEDEV), University of Geneva, Switzerland; 3) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford OX3 7BN, UK.

Estimation of haplotypes from genotypes, known as phasing, is a central part of the pipeline of many modern genetic analyses. Such haplotypes are often estimated as an imperfect mosaic of high quality haplotypes (copying states) from a reference panel. Increasingly, both reference panels and unphased genotypes are derived from sequencing data and include large numbers of low frequency variants that are much harder to phase. Consequently, selection of the most informative set of copying states in a computationally tractable way is becoming a fundamental problem for the field. Despite their challenges, rare variants can also be phase informative: sharing of such rare variants between two individuals is more likely to arise from a recent common ancestor and, hence, also more likely to indicate similar shared haplotypes. Our method exploits this idea to select a small set of highly informative copying states. When combined with SHAPEIT2, we obtain significant gains in phasing accuracy over the current selection approach, as well as an improvement in speed. We tested our method using 7,510 UK10K haplotypes. We phased two regions of chromosome 20, comprising 48MB, for 45 individuals from this dataset using the remaining haplotypes as a reference panel. Our method of choosing states consistently improved accuracy compared to the current version of SHAPEIT2 and showed less variation over different runs. Averaged over individuals, regions phased and 20 different runs, our method achieved a 33% improvement in switch error rate. In addition, we phased the same regions for two high coverage (130x) trio parents of European ancestry. Our new version of SHAPEIT permits the rare variant haplotype selection method to be used in combination with phase-informative paired end reads. Combining these sources of information led to a total reduction in switch error rates of 61. 4% when averaged over both trio parents and 20 runs.

1278W

Minimac4: A next generation Imputation Tool for Mega Reference Panels. *S. Das, G. Abecasis, C. Fuchsberger.* Department of Biostatistics, University of Michigan, Ann Arbor, MI.

Genotype Imputation is a key component in genetic association studies increasing power, facilitating meta-analytic and fine-mapping efforts, and aiding in interpretation of signals. Statistical methods for imputation have developed immensely over the last few years enabling researchers to draw benefits from increasingly large sequencing-based reference panels. Modern reference panels like the Haplotype Reference Consortium (HRC) with over 32,000 whole genome sequenced samples can boost the imputation accuracy of causal variants in the lower end of the allele frequency spectrum. However, computational resources needed to impute study samples from these panels are still quite demanding and not feasibly available to all researchers. In 2015, we implemented a web imputation server that allows users to impute study samples using the HRC reference panel without having direct access to the data. In this study, we devise a substantially faster computation tool for imputation on the server that will allow an imputation throughput of 10,000s of genomes a day using the HRC reference panel. To attain that, we developed a novel method for reducing the state space by collapsing haplotypes that are identical only at positions that were genotyped in the study sample. Involving a complex implementation of hidden markov models which tracks “fuzzy” alleles at intervening sites, this additional round of collapsing produces significant cost savings. We are also exploring approximate versions of this model that may slightly decrease imputation accuracy (compared to current approaches) but that will scale to reference panels with 100,000s of samples. The ability of these new methods to handle much larger reference panels should compensate for any minor decrease in imputation accuracy compared to current methods that cannot feasibly scale to very large samples.

1279T

Beyond Homozygosity Mapping: Family-Control analysis based on Hamming distance for prioritizing variants in exome sequencing. *A. Imai[1,2], A. Nakaya[2], S. Fahiminiya[3], M. Tétreault[3], J. Majewski[3], Y. Sakata[1], S. Takashima[1,4], M. Lathrop[3], J. Ott[5,6].* 1) Department of Cardiovascular Medicine, Osaka University Graduate School of Medicine, Suita, Japan; 2) Department of Genome Informatics, Osaka University Graduate School of Medicine, Osaka, Japan; 3) McGill University and Genome Québec Innovation Centre, Montréal, Canada; 4) Department of Medical Biochemistry, Osaka University Graduate School of Medicine, Osaka, Japan; 5) Institute of Psychology, Chinese Academy of Sciences, Beijing, China; 6) Laboratory of Statistical Genetics, Rockefeller University, New York, USA.

A major challenge in current exome sequencing in autosomal recessive (AR) families is the lack of an effective method to prioritize single-nucleotide variants (SNVs). AR families are generally too small for linkage analysis, and length of homozygous regions is unreliable for identification of causative variants. Various common filtering steps usually result in a list of candidate variants that cannot be narrowed down further or ranked. To prioritize shortlisted SNVs we consider each homozygous candidate variant together with a set of SNVs flanking it. We compare the resulting array of genotypes between an affected family member and a number of control individuals and argue that, in a family, differences between family member and controls should be larger for a pathogenic variant and SNVs flanking it than for a random variant. We assess differences between arrays in two individuals by the Hamming distance and develop a suitable test statistic, which is expected to be large for a causative variant and flanking SNVs. As we are unsure of the optimal distance from a candidate variant within which to consider flanking SNVs, we maximize the primary test statistic over a wide range of such distances and prioritize candidate variants based on this maximum statistic. We applied our approach to six patients with known pathogenic variants and found these to be in the top 2 to 10 percentiles of ranks. While homozygosity mapping requires various parameters to be fixed at the outset, our approach works with a single test statistic estimated by the data.

1280F

Web application for statistical power calculations in genotype-based recall randomized controlled trials. *N. Atabaki Pasdar[1], A. Ali[1], M. Ohlsson[2], D. Shungin[1], T. V. Varga[1], A. Kurbasic[1], E. Ingelsson[3], E. R Pearson[4], P. W. Franks[1,5,6].* 1) Department of Clinical Sciences, Genetic and Molecular Epidemiology Unit, Lund University, Malmö, Sweden; 2) Department of Astronomy and Theoretical Physics, Computational Biology and Biological Physics Unit, Lund University, Lund, Sweden; 3) Department of Medical Sciences, Molecular Epidemiology, Uppsala University, Uppsala, Sweden; 4) Division of Cardiovascular & Diabetes Medicine, Medical Research Institute, University of Dundee, Dundee, UK; 5) Department of Public Health & Clinical Medicine, Umeå University, Umeå, Sweden; 6) Department of Nutrition, Harvard School of Public Health, Boston, MA, USA.

Validation of gene ×environment interaction results from epidemiological studies in randomized clinical trials (RCTs) is usually hampered by insufficient statistical power. In this framework we test if a genotype-based recall (GBR) approach of recruiting two groups of participants with distinct genetic profiles can yield sufficiently higher statistical power with reduced sample sizes, leading to a reduction of experimental costs, compared with conventional RCTs of comparable sample size. To this end, we modelled GBR sampling, with participants chosen from the two extremes of a genetic risk score (GRS) distribution, and compared this with conventional sampling. We performed power calculations using simulations in the R program using assumptions from the Diabetes Prevention Program. We have calculated the required sample sizes to reach sufficient statistical power when analyzing the interaction between a genetic factor and intensive lifestyle intervention in a linear regression model, with 1-year small low-density lipoprotein (LDL) particles level as the outcome. Similarly, the statistical power for the interaction effect between a genetic factor and metformin treatment was simulated in a Cox proportional hazards regression model, with time to developing type 2 diabetes as the outcome. Statistical power in various scenarios including different effect sizes, allele frequencies, initial sampling frames and error rates were also examined. Results from almost all simulations confirm that GBR is more powerful than conventional sampling to detect gene ×environment interactions in both linear and Cox regression models. For instance, in the linear regression with a GRS comprised of common SNPs conveying large effects, the sample sizes required to achieve 80% power in GBR and conventional sampling are ~100 and ~800, respectively. With a GRS comprised of common frequency SNPs that convey small effects, these sample sizes are ~1000 and ~3900, respectively. With a GRS comprised of low-moderate frequency SNPs that convey large effects, these sample sizes are ~300 and ~1600, respectively. With a GRS comprised of low-moderate frequency SNPs with small effects, these sample sizes are ~2700 and ~7000, respectively. We additionally have developed an online application for statistical power calculations for gene-treatment interactions for both linear and Cox regression models and made available to the community to facilitate the design of genotype-based recall clinical trials.

Structural equation modeling of tuberculosis immune response using genetic data and pedigree structure. *N. B. Hall[1], R. P. Igo[1], W. H. Boom[2,3], M. Joloba[4,5], E. Wampande[5,6], N. J. Morris[1], C. M. Stein[1,7].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Division of Infectious Diseases, Case Western Reserve University, Cleveland, OH; 3) Department of Medicine, Case Western Reserve University, Cleveland, OH; 4) Uganda-CWRU Research Collaboration, Kampala, Uganda; 5) College of Health Sciences Makerere University and Mulago Hospital, Kampala, Uganda; 6) College of Veterinary Medicine, Animal resource and Bio-security, Kampala, Uganda; 7) Tuberculosis Research Unit, Case Western Reserve University, Cleveland, OH.

Structuralequation modeling (SEM) is a hypothesis-driven approach to the analysis of multifactorial phenotypes. SEM involves the estimation of multiple simultaneous equations using the data's covariance structure. Models represent biological and epidemiological relationships among latent and observed variables, using structural and measurement equations to estimate them. This multivariate approach models complex relationships between variables with multiple correlated variables. Previous methods using SEM to model data have not been suited to the use of family data with both measurement and structural equations. Our objective was to use a novel approach to SEM to include both genetic and pedigree data to identify factors associated with tuberculosis (TB) immune response. Strum is a user-friendly R package which implements a SEM framework that incorporates pedigree information, facilitating the use of family data, as developed by Morris and colleagues. This framework allows for latent measures and covariates within a structural model. It can perform genetic association and linkage analysis, and estimate polygenic effects. We demonstrate the utility of this method using data gathered through a household contact study of tuberculosis (TB) in Kampala, Uganda. In this analysis, 1407 individuals from this study were used to model interferon-γ (IFNg) response to Mycobacterium tuberculosis (Mtb) as a latent variable,. SNPs from 8 candidate genes, the 3 main lineages of Mtb found in Uganda, and production levels of IFNg in response to various Mtb-specific antigens were included in the model. Human genotype data came from a custom Illumina panel as well as an Omni5 chip, and Mtb lineage was determined using phylogenetic analysis using 8 SNPs genotyped. Strum was used to comparatively fit models to identify SNPs and Mtb lineages independently associated with IFNg response. The most parsimonious model had a theoretically corrected chi-square parameter with p-value =0. 69, indicating a good fit. A significant association was seen between IFNg response and a SNP in*TICAM2*(p-value = 0. 007), which we previously identified as associated with TB, but none of the Mtb lineages were associated with IFNg response. Antigens ESAT6 (0. 012) and AG85B (0. 006) significantly captured IFNg responsiveness. By revealing the independent effects of a human gene and Mtb-specific antigens, this demonstrates the value of SEM to examine multiple biological risk factors simultaneously.

FastPop: a rapid principle component derived method to infer intercontinental ancestry using genetic data. *Y. Li[1], J. Byun[1], G. Cai[2], X. Xiao[1], J. Dennis[3], D. Easton[3], I. Gorlov[1], M. Seldin[4], C. Amos[1].* 1) Department of Biomedical Data Science, Dartmouth College, Hanover, NH; 2) Department of Genetics, Dartmouth College, Hanover, NH; 3) Centre for Cancer Genetic Epidemiology, Cambridge University, Cambridge, UK; 4) Rowe Program in Genetics, U. C. Davis, Davis, CA.

First three and last two authors contributed equally**Summary:**PCA has become a standard procedure in population genetics study for substructure analysis. The eigenvectors from PCA are easy to use for population adjustment in GWA studies. However it lacks the ability to provide clear information for ancestral origin, and usually does not yield an approach that can be generalized from study to study. To fill this gap, we developed FastPop, an efficient R packagefor inference of ancestry with PCA scores as the input. FastPop will first compute scores for individuals based on eigenvectors from PCA analysis, and then estimate the proportional ancestry of each individual based on the scores. We demonstrate the use of our software using markers that are present on the Core Content of Illumina products. We selected 2318 SNPs across the whole genome based on having a large fixation index value among European, African and Asian populations for PCA analysis. We conducted PCA analysis of 505 Hapmap samples with European, African or Asian ancestry along with a collection of 19661 additional samples of unknown ancestry. We also ran Structure program on the same dataset to benchmark the performance of FastPop. The results from FastPop are highly consistent with that from structure across the 19661 samples. The correlations of the results between FastPop and structure are 0. 99, 0. 97 and 0. 99 for European, African and Asian, respectively. Compared with Structure, FastPop is more efficient as it can finish ancestry inference for 19661 samples in 16 minutes compared with 21-24 hours required by structure. FastPop can also provide PCA scores based on SNP weights so the scores of reference population such as Hapmap samples can be applied to other studies providing same set of markers are used.

Availability and Implementation: FastPop is an R package that can be easily installed and run. It has three functions:function “PCAScore” enables the user to compute scores based on eigenvectors from PCA analysis given by 2318 SNP weights;function “InterContinentalDistanceMetrics” calculates the proportion of each continental ethnicity from scores of individuals and this function also works for inference using eigenvectors as input directly; function “PCAScore_plot” helps to visualize and compare new scores with 505 Hapmap samples chosen to indicate each centroid on three Continental definitionsThe package is freely available at https://sourceforge. net/projects/fastpop/files/.

Individualized Coherent Absolute Risk Estimator (iCARE): A Flexible Tool for Absolute Risk Estimation Using Genetic and Environmental Risk Factors. *P. Maas, N. Chatterjee.* National Cancer Institute, Division of Cancer Epidemiology and Genetics, Biostatistics Branch, Rockville, MD.

Background

Large genome-wide association studies have led to the discovery of many low penetrant, common single nucleotide polymorphisms (SNPs) associated with risk of complex chronic diseases such as breast cancer, type-2 diabetes and coronary heart disease. The utility of these SNPs, in combination with other risk factors, for public health strategies of disease prevention needs investigation. Evaluation of absolute risk, as opposed to relative risk which is typically used for summarizing associations, is fundamental for these public health applications.

Methods

We present a new tool for building absolute risk models and estimating absolute risk based on SNP and risk factor profiles for individual subjects. Application of the tool requires users to specify the disease incidence rate in the underlying population, a model for relative risk and the associated parameters specifying the joint effects of the risk factors, and a reference sample of individual-level data for the joint distribution of the risk factors in an underlying population. As output, the tool produces absolute risk estimates over specified age intervals. If SNP or risk factor information is missing for an individual subject, the tool produces an appropriate model-averaged risk with respect to the reference distribution. We discuss the methodology underlying the absolute risk calculation and the tool’s handling of missing data.

Applications

We illustrate the utility of the tool by applying it to build a model for breast cancer risk prediction, incorporating information on a total of 91 SNPs and 10 risk factors. This application highlights the value of evaluating absolute risk, and particularly risk stratification, in a public health context.

Conclusion

The iCARE tool provides researchers and clinicians a flexible way to rapidly translate etiologic knowledge, including genetic susceptibility, into an understanding of risk and a guide for risk reduction interventions.

1284W

Doing better than best in linear mixed model association testing. *J. A. Mefford, J. Witte, N. Zaitlen.* University of California, San Francisco, San Francisco, CA.

Linear mixed models (LMM) are used in GWAS to improve power for detecting associations and to control for confounding by population structure. The power gains arise by accounting for the ancillary contributions of other genetic features to the phenotype of interest. We maximize such gains with a novel leave-one-out cross validation approach to generate “better”, cross-validated best linear unbiased predictions (cvBLUPs). Existing LMM-GWAS approaches estimate variance components and test associations for individual SNPs using a generalized least squares formulation. Another use of a fitted LMM is the generation of BLUPs--estimates of the realized values of random effects for individuals. Existing LMM approaches over-fit to the available data, causing the BLUPs to be correlated with un-modeled contributions to the phenotype, including the effects of test-SNPs. To address this, we generate cvBLUPs, which we show are independent of un-modeled factors. Using these cross-validated genetic predictions in association tests allows unbiased estimates of the test-SNP effect size, even in analyses with multiple variance components. In addition to providing the first method for unbiased estimation with multiple variance components, we leverage these predictions to improve power. We use cross-validated estimates of the random genetic effects to weight the contributions of features to the relatedness matrix, update the covariance structure, and calculate re-weighted cross-validated predictors (wcv-BLUPs). This improves power by allowing the model to leverage the improved effect size estimates from cvBLUP. To evaluate our method we examine performance on simulated and real data sets. We first simulate GWAS under different settings of number of subjects, genetic markers, fraction of causal markers, and population structure. The wcv-BLUP based tests have greater power than standard LMM approaches (EMMAX, GCTA, GEMMA), obtaining up to a 30% increase an effective sample size. We then apply our methods to gene expression data from the GEUVADIS cohort. We use two variance components to capture the genetic and expression covariances with two sets of cvBLUPs, one for each variance component. cvBLUP cuts spurious correlation of naïve BLUPs with the phenotype, from 96 to 11, for cvBLUPs based on trans-SNPs in an analysis of gene expression. Additional features, such as non-infinitesimal models (BOLT-LMM) and leverage of data from external cohorts (LDPred) are trivially included.

1285T

Analyzing case-parent trio data with the R package trio. *H. Schwender[1], Q. Li[2], C. Neumann[3], M. A. Taub[4], S. G. Younkin[5], P. Berger[1], R. B. Scharpf[6], T. H. Beaty[7], I. Ruczinski[4].* 1) Mathematical Institute, Heinrich Heine University, Duesseldorf, Germany; 2) Inherited Disease Research Branch, National Human Genome Research Institute, Baltimore, MD, USA; 3) Faculty of Statistics, TU Dortmund University, Dortmund, Germany; 4) Department of Biostatistics, Johns Hopkins University, Baltimore, MD, USA; 5) Department of Biostatistics and Medical Informatics, University of Wisconsin, Madison, WI, USA; 6) Department of Oncology, Johns Hopkins University, Baltimore, MD, USA; 7) Department of Epidemiology, Johns Hopkins University, Baltimore, MD, USA.

Case-parent trio designs are frequently employed in genome-wide association studies to detect SNPs associated with disease. The most popular statistical tests in this study design are transmission/disequilbrium tests (TDTs), considering either the alleles or the genotypes as units in the analysis. While the genotypic TDT can be extended to the test for both gene-environment interactions and interactions between pairs of SNPs, higher-order interactions require procedures such as trio logic regression and trioFS that more cleverly search for association with disease without evaluating all possible interactions. All these procedures are implemented in an R package called trio as user-friendly functions enabling efficient and fast association analysis. Besides these functions, trio also contains functionalities for, e. g. , simulating trio data, estimating sample size and power, dealing with ped and vcf files, and estimating measures of linkage disequilibrium as well as LD-blocks. In this presentation, we exemplify the usage of the functions in trio, which is freely available at http://www. bioconductor. org, by reanalyzing data from the International Cleft Consortium comprising genotypes from about 2000 children with different types of clefts.

1286F

A new method for ancestry specific association mapping in admixed populations (asaMap). *L. Skotte[1], T. S. Korneliussen[2], H. O. H. Sirelkhatim[3], I. Moltke[3], A. Albrechtsen[3].* 1) Department of Epidemiology Research, Statens Serum Institut, 2300 Copenhagen, Denmark; 2) Centre for GeoGenetics, Natural History Museum of Denmark, University of Copenhagen, 1350 Copenhagen, Denmark; 3) The Bioinformatics Centre, Department of Biology, University of Copenhagen, 2200 Copenhagen, Denmark.

We introduce a new statistical method (asamap) for association mapping in recently admixed populations. Unlike most current methods for association mapping, asamap does not assume that the effect of the tested variant is independent of the local ancestry of the allele, but instead asamap estimates ancestry specific effect sizes. The new method does not require exact knowledge of the local ancestry of each allele, which can be difficult to infer without uncertainties, yet simulations show a dramatic increase in statistical power to detect associations in some scenarios (e. g. an increase in statistical power from 15% to 79% for a SNP with an effect size of 0. 3 standard deviation in one ancestral population and no effect in the other population, based on 2500 samples with admixture proportions uniformly sampled in {0, 0. 25, 0. 5, 0. 75, 1} and a p-value cutoff of 10e-8). In addition, asamap allows testing for a difference in effect size between ancestral populations which may indicate that a SNP is non-causal. We demonstrate the usefulness of asamap on data from the Greenlandic population.

Assessing mitochondrial DNA variation and copy number in lymphocytes of ~2,000 Sardinians using tailored sequencing analysis tools. *J. Ding[1], C. Sidore[2,3], T. J. Butler[1], M. K. Wing[2], Y. Qian[1], O. Meirelles[1], F. Busonero[2,3], L. C. Tsoi[2], A. Maschio[2,3], A. Angius[3], H. M. Kang[2], R. Nagaraja[1], F. Cucca[3], G. R. Abecasis[2], D. Schlessinger[1].* 1) Laboratory of Genetics, National Institute on Aging, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy.

DNA sequencing identifies common and rare genetic variants for association studies, but studies typically focus on variants in nuclear DNA and ignore the mitochondrial genome. In fact, analyzing variants in mitochondrial DNA (mtDNA) sequences presents special problems, which we resolve here with a general solution for the analysis of mtDNA in next-generation sequencing studies. The new program package comprises 1) an algorithm designed to identify mtDNA variants (i. e. , homoplasmies and heteroplasmies), incorporating sequencing error rates at each base in a likelihood calculation and allowing allele fractions at a variant site to differ across individuals; and 2) an estimation of mtDNA copy number in a cell directly from whole-genome sequencing data. We also apply the methods to DNA sequence from lymphocytes of ~2,000 SardiNIA Project participants. As expected, mothers and offspring share all homoplasmies but a lesser proportion of heteroplasmies. Both homoplasmies and heteroplasmies show 5-fold higher transition/transversion ratios than variants in nuclear DNA. Also, heteroplasmy increases with age, though on average only ~1 heteroplasmy reaches the 4% level between ages 20 and 90. In addition, we find that mtDNA copy number averages ~110 copies/lymphocyte and is ~54% heritable, implying substantial genetic regulation of the level of mtDNA. Copy numbers also decrease modestly but significantly with age, and females on average have significantly more copies than males. The mtDNA copy numbers are significantly associated with waist circumference (p-value = 0. 0031) and waist-hip ratio (p-value = 2. 4×10-5), but not with body mass index, indicating an association with central fat distribution. To our knowledge, this is the largest population analysis to date of mtDNA dynamics, revealing the age-imposed increase in heteroplasmy, the relatively high heritability of copy number, and the association of copy number with metabolic traits.

1288T

PODKAT: a software package implementing the position-dependent kernel association test. *U. Bodenhofer, S. Hochreiter.* Institute of Bioinformatics, Johannes Kepler University, Linz, Austria.

High-throughput sequencing technologies have facilitated the identification of large numbers of single-nucleotide variations (SNVs), many of which have already been proven to be associated with diseases or other complex traits. Several large sequencing studies, such as, the 1000 Genomes Project, the UK10K project, or the NHLBI-Exome Sequencing Project, have consistently reported a large proportion of private SNVs, that is, variants that are unique to a family or even a single individual. The role of private SNVs in diseases is poorly understood, largely due to the fact that it is statistically very challenging to consider private SNVs in association testing. While it is generally impossible to make use of private SNVs in single-marker tests or in correlation-based tests like the popular SNP-set (Sequence) Kernel Association Test (SKAT), also burden tests are facing serious statistical issues.

We have proposed the *Position-Dependent Kernel Association Test,* which is designed for detecting associations of very rare and private SNVs with the trait under consideration even if the burden scores are not correlated with the trait. The test assumes that, the closer two SNVs are on the genome, the more likely they have similar effects on the trait under consideration. This assumption is fulfilled as long as deleterious, neutral, and protective variants are grouped sufficiently well along the genome.

This contribution highlights a recently released software package, PODKAT, that implements the position-dependent kernel association test along with the popular SKAT test and all necessary tools for defining regions of interest, multiple testing correction, filtering, and visualization of results. The package is based on the widely used scientific computing platform R. It is publicly and freely available via the Bioconductor project. It is able to read data directly from VCF files and facilitates easy parallelization on multi-processor systems or computing clusters. Due to the special memory management strategies, analyses of large studies can even be performed on regular desktop computers (at the cost of much longer computation times). We will present the PODKAT package in detail along with examples of analyses performed on the real-world data sets, such as, the UK10K whole-genome cohorts.

1289F

An extension of Conditional Inference Forest methodology for predictive biomarkers and personalized medicine applications. *B. Dizier[1,2], K. van Steen[1,2].* 1) Systems and Modeling Unit, Department of Electrical Engineering and Computer Science (Montefiore Institute), University of Liege, Quartier Polytech 1, Allee de la Decouverte 10, 4000 Liege, Belgium; 2) Systems Biology and Chemical Biology, GIGA-R, University of Liege, Quartier Hopital, Avenue de l'Hopital 11, 4000 Liege, Belgium.

Heterogeneity of treatment effect is a major hurdle for new drug development. When treatment effect is heterogeneous, average treatment effect estimation of new drug treatment effect is biased and requires very large trials to demonstrate a significant effect. This increases costs, time and risk of drug development. There is big hope that personalized medicine would bring solutions to this issue by enabling identification of patients more likely to benefit from the new drug to demonstrate efficacy. Generating actionable information from all the data generated by high-throughput technologies requires robust methodologies to avoid the pitfalls of exhaustive subgroup analysis. Recursive partitioning is a popular non-parametric modelling technique for regression and classification problems. Conditional Inference Forest is an appealing implementation of recursive partitioning that provides control of type I error during tree growth and unbiased variable selection. Here, we present a novel machine learning approach based on recursive partitioning for estimation of individual treatment benefit through counterfactual framework in time to event outcomes. The estimate of individual treatment benefit is used to assess heterogeneity of treatment effect and potential presence of subgroups that may derive benefit/harm from the new drug. Conditional on the presence of treatment effect heterogeneity, predictive biomarkers that could potentially become companion diagnostics for patient stratification or help understanding drug mode of action are identified through variable importance. The methodology allows for prognostic index or propensity score adjustments in case of strong prognostic effects (independent of treatment) and deviation from randomization between treatment arms. The performance of the novel methodology is further evaluated and validated via application to synthetic and real-life data.

1290W

Axiom™ HLA Analysis – a tool to impute HLA types. *Y. Lu, C. Patel, J. Danzer, M. Dong, M. McCrumb, R. Griffis, N. Hashmi, T. Hoang, J. Burrill, T. Webster, J. Schmidt.* Affymetrix Inc, Santa Clara, CA.

Thehuman leukocyte antigen (HLA) gene family encodes the human version of the major histocompatibility complex (MHC)- cell-surface proteins that regulate the humanimmune system. These genes play various roles in autoimmune/infectious diseases, severe drug responses, and transplant rejection, which are the focuses of many association studies. However, the highly polymorphic nature of this region and the prevalence of pseudogenes make it a very challenging task to accurately genotype or sequence the different HLA alleles with traditional approaches. Axiom™ HLA Analysis is an application designed for automated high-resolution HLA typing of Axiom® genotyping array data. Axiom HLA Analysis can be used for SNP genotypes from any platform, as long as the genotyping platform has sufficient density in the MHC region and provides high-accuracy genotypes. It uses a multi-population reference panel and an HLA type imputation model, HLA*IMP:02 (Alexander Dilthey, Stephen Leslie, *et al.*) to utilize the long-rang linkage disequilibrium between SNPs and HLA alleles to statistically infer HLA types. The direct SNP genotypes are used to impute HLA types for the three MHC class I genes (A, B, and C) and eight MHC class II genes (DPA1, DPB1, DQA1, DQB1, DRB1, DRB3, DRB4, DRB5). The integration of HLA typing with whole-genome data produced by high-density Axiom® genotyping arrays for GWAS enables a novel combination of direct and hypothesis-free discovery of immune system variation associations. We show that Axiom HLA Analysis produces accurate 2- and 4-digit resolution across multiple ethnic groups, when compared with HLA types produced by alternate technologies, and works robustly even when the number of directly genotyped SNPs in the MHC region is significantly lower than those present on Axiom arrays.

1291T

Tag SNP selection for low frequency variant imputation in populations of diverse ancestry. *G. L. Wojcik[1], C. R. Gignoux[1], C. Fuchsberger[2], D. Taliun[2], R. Welch[2], A. R. Martin[1], H. R. Johnston[3], S. Shringarpure[1], C. Pethiyagoda[7], J. O'Connell[7], L. McAuliffe[7], Z. S. Qin[3], K. C. Barnes[5], G. Abecasis[2], C. S. Carlson[4], H. M. Kang[2], M. Boehnke[2], C. D. Bustamante[1], E. E. Kenny[6].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Biostatistics, School of Public Health, University of Michigan, Ann Arbor MI; 3) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, Atlanta GA; 4) Fred Hutchinson Cancer Research Center, Seattle WA; 5) Department of Medicine, Johns Hopkins University School of Medicine, Baltimore MD; 6) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York NY; 7) Illumina, Inc, 5200 Illumina Way, San Diego CA.

The emergence of large sequenced reference panels in the past year has facilitated a new focus on accurate imputation of low frequency variants (LFV; 0. 005-0. 05 MAF). In tandem, a new generation of genotyping arrays are being developed targeting tag SNPs that will enrich for imputation at the rarer end of the frequency spectrum. Selection of these tag SNPs poses several challenges as LFVs tend to be continentally or even population specific, with fine-scale LD structure reflecting recent demographic events. To address these challenges, we have developed a novel algorithm to select tag SNPs considering both population-specific and trans-ethnic tagging performance, that maximizes imputation accuracy rather than pairwise coverage. This is achieved via a leave-one-out internal validation approach that allows direct comparison of tag SNP performance for each iteration of potential scaffold sites. This method was recently applied to boost diverse population coverage for the Multi-ethnic Genotyping Array (MEGA), a collaboration between Illumina and multiple consortia (PAGE, CAAPA, and T2D Genes), by leveraging the whole genome sequences available in the 1000 Genomes Project Phase 3 (TGP) release. We will present results that explore the effect of minimum r2 and minor allele frequency (MAF) threshold for tag SNP selection using various methods of prioritization across the 26 TGP populations. By prioritizing tags that contribute information across multiple populations, this method provides enhanced imputation accuracy compared to naive selection, for example, improving imputation accuracy by 9% for 0. 01-0. 02 MAF SNPs in East Asian populations. Consistent with demographic history, African ancestry populations contributed the largest proportion of tags informative to all populations, but required the densest number of tag SNPs to maximize LFV imputation. However, recent explosive growth in non-African populations means tag SNPs capture on average 30% less variation than in African populations [9. 8 SNPs/tag in East Asians and 13. 8 SNPs/tag in Africans]. When applied to the 1. 5M GWAS scaffold on MEGA, imputation accuracy was found to be ≥0. 89 for SNPs with MAF≥0. 005 and ≥0. 95 for MAF≥0. 05 in all 6 TGP continental populations. This unified framework for tag SNP selection and imputation evaluation will be useful for designing reference panels, large multi-ethnic epidemiological studies and biobanks, as well as future biological repositories.

1292F

A unifying method for multiple phenotype, multiple variance component mixed models. *A. Dahl, J. Marchini.* Department of Statistics, University of Oxford, Oxford, United Kingdom.

Mixed modelshaverecently re-emerged as a state-of-the-art approach to control forrelatedness, populationstructure andgenome-widepolygenicityinhumanGWAS. Moreover, mixed models are becoming even more prominent as the field moves beyond this standard analysis, as they can be broadly used to decompose phenotypic variation into biologically meaningful components. Recently, single phenotype, single random effectmixed modelshave been generalized in two distinct directions. First,single phenotypemixed models with multiple random effects have been applied to partition heritability amongst functionally meaningful categories, to test gene-based association and to improve phenotype and breeding value estimation. Second, mixed models with multiple phenotypesand one random effect have beenused to learn heritable phenotype networks, boost power in association studies and impute missing phenotype data.

We have generalized these approaches by developing the first efficient method to simultaneously model multiple phenotypes and multiple variance components. Furthermore, our method can utilize a wide range of likelihood penalty functions, providing additional statistical robustness, computational efficiency and biological interpretability. Even without penalization, our method can be run on tens of thousands of individuals, hundreds of variance components and dozens of phenotypes.

To demonstrate one possible application of our method, we performed a gene-based association test with multiple phenotypes whilecorrecting for confounding structure. Specifically, we found that the*FADS1*gene significantly associates with LDL and triglyceride traits in 5,163 samples from the NFBC19666 study (-log10(p)=8. 19). We willalsoillustrate the performance of this method on simulateddata.

MEGSA: A powerful and flexible framework for analyzing mutual exclusivity of tumor mutations. *X. Hua[1], P. L. Hyland[2], J. Huang[3], B. Zhu[1], N. E. Caporaso[2], M. T. Landi[2], N. Chatterjee[1], J. Shi[1].* 1) Biostatistics Branch, Division of Cancer Epidemiology & Genetics, National Cancer institute, National Institute of Health, Bethesda, MD; 2) Genetic Epidemiology Branch, Division of Cancer Epidemiology & Genetics, National Cancer institute, National Institute of Health, Bethesda, MD; 3) Laboratory of Cancer Biology and Genetics, Center for Cancer Research, National Cancer Institute, National Institute of Health, Bethesda, MD.

The central challenge in tumor sequencing studies is to identify driver genes and pathways, investigate their functional relationships and nominate drug targets. The efficiency of these analyses, particularly for infrequently mutated genes, is compromised when patients carry different combinations of driver mutations. Mutual exclusivity analysis helps address these challenges. To identify mutually exclusive gene sets (MEGS), we developed a powerful and flexible analytic framework based on a likelihood ratio test and a model selection procedure. Extensive simulations demonstrated that our method outperformed existing methods for both statistical power and the capability of identifying the exact MEGS, particularly for highly imbalanced MEGS. Our method can be used for *de novo* discovery, pathway-guided searches or for expanding established small MEGS. We applied our method to the whole exome sequencing data for fourteen cancer types from The Cancer Genome Atlas (TCGA). We identified multiple previously unreported non-pairwise MEGS in multiple cancer types. For acute myeloid leukemia, we identified a novel MEGS with five genes (*FLT3*, *IDH2*, *NRAS*, *KIT* and *TP53*) and a MEGS (*NPM1*, *TP53* and *RUX1*) whose mutation status was strongly associated with survival (*P*=6. 7×10-4). For breast cancer, we identified a significant MEGS consisting of *TP53* and four infrequently mutated genes (*ARID1A*, *AKT1*, *MED23* and *TBL1XR1*), providing support for their role as cancer drivers.

1294T

An improvement of the *funNorm* normalization method for methylation data from multiple cell or tissue types: *funtooNorm*. *C. M. T. Greenwood[1,2,13,17,18], K. Oros Klein[1,17], S. Grinek[1,17], S. Introduction: Since methylation patterns differ substantially across cell types or tissues, methods for normalization that take this into account may have improved performance. Here we extend the recently-published *funNorm* algorithm [Fortin et al. Genome Biology 2014], designed for normalization of methylation measurements from the Illumina Infinium HumanMethylation450 BeadChip, to allow normalization adjustments to vary by cell or tissue type. **Methods:**The relationships between quantiles of methylation signals and the Illumina control probes are allowed to vary by cell or tissue type, through the use of partial least squares regression models followed by smoothing across the quantiles. **Results:**We analyzed three data sets containing varying numbers of repeated samples and 2-3 different tissues or cell types each (Replication Data: 69 samples on 10 individuals, whole blood, blood spots, and buccal cells; Systemic Auto-Immune Disease Data: two samplings of T-cells (10 individuals) and Monocytes (8 individuals); Gestational Diabetes Data: Placenta and cord blood (one technical replicate each). For technical replicates, the variability between replicates was reduced by as much as 50% in some tissue types. Improvement between biological replicates was of the order of 10-20% in most cell types or tissues examined. Results were quite similar across probe annotations. Notably, agreement between replicates for the X chromosome was substantially improved. **Conclusions:**This normalization method, an extension of *funNorm*, has optimized performance for multiple tissues or cell types in a single data set. A Bioconductor package, *funtooNorm*, implements this approach, and also includes visualization of cross-validation results to facilitate selection of the best number of PLS components.

Leveraging the diploid genome to increase power in *QTL studies. *M. Subramaniam[1], C. J. Ye[1], N. Zaitlen[2].* 1) Department of Epidemiology and Biostatistics, University of California San Francisco, CA; 2) Department of Medicine, University of California San Francisco, CA.

Next generation sequencing coupled with molecular assays has enabled unprecedented opportunities to quantitatively measure genome function. When combined with dense genetic data, quantitative trait locus (QTL) mapping of functional genomic traits is a fundamental tool for understanding the genetic basis of processes such as transcription regulation. In standard *QTL analysis, genotypes are tested for association with estimated abundance of each genomic feature. While powerful, this approach ignores the diploid nature of our genomes, testing combined abundances across both alleles of every feature. In this work, we develop a new phase aware test for *QTL analysis (PhAT-QTL) leveraging allele specific estimates of genomic features. Briefly, we phase the genotypes of all individuals in the study and then test for association between the haploid count of each SNP and the allele specific expression level of the gene on the same haplotype. We use a linear mixed model to account for the correlated environments of haplotypes from the same individual. Through analytical derivations and simulations, we show that power increases relative to standard genotype based tests as a function of the number of heterozygotes and the noise correlation between haplotypes. Simulations show that phasing error and allele specific transcription quantification error results in a loss of power as opposed to bias. We apply PhAT-QTL to a new RNA-sequencing dataset in stimulated dendritic cells from 250 healthy human donors. In addition to having more power to detect eQTLs, and trQTLs, we scanned for specific cases where PhAT-QTL detects allele specific expression but no known eQTLs. In those cases, we consider a model of autoregulation in which the total expression level across both copies of a gene is constrained due to cellular feedback. In simulations and analysis of real data, PhAT-QTL obtained up to a 40% increase in effective sample size as compared to standard genotype based eQTL association test. With denser genetic maps and technological advances to obtain longer reads, we expect PhAT-QTL to be broadly applicable to a number of other *QTL analyses and will greatly impact the discovery of previously undetectable signals.

Firth Logistic Regression Reduces Estimation Bias for Rare Variant Analysis or Small-Sample Studies. *H. Zhou, V. Pradhan.* Pfizer, cambridge, MA.

Logistic regression has been widely used to test associations between genotypes and binary outcomes. The advantages of Logistic regression include ease of implementation and the ability to adjust for covariates. However, when rare variants are studied (even jointly) or when studies have limited sample size (such as pharmacogenetic studies of early stage clinical trials), separation occurs frequently. Separation is a phenomenon where one or a linear combination of the covariates completely separates the response and non-response hyperplanes; as a result, at least one of the parameter estimates diverges to infinity. In genetic studies, separation happens when only one type of events occurs in a certain genotype group. As a result, in fitting logistic regression model genetic effect size estimates and standard errors become infinite, and confidence interval becomes uninformative. Although Fisher's exact test has been used frequently to deal with the separation issue, in absence of using additional covariate information, it is less effective. In addition, as maximum likelihood estimation used by Logistic regression is only asymptotically unbiased, bias will be present when analyzing rare variants or small sample data. A simple approach called Firth Logistic regression provides an efficient solution and handles the issue of separation. By multiplying a penalty function to the likelihood known as Jeffreys invariant prior, Firth Logistic regression produces finite parameter estimates and substantially reduces bias due to small sample size (Heinze and Schemper (2002), Maiti and Pradhan (2007)). In the current study, we generate rare variant data with a wide range of disease prevalence, genetic effect sizes, and genetic structures, and show that Firth Logistic regression reduces estimate bias for both single marker analysis and joint analysis using the collapsing approach. In addition, we simulate a small-sample genome-wide association analysis utilizing the data from a real phase II pharmacogenetic study and show that compared to conventional Logistic regression, Firth Logistic regression preserves the type-I error rate and provides valid p-values. Because of the effectiveness of penalized maximum likelihood estimation, future work should focus on extend the approach to continuous outcome analysis.

Longitudinal Gaussian graphical model integrating gene expression and sequencing data for autism risk gene detection. *K. Lin[1], H. Liu[2], K. Roeder[1].* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, PA; 2) Department of Operations Research and Financial Engineering, Princeton University, Princeton, NJ.

Detection of genes influencing autism spectrum disorder (ASD) has been challenging since hundreds of risk genes affect neurodevelopment through complex interactions. Our approach to find ASD genes overcomes this challenge by integrating brain gene expression data with DNA sequence data, especially *de novo* variations. To do so we first estimate a gene interaction network in post-conception brains measured by gene expression. Under the assumption that genes interacting with bona fide ASD genes are themselves likely to affect ASD risk, we substantially augment the genetic signal by this integration. The brain microarray dataset comes from the BrainSpan data while the gene sequencing data are the marginal genetic signals measured by Transmission and De Novo Association (TADA) scores originating from data compiled by the Autism Sequencing Consortium. We build upon an existing technique, called DAWN, which was recently used to analyze network data from BrainSpan samples from the prefrontal cortex and primary motor-somatosensory cortex of 10-19 postconceptual weeks old. An advantage of this analysis is that it uses gene expression tissue known to be associated with a key developmental time and region of the brain associated with autism, but the number of samples available from this spatio-temporal period is extremely limited. We extend this method by 1) using a novel longitudinal transformation to incorporate more spatio-temporal regions of the BrainSpan data for our gene network estimated by neighborhood selection and 2) using modern high-dimensional hypothesis tests on every edge of the Gaussian graphical model to prune our gene network, making it more insensitive to tuning parameter mis-specifications. By improving the gene network estimation, we detect 200+ genes, roughly a fourth which are validated by new sequencing data -- an improvement over previous analyses. Our detected risk genes are significantly enriched for biological processes related to chromatin modification, neurogenesis, and others.

Allele Frequencies of Metabolic Syndrome-related SNPs in a Mexican Mestizo population. *R. Arguello[1,2], RI. De la Cruz-Granados[1], FF. Gonzalez-Galarza[1], JE. Gaytan-Arocha[1], RD. Arellano-PerezVertti[1], FO. Gonzalez-Galarza[2], AY. Garcia-Marin[1], EA. Ramirez-Ramirez[1,2], KL. Valdes-Morales[1], D. Delgadillo-Guzman[1].* 1) Faculty of Medicine, Autonomous University of Coahuila, Torreon, Coahuila, Mexico; 2) Instituto de Ciencia y Medicina Genómica. Torreón, Coahuila, México.

IntroductionMetabolic Syndrome is a combination of several diseases which include: central obesity, hypertriglyceridemia, low serum levels of high density lipoproteins, hyperglycemia, and hypertension; all of this is translated as an increased risk of cardiovascular disease and type 2 diabetes. In the past years, GWAS have contributed to reveal genetic variants with a probable association with this phenotype. Our goal was to mine the results of these GWAS to obtain a list of relevant disease-associated SNPs and assess the allele frequencies of risk variants in our sample and compare them to those reported in MEX Hap-Map population. **Methods**A sample of 100 Mexican volunteers of the geographic area known as Comarca Lagunera, which includes the territories of Coahuila and Durango states was analyzed with an Illumina HumanOmniExpress-24microarray. Patients were genotyped disregarding age, ethnicity, sex, or any known disease. Allele frequencies of 40 disease-related SNPs (rs10830962, rs174546, rs3099844, rs782590, rs10838681, rs1883025, rs3757840, rs7841189, rs1127065, rs2083637, rs3764261, rs7865146, rs12957347, rs2113334, rs4846922, rs7903146, rs13226650, rs2217332, rs496300, rs8060686, rs1532085, rs2266788, rs531676, rs886427, rs1535, rs2292354, rs560887, rs9315632, rs157582, rs247617, rs673548, rs964184, rs164898, rs268, rs6947830, rs9940128) were analyzed and compared with MEX Hap-Map population. **Summary of Results**38 out of 40 SNPs revealed similar allele frequencies to those of MEX Hap-Map population. The risk alleles had a low prevalence in both populations. When analyzing our patients individually, 5% patients had more risk alleles than non-risk alleles, 11% had the same number of risk and non-risk alleles, and 84% had more non-risk than risk alleles. This result is somewhat unexpected, since the prevalence of the disease is high amongst Mexican general population. **Conclusions**The allele frequencies of the 40 SNPs are similar amongst our study group and MEX Hap-Map population. The low number of risk alleles in the majority of our individuals does not explain the high prevalence of the disease. It has not scaped to our attention that unknown variants, non genetic factors, or both, may be contributing to the onset of disease. Nonetheless, this demonstrates the need for a wider study in Mexican Population.

1299W

Allele Frequencies of childhood-onset Acute Lymphoblastic Leukemia-associated SNPs in a Mexican Mestizo Population and their relationship with disease presentation. *HM. Arredondo[1,2], EA. Ramírez-Ramírez[1,2], KL. Valdés-Morales[2], AY. García-Marín[2], FF. González-Galarza[2], FO. González-Galarza[1], D. Delgadillo-Guzmán[2], RD. Arrellano-Pérez Vertti[2], JR. Arguello-Astorga[1,2].* 1) Instituto de Ciencia y Medicina Genómica, Torreón, Coahuila, Torreón, Mexico; 2) Facultad de Medicina, Universidad Autónoma de Coahuila, Torreón, México.

Objective: To asses the frequency of the Acute Lymphoblastic Leukemia-associated SNPs in a well characterized Mexican population, in comparison with the MEX Hap-map population and correlate it with the frequency of the disease in México. Methodology: In this study, we extracted DNA from saliva samples of 50 healthy volunteers and analyzed them in a microarray plataform with a customized Illumina Omin-expreess chip. 32 SNPs related with Childhood onset Acute Lymphoblastic Leukaemia were selected from NCBIs GWAS catalog (rs3824662 rs10828317, rs10821936, rs6964969, rs4982731, rs7142143, rs17079534, rs17837497, rs10170236, rs6683977, rs1496766, rs9958208, rs7578361, rs41322152, rs546784, rs4132601, rs7089424, rs2239633, rs10821936, rs11978267, rs2089222, rs11155133, rs2191566, rs7554607, rs12621643, rs10873876, rs9290663, rs6428370, rs1881797, rs563507, rs10849033, rs1879352), and the Allele frequencies of them compared with the MEX Hap-map population. The SNPs in which we didn't have the allele frequencies of both datasets were excluded, as well as those in which the Risk allele had a lower frequency than the MAF. A t-student test was performed to compare the allele differences in both populations. Also, Frequency analysis was performed to count the SNPs in Hardy-Weinberg disequilibrium and denote the ones in which the risk allele had a higher frequency than the wild type. Results: The allele frequencies in our study group were consistent with the MEX Hap-map population; without a significant variation in 9 out of 10 SNPs. From the studied SNPs, 5/10 were not in Hardy-Weinberg equilibrium and of those 5, only 1 had higher frequencies on the risk allele in comparison with the wild type allele. Conclusions: Our small cohort closely resembles the MEX Hap-Map population. Mexicans have been reported to have a higher incidence of Childhood-onset Acute Lymphoblastic Leukemia in comparison with Worldwide incidence. The fact that half of the SNPs are not in Hardy-Weinberg equilibrium and only one of those has a higher frequency in the risk allele than in the wild-type one does not explain the high incidence of the disease in Mexican population. The low coverage and the small number of subjects in both cohorts may not help in making a statistically significant result, but denote the importance of making a larger case-control study in a Mexican population in order to demonstrate the existence (or non existence) of a derivative genetic cause of this disease.

1300T

Deep learning and the prediction of human disease risk. *N. Furlotte, D. Hinds.* 23andMe, Mountain View, CA.

The accurate prediction of disease risk using genetic data remains one of the key challenges in human genetics research. Regression and whole-genome based methods that model the phenotype of interest as a linear function of a set of genetic variants have shown much promise, but generally their predictive power remains limited. One of the frequent criticisms of these methods is that they do not account for higher order interaction effects or more generally that they assume a restrictive genetic architecture when constructing the predictive model.

Artificial neural networks (ANNs) have experienced a resurgence in interest due to the success of deep learning in image and speech processing. These machines do not enforce a rigid relationship between the predictors and the target and can be thought of as general function approximators. Motivated by this feature and the general success of ANNs, recent work has suggested that ANNs might have an advantage over traditional methods of phenotype prediction and promising results have been demonstrated for genome-enabled trait prediction in cattle. However, there has been little recent work in developing and applying neural network-based approaches to the problem of predicting phenotypes and disease risk in human populations.

The development of deep learning based methods for human phenotype prediction has a number of challenges. First, deep learning methods require a large amount of training data. Second, there is not a standard methodology for applying deep learning techniques to prediction tasks or more practically there is not a well-defined network structure given the input data. Finally, large multi-layered networks can be computationally cumbersome to train and it can be difficult to control for overfitting.

In this project, we investigate these challenges and assess the ability of deep learning and ANN based methods to predict phenotypes with genetics by utilizing the large-scale 23andMe database of more than one million customers, 80 percent of whom consent to research. We compare the performance of standard methods like linear, logistic and ordinal regression with whole-genome-based and ANN-based predictive methods and evaluate performance across a spectrum of morphological and disease-related traits. In addition, we compare performance across different network architectures. Our results suggest a potential for applying deep learning methods to improve disease risk prediction.

Summary Statistics Imputation utilizing Fine-mapping Approach. *Y. Wu[1], E. Eskin[1,2].* 1) Computer Science, UCLA, Los Angeles, CA; 2) Human Genetics, UCLA, Los Angeles, CA.

Genotype imputation has been widely utilized for two reasons in the analysis of Genome Wide Association Studies (GWAS). One reasonis to increase the power for association studies when the causalSNPs are not collected in the GWAS study. The second reason is to aid in the interpretation of a GWAS result by predicting the association statistics at untyped variants. In this project, we show that the prediction of association statistic at untyped variants which do in fact have an influence on the trait is overly conservative. This is because current imputation methods assume that none of the variants in a region affect the trait which is often inconsistent with the observed data. In this paper, we propose a new method, Summary-Imp, which can impute the associationstatistics at untyped variants taking into account that some of the variants in the region may affect the trait. Our method builds on recent methods that impute the marginal statistics for GWAS utilizingthe fact that the marginal statistics follows a multivariate normal distribution. We utilize both simulated and real data sets toassess the performance of our method. We show that traditional imputation approaches underestimate the association statistics for variants involved in the trait while our approach provides less biased estimates of these association statistics.

1302W

The causal effect of adiposity on vascular dysfunction in healthy adolescents. *K. H. Wade[1,2], T. Khan[3], J. E. Deanfield[3], A. D. Hughes[4], N. Chaturvedi[3], A. Fraser[1,2], D. A. Lawlor[1,2], G. Davey Smith[1,2], N. J. Timpson[1,2].* 1) Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 2) School of Social and Community Medicine, Faculty of Medicine and Dentistry, University of Bristol, Bristol, BS8 2BN, UK; 3) Vascular Physiology Unit, Institute of Cardiovascular Science, University College London, London W1T 7HA; 4) Cardiometabolic Phenotyping Group, Institute of Cardiovascular Science, University College London, London, W1T 7HA.

Adiposity is a known risk factor for vascular dysfunction in adults, with some evidence that this effect may be apparent in early life. However, conventional cross-sectional and case-control studies may suffer from reverse causation, confounding and other sources of bias. In the Avon Longitudinal Study of Parents and Children (ALSPAC), a large UK birth cohort, we used an allelic score comprising 97 genetic variants as an instrument to test the causal effect of body mass index (BMI) on a range of detailed vascular phenotypes measured at 11 and 18 years. Alongside confirmatory evidence for a positive causal role of adiposity on systolic and diastolic blood pressure at 11 and 18 years of age, we found positive effects of BMI on pulse rate (0. 70bpm; 95% CI: 0. 25, 1. 16; *P*=2. 51x10-03), brachial artery diameter (0. 04cm; 95% CI: 0. 02, 0. 05; *P*=5. 49x10-09) and brachial artery compliance (0. 02mm2/mmHgx10-3: 95% CI: -0. 003, 0. 04; *P*=0. 09) at age 11, and on left atrial size (0. 08cm; 95% CI: 0. 05, 0. 11; *P*=1. 03x10-08), left ventricular diameter during diastole (0. 04cm; 95% CI: 0. 01, 0. 07; *P*=0. 004), left ventricular mass indexed to height in meters2. 7 (1. 00g/m2. 7; 95% CI: 0. 64, 1. 36; *P*=5. 10x10-08) and e', the peak velocity of the lateral mitral annulus in early diastole, (0. 01cm/s; 95% CI: 0. 0004, 0. 03; *P*=0. 04) at age 18. We found inverse associations (not in the hypothesised causal direction) of BMI on pulse wave velocity (PWV) at 11 and 18 (-0. 01m/s; 95% CI: -0. 01, -0. 002; *P*=0. 01 at age 11 and -0. 01m/s; 95% CI: -0. 02, -0. 002; *P*=0. 01 at age 18). Although our results suggest that increased BMI is causally related to most measures of adverse cardiovascular health in childhood and adolescence, we also found a paradoxical benefit of greater BMI on brachial artery compliance and PWV, suggesting that the aetiology of cardiovascular health is complex. Therefore, caution may be needed when assessing likely implications of policy approaches targeting adiposity on the cardiovascular risk profile throughout the lifecourse. Further replication of these findings using Mendelian randomization studies across all ages, together with two-step mediation analyses of the association between adiposity and cardiovascular intermediates, might help to better understand how adiposity influences cardiovascular health across the lifecourse.

1303T

Estimating aggregate penetrance of actionable genomic findings in European American and African American exomes. *R. C. Green[1,2,3,4], P. Natarajan[2,3,5], N. B. Gold[2,6], A. G. Bick[2,3,7], H. McLaughlin[2,4,8], P. Kraft[2,9], H. L. Rehm[2,4,8], G. M. Peloso[2,3], J. G. Wilson[10], A. Correa[11], J. G. Seidman[2,7], C. E Seidman[1,2,7,12], S. Kathiresan[2,3,5].* 1) Department of Medicine, Brigham and Women's Hospital, Boston MA; 2) Harvard Medical School, Boston, MA; 3) Broad Institute of MIT and Harvard, Cambridge, MA; 4) Partners HealthCare Personalized Medicine, Boston, MA; 5) Department of Medicine, Massachusetts General Hospital, Boston, MA; 6) Boston Children's Hospital, Boston, MA; 7) Department of Genetics, Harvard Medical School, Boston, MA; 8) Department of Pathology, Brigham and Women's Hospital, Boston, MA; 9) Departments of Statistics and Epidemiology, Harvard School of Public Health, Boston, MA; 10) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MI; 11) Departments of Pediatrics and Medicine, University of Mississippi Medical Center, Jackson, MI; 12) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA.

Background: The American College of Medical Genetics and Genomics has recommended that pathogenic (PVs) and likely pathogenic variants (LPVs) in 56 genes, corresponding to 24 actionable diseases, should be returned as secondary findings with clinical sequencing. However, the penetrance of these variants in populations unselected for family history is largely unknown. We tested the hypothesis that persons carrying PVs and LPVs in these genes are more likely to manifest suggestive clinical features (SCFs) of corresponding actionable diseases. Methods: Among 462 European American Framingham Heart Study (FHS) participants and 3,223 African American Jackson Heart Study (JHS) participants, 642 and 4,429 unique variants, respectively, were classified across the 56 genes, without knowledge of clinical information, as either PVs, LPVs, of uncertain significance, or benign. Clinical history of cancer, and data from the most recent echocardiograms, electrocardiograms, and lipid measurements on all participants were ascertained without knowledge of genetic variants. Within each cohort, we compared the observed number of SCFs among those with corresponding PVs/LPVs to the number expected, assuming rates of SCFs were identical among individuals with and without PVs/LPVs. Results: PVs/LPVs in the 56 genes were found in 8 FHS (1. 7%) and 67 JHS participants (2. 1%). Persons with PVs/LPVs were more likely than expected to have SCFs in both the FHS (50. 0% vs 10. 8%) and the JHS (19. 6% vs 7. 3%). Standardized incidence ratios of SCFs among FHS and JHS participants with PVs/LPVs were 4. 63 (95% CI 1. 25-11. 9;*P*= 0. 006) and 2. 69 (95% CI 1. 34-4. 82; *P*= 0. 001), respectively. Conclusion: Unselected participants in population-based studies carrying PV/LPVs in genes for actionable conditions have an increased risk of displaying features associated with the corresponding clinical diseases.

1304F

Improved Association Testing with Linear Mixed Models by Modeling Non-Genetic Phenotypic Covariance Structures. *M. Conomos[1], S. M. Gogarten[1], T. Sofer[1], A. M. Stilp[1], A. Szpiro[1], T. Lumley[2], K. M Rice[1], C. C. Laurie[1], T. A. Thornton[1].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Statistics, The University of Auckland, Auckland, New Zealand.

Linear mixed models (LMMs) have emerged as a prevalent analysis approach for genome-wide association studies (GWAS) of complex traits. LMMs account for phenotypic correlation of sample individuals due to genetic similarity by including an empirical genetic relationship matrix (GRM) constructed from observed genotype data in the model covariance structure. However, it is plausible that shared environments, such as household or geographic location, may also result in correlated phenotypes among sample individuals, and these structures are often overlooked in the GWAS setting. We developed a computationally efficient LMM for GWAS that allows for the modeling of additional phenotypic covariance structure, beyond that due to shared polygenic effects. We applied our LMM to quantitative traits measured in the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), a cohort study of approximately 13,000 self-identified Hispanics/Latinos from the U. S. collected via a community-based household sampling design. Through variance component estimation, we found that shared household often explains a significant proportion of phenotypic variability, even after accounting for that attributed to shared genetic effects. Furthermore, standard implementations of LMMs for GWAS make the implicit assumption of residual homoskedasticity, which may be violated in samples with complex population structure. Individuals in HCHS/SOL self-reported membership to six ethnic background groups, and we found strong evidence of non-constant variance across these groups for nearly all phenotypes. Traditionally, the use of robust standard errors and GEE can be used to alleviate issues of non-constant variance; however, in the context of GWAS, these approaches result in a loss of efficiency to detect associations as well as severe inflation of test statistics at markers with low minor allele frequencies. To address this issue, a further adaptation to our LMM allows for group-specific residual variances. Through the comparison of genetic association testing results from LMMs with different covariance structure models, we demonstrate that accounting for phenotypic similarity due to shared environment and allowing for heteroskedasticity by background group can lead to both better control of type-I error and improved signal at previously identified associations. These results illustrate the potential value of collecting environmental and demographic information in future genetic studies.

Using multi-way admixture mapping to elucidate TB susceptibility in the South African Coloured population. *M. Daya[1], L. van der Merwe[1], C. R. Gignoux[2], P. D. van Helden[1], M. Moller[1], E. G. Hoal[1].* 1) Human Gen & Molecular Biol, Stellenbosch Univ, Cape Town, Tygerberg, South Africa; 2) Department of Genetics, Stanford University, Stanford, California, USA.

The admixed South African Coloured population is ideally suited to the discovery of tuberculosis susceptibility genetic variants and their probable ethnic origins, but previous attempts at finding such variants using genome-wide admixture mapping were hampered by the inaccuracy of local ancestry inference. In this study, we infer local ancestry using the novel algorithm implemented in RFMix, with the emphasis on identifying regions of excess San or Bantu ancestry, which we hypothesize may harbour TB susceptibility genes.

Using simulated data, we demonstrate reasonable accuracy of local ancestry inference by RFMix, with a tendency towards miss-calling San ancestry as Bantu. Regions with either excess San ancestry or excess African (San or Bantu) ancestry are less likely to be affected by this bias, and we therefore proceeded to identify such regions, found in cases but not in controls (642 cases and 91 controls). A number of promising regions were found (overall p-values of 7.19×10^{-5} for San ancestry and less than 2.00×10^{-16} for African ancestry), including chromosomes 15q15 and 17q22, which are close to genomic regions previously implicated in TB. Promising immune-related susceptibility genes such as the *GADD45A*, *OSM* and *B7-H5* genes are also harboured in the identified regions.

In conclusion, admixture mapping is feasible in the South African Coloured population and a number of novel TB susceptibility genomic regions were uncovered.

1306T

Multivariate genome-wide association study for metabolic syndrome. *Y. Lee[1,2], S. Park[1,3], BJ. Kim[1], J. Lee[1], S. Won[1,4].* 1) Korea Center for Disease Control and Prevention, Osong, South Korea; 2) Healthcare System Gangnam Center, Seoul, South Korea; 3) Soonchunhyang University, Seoul, South Korea; 4) Seoul National University, Seoul, South Korea.

Metabolic syndrome (MetS) is a kind of disease which is determined co-occurrence of three of five following medical conditions: abdominal obesity, elevated blood pressure, elevated fasting plasma glucose, high serum triglycerides, and low high-density cholesterol levels. It is well known that people with MetS become more dangerous to cardiovascular disease (CAD) or type 2 diabets mellitus (T2D). For several years, many genome-wide association studies (GWASs) have been conducted, but the genetic determinants of the MetS were still limited and most of variants were related with each metabolic trait not MetS. Recently, various programs which can conduct multivariate GWAS were developed and we considered Genome-wide Efficient Mixed Model Association (GEMMA) and More powerful Family based Quasi Likelihood Score test (MFQLS) programs for detecting new genetic variants. We identified rs4742875 on 9q31. 1 (P = 1. 23 x 10–7) with some previously reported variants related with MetS or metabolic traits by using Korean population-based data. These findings may provide additional insights into understanding disease pathology.

1307F

Meta-analysis of genome-wide association studies with correlated individuals: application to the Hispanic Community Health Study / Study of Latinos (HCHS/SOL). *T. Sofer[1], J. Shaffer[2], M. Graff[3], Q. Qi[4], A. M. Stilp[1], S. M. Gogarten[1], K. E. North[3], C. R. Isasi[4], B. S. Weir[1], C. C. Laurie[1], A. A. Szpiro[1].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 4) Department of Epidemiology & Population Health, Albert Einstein College of Medicine, Bronx, NY.

Motivation and application: Multiple GWAS are often meta-analyzed to increase the power to detect associations of traits with genetic variants. Meta-analysis also may be performed within a single study that is stratified by, e. g. , genetic groups of the study participants. Having correlated individuals between the studies or strata may complicate meta-analyses of GWAS results, potentially limiting power and inflating Type 1 error. In the Hispanic Community Health Study/Study of Latinos (HCHS/SOL), there are 12,803 genotyped individuals, each belonging to one of 6 genetic strata defined by both self-reported Hispanic/Latino subgroup and genetic similarity. Sources of correlations between study individuals include genetic relatedness, shared household, and shared community. **Methods:** We propose a linear mixed effect model that yields estimates of the covariance between the effect estimates across strata and implement a computationally efficient method for meta-analysis ("MetaCor") that uses these covariance estimators. **Simulations:** We generated datasets with individuals from 3-member clusters, stratified by sex. Sources of correlations were genetic similarity and correlated residuals. We compared MetaCor to (1) no stratification, (2) not accounting for correlations, and (3) removing people to generate independent strata ("StratInd"). **Results:** In simulations, MetaCor and StratInd always protected type 1 error; however, MetaCor was more powerful than the alternatives. In the data analysis we compared MetaCor to StratInd. To generate 6 genetic strata with low correlations, we created a data set of 11,788 individuals such that any genetic group did not have a person living in the same household with someone, or a relative of up to 3rd degree, from another genetic group. In BMI analysis, StratInd had high inflation (χ=1. 065) compared to MetaCor (χ=1. 034 on the entire data set). Given the surprisingly high inflation of StratInd, we applied MetaCor to the same set of 11,788 individuals, yielding χ=1. 032. For power, we studied MetaCor in GWAS of dental caries. The top hit, rs7791001, had p-value=4. 65x10-8 (StratInd), and 3. 66x10-8 (MetaCor). **Conclusion:** Simulations and data analyses show that our test is powerful, and effective in control of inflation. An important consequence of our investigation is that even having distant relatives (4th degree) between GWAS studies can inflate meta-analysis results, and that our proposed method results in notable improvement.

GWAS-based Mendelian-Randomization and Path Analyses of Causal Effects of Lipid Risk Factors on Coronary Artery Disease. *Y. Tan[1,2], D. Liu[1,2,3].* 1) Biochemistry and Molecular Biology , Pennsylvania State University College of Medicine, Hershey, PA, 17033; 2) Institute of Personalized Medicine, Pennsylvania State University College of Medicine, Hershey, PA,17033; 3) Deptment of Public Health Sciences, Pennsylvania State University College of Medicine, Hershey, PA, 17033.

Plasma lipid levels haven been identified as a inheritable and heritable risk factors for coronary artery disease (CAD), one of the leading causes of death. Due to some confounders, it is difficult to infer if the high risk is attributed to causal effects of these risk factors on CAD. For this reason, genetic variants associated with lipid levels may qualify as instrument variables and be used to carry out Mendelian randomization (MR) analysis. To define causal effects of risk factors on a disease, we developed a method called GWAS-based MR path analysis (GMRP). GWAS or GWAS meta-analysis provides genome-wide SNPs associated with risk factors for choice of instrumental variables and MR analyses exclude confounders and quantize bivariate outcome variable, which provide a way to path analysis of diseases. To choose valid SNPs for MR analyses, we formulized Do et al's ad hoc criteria. We obtained 368-768 SNPs from Willer et al's GWAS meta-analyzed data using our method and performed GMRP analyses of beta values of these SNPs on LDL, HDL, triglycerides (TG) and CAD. The results show that LDL and TG had significant direct causal risks for CAD while HDL had significant direct protection effect against CAD, which is opposed to Do et al's result of MR analysis of 185 SNPs. Adding total cholesterols (TC) into the multivariate regression models changed HDL significant protection effect against CAD to weak risk, but significantly strengthened direct causal effects of LDL and TG on CAD. However, indirect causal effects of HDL from TG to CAD, from TC to CAD and from TG to TC and to CAD made HDL be still significantly negatively correlated to risk for CAD. We used direct path coefficients of SNPs onto these risk factors and CAD to execute GMRP analyses and found that the beta values of these lipid variables became very small but their direct and indirect path coefficients onto CAD were not significantly altered, meaning that path coefficients can be defined as causal effects on CAD. Linkage disequilibrium had obvious impacts on analysis of causal effects of CAD.

A Mendelian Randomization Study of the Effect of Type-2 Diabetes on Bone Mineral Density. *O. S. Ahmad[1,2], J. A. Miller[3], M. Mujammami[1,2], J. B. Richards[1,2,3,4].* 1) Department of Medicine, McGill University, Montreal, Quebec, Canada; 2) Centre for Clinical Epidemiology, Lady Davis Institute for Medical Research, Jewish General Hospital, McGill University, Montreal, Quebec, Canada; 3) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 4) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK.

Although patients with type-2 diabetes (T2D) have on average a higher bone mineral density (BMD) than patients without the disease,observational studies provide evidence for both poorer bone qualityand higher fracture risk for a given BMDin patients with T2D compared to those without this condition. Because of confounding in observational studies between T2D and other metabolic factors known to influence bone homeostasis, the precise effect of T2D on BMD is unclear. Here, we analyze genome-wide association study (GWAS) data to obtain quantitative estimates of the causal effect of T2D (with data from 34,840 T2D cases, 114,981 controls)and fasting glucose (data from 133,010 non-diabetic individuals)on BMD (data from 50,933 individuals)using *Mendelian randomization* (MR), an application of the method of instrumental variables to the analysis of genetic data. Using multiple genetic variants associated with T2D and related metabolic traits, we find that a genetically increased risk of T2D increases femoral-neck BMD (+0. 03 standard deviation (SD) increase in BMD [95%CI: 0. 01 - 0. 06, P = 0. 017] per unit increase in log-odds of T2D). We find also that an increase in fasting glucose increases femoral-neck BMD in a pooled sample of non-diabetic individuals (+0. 13 SD increase in BMD [95%CI: 0. 02 - 0. 25, P = 0. 027] per 1 mmol/Lincrease in fasting glucose). These findings provide evidence for a causal relationship between genetically increased risk of T2D, fasting glucose, and BMD.

1310F

Contribution of variants at genes expressed in fetal and adult pancreatic islets to type 2 diabetes risk. *K. Gaulton[1], D. Calderon[2], D. Golan[3,4], M. Cruz[5], A. Valladares-Salgado[5], E. Parra[6], T. Raj[7,8], J. Below[9], C. Hanis[9], A. Morris[10], M. McCarthy[1,11,12], J. Pritchard[3,13,14], GoT2D consortium, AGEN-T2D consortium, MAT2D consortium, SAT2D consortium.* 1) Wellcome Trust Centre for Human Genetics, Oxford, UK; 2) Biomedical Informatics, Stanford University, Stanford, CA; 3) Department of Genetics, Stanford University, Stanford, CA; 4) Department of Statistics, Stanford University, Stanford, CA; 5) Unidad de Investigación Médica en Bioquímica, Hospital de Especialidades, Centro Médico Nacional Siglo XXI, IMSS, Mexico City, Mexico; 6) Department of Anthropology, University of Toronto at Mississauga, Mississauga, Ontario, Canada; 7) Departments of Neurology and Medicine, Brigham and Women's Hospital, Boston, MA; 8) The Broad Institute of Harvard and MIT, Cambridge, MA; 9) School of Public Health, The University of Texas Health Science Center at Houston; 10) Department of Biostatistics, University of Liverpool, Liverpool UK; 11) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, UK; 12) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, UK; 13) Department of Biology, Stanford University, Stanford, CA; 14) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

Type 2 diabetes (T2D) is a complex disorder that affects over 250 million individuals worldwide. Recent studies have suggested that population risk of T2D is mediated through a substantial number of variants of modest effect, many of which alter pancreatic islet function. We sought to more precisely characterize the contribution of altered islet function to T2D by combining genome-wide T2D association data in Europeans, South and East Asians, and Mexican-Americans and glycemic association data in Europeans with gene expression from FACS-sorted alpha and beta cells from fetal and adult pancreas. We first weighted variants in each expression dataset as a function of the inverse variant distance to the closest gene and the relative cell-type expression of that gene, and then applied a polygenic regression model (polyTest) to variants genome-wide to estimate the contribution of each cell-type to the observed phenotypic variance. We identified a significant effect of European T2D in genes expressed in beta cells from both adult and fetal pancreas (b=6. 2, *P*=. 0017; b=3. 7, *P*=. 009), which remained even when removing variants with strong T2D association (*P*<. 0001). We further found significant effect of fasting glucose in beta cells from adult pancreas only (b=22. 0, *P*<1x10-10), and no effect of fasting insulin for all cell types. Finally, South Asian T2D samples showed stronger effect in beta cells from adult pancreas (b=17. 7, *P*=. 001), whereas Mexican-American T2D samples showed stronger effect in alpha and beta cells from fetal pancreas (b=20. 1, *P*=. 0002; b=16. 1, *P*=. 0003). Our preliminary results thus suggest that genes expressed in both fetal and adult islets contribute to T2D risk, and further that exploiting the highly polygenic inheritance of T2D using detailed genomic annotation can uncover disease mechanisms.

Single-variant and Gene-based Tests to Detect Genetic Loci Associated with Diabetic Retinopathy: 1000G Imputation and Whole Exome Sequencing Data. *J. Kim[1], J. E. Below[1], R. E. Klein[2], B. E. K. Klein[2], C. L. Hanis[1].* 1) Epidemiology, University of Texas School of Public Health, Houston, TX; 2) Ophthalmology and Visual Sciences, The University of Wisconsin School of Medicine and Public Health, Madison, WI.

Diabetic retinopathy (DR) is the most common microvascular complication of diabetes and can lead to blindness. Familial aggregation of severe DR in family studies estimate heritability at 24%~52%. Linkage studies and genome-wide association studies (GWAS) have found genetic loci predictive of severe DR risk, but findings are largely inconsistent across studies. To identify common and rare genetic loci contributing to severe DR, we used three approaches; 1) GWAS of common SNPs using Affymetrix Genome-wide Human SNP Array 6. 0 data imputed to the 1000 Genome Phase 1 reference (7. 9 million SNPs passing quality control), 2) single variant tests of common genetic variation from whole exome sequencing (WES) data, and 3) gene-based tests of rare variation from the WES data. A total of 747 Mexican Americans with type 2 diabetes from Starr County, Texas, were included in the GWAS analyses. WES data were available on a subset of 675. Cases included subjects who had moderate or severe non-proliferative DR or proliferative DR. Tests were implemented with three comparisons; 1) comparing cases to controls with no DR (total n=462, logistic model), 2) changing the control definition to include those with mild retinopathy (total n=747, logistic model), and 3) using an ordinal classification of none, mild, and severe DR (total n=747, proportional odds model). WES data were analyzed with comparisons 1 and 2. We evaluated score statistics and optional sequence kernel association tests (SKAT-O) for single variant and gene-based testing, respectively. All analyses were adjusted for age, duration of diabetes, body mass index, systolic blood pressure, fasting glucose, and cholesterol. No loci showed a significant association after Bonferroni correction; however, we found suggestive signals in nine loci on chromosome 3, 4, 6, 11, and 21 in all the GWASs (p=5. 42E-8~8. 27E-6). In singe variant tests using WES data, *IRAK2* and *DAZL* on chromosome 3 and *NOX3* on chromosome 6 were associated with severe DR (P=. 02~. 03). *DAZL* had a DR-related variant in the 5' UTR in the single variant tests and also showed associations with severe DR in gene-based test (P=. 03~. 05). *IRAK2* and *NOX3* have biological relevance to diabetic retinopathy through the interleukin-1 receptor (*IL1R*) and inflammatory cytokines. *DAZL* is a novel gene not previously reported. These preliminary findings provide additional evidence implicating genes in the pathology of DR.

1312T

Identification of Causal Mechanisms in Diabetes Pathophysiology in the Risk of Primary Open-Angle Glaucoma. *L. Shen[1], S. Walter[2], R. Melles[3], M. Glymore[2], E. Jorgenson[1].* 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) Department of Epidemiology and Biostatistics, University of California, San Francisco,CA; 3) Department of Ophthalmology, Kaiser Permanente Northern California Redwood City Medical Center, Redwood City, CA.

Although type 2 diabetes (T2D) has been implicated as a risk factor for glaucoma, the potential for unmeasured confounding, unambiguous temporal order and possibility of shared causes have hampered causal conclusions. We performed separate sample Mendelian Randomization using the Genetic Epidemiology Research Study on Adult Health and Aging (GERA) cohort (n=69,685) to estimate effects of T2D on primary open angle glaucoma (POAG; 3,554 cases). Genetic instrumental variables (IVs) for overall and mechanism-specific (i. e. , linked to T2D via influences on adiposity, β-cell function, insulin regulation, or other metabolic processes) T2D risk were constructed using 39 genetic polymorphisms established to predict T2D in large-scale genome-wide association study of T2D. IV estimates indicated T2D increased POAG risk (OR=2. 53, 95% CI: 1. 04, 6. 11). The IV for β-cell dysregulation also significantly predicted POAG (ORβ-cell=5. 26, 95% CI: 1. 75, 15. 85), even among individuals without diagnosed T2D, suggesting that metabolic dysregulation may increase POAG risk prior to T2D diagnosis. T2D risk variant in the *MTNR1B* gene predicted risk of POAG independently of T2D status, indicating possible pleiotropic physiological functions of melatonin, but IV effect estimates were significant even excluding *MTNR1B* variants. This is the first genetic IV study of T2D and glaucoma, providing a powerful approach to evaluating this hypothesized effect. Our findings substantially bolster observational evidence that T2D increases POAG risk.

Playing musical chairs in multi-phenotype studies improves power and identifies novel associations. *H. Aschard[1], P. Kraft[1], N. Zaitlen[2].* 1) Department of Epidemiology, Harvard School of Public Health, Boston, MA; 2) Department of Medicine Lung Biology Center, University of California San Francisco, San Francisco, CA.

Variability in complex human traits is associated with many factors, including exposures, biomarkers and genetic variants, all of which are increasingly collected in large-scale cohorts. Identifying the genetic variants that are causally associated with human phenotypes among the tens of millions of variants that are typically tested remains a challenge. Current strategies to improve power to identify modest genetic associations mostly consist of applying univariate statistical approaches such as linear or logistic regression (LR) and increasing study sample sizes. While successful, these approaches do not leverage the environmental and genetic factors shared between the multiple phenotypes typically collected in contemporary cohorts. Here we develop a method called Musical Chairs (MC) that improves identification of small effects in studies where a large number of correlated variables have been measured on the same samples. When testing a specific variant for association with a phenotype of interest, including additional correlated phenotypes as covariates can increase or decrease power depending on the underlying causal relationship between the genetic variant, the phenotype, and the covariates. MC is a data-driven approach that leverages our previous work (Zaitlen et al PG 2012, Aschard et al AJHG 2015) to select covariates that will increase power for each SNP-phenotype pair considered. MC is computationally efficient and maintains a controlled false positive rate even in the presence of thousands of phenotypes. Simulations based on phenotypic correlation structures from real cohorts provide direct support that large sets of correlated variables can be leveraged to achieve dramatic increases in statistical power equivalent to a two or even three or four fold increase in sample size. To demonstrate the power of our approach in real data with thousands of phenotypes, we performed a genome-wide screen for cis expression QTLs in the GEUVADIS cohort. We examined the expression of 12,167 genes in 375 individuals of European descent. At a stringent FDR of 0. 1% standard LR identified 1,660 genes with at least one cis-eQTL within 50kb of the gene while our MC approach identified 2,154 genes, and increase of 30%. As cohorts move toward large-scale phenotypes collections as in the electronic health records of the UK Biobank, Million Veterans, Kaiser, and Mt. Sinai cohorts, MC will improve the ability of the community to identify associated genetic variants.

1314W

Reducing false-negative exclusion of GWAS by using redescription and computational topological analysis to identify complex phenotypes describing pathways. *D. E. Platt[1], P. Zalloua[2, 3], S. Basu[4], L. Parida[1].* 1) IBM T. J. Watson Research Center, Yorktown Hgts, NY, USA; 2) Lebanese-American University, Byblos, Lebanon; 3) Harvard School of Public Health, Boston, MA; 4) Dept. of Mathematics, Purdue University, West Laffayette, IN.

Coronary artery disease (CAD) progression starts damage to arterial epithelial layers, which may take years to develop. CAD risk factors form a highly correlated cluster of conditions called metabolic syndrome with diverse pathways. Odds ratio associated with some pathway producing CAD is identical to the odds ratio that CAD was caused by that pathway, leading to dilution. GWAS promised to reveal clear genetic causes of disease. Yet, identified SNPs only account for≈10% of CAD, leaving the remaining heritability unexplained. One gap is the large probability of false negatives given the genome-wide false-positive threshold. Also, genome-wide logistic regressions subtract other risk factors by including "adjustments," though, isolating genetic impact specific to CAD excludes the genetics of pathway-induced pathogenic etiology. In this study, we applied pattern discovery seeking significant phenotypic associations to select statistically significant combinations of factors that would yield significant logistic regressions. Pathway mechanisms link putative phenotypes: condition *A* implies the presence of condition *B*, or *A⇒B*, and therefore also that *A=A⇒B*. Therefore, the list of subjects *S(A)* associated with condition *A* will be the same as the list *S(A⇒B)*. Therefore, we sought clusters of patterns sharing similar sets of subjects measured by Jaccard distances commensurate with epidemiological odds ratios. Such clusters represent the same groups of subjects identified by multiple different patterns, or "redescriptions," reflecting underlying pathway-specific etiology. As such, the patterns become multicomponent phenotypes suitable for GWAS. The structure of these clusters was further explored using computational topological analysis, seeking to identify Vietoris-Rips complexes, where the patterns are vertices, the Jaccard distances provide the filtration, and the lifetimes of the generators of interest are within the Jaccard threshold. The generator complexes are also candidate phenotypes. We applied logistic regression to SNPs drawn from the RAAS complex, as well as GWAS predicting these complex phenotypes. We also identified SNPs individually predicting all conditions comprising complex phenotypes, requiring the joint significance to be genome wide. This greatly increases sensitivity, reducing the threshold excluding false negatives, but at the cost of requiring significance of for multiple factors.

1315T

Using imputed genotype data in joint score tests for genetic association and gene-environment interactions in case-control studies. *M. Song, N. Chatterjee.* Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Rockville , MD.

BackgroundGenome-wide association studies (GWAS) are now routinely imputed for untyped SNPs with powerful tools such as IMPUTE2 and various reference panels such as HapMap2 or 1000Genome. The use of predicted allele count for imputed SNPs as the dosage variable is known to produce validscore-test for genetic association. **Methods**In this report, we investigate how to best handle imputed SNPs in various modern complex tests for genetic association incorporating gene-environment interactions in case-control studies. We focus testing under a logistic regression framework using various alternative methods that rely on varying degree on the assumption of gene-environment independence in the underlying population. As increasingly large scale GWAS are being performed through consortia effort, where it is preferable to share only summary-level information across studies, we also explore how these methods could be implemented in the context of meta-analysis. The methods are evaluated using simulation studies and through analysis of a GWAS of lung cancer accounting for interaction of genotypes with smoking status. **Results**Both simulation studies and the real data application illustrate that the proposed methods can maintain type-I errors for joint tests for genetic association and interactions for common SNPs. For less frequent variants, however, application of some of these methods, whether the genotype data is imputed or not, requires caution because of inaccuracy of the asymptotic standard error calculations in the presence of sparse genotype-exposure combinations. Methods exploiting gene-environment independence showed stronger enrichment for signal for joint test of genetic association and interaction for the analysis of lung cancer GWAS with the pattern being consistent with the simulation studies of power.

1316F

Statistical properties of spatial regression based longitudinal analysis. *T. Schwantes-An, H. Sung, A. F. Wilson.* Genometrics Section, Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD.

Large-scale longitudinal genetic studies of complex diseases with multiple measures of the same phenotype(s), coupled with low-cost genotyping and next generation sequencing technologies, are now available for genetic analysis. At least three different approaches can be taken in the analysis of these data. In the first, repeated phenotypic measures can be summarized into a single measure in order to detect associations between causal variants and phenotypes. In the second, the repeated measures can be used to reduce the variation of the phenotype, in effect, increasing the relative heritability of the trait. In the third, these measures can be used to measure changing effects of causal variants on the same phenotype over time. In this study we investigate the statistical properties of a method based on spatial regression to order to identify causal variants that have changing effects on phenotypes over time. Ordinarily, spatial regression is used to adjust for the fact that points that are closer together in a three dimensional space are more correlated than points that are far apart. Therefore, instead of summarizing repeated measures into a single value to identify a static association, a "map" of association results across the genome can be defined with the map distance of single nucleotide polymorphisms (SNPs) as one dimension and time as the other dimension. Moran's I statistic is used to test autocorrelation to determine if the observed patterns of associations are significant over time. Two thousand replications of simulated quantitative phenotypes for 2000 individuals were used to compare the power and type I error of this approach with two commonly used longitudinal analysis methods -- slope (the rate of change between first and last exams for a given trait) and Max-Min (the absolute difference between maximum and minimum trait values). At a critical value of 0. 05, the special regression method has an inflated type I error (18. 2% at a p-value threshold of 0. 05) while the type I error for slope and Max-Min are 5. 3% and 5. 5%, respectively. However, after adjusting the critical level (0. 004) to reflect the nominal type I error rate the power to identify a locus with locus specific heritability of 0. 01 was 87. 5% compared to methods using the slope (72. 1%) and Max-Min (8. 3%).

1317W

Exploring genetic variants for anthropometric traits in Hispanic/Latino populations. *M. Graff[1], L. Fernandez-Rhodes[1], H. M. Highland[1,16], C. Schurmann[2], Y. Feng[3], M. Cruz[4], A. Despite the increased prevalence of obesity in Hispanic/Latino populations, no large-scale GWAS for any obesity-related traits have been performed. Hispanic/Latino populations are diverse and genetically admixed with recent origins from Europe, Africa and the Americas. Using genome-wide imputation to multiethnic 1000 Genomes Phase 1 reference panels in up to 44,405 individuals of Hispanic/Latino descent across 11 studies, we performed a genome-wide search for loci associated with anthropometric traits, including body mass index (BMI), waist-to-hip ratio adjusted for BMI (WHRadjBMI) and height. Each study adjusted traits for age, sex, study specific covariates, and principal components to correct for population stratification. Assuming an additive genetic model, we tested the association of over 20 million variants using fixed-effects inverse variance weighted meta-analyses in men and women combined. For BMI, we observed genome-wide significant (P<5E-8) associations at 11 established BMI loci (near *SEC16B, TCF7L2, LMX1B, OLFM4, TMEM18, MTCH2, C6orf106, ELAVL4, MC4R, ETV5,* and *FTO*) and two novel loci (in/near *PPP1R3B* and *PAX3*) both driven by common variants (minor allele frequencies>5%), that showed the largest minor allele frequencies among Native American reference samples. *PPP1R3B* (a serine/threonine-protein phosphatase) is expressed in liver and skeletal muscle and regulates glycogen synthesis and has previously been associated with lipid traits in European ancestry populations. *PAX3* encodes a transcription factor that aids in converting white to brown-like adipo-

cyte progenitors. For WHRadjBMI, we did not confirm any known loci at genome-wide significance but we identified a novel locus near *TAOK3* (a serine/threonine-protein kinase) driven by a rare variant (minor allele frequency=0. 8%, polymorphic in African ancestry only) and beta=0. 02 WHR unit change, p=4. 8x10-08. For height, we observed 37 known loci and identified two novel loci near *BRK1* and *RABGAP1,* which were also driven by variants with minor allele frequencies that were largest among Native American reference samples. Follow-up in replication cohorts is underway and any replicated loci will be further interrogated in analyses to fine-map loci and identify causal variants. These results show strong preliminary evidence that future discovery efforts in Hispanic/Latino populations can further inform the genetic architecture of anthropometric traits.

1318T

A recall-by-genotype study linking *ZNF804A* variants to sleep neurophysiology phenotypes. *L. J. Corbin[1], U. Bartsch[2], C. Hellmich[2], C. Durant[3], M. W. Jones[2], N. J. Timpson[1].* 1) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK; 2) School of Physiology and Pharmacology, University of Bristol, Bristol, UK; 3) Clinical Research and Imaging Centre (CRICBristol), University of Bristol, Bristol, UK.

Some patients suffering from schizophrenia have been shown to have changes in sleep patterns compared with healthy subjects. Deficits in memory processing have also been noted. Since current schizophrenia treatments largely fail to treat cognitive symptoms, these sleep abnormalities may constitute important targets for novel therapeutic intervention. However, the underlying biological processes are not well understood. Family studies have shown that more than 40% of the variation in incidence of schizophrenia may be attributable to differences in genes. Initial genome-wide studies have shown evidence for association of common variants at several loci, of which rs1344706 (in *ZNF804A*) was amongst the strongest. Brain imaging studies suggest rs1344706 may be associated with differences in neuronal connectivity during wakefulness in individuals unaffected by psychiatric illness. To further explore the role of *ZNF804A* in healthy people, a recall-by-genotype (RBG) study was designed to investigate neuronal activity during sleep. 200 male participants from the Avon Longitudinal Study of Parents and Children were invited to take part on the basis of genotype at rs1344706. An equal number of major and minor allele homozygotes were invited with frequencies of 54% and 46%, respectively, achieved in the final study sample (n=26), comparing to 36% and 17% in the overall cohort. Participants completed 2 overnight stays, approximately 2 weeks apart, during which sleep was monitored using polysomnography (PSG). Participants also performed a motor sequence task. Information about habitual sleep behavior was collected using sleep questionnaires, sleep diaries and actigraphy. This study has generated ~400 hours of PSG data and ~8700 hours of actigraphy data, with a very low rate of missing data. In addition to the standard sleep scoring of data, analyses will be performed to assess the individual characteristics of slow-waves and spindles, as well as their coordination, and how these differ across the genetic stratum. The relationship between these derived sleep phenotypes and task performance will be investigated. This RBG experiment has generated dense, high quality phenotypic measures related to sleep neurophysiology and behavior in a subset of individuals selected according to genotype. Using an RBG approach, it is possible to explore genes relevant to disease in healthy individuals, in a financially and pragmatically feasible sample size.

1319F

A practical guide for GWAS based Mendelian randomization analysis. *Y. Hu, D. Hinds.* 23andMe Inc, Mountain View, CA.

GWAS identify an ever-increasing number of trait-associated genotypes. These genotypes are randomly assigned at meiosis and independent of non-genetic confounding, and so can be used as instrument variables in Mendelian randomization (MR) to infer causal roles of the GWAS studied traits. The underlying MR model has been built on continuous instruments and many currently published MR studies are on continuous traits such as lipid levels and body mass index (BMI).

Although the existing method and experience cannot be directly applied to binary GWAS traits, a majority of the currently published GWAS studies are on binary traits. Understanding how to perform a MR analysis on binary intermediate traits would greatly extend the application of MR in genetic studies. Here, we evaluate ways to test and estimate causal effect. We demonstrate with simulations that the causal effect, sample size and strength of the instrument together influence the power of MR analysis. For example, with a normally distributed genetic risk, when the odds of the binary intermediate trait increase by 14%, a cohort of sample size 60,000 has a power of 76% to detect a causal effect of odds ratio (OR) 2. 5 between the binary intermediate trait and the outcome. The power decreases to 27% when the causal effect of OR reduces to 1. 5, illustrating that a large sample size is needed for typical GWAS identified SNPs with small genetic effect size and when the causal effect is small.

Finally, we apply our strategies on 23andMe's large cohort of research participants to evaluate the causal role of morning person to BMI and depression, and high cholesterol to heart disease. We found no evidence for the protective role of morning person for low BMI and less depression, but we replicated previous findings that high cholesterol causes heart disease. Taken together, these findings suggest we have extended the MR methodology to determine causal effect for binary traits, greatly enhancing the utility of the approach.

Genetically elevated fasting glucose levels and risk of hypertension in African Americans: a Mendelian randomization analysis. *S. Tajuddin[1], M. Nalls[2], A. Zonderman[1], M. Evans[1].* 1) Laboratory of Epidemiology and Population Sciences, National Institute on Aging, National Institutes of Health, Baltimore, MD; 2) Laboratory of Neurogenetics, National Institute on Aging, National Institutes of Health, Bethesda, MD.

Hypertension (HTN) causes significant morbidity and mortality, and disproportionately affects African Americans (AAs) and low socioeconomic status populations. Elevated fasting glucose (FG) levels are associated with increased risk of HTN in observational analyses while individuals with HTN are at higher risk of developing diabetes mellitus. Whether the association between elevated FG and HTN is truly causal is unknown and could be the result of confounding or reverse causality. The aim of the study was to test the hypothesis that elevated FG is causally associated with HTN risk. We performed a Mendelian randomization (MR) analysis in 942 AA participants from the Healthy Aging in Neighborhoods of Diversity across the Life Span study (HANDLS) by using FG associated allele score as an instrumental variable (IV). We constructed the allele score using five significantly associated SNPs located at *PTPRD, TMEM163-MGAT5*, and *LOC285692 l*oci selected from a genome-wide association analysis of FG. For observational analysis, we fitted a multivariable adjusted logistic regression model to assess the association between FG and HTN risk. Causal estimate of fasting glucose on HTN risk was derived by logistic control IV function estimator – a two-stage regression analysis comprising (1) linear regression of FG on allele score adjusted for potential confounders, and (2) logistic regression to assess the association between genetically predicted FG values and risk of HTN adjusting for residuals from the first-stage regression. The allele score was positively associated with FG levels (beta=0. 143, standard error=0. 023, *P*=1. 45E-9, F-statistic=37. 3) but not with HTN risk (odds ratio (OR)=0. 90, 95% confidence interval (CI) 0. 56-1. 46), which together suggest the allele score is a strong instrumental variable. In observational analysis, increased FG levels were significantly associated with increased risk of HTN [OR=2. 03, 95%CI 1. 13-3. 65, *P*=0. 02]. In MR analysis, genetically elevated FG levels were significantly associated with increased risk of HTN (causal OR=15. 08, 95%CI 12. 98-17. 19, *P*=0. 01). In summary, our findings provide the first evidence that the genetic loci that elevate FG are causally associated with increased risk of HTN among community dwelling AA adults, suggesting that improved glycemic control may reduce risk of HTN. Replication study in independent AA cohorts is warranted.

Test of Genotypic Association Allowing for Sequencing Misclassification. *L. Zhou, W. Kim, D. Londono, A. Musolf, T. Matise, D. Gordon.* Genetics Dept, Rutgers, the State University of NJ, Piscataway, NJ.

Genome-wide association studies (GWAS) have led to identification of an ever-increasing number of single nucleotide polymorphisms (SNPs) for further studies. However, the presence of genotype sequencing misclassification, differential or non-differential, among cases and controls may cause either an increase in the false positive rate or a decrease in the power of statistical tests. A commonly used statistic to test for association between SNPs in cases and controls is the chi-square test of independence. This statistic tests whether genotype frequencies (single or multi-locus) differ between case and control groups. This is commonly referred to as a test of association. Regions of the genome where frequencies significantly differ are regions that may harbor a disease locus or loci. Several researchers have documented that genotype misclassifications may alter either the null or alternative distribution of the chi-square test. Our overall objective is the development of a statistical test of association that uses NGS data and is robust to random sequencing misclassifications, both non-differential and differential. More concretely, we develop a chi-square test of independence that uses parameters such as the observed alternative variant reads at a given polymorphic site, the coverage per individual, the individual's phenotype, and error model parameters. This statistic is developed in a log-likelihood framework and the Bootstrapping approach is applied to approximate the type I error. We also apply the factorial design to determine the performance of our statistic under specific situations.

1322F

Novel Association Testing Based on Genetic Heterogeneity in GWAS. *W. Pan, Z. Xu.* Division of Biostatistics, University of minnesota, Minneapolis, MN.

The commonly used association tests in GWAS all aim to detect single SNPs with allele frequency (AF) differences between cases and controls. Although many disease-associated SNPs have been identified, they can only account for a small proportion of the genetic variance for a common disease. Two of several possible reasons are small effect sizes and genetic (or locus) heterogeneity, which are related to each other and have been confirmed by completed GWAS. Under genetic heterogeneity it is assumed that a complex disease is not caused by a single SNP or single gene, but by multiple variants in multiple functionally related genes forming a pathway, motivating the application of pathway analyses. However, as for single SNP tests for AF differences, in addition to incomplete annotations of biological pathways, existing pathway methods do not directly take advantage of existing genetic heterogeneity to boost statistical power. Here we propose and apply a single SNP-based test to explicitly account for genetic heterogeneity: it is assumed that a patient population of a complex disease can be decomposed into multiple subpopulations, each with a possibly different set of causal SNPs; under this model, even if the AF of a causal SNP for the whole patient sample is the same as that of the controls, in which the conventional AF tests have no power, our proposed test retains power to detect the causal SNP. We apply the proposed test to the WTCCC data, demonstrating that it can detect novel SNPs and loci missed by the conventional AF tests. For example, when applied to the WTCCC Crohn's disease data, the proposed test detected 128 significant SNPs, while the conventional trend test identified only 60 significant SNPs, among which 46 were common; compared to 32 new loci detected by the meta-analysis of Franke et al (2010) that included the WTCCC data as a subsample and contained a much larger sample size, the new test and the conventional test (based on the WTCCC sample) identified 21 and 8 loci respectively, which overlapped with those of the meta-analysis at 7 and 5 loci respectively. In addition to annotated pathways, the new test can be generalized to discover de novo (i. e. un-annotated) disease-associated pathways. Its relationships with (and advantages over) some existing tests will be discussed.

1323W

Admixture Mapping with Mixed Models. *L. Brown, T. Thornton.* Biostatistics, University of Washington, Seattle, WA.

Genetic studies in recently admixed populations can provide insight into risk factors contributing to disease. Population admixture results in combined genomes from previously isolated ancestral populations that may have discernible allele frequency differences due to natural selection and genetic drift. Genetic variants that show differential risk by ancestry can be identified using admixture mapping. Due to long range correlation in local ancestry values, admixture mapping is not limited to identifying causal variants tagged by single nucleotide polymorphisms alone because local ancestry captures both common and rare variation. When applied to genome-wide association data, mixed model methods have been shown to protect against spurious associations in structured samples by directly accounting for sources of dependence including cryptic relatedness and population stratification. We present a mixed model approach for admixture mapping in the presence of population structure and known or cryptic relatedness. We demonstrate that our proposed method provides a substantial improvement over widely used admixture mapping approaches and identifies variants not found by association studies applied to the same data.

Novel Genetic Risk Prediction Model using Multiple Secondary Traits. *W. Chung[1], J. Chen[2], C. Chen[1], P. Kraft[1,3], L. Liang[1,3].* 1) Program in Genetic Epidemiology and Statistical Genetics, Department of Epidemiology, Harvard T. H. Chan School of Public Health, Boston, MA; 2) Division of Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN; 3) Department of Biostatistics, Harvard T. H. Chan School of Public Health, Boston, MA.

Despite the success of recent genome-wide association studies (GWAS), for most human complex diseases and traits, a large fraction of overall heritability remain unexplained and the accuracy of genetic risk prediction is generally low because most causal variants have small effect size. Recent studies have shown that human complex traits may share similar genetic architecture with other clinical or molecular phenotypes, such as disease-related traits or gene expression levels. Combining information across such secondary traits might increase the effective sample size for model training, and therefore improve prediction accuracy of the primary trait of interest. In this paper, we develop a new statistical framework for genotype-based risk prediction of complex traits using multiple secondary phenotypes and whole-genome single nucleotide polymorphism (SNP) data. Based on penalized least squares methods, we developed a novel cross trait penalty function to incorporate the shared genetic effects across traits. Our approach has several advantages (1) extracting information from the secondary traits that is useful for primary trait but tuning down information that is not useful; (2) the primary trait and secondary traits can come from same set of subjects or different sets of subjects; (3) our novel implementation of a parallel computing algorithm utilizing Message Passing Interface (MPI) makes it feasible to apply penalized least squares methods on millions of SNPs from thousands of samples. We evaluated our method on GWAS datasets using the Lasso and the minimax concave penalty (MCP) for inducing a sparse solution. We performed large-scale simulation studies to illustrate the excellent performance of our multi-trait approach. For example, when the cross-trait heritability is 50%, the prediction R2 improved from 16% (single trait model) to 21% (two-trait model) when using 1 million SNPs on 7400 training samples and 5900 testing samples. We further applied our method to real GWAS data using body mass index (BMI) as the primary trait and age at menarche as the secondary trait. With 12,000 individuals and 2,000,000 SNPs, the gain in prediction accuracy of our multi-trait approach is 15. 7% using Lasso penalty and 16. 0% using MCP penalty. Finally, comparing to prediction using SNPs within 1kb of 96 BMI loci curated at the NHGRI GWAS category (access 2015. 6. 10), our method has more than 10 times increment in prediction R2 using the same training and testing dataset.

1325F

Functional-Trait GWAS—Going Beyond Single-Value Traits. *N. Fusi, J. Listgarten.* Microsoft Research, CAMBRIDGE, MA.

Practically all genome-wide association studies examine either one trait at a time, or several independent/related traits where the relationship among traits does not contain particularly rich structure (i. e. , none beyond simple pairwise correlations). However, with the advent of wearables for health, or “quantified health”, and the approaching ubiquity of electronic health records, traits collected over time are becoming widely available. Longitudinal traits are one example of functional traits—traits which can be viewed as a function of some variable, such as time (e. g. , clinical history), or space (e. g. , position along the genome). Such structured, functional traits offer new opportunities to dissect the genetics of disease by offering richer traits than were previously available. However, truly benefiting from such opportunities requires that the rich structure within these traits can be leveraged by the statistical model of choice. Rich trait structure arises from constraints in the physical world, such as that time moves forward and is smoothly varying, or that the correlation between positions on the genome is slowly decreasing according to linkage disequilibrium. Appropriate modelling approaches in such a setting not only assume that such constraints exist, but, also, critically, that genetic effects can dramatically alter this structure, even while the mean structure for one genotype alone is, for example, smoothly varying. Although several approaches for analyzing longitudinal traits have been presented in recent years, these are computationally slow, and yet, do not generally make effective use of the rich trait structure to increase power. In our work, we show that (i) with a clever insight, a fairly simple model can outperform significantly more complex and computationally expensive models, and (ii) if one is willing to incur the cost of expensive models then one can do much better than existing approaches; in particular, our more expensive models can handle missing function values (e. g. , missing time points in the trait), unevenly sampled functional values (e. g. , not the same time points for all individuals), and can take in to account function domain distance between the observed points (e. g. , points closer in time should appear more similar than points further away in time).

A general and flexible framework for meta-analyzing dependent studies with overlapping subjects in association mapping. *B. Han[1], D. Duong[2], J. H. Sul[3,4], P. I. W. de Bakker[5,6], E. Eskin[2,7], S. Raychaudhuri[3,4,8,9,10].* 1) Asan Institute for Life Sciences, University of Ulsan College of Medicine, Asan Medical Center, Seoul, 138-736, Republic of Korea; 2) Computer Science Department, University of California, Los Angeles, California, 90095, USA; 3) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, 02115, USA; 4) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, 02142, USA; 5) Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, 3584 CX Utrecht, The Netherlands; 6) Department of Medical Genetics, University Medical Center Utrecht, 3584 CX Utrecht, The Netherlands; 7) Department of Human Genetics, University of California, Los Angeles, California, 90095, USA; 8) Division of Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, 02115, USA; 9) Partners Center for Personalized Genetic Medicine, Boston, Massachusetts, 02115, USA; 10) Faculty of Medical and Human Sciences, University of Manchester, Manchester, M13 9PL, UK.

Meta-analysis strategies have become critical to augment power of genome-wide association studies (GWAS). To reduce genotyping or sequencing cost, many studies today utilize shared controls, and these individuals can inadvertently overlap among multiple studies. If these overlapping individuals are not removed prior to meta-analysis or taken into account during meta-analysis, they can induce dependence between studies, resulting in spurious associations. A simple solution would be to manually split the overlapping subjects into separate studies, but this can be sub-optimal in terms of statistical power. Moreover, splitting genotype data is often not possible in practice if the primary genotype data are not shared. Previous studies addressed this challenge, but only focusing on specific meta-analysis models such as the fixed effects model (FE), but not on the random effects model (RE). However, application of the RE models to meta-analyses recently became crucial because of the expected heterogeneity in cross-disease analysis, cross-population analysis, and cross-tissue eQTL analysis. In this paper, we propose a flexible and general framework for meta-analyzing dependent studies. The philosophy of our framework is unique, in that our framework does not compete with existing methods; it enables them to account for overlapping subjects. Given dependent studies, our framework transforms the data so it can be used in methods that strictly assume independence between studies. Specifically, our method *decouples* dependent studies into independent studies, adjusting association statistics to account for uncertainties in dependent studies. As a result, our approach enables general meta-analysis methods, including the FE and RE models, to account for overlapping subjects. Moreover, to apply our approach, existing software packages and pipelines for meta-analysis can be re-used without changes, because our method only involves a transformation of the data. We performed a meta-analysis of three autoimmune diseases with shared controls using the Wellcome Trust Case Control Consortium (WTCCC) data, to demonstrate that our framework improved statistical significance of known candidate loci associated to multiple autoimmune diseases. We also show that in a multi-tissue mouse eQTL study, cross-tissue analysis using our method increases the number of discovered eQTLs by up to 19% compared to existing methods.

1327T

Semi-parametric Allelic Tests For Mapping Multiple Phenotypes: Binomial Regression And Mahalanobis Distance. *A. Majumdar[1,2], J. Witte[1], S. Ghosh[2].* 1) Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA; 2) Human Genetics Unit, Indian Statistical Institute, Kolkata.

Binary phenotypes commonly arise due to multiple underlying quantitative precursors and genetic variants may impact multiple traits in a pleiotropic manner. Hence, simultaneous analysis of such correlatedtraits may be more powerful compared to analyzing individual traits. Various genotype-level methods oftesting for association, such as MultiPhen [O'Reilly et al. , 2012] have been developed in order to identifygenetic factors underlying a multivariate phenotype. For univariate phenotypes, the usefulness and applicability of allele-level tests have been investigated [Guedj et al. , 2006, 2008;Zheng, 2008], and for a case-control phenotype, the chi-square test of allele frequencydifference among cases and controls is a commonly used method for identifying genetic associations. However, allelic methods for mapping association with multivariate traits have not been studiedmuch in the literature. In this article, we explore two allele-level tests of association for analyzing multivariate phenotypes: one based on a Binomial regression model in the framework of inverted regressionof genotype on phenotype(termed BAMP, Binomial regression-based Association of Multivariate Phenotypes) and the other based on the Mahalanobis distance between the two sample means of vectors ofthe multivariate phenotype corresponding to the two alleles at a SNP adopting the set-upof regressing phenotype on genotype (termed DAMP, Distance-based Association of Multivariate Phenotypes). These methods inherit the flexibility of incorporating both discrete as well as continuous traits inthe multivariate phenotype vector. Some desirable theoretical properties for BAMP are studied. Usingsimulations, the potential of the methods in enhancing the power of detecting genetic association withmultiple traits is evaluated in comparison with MultiPhen, which is based on a genotype-level test. Wefind that the allelic tests yield marginally higher power compared to MultiPhen for multivariate phenotypes. We also find that, for one or two binary traits under a recessive mode of inheritance, allelic testsare substantially more powerful than MultiPhen. The allelic tests and MultiPhen are applied to two realdata and the results offer some support for the simulation study. Since the allelic tests are applicableunder Hardy-Weinberg Equilibrium (HWE), we propose a hybrid approach for association mapping ofmultivariate phenotypes that implements MultiPhen when HWE is violated and BAMP otherwise.

1328F

Evaluation of GWAS-identified 55 SNPs for association with body mass index (BMI) in north Indian population. *B. Mittal[1], A. Srivastava[1], J. Prakash[2], N. Srivastava[2].* 1) Dept Med Gen, Sanjay Gandhi Med Inst, Lucknow, UP, Uttar Pradesh, India; 2) Dept of Physiology, King George Medical University, Lucknow, UP, India.

Background: Several GWAS have identified large number of risk SNP with obesity but require replication in different populations. **Aims and objectives:** We evaluated association of 55 recently identified SNPs across 28 genes in GWAS and additional candidate genes with BMI in general population of northern India. **Materials and methods:** Overall 480 individuals out of 809 were selected befitting strict inclusion/exclusion criteria. Genotyping were performed by Sequenom Mass ARRAY platform or Taqman probes. Statistical analysis was conducted using SPSS ver. 19, SNPStats and GMDR softwares. **Results:** Single locus analysis revealed significant associations of 50 SNPs in FTO, IRX3, BDNF, TMEM18, GHSR, GHRL, KCNJ11, CDKAL1, UCP3, TCF7L2, ADRB1, ADRB2, FAIM2, SH2B1, NPC1, MC4R, POMC, LEPR, GNPDA2, SEC16B, LYPLA1, NEGR1 and MAF with BMI score in Indian population. A strong linkage disequilibrium was observed between FTO and IRX3 SNPs specified as *FTOrs17817449-IRX3rs3751723* (D'=0. 84), *FTOrs8050136-FTOrs1421085* (D'=0. 95); *FTOrs8050136-FTOrs9939609* (D'=0. 94) and *FTOrs1421085-FTOrs9939609* (D'=0. 90). In GMDR analysis of FTO and IRX3 genetic variants revealed the best candidate interaction model- *FTOrs9939609; FTOrs17817449;* IRX3rs3751723 (P< 0. 0001; OR (95%CI) 3. 5(2. 1-5. 9). CART analysis counting all investigated genetic variants of the study revealed the risk associated with obesity using the terminal nodes, individuals carrying the combination of genotypes exhibited a significantly higher risk for obesity such as *FTO rs9939609 (TT) + TMEM18 rs6548238 (CC) + POMC rs1042571 (CT+TT)* [Node 2] (OR=4. 0(1. 8-8. 9); p=0. 0003); *FTO rs9939609 (CC+TC) + TCF7L2 rs7903146(TT)* [Node 3] (OR=6. 4(3. 2-13. 39); p=0. 0000001) and *FTOrs9939609 (TT) + TMEM18rs6548238 (TT+CT)* [Node 4] (OR=6. 6(3. 3-13. 85); p=0. 0000001). The combined genotypes *FTO rs9939609 (CC+TC) and TCF7L2 rs7903146 (TT+CT)* [Node 5] revealed the highest risk (OR=15. 92(7. 7-34. 25); p=0. 0000001). Pathway wise estimated G-Scores for risk alleles was also calculated for obesity (P=0. 001). In silico analysis of interaction network generated by GENEMANIA revealed direct and indirect connections among them via co-expression, gene interactions and physical interactions. **Conclusions:** FTOrs9939609; FTOrs17817449; IRX3rs3751723, TCF7L2 rs7903146 and TMEM18rs6548238 emerged as major SNPs contributing to higher BMI risk in North Indian population. **Financial support from DBT and ICMR Govt. of India.**

1329W

The use of Complimentary Pairs Stability Selection as an approximation to analysis with replication data. *J. A. Sabourin[1], C. D. Cropp[2,3], Y. Kim[1,4], L. C. Brody[5], J. E. Bailey-Wilson[2], A. F. Wilson[1].* 1) Genometrics Section, CSGB / NHGRI / NIH, Baltimore, MD; 2) Statistical Genetics Section, CSGB / NHGRI / NIH, Baltimore, MD; 3) Translational Genomics Research Institute (TGen)/Integrated Cancer Genomics Division/Phoenix, AZ; 4) Macrogen Clinical Laboratory/Bioinformatics/Rockville, MD; 5) MGMGB NHGRI / NIH, Bethesda, MD.

One of the standard ways to validate an association study for biologically meaningful findings is to replicate the findings in an independent dataset. Although replication datasets may be available for the primary phenotypes in a given study, it is likely that many of the findings for phenotypes of secondary interest will not be reported due to the lack of available resources for replication data and/or functional validation. In this study, we investigate an alternative analysis approach using complimentary pairs stability selection that may be viewed as an approximation to replication. Specifically, the sample is randomly split into two halves, which are conditionally independent, and a simple regression-based GWAS is performed on each half. A SNP is defined as corroborated if its p-value is found to be significant in both halves of the data, similar to seeking significance in discovery and replication data. This procedure is performed for many random splits of the data, and SNPs that are corroborated in a high proportion of the random splits are considered as candidates for association with the phenotype. Since only one half of the samples are analyzed at a given time, a loss in power is expected with this type of approach. Due to the conditional independence of the two halves of the data, the square of the significance threshold characterizes the nominal type I error rate (rather than the significance threshold in a standard GWAS); this allows for the use of a less stringent significance threshold that counters the loss in power due to the smaller sample size. The Trinity data is comprised of 2,232 healthy young students at Trinity College Dublin in Ireland with 3 primary and 35 secondary interest quantitative phenotypes. Genotyping with an Illumina 1M HumanOmni1-Quad chip was performed at the Center for Inherited Disease Research (CIDR). A simulation study was performed to evaluate type I error and power of this approach using the Trinity genotypes and simulated phenotypes that followed either genetically null or simple single SNP models. Simulation results demonstrated that this approach maintains the same power as the standard GWAS while reducing the type I error. We analyzed all phenotypes from the Trinity data with this method. In order to validate this method, the primary phenotype results were compared and found consistent with those obtained using independent replication data and/or functional studies.

1330T

Using the Coriell Personalized Medicine Collaborative to illustrate the challenges in translating GWAS results to clinical care. *L. B. Scheinfeldt, N. P. Gerry, M. F. Christman.* Coriell Institute for Medical Research, Camden, NJ.

Several factors contribute to health-related quality of life, including: healthcare quality and access, behavior, environment, and genetics. Genetic information contributes through research that focuses on the underlying biology and inherited component of disease and implementation that applies research knowledge in a clinical setting to improve health outcomes. Clinical genetic testing for Mendelian disorders is standard of care in many cases; however, it is less clear to what extent and in which situations clinical genetic testing will improve prevention, diagnosis and/or prognosis of complex disease. One of the challenges in implementing clinical genetic testing in the management of complex disease is that much of the research reported to date relies on tag SNPs to act as proxies for assumed underlying functional variants that are not yet known. This assumption is especially problematic when reported studies do not include representative population samples, and the results are generalized. Here we use the Coriell Personalize Medicine Collaborative to evaluate how well the reported genetic risk variant for coronary artery disease (rs1333049) tags surrounding variants in the 1000 genomes data across 26 continental population samples. We evaluated variants within 4 distance windows, 5kb, 10kb, 50kb, 100kb, and performed one million simulations for each distance window where we randomly assigned a 'functional' variant within each window that was in high linkage disequilibrium (R2≥0. 8) with rs1333049 in the CEU. We evaluated how often this simulated functional variant was in high LD (R2≥0. 8) with rs1333049 in all of the other population samples. Asexpected, we found good replication in the FIN and GBR; however, we only correctly tagged the simulated functional variant 56% of the time in the IBS and 19% of the time in the TSI. Results were similarly low or lower in other continental groups (2-53%). Our results indicate a relatively large error rate when generalizing increased genetic risk (using rs1333049) of coronary artery disease across diverse population samples, even when generalizing within continents. Taken together, our results highlight the importance of including diverse populations in GWAS. Future work focused on identifying functional variants will eliminate the need for tag SNPs; however, until functional variants are known, caution should be used in the interpretation of genetic risk for complex disease using tag SNPs.

Identification of a possible susceptibility locus for UVB-induced skin tanning phenotype in Korean females using genome-wide association study. *YA. Shin[2], TJ. Kwak[1], YH. Chang[1], JM. Shin[3], JH. Kim[2], SK. Lim[3], SH. Lee[1], MG. Lee[4], TJ. Yoon[5], CD. Kim[3], JH. Lee[3], JS. Koh[6], YK. Seo[6], MY. Chang[1], Y. Lee[3].* 1) LG Household and Healthcare, Daejeon, Korea; 2) Theragen-Etex Bio Institute, Advanced Institute of Convergence Technology, Kwanggyo Technovalley, Korea; 3) Departmentof Dermatology, School of Medicine, Chungnam National University, Daejeon, Korea; 4) Departmentof Dermatology, School of Medicine, Yonsei University, Seoul, Korea; 5) Departmentof Dermatology, School of Medicine, Gyeongsang National University, Jinju, Korea; 6) Dermapro skin research center, Seoul. Korea.

Human skin pigmentation is regulated by various factors including genetic, environmental and endocrine components that modulate the amount, type and distribution of melanin. Among these factors, genetic contribution is one of the most potent determinants of the skin pigmentation phenotype, which displays polygenic quantitative traits. To investigate the genetic factors influencing ultraviolet (UV)-induced skin pigmentation, A multistage genome-wide association (GWA) analysis was conducted in Korean females after UV exposure. Previously, GWA studies evaluating ~500,000 single nucleotide polymorphisms (SNPs) in 99 Korean females identified eight SNPs that were highly associated with tanning ability. To confirm these associations, we genotyped the SNPs in an independent replication study (112 Korean females). We found that a novel intronic SNP yielded significant replicated associations with skin tanning ability. To understand the functional consequences of this locus located in the non-coding region, we investigated the role of this gene in human melanocytes using a recombinant adenovirus expressing a microRNA specific. Inhibition of gene expression significantly increased the expression and activity of tyrosinase in human melanocytes. Taken together, our results suggest that the genetic variants could be determinants in the UV-induced tanning ability of Korean females. The gene represents a new candidate gene to evaluate the molecular basis of the UV-induced tanning ability in individuals.

Joint analysis of multiple traits using optimal principal components of heritability. *Z. Wang, Q. Sha, S. Zhang.* Mathematical Sciences, Michigan Technological University, Houghton, MI.

The joint analysis of multiple traits has recently become popular since it can increase statistical power to detect genetic variants, and there is increasing evidence showing that pleiotropy is a widespread phenomenon in complex diseases. Currently, several statistical methods have been proposed to jointly analyze multiple traits in genome-wide association studies (GWAS). However, each of these existing methods has good performance only on some specific scenarios, and no method has acceptable performance in all scenarios. In this paper, we proposed an Optimal Principal Components of Heritability (PCH-O) method to jointly analyze multiple traits in GWAS. We used extensive simulation studies to evaluate the performance of PCH-O and compared the power of PCH-O with some existing methods. Our simulations showed that PCH-O has correct type I error rates. Power comparisons showed that PCH-O either is the most powerful one or has comparable power with the most powerful one. Thus, PCH-O has good performance in a wide range of scenarios.

1333T

Privacy Leaks in Quality Control for Meta-analysis and Effective Countermeasures. *W. Xie[1], M. Kantarcioglu[2], J. C. Denny[3,4], T. L. Edwards[5], N. J. Cox[6], B. A. Malin[1,3].* 1) Electrical Engineering and Computer Science, Vanderbilt University, Nashville, TN; 2) Department of Computer Science, University of Texas at Dallas, Richardson, TX; 3) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 4) Department of Medicine, Vanderbilt University, Nashville, TN; 5) Division of Epidemiology, Department of Medicine, Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 6) Division of Genetic Medicine, Vanderbilt University, Nashville, TN.

Quality control (QC) is fundamental to genome research. This is especially the case for genome-wide association studies (GWAS) conducted via meta-analysis in consortia, where data are contributed by disparate and heterogeneous cohorts. Often, QC on GWA meta-analysis proceeds by sharing and contrasting summary statistics beyond their originating cohorts, under the belief that such summaries are privacy-preserving and ethically safer to disclose than individual-level genome. This work challenges such a belief by pinpointing privacy vulnerabilities of standard QC practices that could leak sensitive information of individual participants. In particular, by systematically assessing privacy implications of various QC procedures, we empirically demonstrate that private traits (e. g. , disease status or study participation) can be ascertained with high accuracy leveraging QC summary statistics such allele frequency, effect size, effect direction, etc. We later demonstrate how to mitigate the privacy risks through novel technological methods based on distributed computing and Cryptography, and present an end-to-end QC pipeline that guarantees genome privacy. Empirical evaluations on several consortia studies show that our secure pipeline enhances privacy effectively, and incurs negligible overhead in terms of runtime and monetary cost. We believe that our privacy assessment and proposed protections are highly relevant to future genome research, in which genome privacy is increasingly a concern due to the formation of even larger collaborative studies/consortia and inclusion of even more cohorts on a national or global scale.

1334F

Bayesian large-scale regression with GWAS summary statistics. *X. Zhu[1], M. Stephens[1,2].* 1) Department of Statistics, The University of Chicago, Chicago, IL; 2) Department of Human Genetics, The University of Chicago, Chicago, IL.

Recent work has revealed potential merits of performing multiple-SNP analysis. Existing multiple-SNP methods require individual phenotypes and genotypes, which are not available for large GWAS. In contrast, single-SNP association summary statistics are often released in public domain. Here we present a new Bayesian regression method for large-scale multiple-SNP analysis, using only GWAS summary statistics and estimated population LD from a public reference panel. Our method takes advantage of the fact that, under standard genetic association model, the posterior of multiple-SNP effect sizes depends on the individual-level GWAS data only through the single-SNP summary statistics and the cohort sample LD. We estimate the unknown cohort LD by its posterior mean given the public panel. Using (singular) Wishart distribution theory, we prove that the estimated cohort LD is actually an estimated population LD, and we use a shrinkage estimator based on genetic maps (Wen and Stephens, 2010) to facilitate fast computation. We approximate the likelihood by a multivariate normal distribution, and derive its connection with previous work, including BIMBAM (Servin and Stephens, 2007), ABF (Wakefield, 2009), CAVIAR (Hormozdiari et al, 2014) and LDSC (Bulik-Sullivan et al, 2015). We specify two types of flexible prior on the effect sizes, and develop MCMC algorithms for posterior inference. We consider three applications of our method: fine mapping, detecting genome-wide associations, and estimating the proportion of phenotypic variation explained (PVE) by available genotypes. Simulations show that our method is robust to a wide range of genetic architectures with varying proportion of causal variants and amount of true PVE, and comparable to existing tools that require individual-level data. We illustrate the method on the summary statistics of 1,064,575 SNPs from 253,288 individuals in a GWAS of human height (Wood et al, 2014). Our estimated total PVE is 60. 4% (95% C. I. [54. 9%, 65. 5%]), and we observe a significant correlation between the estimated PVE of each chromosome and chromosome length (R2=0. 779, p=5. 5e-8). We include 384 previous GWAS significant SNPs identified by GCTA-COJO (Yang et al, 2012) in our analysis, and detect 125 of them with strong evidence (posterior inclusion probability > 0. 9). We also identify that 314/360/371 of these 384 previous hits are located in 10/20/40-Kb regions that show strong signal (posterior expected number of included SNPs >= 1).

Genetic determined lipoprotein cholesterol levels and age-related macular degeneration. *C. Y. Cheng[1,2,3], Q. Fan[1], E. S. Tai[4,5], G. Cheung[1,2], X. Sim[5], C. C. Khor[6], Y. Y. Teo[4], K. Park[7], C. Pang[8], N. Yoshimura[9], T. Y. Wong[1,2,3].* 1) Singapore Eye Research Institute, Singapore National Eye Centre, Singapore; 2) Duke-NUS Graduate School of Medicine, Singapore; 3) Department of Ophthalmology, National University of Singapore, Singapore; 4) Department of Medicine, National University of Singapore, Singapore; 5) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 6) Division of Human Genetics, Genome Institute of Singapore, Singapore; 7) Department of Ophthalmology, Seoul National University Bundang Hospital, Korea; 8) Department of Ophthalmology and Visual Sciences, The Chinese University of Hong Kong, Hong Kong; 9) Department of Ophthalmology and Visual Sciences, Kyoto University Graduate School of Medicine, Japan.

The nature and underlying mechanisms of associations between plasma lipoprotein cholesterol levels and the risk of age-related macular degeneration (AMD) are unclear. Using a genetic approach, we aimed to investigate whether genetic determined plasma lipoprotein cholesterol levels were associated with an increased risk of neovascular AMD in East Asians. We assessed genetic variants influencing plasma lipoprotein cholesterol levels in 23,520 East Asians from the Asian Genetic Epidemiology Network (AGEN). The diagnosis of neovascular was made based on clinical examinations and retinal photographs. We identified 62 cholesterol-associated common SNPs, including 31 SNPs for high-density lipoprotein (HDL) cholesterol, 16 for low-density lipoprotein (LDL) cholesterol, and 15 for triglycerides. Using these cholesterol-associated as instrumental variables, we tested the association between a change in genetically determined lipoprotein cholesterol levels of 1 standard deviation (SD) with the risk of AMD in 2,219 AMD cases and 5,275 controls from the Genetics of AMD in Asians (GAMA) Consortium. The association was quantified by combining the instrument variable estimators of each SNP, using fixed-effects models with inverse-variance weighting. We found that higher plasma HDL cholesterol was associated with an increased risk of neovascular AMD (odds ratio [OR] = 1. 48 per SD increase in plasma HDL levels; P = 0. 002) using fixed-effects models. After removing *CETP* (MIM 118470) rs2303790 (which was previously identified as AMD risk locus in East Asians) from the analysis, there was no more significant association between HDL levels and the risk of neovascular AMD (D442G; OR = 1. 31, P = 0. 375). LDL cholesterol and triglycerides levels did not increase the susceptibility to neovascular AMD (OR = 1. 11, P = 0. 724; and OR =1. 04, P = 0. 760, respectively). The moderate association between genetically determined HDL levels and an increased risk of neovascular AMD in East Asians was mainly driven by the *CEPT* D442G variant. Genetically determined LDL cholesterol and triglycerides do not affect the risk of neovascular AMD.

1336T

Detecting allele specific expression in large scale genetic expression studies using overdispersed Poisson linear models. *G. Gliner[1], Y. Park[2], C. Brown[2], B. E. Engelhardt[3].* 1) Operations Research and Financial Engineering, Princeton University, Princeton, NJ, USA; 2) Department of Genetics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA 19104, USA; 3) Computer Science Department and Center for Statistics and Machine Learning, Princeton University, Princeton, NJ 08540, USA.

Non-coding cis-regulatory mechanisms underlying variation in gene expression levels often show signatures of differential expression of the alleles at coding polymorphisms within the gene, a phenomenon known as allele specific expression (ASE). Detection of significant association between non-coding regulatory variants and gene expression levels (eQTLs) has proven to be a powerful method to study the genetic origins of phenotypic variation. Furthermore, high-resolution genotype and RNA-seq study data motivates the development of systematic statistical models that identify and quantify ASE on a genome-wide scale. To search for significant differential expression levels at bi-allelic single nucleotide polymorphisms (SNPs), current methods test the relative abundance of expression levels of two coding alleles at a coding SNP in each heterozygous sample, where the null model is that the two alleles have equal levels of expression. We present a Bayesian ASE detection method that applies an overdispersed Poisson linear model (OPLM) to recover coding SNPs that show evidence of ASE using phased genotype and mapped RNA-seq data. The OPLM identifies ASE by quantifying the imbalance in gene expression levels between reference and alternative alleles at a given coding locus. This statistical model quantifies the statistical significance of deviations from the null hypothesis of no ASE. While most state-of-the-art methods control for the effects of RNA-seq mapping bias, they only search for ASE locally. We extend the OPLM framework to include all non-coding genetic variants in a gene as candidates for ASE in a single model, combining evidence for ASE across loci and homozygous samples to better control for mapping bias and share statistical support. To empirically validate our method, OPLMs to extract ASE, or OPLEASE, we apply it to publicly available data from the GEUVADIS consortium and compare results to leading ASE detection methods RASQUAL [Kumasaka et al. 2015] and Battle's ASE method [Battle et al. 2014]. We apply it to the Genotype Tissue Expression (GTEx) consortium v6 data to identify ASE loci across tissues. We find that our approach is highly complementary to related methods by improving ASE detection when multiple heterozygous loci are available in a gene and by providing a model to interpret the allele-specific effects of the collective cis-eQTLs on gene transcription by sharing effects across genetic loci, genes, and individuals.

1337F

A unified framework of association mapping for admixed samples. *Y. Guan.* Pediatrics and Molecular & Human Genetics, Baylor College of Medicine, Houston, TX.

Admixed samples provide great opportunities in disease association mapping. First, the variation of local ancestry across individuals provide "free" genetic variates to be associatd with disease phenotypes. Second, the local ancestry of each marker serves as a background forgenotypes to have differential effects conditioning on a specific ancestry. Our working hypothesis is that an allele can have positve, zero, and negative effect sizes toward a phenotype depending on its ancestral background. Thus incorportating the local ancestry to test for genetic association evidently increase power when the allele does have differential effect sizes. Current literature separates the mapping by admixture and mapping by marker, and ignores the possibility of differential effects. We developed a unified framework for association mapping for admixed samples. Our approach based on a highly efficient, model-based, local ancestry inference method ELAI. The statistical model underlying ELAI is a two-layer cluster model where each layer represents ancestral hapltoypes of different age. Our statistical model links the phenotype with genetic markers and all cluster loadings (both old and young haplotypes). If jointly significant, we further disect association signals into genetic markes and old and young cluster loadings. If genetic marker is significant, it is significant after controlling for local ancestry. If old cluster loadings are significant, it is signal for mapping by admixture. If young cluster loadings are significant, it is signal for haplotype associations after controlling for local ancestry. BecauseELAI automatically incorporate training samples, the imputation based association mapping can be performed simultaneously -- both single-marker test and haplotype test. We illustrate our methodusing two Mexican GWAS datasets.

1338W

Impact of gene-environment correlation on genome-wide analysis. *C. Chen[1,2], J. Smoller[1,2], B. Neale[1,2].* 1) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA.

Gene-environment correlation (rGE) refers to the phenomenon of genetic influences on environmental exposure. For diseases with strong environmental risk factors, rGE may play an important role in discover genetic effects, direct or mediated through environmental factors. We investigate the impact of rGE on genome-wide analyses including association tests, SNP-based heritability (h2g) estimation, and stress-diathesis model (SDM) analysis. SDM analysis refers to detecting the induced inverse relationship between genetic risk loading and environmental risk loading among disease cases under the liability-threshold model. To examine the impact of rGE, we use simulated and real genome-wide genotype data, and simulated phenotypes and environmental exposures under the polygenic model with given h2g and prevalence (for binary variables). The simulations were done in 3 settings: 1) causal genetic variants and environmental exposures affect disease risk independently (no rGE); 2) causal genetic variants affect disease risk only through their influences on environmental risk exposures (complete rGE); 3) genetic variants affect disease risk both directly and through effects on environmental risk exposures (partial rGE)We applied genome-wide analyses on simulated datasets with different modeling strategies. We showed that conditioning on environmental factors will remove the genetic effects through rGE and reduce power to detect genetic risk variants but increase power when these is no rGE. We also showed that conditioning on environmental factors will lower the h2g estimates when rGE is present, but increase h2g estimates when there is no rGE. Finally, we examined the SDM analysis under different simulation settings. We used a polygenic risk score as the measure of genetic loading for disease risk. We demonstrated that the expected inverse relationship between disease genetic loading and environmental loading will not always hold under different combinations of rGE and direct genetic effects. In conclusion, potential rGE should be considered when conditioning on environmental risk factors in genome-wide association tests and h2g estimation. The SNP-based heritability of the environmental factors can be a measure of genome-wide rGE and potentially inform on the impact of genome-wide analysis.

1339T

Assortative mating causes biases in SNP-heritability estimates. *R. Tahmasbi[1], T. de Candia[1,2], M. Jones[1,2], D. Evans[4], G. Carey[1,2], L. Eaves[3], M. Keller[1,2].* 1) Institute for Behavioral Genetics (IBG), University of Colorado, Boulder, CO; 2) Department of Psychology and Neuroscience, University of Colorado, Boulder, CO; 3) Departments of Human Genetics and Psychiatry, Virginia Institute for Psychiatric and Behavioral Genetics, Richmond VA; 4) Diamanti Institute, University of Queensland, Australia.

Assortative mating occurs when individuals mate with people similar to themselves on a given trait. Assortative mating is known to lead to downward biases in estimated heritability in twin studies, but its effects on heritability estimated from genome-wide similarity at measured SNPs (SNP-heritability) in unrelated individuals have not yet been quantified. Here, we derive the expected biases in SNP-heritability under assortative mating, and show that these expectations match those observed in simulations. In general, assortative mating causes long-range statistical associations between causal variants (gametic phase disequilibrium), which alters the phenotypic (co)variance matrix in a way that is unaccounted for in the genomic relationship matrix. This causes SNP-heritability to be biased upwards as a function of the degree of mate similarity and the equilibrium heritability of the trait. For highly heritable traits (h2~. 60-. 80) with modest spousal similarity (r~. 20-. 30), such as height or IQ, we find that the estimated SNP-heritability is expected to be ~20% to 30% higher than the true equilibrium SNP-heritability. We discuss several unsuccessful attempts to mitigate this bias. Finally, we describe several signatures of estimation bias due to assortative mating and demonstrate evidence of these using height as a test phenotype. We conclude that, to the degree that assortative mating has occurred, SNP-heritability estimates are expected to be biased upwards.

1340F

Multi-Trait Analysis of Genomic heritability and genomic correlations in the Training Interventions and Genetics of Exercise Response (TIGER) study. *A. I. Vazquez[1], H. Kim[2], J. R. Fernandez[3], M. S. Bray[4].* 1) Epidemiology and Biostatistics, Michigan State University, Lansing, MI; 2) Biostatistics, University of Alabama at Birmingham, Birmingham, AL; 3) Nutrition Sciences, University of Alabama at Birmingham, Birmingham, AL; 4) Nutritional Sciences, University of Texas at Austin, Austin, TX.

While the incidence of obesity continues to rise, fat accumulation and sedentary life are established risk factors for many chronic diseases. Though the genetic basis of obesity and body composition has been well-established, current approaches to gene discovery have explained a very small fraction of the variability in these traits. Alternatively, by simultaneously regressing all available molecular markers, we can explain a sizeable proportion of the inter-individual differences observed in these complex traits because small-effect markers not captured by GWAS can be taken into account. We estimated SNP-derived genomic heritabilities (GH) of body composition traits. Additionally, since these traits are highly correlated, we further differentiated phenotypic correlations from genomic and environmental correlations (GC, EC) observed between these traits. We used 991 non-Hispanic white (W) and 701 African American (AA) young adults genotyped using the MetaboChip (Illumina, Inc.). Measures of BMI, lean mass (Lean), fat mass (Fat) and percent fat (%Fat) were obtained. GH, GCand ECamong variables were estimated though bivariate analysis in a Bayesian context. GHestimates and standard deviations (in parentheses) for each trait were: BMI=0. 23(0. 09); Lean=0. 31(0. 09); Fat=0. 18(0. 07); %Fat=0. 32(0. 07) in Whites, and BMI=0. 18(0. 07); Lean=0. 27(0. 08); Fat=0. 21(0. 08); %Fat=0. 35(0. 09) in Blacks. These estimates represent the amount of inter-individual variation attributable to markers on the MetaboChip. The GCand EC, respectively, between BMI and other traits were as follows: Lean=0. 19 (0. 08) and 0. 32 (0. 08), Fat=0. 15 (0. 06) and 0. 69 (0. 06), and %Fat=0. 03 (0. 06) and 0. 17 (0. 06) in W. In AA, the estimated correlations with BMI and related traits were Lean=0. 11 (0. 07) and 0. 38 (0. 07), Fat=0. 20 (0. 08) and 0. 73 (0. 08), and %Fat=0. 05 (0. 06) and 0. 09 (0. 06). Genomic correlations result from pleiotropic effects of SNPs related to more than one trait. Our estimates of GHin BMI explain more than seven times the variability explained by all markers identified through GWAS. 11-20% of co-variability in BMI and fat and lean mass was accounted for by shared genetic effects, while shared genes jointly accounted for only 3-5% of co-variability in BMI and %fat, suggesting non-pleiotropic effects between genes influencing these two traits. Our results support the hypothesis that genes related to body mass are distinct from those encoding adiposity.

1341W

Bivariate Analysis and Prediction of AMD progression Using Genetic Scores. *Y. Ding[1], Q. Yan[2], Y. Liu[1,2], L. G. Fritsche[3], G. R. Abecasis[3], A. Swaroop[4], E. Y. Chew[4], D. E. Weeks[5,1], W. Chen[2,1,5].* 1) Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Pediatrics, University of Pittsburgh, Pittsburgh, PA; 3) Biostatistics, University of Michigan, Ann Arbor, MI; 4) National Eye Institute (NIH/NEI), DC; 5) Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Age-related Macular Degeneration (AMD), the leading cause of blindness in the developed world, accounts for more than 50% of all blindness in the United States. Multiple large-scale genetic studies have had remarkable successes in identifying disease-susceptibility genes for AMD. However, the genetic causes for disease progression have not been well studied yet. In this National Eye Institute (NEI) funded research project, using the data from two large multi-center randomized clinical trials -- AREDS (Age-Related Eye Disease Study) and AREDS2, we perform a novel analysis to evaluate the effect of the known AMD risk SNPs on disease progression and establish prediction models for AMD progression. Specifically, we calculate the time-to-advanced AMD (either choroidal neovascularization or geographic atrophy) from the baseline visit time for each eye of each patient, and model this eye-level progression time using a bivariate approach, which appropriately accounts for between-eye correlations. For the top SNPs that are significantly associated with AMD progression, we additionally model their effects on transitions between multiple disease progression states through a multistate Markov model, where the transitions among four AMD states are examined. Finally, we develop prediction models on AMD progression based on the genetic score (i. e. , the weighted effects of the known AMD risk variants), demographic factors, and eye-level macular information. We find that the model with genetic score and demographic factors (but without macular information) predicts the progression well, suggesting an effective and efficient screening process which uses only genetic and demographic factors to identify patients at high risk of progression for early interventions.

1342T

A novel gene-based analysis method based on MB-MDR. *R. Fouladi[1, 2], C. Schurmann[3], K. Bessonov[1, 2], JP. Vert[4,5,6], R. J. F Loos[3], K. Van Steen[1, 2].* 1) Systems and Modeling Unit, Department of Electrical Engineering and Computer Science (Montefiore Institute), University of Liège, Quartier Polytech 1, Allée de la Découverte 10, 4000 Liège, Belgium; 2) Systems Biology and Chemical Biology, GIGA-R, University of Liège, Quartier Hôpital, Avenue de l'Hôpital 11, 4000 Liège, Belgium; 3) Icahn School of Medicine at Mount Sinai, New York, NY; 4) MINES ParisTech, PSL-Research University, CBIO-Centre for Computational Biology, 35 rue St Honoré, 77300 Fontainebleau, France; 5) Institut Curie, 75248 Paris Cedex ,France; 6) INSERM U900, 75248 Paris Cedex, France.

Here we present a novel gene-based test that builds upon Model-Based Multifactor dimensionality reduction (MB-MDR). This approach was initially developed to investigate SNP-based interactions from GWAS data. It relies on a natural organization of individuals in multi-locus genotype categories, followed by a labelling of these categories using trait information and appropriate association tests. In a gene-based setting, any set of features (e. g. , SNPs, structural variants, epigenetic markers) that can be mapped to a gene is submitted to a clustering algorithm to find groups of individuals (clusters) with similar "gene-based" profiles. The resulting profile types for a gene can be considered to be category levels of a gene-based summary variable. These categories can be labeled by MB-MDR, as before. Earlier, we obtained promising results when taking rare and common variants as features and genes as regions of interest derived from exome sequencing data from GAW17. Here we show the utility of the approach on common variants derived from GWAS data, provided optional parameters are optimized to the new analysis context, including those related to kernel selection prior to clustering. In particular, we explore the pros and cons of using diffusion kernels as a special case of exponential kernels based on the heat equation. This allows the incorporation of biological information via defining a meaningful graph structure on the input features to each gene. In addition, special attention is given to the automatic detection of the optimal number of aforementioned clusters and the optimal minimal cluster size. The newly proposed gene-based tool is evaluated on synthetic data via extensive simulations. We furthermore show its practical use on real-life data from the BioMe Biobank (Mount Sinai school of medicine, USA) for Type II diabetes.

1343F

Identification of significant genetic variants via SLOPE and Group SLOPE. *A. Gossmann[1,3], S. Cao[2,3], Y. -P. Wang[2,3].* 1) Department of Mathematics, Tulane University, New Orleans, LA; 2) Department of Biomedical Engineering, Tulane University, New Orleans, LA; 3) Center for Bioinformatics and Genomics, Tulane University, New Orleans, LA.

The method of *Sorted L-One Penalized Estimation*, or SLOPE, is a novel sparse regression method for model selection introduced in a sequence of recent papers by Bogdan, van den Berg, Sabatti, Su and Candes (Bogdan *et al* 2013 arXiv, Bogdan *et al* 2014 arXiv, Candes and Su 2015 arXiv). It estimates the coefficients of a linear model that possibly has more unknown parameters than observations. In a sense, the SLOPE method combines the ideas of the LASSO method (Tibshirani 1994 Journal of the Royal Statistical Society) and the Benjamini-Hochberg procedure (Benjamini and Hochberg 1995 Journal of the Royal Statistical Society). In many settings SLOPE is shown to successfully control the false discovery rate (the proportion of the irrelevant among all selected predictors) at a user specified level. We evaluate its performance on realistic simulated genetic data, and show its superior feature selection capabilities over LASSO and similar penalized regression methods. Often in genetic data sets, group structures among the predictor variables are given as prior knowledge, such as SNPs in a gene or genes in a pathway. Following this motivation we extend SLOPE in the spirit of Group LASSO (Yuan and Lin 2006Journal of the Royal Statistical Society) to *Group SLOPE*, a method that can handle group structures between the predictor variables, which are ubiquitous in real genetic data. Our simulation results show that the proposed Group SLOPE method is capable of controlling the false discovery rate at a specified level, and its superior variable detection capabilities over Group LASSO.

1344W

Allele Specific Expression Can Substantially Limit Genotype/Phenotype Associations. *J. Dannemiller.* Psychology, Rice University, Houston, TX.

Allele Specific Expression (ASE) can significantly alter quantitative traits. *Purpose:* To derive expressions for and simulate the effects of ASE on the percentage of phenotypic variance explained (PVE) by a single, hypothetical protein-coding SNP. *Methods:* Statistical expressions were derived to estimate the impact of ASE on PVE. Gillespie's (1976) *Monte Carlo* method of simulating transcription and translation was also used as a check on the derived expressions with biologically realistic rates for mRNA transcription and degradation and for protein translation and degradation. ASE was assumed to be produced by a single bi-allelic, regulatory SNP (T/C for convenience) in *linkage equilibrium* with the coding SNP (A/G for convenience) that produced phenotypic variation. All [C/T,A/G] haplotypes were assumed present in the population. It was assumed that the T allele at the regulatory locus produced ASE, and that the G allele at the coding locus produced a protein that was 25% more biologically active than the protein produced by the A allele. Both loci were assumed to be independently in H-W equilibrium with a minor allele frequency (MAF) of 0. 5 for the regulatory SNP and 0. 2 and 0. 5 for the coding SNP (in separate experiments). The expression rate for any coding allele in *cis* with a T allele was randomly drawn either from a lognormal ASE density distribution or from an empirical distribution of ASE ratios modeled on the data in Valle et al. (2008) for the gene *TGFBR1*. The phenotype was the product of the final number of protein molecules times the activity level of each of the protein molecules (1. 00 or 1. 25) summed across the products of the two alleles and averaged across 200 cells for each of 600 subjects per experiment. With no ASE, PVE was varied using phenotype-perturbing, additive Gaussian noise from near 0% (polygenic trait) to 100% (monogenic, Mendelian trait). The impact of ASE was defined as the difference in the PVEs with and without ASE for a fixed level of noise. *Results:* As the PVE *without* ASE increased from near 0% to 100%, the PVE *with* ASE increased but quickly reached asymptote near 12%. When the PVE by the coding SNP was set at approximately 5%, adding the genotype of the regulatory SNP as a predictor still only doubled the PVE to near 10%. *Conclusion:* ASE and potentially other regulatory polymorphisms may limit severely genotype/phenotype associations because of the apparently random nature of the allelic expression ratios across subjects.

Improved fine mapping using generalized likelihood ratios. *W. Li[1,2,3], L. Strug[1,3].* 1) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 2) The Center for Applied Genomics, Hospital for Sick Children, Toronto, Canada; 3) Program in Genetics and Genome Biology, Research Institute, Hospital for Sick Children, Toronto, Canada.

As genomic dataset continues to grow, so do the number of statistical tests required to fully interrogate them. Statistical methodologies with more sensible solutions to the multiple hypothesis testing problem are required. The Evidential Paradigm (EP) measures statistical evidence using the likelihood ratio at two *simple* hypotheses. EP is attractive for use in 'big data' applications because it decouples statistical evidence from error probabilities, and as a consequence does not require conventional multiple test adjustments (Strug & Hodge, 2006). Although the simple vs. simple hypothesis set-up is applicable to many study designs, some research questions such as genetic association or bioequivalence trials are naturally formulated as composite hypotheses. To extend EP to accommodate composite hypotheses (EPC), Bickel (2012) and Zhang & Zhang (2013) proposed the Generalized Likelihood Ratio (GLR). We analytically derive the operational characteristics for the GLR and show that it has small and bounded error probabilities for normal data and fixed-dimensional parametric models asymptotically. Unlike conventional approaches, GLR can glean additional information from the data such as whether there is strong evidence supporting the null hypothesis. We provide guidelines for study planning under EPC, and compare sample size calculations to the Neyman-Pearson approach. The sample size required for a high chance of observing strong evidence in support of the correct hypothesis depends on the size of the null composite hypothesis, and one generally needs larger sample sizes in EPC. We propose the 'London' plot for easy visualization and separation of association evidence across the genome. Using simulation, we show how the data can support either composite hypothesis with increasing sample size, allowing regions of interest to be more clearly demarcated than in Manhattan plots. Furthermore, specifying an interval/composite null hypothesis, instead of a point null, can guard against statistically significant but practically insignificant findings, a problem often seen in p-value based methods. We applied the EPC to a genetic modifier study of Cystic Fibrosis lung disease within a previously reported associated region. The GLR provided confirmatory results at the associated markers, and markers previously showing weak/inconclusive association evidence began to show support for the hypothesis of no association, allowing for improved fine mapping of the locus.

1346F

A new and scaleable Bayesian framework for joint re-analysis of marginal SNP effects. *P. J. Newcombe[1], D. V. Conti[2], S. Richardson[1].* 1) MRC Biostatistics Unit, Cambridge, United Kingdom; 2) Division of Biostatistics, Department of Preventive Medicine, Zilkha Neurogenetic Institute, University of Southern California, US.

Recently, large scale GWAS meta-analyses - accumulating information over tens of thousands of people - have boosted the number of known signals for some traits into the tens and hundreds. However, the availability of many correlated single nucleotide polymorphisms (SNPs) presents analytical challenges and typically variants are only analysed one-at-a-time. This complicates the ability of fine-mapping to identify a small set of SNPs for further functional follow up. We describe a new and scaleable algorithm for the re-analysis of published marginal associations under joint multi-SNP models, in which correlation is accounted for according to estimates from a reference dataset. SNPs which best explain the joint pattern of effects are highlighted via an integrated Bayesian penalized regression framework. Through a realistic simulation study, including an application to 10,000 SNPs, we demonstrate substantial gains in the proportion of true signals among top ranked SNPs (positive predictive value) using our multivariate framework. We also present a real data application to published results from MAGIC (Meta-Analysis of Glucose and Insulin Related Traits Consortium) - a GWAS meta-analysis of more than 15,000 people, in which we re-analyse several top loci associated with glucose levels two hours after oral stimulation. Our algorithm was able to rule out many SNPs as false positives and for one gene, *ADCY5*, joint modeling of the pattern of effects across the locus highlighted an alternative, and more plausible, SNP to the reported index.

1347W

Test rare variants for multiple traits in admixed populations. *X. Wang, X. Zhao, C. Huang.* Joseph J. Zilber School of Public Health, P. O. Box 413, University of Wisconsin-Milwaukee, Milwaukee, WI.

Pleiotropy, effect of one variant on multiple traits, is a widespread phenomenon in complex diseases. Joint analysis of multiple traits such as systolic and diastolic blood pressures evaluated in hypertension can increase statistical power to detect disease susceptible genetic variants. However, testing rare variants for multiple traits in admixed populations such as African Americans and Hispanic Americans is challenging due to the extreme rarity of individual variants, allelic heterogeneity, and the confounding issue of population stratification. Population stratification has long been recognized as an issue in genetic association studies because unrecognized population stratification can lead to both false-positive and false-negative findings and can obscure true association signals if not appropriately corrected. This issue can be even worse in rare variant association analyses because rare variants often demonstrate stronger and potentially different patterns of stratification than common variants. To correct for population stratification for multiple traits in genetic association studies, we proposed two novel methods to test the gene- or pathway-based effect of genetic variants for admixed populations. For the first method, using generalized linear model, we treat the combination of local ancestry weighted variants as response variable and the combination of traits as predictors. For the second method, using generalized linear model, we treat the ancestry-based weighed dosage score as response variable and the combination of traits as predictors. To test association between the multiple traits and the test genomic region, we have developed a score test in the first method and a bootstrap confidence interval test in the second method. We used simulated sequence data to show that our proposed tests have controlled type I error rates, whereas naïve application of existing rare variants tests for multiple traits leads to inflated type I error rates. We will evaluate power of the novel methods in simulation studies and real data analysis.

Investigation of heterogeneity of genetic effects in severe malaria sub-phenotypes across sub-Saharan Africa, Asia and Oceania. *G. M. Clarke[1], G. Band[1], Q. S. Le[1], C. C. A. Spencer[1], K. A. Rockett[1,2], D. P. Kwiatkowski[1,2], MalariaGEN Consortium.* 1) Kwiatkowski Group, Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Warwickshire, UK, United Kingdom; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SA.

Recent studies of genetic association with severe malaria sub-phenotypes have found evidence of heterogeneity of genetic effect across phenotypes suggesting that many studies for the more general severe malaria outcome could fail to identify relevant genetic variants. We use genome-wide data in 11,625 cases of severe malaria and 11,435 population controls in three African populations to examine association between severe malaria sub-phenotypes severe malarial anaemia and cerebral malaria allowing for heterogeneity of genetic effects. We highlight a complex pattern of effects underlying severe malarial anaemia and cerebral malaria at the *G6PD* locus and show that allowing for heterogeneity of effects increases the ability to detect signals of association that would otherwise go unnoticed. Our analyses also allow dissection of signals of association at known severe malaria loci.

A High-Throughput Platform for Functional Validation of CFTR Variants. *A. A. Sockell[1], A. Rychkova[1], H. A. Costa[1], A. S. Verkman[2], M. C. Bassik[1], C. D. Bustamante[1].* 1) Department of Genetics, Stanford University, School of Medicine, Stanford, CA; 2) Department of Medicine, University of California San Francisco, San Francisco, CA.

Rapid, accurate, and inexpensive genome sequencing promises to transform medical care, but a critical hurdle to enabling personalized genomic medicine is predicting the functional impact of novel genomic variation. Several computational tools currently exist for differentiating “benign” from “pathogenic” variants based on genomic context and evolutionary conservation, but all existing approaches suffer from low overall accuracy rates. As a solution to this problem, we are creating a high-throughput validation platform for directly testing the effect of novel variation in disease genes. We are focusing initially on CFTR, a chloride ion channel commonly mutated in cystic fibrosis. Using both public and internal CFTR variant databases, we have developed a tree-based machine learning algorithm with increased variant classification accuracy compared to current computational tools. With these variant classifications in hand, we are now developing an experimental system for functional validation. First, we are synthesizing a library of CFTR variants, which will be stably integrated into Fischer Rat Thyroid (FRT) cells expressing a halide-sensitive YFP reporter gene. FRT cells resemble the epithelial cells that are primarily affected by cystic fibrosis, but do not express any endogenous cAMP-activated transmembrane channels. To verify the validity of variant function in human tissues, we will also use the CRISPR/Cas9 system to install individual variants into the genomes of human lung epithelial cells. With mutant copies of CFTR installed into these cells, we will determine ion conductance properties for each variant by measuring fluorescence of the halide-sensitive YFP reporter. We will also measure transcript levels, and will take advantage of a surface-expressed epitope included in our CFTR constructs to determine the cell-surface expression for each CFTR variant. Together, we expect that these data will allow for robust functional annotation of a broad panel of CFTR variants, which we will use to validate and refine our computational predictions of variant pathogenicity.

The Prevalence of Nonclassic Congenital Adrenal Hyperplasia Mutations in the Ashkenazi Jewish Population. *M. S. Elman[1], R. Morissette[1], T. R. Prezant[2], A. Pulver[3], D. P. Merke[1,4].* 1) NIH Clinical Center, Bethesda, MD; 2) Endocrine Sciences, Laboratory Corporation of America® Holdings, Calabasas, CA; 3) Department of Psychiatry and Behavioral Sciences, Johns Hopkins School of Medicine, Baltimore, MD; 4) The Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD.

Background: Congenital adrenal hyperplasia (CAH) is an autosomal recessive disorder of cortisol biosynthesis most commonly caused by *CYP21A2* mutations (chromosome 6p, HLA-linked) resulting in 21-hydroxylase deficiency. Two major phenotypes exist: classic (severe) and nonclassic (mild, NC-CAH). Classic CAH is part of neonatal screening in the U. S. , occurs in 1 in 15,000 live births, and is life-threatening if not diagnosed and treated in a timely manner. NC-CAH may be asymptomatic but can result in female infertility and pregnancy loss. Neonatal screening does not accurately detect NC-CAH. A study conducted in 1985 using HLA linkage found the prevalence of NC-CAH to be 1 in 1,000 in the general population and more common in certain ethnic groups, such as Ashkenazi Jews (3. 7%), Hispanics (1. 9%), and Yugoslavs (1. 6%) compared to general US Caucasians (0. 1%). We sought to reevaluate the prevalence and carrier frequency of NC-CAH in a representative cohort of Ashkenazi Jews and healthy Caucasians. **Methods:** DNA from healthy Ashkenazi subjects was obtained from The Foundation for Jewish Genetic Medicine, Inc. Johns Hopkins University School of Medicine. Healthy Caucasian DNA was acquired from the Coriell Biorepository. Ethnicity is defined as having four Ashkenazi Jewish grandparents. *CYP21A2* genes were amplified using a gene-specific PCR reaction and analyzed by multiplex mini-sequencing assays for the 12 most common CAH mutations, large gene conversions, deletions, and multiple single nucleotide polymorphisms. Statistics were calculated using the Hardy-Weinberg Law for a population at equilibrium. **Results:** Our results suggest that the 1985 study over-estimated the prevalence of NC-CAH mutations and disease in Ashkenazi Jews. Calculations based on our cohort indicate that 14% of Ashkenazi Jews carry a NC-CAH mutation with 0. 8% affected compared to previous estimates that 31% of Ashkenazi Jews carry a NC-CAH mutation with ~4% affected. Our results also suggest that the life-threatening classic form of CAH is more common in Ashkenazi Jews than in the general population, where the carrier rate is estimated to be 1:60. **Conclusion:** *CYP21A2* genotyping should be considered for prenatal/preconception screening in Ashkenazi Jews, especially females experiencing infertility or miscarriage. Further analysis to clarify potential deletion and duplication genotypes as well as the carrier frequency and prevalence of classic CAH in the Ashkenazi population is underway.

Risk Prediction Modeling of Sequencing Data Using Random Field. *Y. Wen[1], Q. Lu[2].* 1) Statistics, The University of Auckland, Auckland, New Zealand; 2) Department of Epidemiology and Biostatistics, Michigan State University, East Lansing, USA.

The translation of human genome discoveries into individualized prediction and prevention represents one of the major challenges in the coming decades. With the advance in high-throughput sequencing technology, it is feasible to investigate the role of both common and rare variants in disease risk prediction. While the new technology holds great promise to improve individualized disease prediction, the massive amount of data and low frequency of rare variants pose great analytical challenges on risk prediction. In this paper, we develop a forward random field method (FRF) for risk prediction using sequencing data. Subjects' phenotypes are treated as stochastic realizations of a random field on a genetic space, and an individual's phenotype is predicted by adjacent subjects with similar genetic and environment predictors. The FRF method allows for the specification of various similarity measures and the selection algorithm adopted can determine the best similarity measure and reduce the effect of noise, both of which can improve the robustness and prediction accuracy of the method. Like other random filed based methods, the FRF method avoids the specification of the threshold of rare variants and it allows for multiple variants acting with different magnitudes. Through simulations, we demonstrate the proposed FRF method attains a higher or comparable accuracy over commonly used support vector machine based methods under various disease models. We further illustrate the FRF method with an application to the sequencing data obtained from the Dallas Heart Study.

1352F

Evaluation of stepwise and penalized regression methods in selecting a set of genetic predictors explaining quantitative trait variation. *A. J. M. Sorant, A. F. Wilson.* Genometrics Section, Computational and Statistical Genomics Branch, NHGRI, NIH, Baltimore, MD.

In seeking to understand genetic causes of variation in a quantitative trait, one may attempt to fit a regressive model describing the additive effects of a set of genetic variants acting together on the trait as a dependent variable. There are a number of different methods for selecting the proper set of variants to include in the model, as well as a number of different criteria for defining the best result. In a simulation study we considered various methods of choosing causal variants and judged them according to different criteria. Each simulated sample included 500 single nucleotide variants (SNVs) in linkage equilibrium, each having a minor allele frequency (MAF) at least 0. 01. A quantitative trait was determined by five SNVs with MAF 0. 01 with locus-specific heritabilities of 0. 01, 0. 02, 0. 03, 0. 04 and 0. 05, producing an overall trait heritability of 0. 15 in the theoretical population sampled. A total of 750 unrelated observations with complete data were generated for each of 2000 samples. Each sample was analyzed with traditional stepwise regression using p-value selection criteria of 0. 0001 and 0. 05, stepwise regression with the Bayes Information Criterion (BIC), LASSO regression with cross-validation and three different penalty choices, LASSO regression minimizing BIC and LASSO regression with permutations. Because LASSO methods with cross-validation or permutations involve the use of a random number sequence, each of these methods was performed with three different starting seeds, and results were very similar across seeds, especially for the permutation method. Each method was evaluated in terms of power to detect causal SNVs and type I error rate, as well as model p-value, proportion of trait variance explained, BIC and Akaike Information Criterion (AIC) for the selected model. The "best" method, of course, depended on the evaluation criterion used. Stepwise regression with 0. 05 p-value criterion achieved both the best (highest) power over all causal variants (0. 95) and worst (highest) type I error rate (0. 06). The same method using 0. 0001 criterion had the worst (lowest) power (0. 69) and best (lowest) type I error rate (0. 0001). The other methods had power ranging from 0. 70 to 0. 94 and type I error rate ranging from 0. 0008 to 0. 04. The sets selected by each method were also compared for similarity and overlap. The main difference appeared to be the number of SNVs included in the model. Overlap between sets was otherwise quite good.

1353W

Characterizing power of Adjusted-trait Regression in GWAS with quantitative traits. *P. Yajnik, M. Boehnke.* Biostatistics - School of Public Health, University of Michigan, Ann Arbor, MI.

Multiple linear regression (MLR) is commonly used to test for association between genetic variants and quantitative traits and to estimate genetic effect sizes while controlling for the effects of other variables (covariates). Covariates may be included to account for confounding (due to population structure, batch effects or other variants in linkage disequilibrium), to reduce trait variability (when relevant explanatory variables have been measured), or to negate associations that are driven through the action of the variant on an intermediate phenotype. Modern genetic association studies assay a large number of variants and typically fit separate MLR models for each variant. As the dependent variable and covariates are the same across all models, many analysts use a two-stage approach. In the first stage, an 'adjusted' trait is obtained as the residuals from the regression of the trait on the covariates. In the second stage, simple linear regressions are performed to test for association between the adjusted trait and each genetic variant. Analysts may prefer this two-stage adjusted-trait regression (ATR) over MLR since it is faster and makes data-management easier. However, ATR and MLR results are not equivalent. Previous work has shown that ATR produces null-biased estimates and is less powerful than MLR when the genetic variant is correlated with the covariates by deriving approximate relationships between the ATR and MLR test-statistics. These studies used simulations to assess power of ATR when the acceptable type 1 error rate (α) is 0. 05. We extend these results by deriving the exact relationship between the ATR and MLR test-statistics and study the ATR hypothesis test when $\alpha$is at the stringent levels typically used in GWAS and other large-scale genetic association studies. We show that the discrepancy of power between ATR and MLR increases as $\alpha$is made more stringent. We confirm that ATR is conservative when the correlation between genetic variant and covariates is high but is anti-conservative when the correlation is low and the ratio of covariates to sample size is large. We note that the covariates typically used in GWAS rarely exhibit correlations with variants that are large enough to cause substantial differences between ATR and MLR. However, ATR may exhibit substantial loss of power for variants that are in high linkage-disequilibrium with variants included as covariates during regional conditional analysis.

Estimates of genetically regulated gene expression and associated genetic predictors explain variance of type 2 diabetes. *J. Torres[1], H. Wheeler[1], E. Gamzon[2], K. Shah[1], N. Knoblauch[3], J. Below[4], C. Hanis[4], D. Nicolae[1], N. Cox[2], H. Im[1], The GTEx Project.* 1) Medicine/Genetic Medicine, The University of Chicago, Chicago, IL; 2) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 3) Committee of Genetics, Genomics and Systems Biology, The University of Chicago, Chicago, IL; 4) Department of Epidemiology, Human Genetics and Environmental Sciences, The University of Texas Health Sciences Center at Houston, Houston, TX.

Expression quantitative trait loci (eQTLs) mapped in insulin-responsive peripheral tissues are not only enriched among the set of variants that associate most strongly with type 2 diabetes (T2D) but they also account for a disproportionate share of disease heritability. This highlights an important role for variants regulating gene expression in the genetic architecture of T2D risk and provides an avenue for improved disease gene mapping. One approach that leverages the plethora of functional genetic data from large-scale collaborative efforts such as the Genotype-Tissue Expression Project (GTEx) is Predicted Expression Scan (PrediXcan), whereby machine learning approaches are used to train models that estimate the genetic component of gene expression for each gene expressed in a tissue. These predicted expression traits are then used as the basis for a gene-based association test that provides tissue-level and directional information. Here, we apply penalized regression to genotype and RNA-seq data for 14 T2D-relevant tissues (including subcutaneous adipose, liver, pancreas, and skeletal muscle) from the GTEx project to identify a set of SNP predictors of tissue-dependent gene expression. We investigated both the T2D heritability accounted for by these predictors in the WTCCC and Starr County, TX, T2D datasets as well as the phenotypic variance explained collectively by the predicted transcriptome – a measure we term "regulability" (in contrast to heritability). We show that SNP sets of predictors of gene expression explain disproportionately high (relative to the number of markers in each SNP set) shares of disease heritability (7-fold enrichment over SNP set proportion for Whole Blood eQTLs) and that regulability estimates account for significant portions of the phenotypic variance of T2D for each of the evaluated tissues (across tissues, the mean proportion of explained variance = 0. 15 ±0. 03 and 0. 38 ±0. 09 for WTCCC and Starr County, respectively). These results support the utility of applying predicted expression to gene mapping and implicate an important role for eQTLs that elicit effects across tissues.

Background: Preeclampsia is a hypertensive complication of pregnancy characterized by novel onset of hypertension after 20 weeks gestation, accompanied by proteinuria. Affecting over 5% of pregnancies, preeclampsia represents a substantial burden to maternal and neonatal health. Epidemiological evidence suggests that genetic susceptibility exists for preeclampsia; however, whether preeclampsia is the result of underlying genetic risk for essential hypertension has yet to be investigated. Based on the hypertensive state that is characteristic of preeclampsia, we aimed to determine if established genetic risk scores (GRS) for hypertension and blood pressure are associated with preeclampsia. **Methods:** Subjects consisted of 162 preeclamptic cases and 108 normotensive pregnant controls, all of Iowa residence. Subjects' DNA was extracted from buccal swab samples and genotyped on the Affymetrix Genome-wide Human SNP Array 6. 0 (Affymetrix, Santa Clara, CA). Missing genotypes were imputed using MaCH and Minimac software. GRS were calculated for hypertension, systolic blood pressure (SBP), diastolic blood pressure (DBP) and mean arterial pressure (MAP) using established genetic risk loci for each outcome. Regression analyses were performed to determine the association between GRS and risk of preeclampsia. These analyses were replicated in an independent US population of 516 cases and 1,097 controls of European ancestry. **Results:** GRS for SBP and DBP were associated with their respective blood pressure measurements, demonstrating that these GRS are valid indicators of genetic contribution to blood pressure. GRS for hypertension, SBP, DBP and MAP were not significantly associated with risk for preeclampsia ($p>0.189$). The results of the replication analysis also yielded non-significant associations between GRS and risk for preeclampsia. **Conclusions:** Genetic risk scores for hypertension and blood pressure are not associated with preeclampsia, suggesting that an underlying predisposition to essential hypertension is not on the causal pathway of preeclampsia. These results suggest that preeclampsia is not an early manifestation of increased genetic risk for chronic hypertension, but rather that it represents a unique hypertensive state. These results also suggest that the increased risk for chronic hypertension following a preeclamptic pregnancy is due to the vascular damage accrued during preeclampsia.

1356W

Isovaleryl-CoA dehydrogenase as a drug target for fibrotic idiopathic interstitial pneumonias. *S. Ross[1], M. Narahara[2,3], N. Soranzo[4,5], J. B. Richards[1,2,6,7].* 1) Centre for Clinical Epidemiology, Department of Epidemiology, Lady Davis Institute for Medical Research, Jewish General Hospital, McGill University, Montreal, Quebec, Canada; 2) Department of Human Genetics, McGill University, Montréal, Québec, Canada; 3) Genome Quebec Innovation, Centre Montreal, Quebec, Canada; 4) Department of Human Genetics, Wellcome Trust Sanger Institute, Hinxton, UK; 5) Department of Hematology, University of Cambridge, Cambridge, UK; 6) Department of Medicine, McGill University Montreal, Quebec, Canada; 7) Department of Twin Research and Genetic Epidemiology, King's College London, UK.

Background: Drug development for complex disease has a high failure rate, due in part to a lack of validated drug targets. Human genetics provides the opportunity to identify causal drug targets in humans, and this paradigm is simplified in the case of metabolomics, where the genetic variants influencing metabolite levels are controlled by few, or even a single enzyme. Using fibrotic idiopathic interstitial pneumonias (IIPs) as an exemplar complex disease, we sought to determine whether the genetic variants underpinning IIPs also directly influence metabolite levels, using the largest GWAS datasets available to date. **Methods and Results**: Effect size estimates of common genetic variants associated with serum metabolite levels were obtained from our previously published GWAS of 7,824 Europeans participants. The corresponding effect estimates of these SNPs on the risk of IIPs were obtained from a GWAS of 9,065 participants of European descent. The rs2034650 [A] polymorphism (near *IVD*) was associated with reduced levels of isovalerylcarnitine (b= -0. 0184, 95% confidence interval (CI): -0. 024, -0. 013; P= 7. 5x10-12) and an increased risk of IIP (odds ratio (OR): 1. 30, 95% CI: 1. 19-1. 41; P= 1. 0x10-11). *IVD* is a mitochondrial matrix enzyme that encodes for isovaleryl-CoA dehydrogenase, which is involved in the production of isovalerylcarnitine. Furthermore, the IVD eQTL (rs2034650; P= 1. 0x10-6, n=142) was significantly associated with skeletal muscle, a major source of mitochondrial metabolites. **Conclusion**: Our results demonstrate the potential role of IVD in the etiology of IIP and provide evidence that IVD is a drug target for the treatment of IIP. These results also provide evidence that metabolomics are a rich source of information for validating drug targets in humans.

1357T

Polygenic risk prediction model based on winner's curse correction and multidimensional thresholding. *N. Chatterjee, J. Shi.* National Cancer Institute, Rockville, MD.

BackgroundEstimates of heritability suggest that genome-wide association studies (GWAS) have the potential to improve genetic risk prediction models, but SNPs discovered at the genome-wide significance level typically have low discriminatory power. **Methods**We explore methods for optimal thresholding and weighting SNPs to improve performance of models exploiting heritability in SNPs that do not achieve genomewide significance. We propose simple modifications to the widely used polygenic risk-score (PRS) modeling techniques that required availability of only GWAS summary-level data. First, motivated from the widely used algorithm lasso, we propose a threshold dependent winner's curse adjustment for marginal association coefficients that are used to weight the SNPs in PRS. Second, to exploit various external functional/annotation knowledge that might identify subset of SNPs highly enriched for association signals, we consider using multiple thresholds for SNPs selection based on group membership and identify optimal set of thresholds based on independent validation dataset. We use summary-level results from available from large GWAS of a wide variety of traits and independent validation datasets to assess the performance of these methods. We use a variety of recently available annotation database, expression and methylation trait analysis to identify groups of SNPs that are likely to be enriched with association and evaluate the utility of this information for risk-prediction for respective outcomes based on the proposed methods. We also study performance of the algorithm using simulation studies that incorporate realistic genetic architecture, linkage disequilibrium pattern and enrichment factor for underlying functional SNPs. **Results**Our analysis show that while a simple winner's curse correction uniformly lead to enhancement of performance of the models across traits, incorporation of functional SNPs was beneficial for only selected traits. Compared to standard PRS algorithm, the proposed methods in combination led to substantial efficiency gain (25-50% increase in the value Nagelkerk R2 statistics) for five out of fifteen different diseases we studied. Our simulation studies provided further clarification why differential treatment of certain category of functional SNPs, even when shown to be highly enriched for GWAS-heritability, does not lead to proportionate improvement in genetic risk-prediction due to non-uniform linkage disequilibrium structure.

1358F

Impact of Surrogate Variable Analysis on eQTL Discovery and Application to RNA-Seq Data. *C. Lu[1], L. Klei[2], K. Roeder[1], B. Devlin[2], The CommonMind Consortium.* 1) Department of Statistics, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213, USA; 2) Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania 15213, USA.

Many things affect gene expression, not all of them will have been measured in a genetic study of such expression. For example hidden variables could influence detection of quantitative trait loci (eQTLs) affecting gene expression. Leek and Storey (2007) proposed a statistical model, Surrogate Variable Analysis (SVA), to estimate the variability of gene expression that is accounted for by these hidden or surrogate variables, and in theory this approach should increase the power of identifying eQTLs. Surprisingly we are unaware of a comprehensive study of the performance of SVA. Hence we studied the performance of SVA for eQTL discovery and other features of expression analysis, evaluating its ability to detect and accurately account for such variables. To do so, we conducted simulation studies and applied SVA to the RNA-Seq data of gene expression from the CommonMind Consortium (CMC), which measured expression from >600 human brains. Simulations generated data involving both confounders and biological gene co-expression, all linear effects, and included cis-eQTLs, trans-eQTLs and differential expression according to disease status. We explored a variety of scenarios for hidden variables and gene co-expression, evaluating how the results of SVA compared to the true generating model (e. g. , coefficient estimates, standard error of coefficient estimates, p-values of estimates, gene clustering structure, False Discovery Rate (FDR), power). These simulations help interpret results from CMC RNA-Seq data, especially those from models with and without SVA. We find that SVA models gene co-expression as well as other hidden factors and thus its results can be challenging to interpret. On the other hand in most situations SVA performed well at estimating surrogate variables and did increase the power of eQTL discovery.

Estimating clinical outcomes and classifying *CFTR* variants of unknown significance in children with a positive newborn screening for Cystic Fibrosis. *D. Conti[1], C. Azen[2], D. Thomas[1], D. Salinas[2].* 1) Preventive Medicine, Univ Southern California, Los Angeles, CA; 2) Pediatrics, Univ Southern California, Los Angeles, CA.

Cystic Fibrosis (CF) is an autosomal recessive disorder caused by a defective trans-epithelial channel called Cystic Fibrosis Transmembrane Conductance Regulator (CFTR). The defective CFTR causes mucus secretions to become thick and viscous, obstructing the lungs and pancreas and consequently causing life-threatening lung infections and malnutrition. Each year approximately 3,700 infants in the US are identified through newborn screening (NBS) to be at risk for developing CF. While approximately 70% of CF cases of European ancestry are due to carrying two copies of the most common variant, F508del, other combinations of any two CF-causing variants can cause disease. With information on over 39,000 patients with CF, the Clinical and Functional TRanslation of CFTR (CFTR2) mutation database has assigned disease liability to 206 of the near 2,000 *CFTR* variants identified. Only 174 have been classified as CF-causing. Thus, there is a great need to predict the clinical outcomes in children with positive newborn screening and to predict the penetrance of variants of unknown significance (VUS). We present a Bayesian hierarchical model, with one level for the phenotypes (e. g. immunoreactive trypsinogen, sweat chloride concentration, pancreatic sufficiency status, *Pseudomonas aeruginosa* colonization), a level for the risk of CF given the disease-causing status of the joint genotype, and a level for the potential for disease-causing of each variant given external information (e. g. genomic annotation, population allele frequency, and CTFR2 database characteristics). We apply our model to data from 848 children with a positive screening test and 2 to 6 year of clinical follow up from over 2 million births from the California Newborn Screening Program. Of the 269 joint genotypes with a VUS, ~7-10% are estimated to have an elevated posterior probability of being classified a CF-causing variant. This translates to ~5% of the 593 individuals carrying a VUS having an elevated posterior probability of having CF. We demonstrate the sensitivity of estimation to various models forms (e. g. with and without phenotype information) and prior specifications (e. g. with and without genomic annotation). We discuss the use of this model to classify previously unobserved VUS, predict clinical status for newborns with a positive screening test, and to impact clinical care protocols.

1360T

Associations of high-risk genetic factors with dementia in the Korean elderly population. *J. J. Lee[1,6], K. Y. Choi[1,2], M. J. Kim[1], N. H. Kim[1,3], J. S. Lee[1,3], S. R. Kang[1,3], Y. Y. Choi[1,2], K. H. Lee[1,3,4,5].* 1) National Research Center for Dementia, Chosun University, Gwangju, South Korea; 2) Department of Premedics, College of Medicine, Chosun University; 3) Department of Life Science, College of Natural Sciences, Chosun University; 4) Department of Biomedical Science, College of Natural Sciences, Chosun University; 5) Department of Marine Life Science, College of Natural Sciences, Chosun University; 6) Department of Computer Science and Statistics, College of Natural Sciences, Chosun University, Gwangju, South Korea.

Dementia is a neurodegenerative disorder that causes cognitive dysfunction and behavioral symptoms. As the aging population in the world increases, the interest in early diagnosis of dementia is becoming a necessity. Genes associated with dementia can be found through Genome Wide Association Study(GWAS) with a large cohort. Although there are many GWAS studies with the Caucasian population, the studies for Asians, in particular Koreans are not sufficient. We have associated the previously reported high-risk single nucleotide polymorphisms (SNPs) with dementia in Korean population. This cohort study was designed with residents aged over 65 years and under 85 years in Gwangju city, Korea. 434 subjects were divided into the normal control group and the dementia group. With highly AD-associated 29 SNPs as reported previously, we have examined SNP genotyping for these subjects by Taqman Assay and Fluidigm using DNA extracted from the blood. We have analyzed the association of each SNP for dementia by logistic regression models using additive model after adjustment of the age, sex, APOE-ϵ4. The associated SNPs were rs11767557 (EPHA1). Odds ratio of rs11767557 is 0. 583 (95% CI:0. 353-0. 961). These results indicate the potential use of some SNPs as genetic markers for determining susceptibility to dementia in Korean population. The further study is necessary to validate the results of this study by using a different Korean elderly population. In addition, a molecular functional study will define the role of genetic polymorphisms in an animal model or *in vitro*.

A generalized joint location-scale association test for uncertain genotypes and related individuals. *D. Soave[1,2], L. Sun[1].* 1) University of Toronto, Toronto, Ontario, Canada; 2) The Hospital for Sick Children, Toronto, Ontario, Canada.

In genetic association studies, it has been pointed out that a number of biologically meaningful scenarios, including GxG and GxE interactions, can lead to variance (scale) heterogeneity of a quantitative trait across genotype groups, and corresponding scale tests have been developed. Recently, a joint location-scale testing framework was proposed for association analysis of genotyped SNPs in a population sample, combining evidence from both the traditional mean (location) test and the newer scale test to achieve better power [Soave, et al. 2015 AJHG in press]. Genotype uncertainty, however, is inherent in both imputed and sequenced data, and these DNA data are also commonly obtained on samples that include related individuals from families or cryptic relationships. A number of modified location tests have been proposed for these more complex data, but the lack of a generalized scale test remains the bottleneck in broader application of the joint location-scale association test. Among many testing procedures for variance heterogeneity, Levene's test is noted for its simplicity and robustness to departures from normality. Extending the work of Glejser [1969] and Iachine et al. [2010], we propose an easy-to-implement extension to Levene's method that formulates the variance test as a generalized least squares regression problem. Unlike Levene's original test, the regression framework is flexible to directly incorporate the probabilistic data associated with genotype uncertainty and the correlation structure associated with related individuals. Performance of the proposed method, including its validity and enhanced power, is demonstrated through simulations and applications.

Meta-Analysis for Discovering Rare-Variant Associations:Statistical Methods and Software Programs. *Z. Tang[1], D. Lin[2].* 1) Biostatistics, Vanderbilt University, Nashville, TN; 2) Biostatistics, University of North Carolina, Chapel Hill, NC.

There is heightened interest in using next-generation sequencing technologies to identify rare variants that influence complex human diseases and traits. Meta-analysis is essential to this endeavor because large sample sizes are required to detect associations with rare variants. In this work, we provide a comprehensive overview of statistical methods for meta-analysis of sequencing studies to discover rare-variant associations. Specifically, we discuss the calculation of relevant summary statistics from participating studies, the construction of gene-level association tests, the choice of transformation for quantitative traits, the use of fixed-effects versus random-effects models, and the removal of shadow association signals through conditional analysis. We also show that meta-analysis based on properly calculated summary statistics is as powerful as joint analysis of individual-participant data. In addition, we demonstrate the performance of different meta-analysis methods using both simulated and empirical data. We then compare four major software packages for meta-analysis of rare-variant associations -- MASS, RAREMETAL, MetaSKAT, and seqMeta -- in terms of the underlying statistical methodology, analysis pipeline, and software interface. Finally, we present a software interface, PreMeta, that integrates the four meta-analysis packages and allows a consortium to combine otherwise incompatible summary statistics.

1363T

Non-Parametric Analysis reveals Novel Genetic Associations with variation in Plasminogen Activator Inhibitor-1 levels. *M. J. White[1,2,3], N. M. Kodaman[2,3], R. H. Harder[3], F. W. Asselbergs[4,5,6], D. E. Vaughan[7], N. J. Brown[8], J. H. Moore[3], S. M. Williams[3].* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) Center for Human Genetics Research, Vanderbilt University, Nashville, TN; 3) Department of Genetics and Institute of Quantitative Biomedical Sciences, Dartmouth College, Hanover, NH; 4) Department of Heart & Lungs, University Medical Center Utrecht, Utrecht, The Netherlands; 5) Institute of Cardiovascular Science, University College London, London, UK; 6) Durrer Center for Cardiogenetic Research, ICIN-Netherlands Heart Institute, Utrecht, The Netherlands; 7) Department of Medicine, Northwestern University, Feinberg School of Medicine, Chicago, IL; 8) Department of Medicine Vanderbilt University, Nashville, TN.

Background: Cardiovascular disease (CVD) consists of multiple conditions with overlapping environmental and genetic risk factors, symptoms, and etiologies. It is a leading cause of death both in the United States and globally. Plasminogen activator inhibitor 1 (PAI-1), a major modulator of the fibrinolytic system, is an important factor in cardiovascular disease CVD susceptibility and severity. PAI-1 is highly heritable, but the few genes associated with it explain only a small portion of its variation. Studies of PAI-1 typically employ linear regression to estimate effects of genetic variants on levels, but PAI-1 is not normally distributed, even after transformation. Therefore, alternative statistical methods may provide greater power to identify important genetic variants. Also, the majority of studies aimed at evaluating the role of genetic variation in PAI-1 have been conducted in Asian and Caucasian populations and in these studies results indicate that genetic impact on PAI-1 levels may be population-specific. To our knowledge, our study represents one of the only large scale evaluation of the impact of genetic variants on PAI-1 in an African population. **Methods and Results:** We analyzed >30,000 variants for association with PAI-1 in a Ghanaian population (n=1105), using median regression, a non-parametric alternative to linear regression. Three variants associated with median PAI-1, the most significant of which was in the gene *arylsulfatase B* (*ARSB*) (p=1. 09 x 10-7). We also analyzed the upper quartile of PAI-1, the most clinically relevant part of the distribution, and found 19 additional SNPs significantly associated in this quartile. Of note, a significant association was discovered between elevated PAI-1 levels and a variant in *period circadian clock 3* (*PER3*). **Conclusions:** Our results reveal novel associations with median and elevated PAI-1 in an understudied population. The lack of overlap between the two analyses indicates that the genetic effects on PAI-1 are not uniform across its distribution; this may impact the development of future therapies and clinical interventions. We also provide evidence of a possibly generalizable circadian clock pathway effect on PAI-1, as a recent meta-analysis performed in Caucasian populations identified another circadian clock gene (*ARNTL*).

Evaluation of alternative imputation strategies for mega-analysis of multiple genotyping cohorts: maximizing imputation yield while minimizing artifacts. *S. C. Nelson[1], D. M. Levine[1], B. Storer[2], L. P. Zhao[2], E. H. Warren[2], P. J. Martin[2], J. A. Hansen[2].* 1) Biostatistics, University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

A key consideration in modern GWAS is how to merge datasets genotyped on different arrays. Genome-wide imputation is an attractive solution that provides a set of variants common to each dataset. However, artifacts leading to false-positive associations are a significant concern and no single multi-platform imputation strategy has emerged as a standard. We have extensively assessed three imputation strategies in a hematopoietic stem cell transplantation study comprising three genotyping arrays: Affymetrix 5. 0 (n=2,999), Illumina Omni1M (n=4,114) and Illumina Omni2. 5 (n=2,219). Using the SHAPEIT2/IMPUTE2 software suite and a 1000 Genomes (1000G) Project Phase 3 reference panel, we assessed the following three imputation strategies: (1) imputing the cohorts together to 1000G using only the three-way intersection of array variants; (2) a two-stage approach in which the Omni2. 5 cohort was first used as an internal reference panel to impute the Affymetrix and Omni1M cohorts, followed by imputation to 1000G; and (3) imputing each cohort separately to 1000G. We sought to identify the strategy that maximized imputation yield (i. e. , the number of imputed variants passing a minimum quality threshold) while minimizing imputation artifacts between batches. We evaluated imputation yield by determining the number of imputed variants passing increasingly stringent quality metrics thresholds (IMPUTE2 “info” score cutoffs). We evaluated imputation artifacts between batches by both (1) calculating the correlation in imputed dosages between cross cohort duplicate sample pairs and (2) examining false positive rates from pseudo-association tests where case/control status was defined by genotyping cohort. While strategy 1 yielded the least imputation artifacts, the relatively sparse imputation basis resulted in the lowest imputation yield. Strategy 2 with a stringent filter on internally-imputed variants yielded well-imputed variants while minimizing batch effects; however, the multi-stage strategy introduced some bias from the Affymetrix cohort having a lower stage 1 call rate compared to Omni1M. Notably, strategy 3 produced relatively few artifacts and reasonable imputation yield. We show that while genotyping cohorts can successfully be merged, considerable attention should be paid to selecting imputation basis variants and that the most straightforward method of imputing cohorts separately and combining for mega analysis (strategy 3) may indeed be the most viable option.

1365W

Finding and characterizing latent genetic sub-structure for imprecisely defined phenotypes. *H. Finucane[1,2], N. Fusi[1], A. Price[2], J. Listgarten[1].* 1) Microsoft Research New England; 2) Harvard School of Public Health.

Some case-control phenotypes, labelled only with 0/1, may actually contain distinct underlying sub-phenotypes; for example, depression is thought to be such a phenotype. Analysis of such imprecisely defined phenotypes has negative consequences. First, it obscures genetic signal, decreasing apparent heritability as well as power for association analysis. Second, it obscures understanding of disease, because only a union of causal genes and pathways can be uncovered. In this work, we apply latent variable models to extract sub-phenotypes jointly from both genotypic and phenotypic data in order overcome these problems. In particular, we seek to identify sub-phenotypes that have higher heritability individually than when grouped together as a single phenotype. We compare several newly-developed methods on simulated data, assessing the relative power and computational complexity of the methods as a function of sample size, level of shared genetic architecture among the sub-phenotypes, polygenicity of the trait, and existence of available auxiliary phenotype information.

Implications of the Co-Dominance Model for Hardy-Weinberg Testingin Genetic Association Studies. *S. Wellek.* Central Institute of Mental Health, University of Heidelberg, Heidelberg, Germany.

The standard way of using tests for compatibility of genetic markers with HWE as a means of quality control in GWAS is to carry out this step of preliminary data analysis with the sample of non-diseased individuals only. We show that this strategy has no rational basis whenever the marker under consideration satisfies the assumption of co-dominance. The mathematical argument behind this statement is made precise and proven as a lemma. The major practical consequence of this theoretical result is that under the co-dominance model, testing for HWE should be done both for cases and controls aiming to establish the combined (intersection) hypothesis of compatibility of both underlying genotype distributions with the HWE assumption. A particularly useful procedure serving this purpose is obtained through applying the confidence-interval inclusion rule derived by Wellek, Goddard & Ziegler (Biom J. 2010; 52:253-270) to both samples separately and combining these two tests by means of the intersection-union principle.

1367F

An approach combining the construction of haplotype collection and the design of population-optimized SNP array on the large-scale whole genome-sequencing project in Japan. *Y. Kawai[1,2], T. Mimori[1], K. Kojima[1,2,4], N. Nariai[1,2], I. Danjoh[1,2], R. Saito[1], M. Yamamoto[1. 2], M. Nagasaki[1,2,3,4].* 1) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Graduate School of Medicine, Tohoku University, Sendai, Miyagi, Japan; 3) Graduate School of Information Sciences, Tohoku University, Sendai, Miyagi, Japan; 4) Department of Cohort Genome Information Analysis, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan.

Genotype imputation is now prerequisite for genome-wide association study (GWAS). Accurate genotype imputation enables to test millions of variants that have been discovered in large-scale whole-genome sequencing project in array-based GWAS. We conducted the whole-genome sequencing of healthy individual in Tohoku region in Japan in the part of prospective genome cohort study and constructed haplotype collection of 1,070 people of cohort participants for the reference panel of whole-genome imputation (referred to as the 1KJPN panel). Furthermore, we developed the customized SNP array "Japonica array" that is optimized for the genotype imputation using the 1KJPN panel. Japonica array contains 659,253 SNPs, including tag SNPs for imputation, SNPs of Y chromosome and mitochondria, and SNPs related to previously reported genome-wide association studies and pharmacogenomics. The imputation performance of Japonica array was compared to the existing GWAS arrays using the 1KJPN panel and the international 1000 genomes project panel. The Japonica array with the 1KJPN panel exhibited better imputation performance over other combinations of SNP array and reference panel. The genomic coverage of imputed genotypes ($r2$ >0. 8) with the Japonica array were 96. 9% and 67. 2% for common (MAF > 5%) and low-frequency SNPs (0. 5% < MAF ≤ 5%), respectively, when the 1KJPN panel is used as reference panel. We demonstrated that the creation of custom-made SNP arrays based upon a population-specific reference panel is a practical way to facilitate further association studies through genome-wide genotype imputations.

1368W

Detecting the source of DNA contamination in genotyping arrays. *G. J. M. Zajac[1,2], L. G. Fritsche[1,2], S. L. Dagenais[3], R. H. Lyons[3], C. M. Brummett[4], G. Abecasis[1,2].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 3) Department of Biological Chemistry and DNA Sequencing Core, University of Michigan, Ann Arbor, MI; 4) Department of Anesthesiology, Division of Pain Medicine, University of Michigan Medical School, Ann Arbor, MI.

Genotyping arrays measure the relative intensities of allele specific probes, which are then used to call the genotype at each locus. The mixture of DNA samples prior to genotyping, known as contamination, increases the probability that the calling software fails to call a genotype or makes an incorrect call, ultimately reducing the power and accuracy of follow-up genetic analyses, such as GWAS. Often, DNA contamination occurs when two or more samples become physically mixed while preparing the genotyping array, making certain contamination scenarios, like the mixture of two samples in adjacent wells on the array, more likely than others. Existing methods to detect the presence of contaminating DNA use deviations from the expected allele intensities in apparently homozygous reference, heterozygous, or homozygous alternate genotypes towards intensities that would be expected based on population allele frequencies at the locus. Here, we propose an improvedmodel that compares the allele specific intensity patterns between pairs of genotyped individuals to identify the source of DNA contamination. Maximizing the likelihood function over not only the proportion of contaminating DNA but also the contributing individual allows an estimate of the most probable contaminant. This approach has several advantages over existing methods and leads to more accurate estimation of the proportion of contaminating DNA. For example, our new approach should be less sensitive to the misspecification of population allele frequencies, which could lead to inaccurate estimates of contamination levels. Furthermore, if the mixed samples are related, then estimated contamination proportions derived using our method should remain accurate independent of the degree of genetic similarity between the mixed samples, whereas existing methods would underestimate this proportion. Importantly, our detecting the source of contamination provides useful information to guide improvements in sample processing and preparation protocols. Experimental results from an ongoing genotyping study of more than 15,000 individuals illustrate how estimating which samples on an array contributed to contamination helps draft effective laboratory protocols to prevent the mixture of DNA samples.

Genetic architecture and disease prediction. *E. Ziv, D. Hu.* UCSF, San Francisco, CA.

Genome wide association studies have identified dozens to hundreds of common single nucleotide polymorphisms (SNPs) for many complex traits. However, most of the heritabillity for most complex traits remains unexplained. Still, for many complex traits, combining all of the known SNPs and some high penetrance mutations which are known to cause disease, can provide some information on risk classification. Here we use some analytical approaches and simulations to address the question of what types of study designs would yield the best discoveries in terms of disease predictionWe use the receiver operator characteristic (ROC) area under the curve (AUC) as the measure of power and use parameters such as allele frequencies and relative risks from studies of breast cancer. Analyzing data from known common single nucleotide polymorphisms and mutations in susceptibility genes contribute to current predictive power. Then, we partition the remaining familial risk into common and rare variants. We show that assuming power for discovery is constrained by sample size only (ie full genome sequence is available), then the greatest boost to ROC AUC is from lowest frequency, highest penentrance variant that can be discovered by the given sample size. We then consider the possibility that some loci can only be discovered by combining evidence from many low frequency variants. We consider that not some risk variants may be misclassified at these loci and evaluate the loss of power for disease prediction under these circumstances. Overall, we find that additional discoveries of low frequency, intermediate penetrance risk variants should yield more predictive power than additional discoveries of common low penetrance risk variants.

1370F

Plan a large-scale genetic association study for predictive modelling. *C. Kuo.* Community Medicine and Health Care, Connecticut Institute for Translational Science, Institute for Systems Genomics, University of Connecticut Health Center, Farmington, CT.

With more and more susceptibility loci identified, the findings can be utilized for disease screening and diagnosis. Typically, a number of risk variants are selected to predict the outcome using a simple method such as logistic regression model for case-control studies. It has been known that a model that includes functional and/or (statistically) significant variants only doesn't lead to a high predictive power and the power significantly improves when using a moderate number of top hits from a large-scale genetic association study. Traditionally, a genetic association study is planned such that the true variants with effect sizes in a range will be detected or saying statistically significant. Motivated by the fact that a discovery study planned this way is not optimal for predictive modelling, I propose a method to calculate predictive power given a sample size, a rank or significance threshold, and other prior information. In other words, this method would allow one to choose a sample size and a number of top hits for a pre-specified predictive power. This method has been validated by simulations and implemented in R for practical use.

1371W

The Alzheimer Disease Sequencing Project: Design and Sample Selection. *G. Beecham on behalf of the Alzheimer Disease Sequencing Project.* Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst. for Human Genomics, University of Miami, Miami, FL.

The Alzheimer Disease Sequencing Project (ADSP) is an initiative to identify genetic variants influencing late-onset Alzheimer Disease (LOAD) risk and protection, with the goal of defining novel drug targets to treat AD. Given a limited budget and large number of samples available, we considered several study designs to maximize power. We chose a family design for whole genome sequencing (WGS), as linkage helps prioritize variants for follow-up. 1,400 multiplex LOAD families were evaluated. Families were of European (EA) and Caribbean Hispanic (CH) ancestry and lacked known mutations for AD. Families were ranked according to number of cases, generations/branches sampled, and lack of APOE e4 alleles. For whole exome sequencing (WES) we considered several case-control designs to select samples from over 30,000 samples available. These included: an unbalanced design with a greater number of cases (to maximize rare AD variants identified), a balanced design optimized to uncover protective variants (comparing high risk AD cases to high risk controls), and a balanced design focused on reducing heterogeneity and misclassification (by comparing low risk cases --younger, few APOE e4--to controls least likely to develop AD by age 85). Risk and rate of conversion to AD were estimated using age, sex and APOE status, and Braak score at autopsy if available. The utility of other AD risk alleles in evaluation was considered. Designs were compared for their power to detect risk and protective variants, allowing for genetic heterogeneity and misclassification. All cases from 111 Tier 1 families were sequenced (N=578). Array data were obtained on all family members to aid QC and linkage. Balanced designs had higher power than unbalanced and protective designs had lower power to identify risk variants. The third design (reduced misclassification and heterogeneity) was well-powered for risk and protective loci. Accordingly, we selected 5,107 cases (age-at-onset=76+/-9. 1;43% male) and 4,976 controls (age-at-exam=86+/-5. 7,41% male). Additional samples include 512 EA and 173 CH cases from lower tier families. This approach balances power and cost considerations while targeting a variety of important hypotheses (risk, protective, SNV, CNV, coding, non-coding, etc), and reflects the design of an important resource for AD genomics research. Additionally, the approach can be utilized by other late-onset, progressive disorders to better maximize power and sample availability.

1372T

PMAD: Precision Medicine Adaptive Designs for Validation of Genetic Biomarker Information for Targeted Therapeutics. *Q. Wu, M. V. Gwengi, L. B. Gillis.* BioStat Solutions, Inc 5280 Corporate Drive Suite C200 Frederick, MD, 21703.

Background: Precision medicine aims to deliver the 'right' drug to the 'right' patient at the 'right' dose at the 'right' time. An important application of precision medicine is in using genetic biomarker information to identify a subpopulation that may show enhanced drug performance. Once a biomarker model has been developed based on (retrospective) clinical trial data, it must be independently validated before the biomarker can be used as a companion diagnostic. Adaptive designs may be advantageous for this validation. Methods: The direct approach to validate the biomarker is to run a clinical trial to evaluate the identified biomarker model and its threshold. Since the genetic signature was derived from limited clinical data, it may not be truly replicable. However, refinements to the biomarker may yield more precise identification of the 'right' patient for the drug with additional study data. With an adaptive design, an interim look could provide information about whether or not the biomarker is replicable as well as how to improve the biomarker profile. An alternative approach is to employ Bayesian methods to update the biomarker model and/or threshold. Both the biomarker model and the threshold are available as prior information. In the adaptive design, the data available at the interim analysis will be used to create a posterior estimate of the genetic signature and corresponding threshold. This new biomarker profile will be independently validated in the second stage of the study. Results: Simulation studies are used to compare the performance of the two proposed validation designs under different scenarios. This newly proposed approach offers scientific innovation, potential cost savings, and increased likelihood of successfully targeting the 'right' patients based on their genetic signature.

1373F

Methodology for the analysis of multi-ethnic genome-wide association studies. *J. P. Cook, A. P. Morris.* Department of Biostatistics, Farr Institute, Liverpool, Liverpool, United Kingdom.

Traditional genome-wide association studies (GWAS) have primarily been conducted using collections of individuals from homogeneous population groups because: (i) geographical confounding between the trait and genetic variation can inflate type I error rates, if not accounted for; and (ii) there may be reduced power due to heterogeneity in allelic effects on the trait between ethnicities. Confounding is typically accounted for by including principal components (PCs) as covariates in a regression framework, and has been demonstrated to control type I error rates within ancestry groups. However, by including genetic data from diverse populations, the first two PCs have also been demonstrated to generate axes of genetic variation that are anchored by individuals of African, European and East Asian ancestry. In this study, we have undertaken simulations of binary outcomes and GWAS data from diverse ancestries to evaluate: (i) type I error and power to detect association in multi-ethnic analyses with adjustment for PCs; and (ii) power to detect heterogeneity in allelic effects between populations by including an interaction between a SNP and the first two PCs. Simulation results demonstrate that type I error rates are controlled by including 10 PCs as covariates in the regression analysis, even in the presence of extreme population structure, and that power to detect heterogeneity between populations is strong, even at modest effect sizes. We applied these methods to a multi-ethnic GWAS of type 2 diabetes (T2D) in the Resource for Genetic Epidemiology Research on Adult Health and Aging (GERA). After quality control, 71,604 unrelated participants, including 9,747 T2D cases, were retained for analysis and imputed up to the multi-ethnic reference panel (Phase 3, October 2014) from the 1000 Genomes Project. Lead SNPs at ten loci attained genome-wide significant evidence ($p<5x10-8$) of association with T2D, including a novel signal mapping to *TOMM40* ($p=2.8x10-9$), a gene previously implicated in Wolfram Syndrome, a neurodegenerative disorder characterised by diabetes. In conclusion, our study demonstrates that incorporation of PCs in multi-ethnic GWAS can fully account for population structure, and can be used to detect heterogeneity in allelic effects between ancestry groups. Furthermore, we provide further insight into the genetic architecture of T2D, and highlight the benefits of multi-ethnic analysis for the discovery of novel loci associated with complex diseases.

1374W

The LASER server: a web-based tool for tracing individual ancestry in a reference principal component space. *D. Taliun[1], S. Schönherr[2], L. Forer[2], M. Boehnke[1], G. Abecasis[1], C. Wang[3].* 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Division of Genetic Epidemiology, Department of Medical Genetics, Molecular and Clinical Pharmacology, Innsbruck Medical University, Innsbruck, Austria; 3) Department of Computational and Systems Biology, Genome Institute of Singapore, Singapore.

Recent genetic association studies focus on detecting association with rare variants, an analysis that typically requires large samples to achieve reasonable statistical power. Augmenting case samples with ancestry matched controls from other studies is a cost effective and attractive way to improve statistical power. A first step in identifying these ancestry matched controls is to define the ancestry of samples from different studies in the same coordinate space. Wang et al. (2014, 2015) introduced the LASER framework that unifies ancestry estimation for sequenced and genotyped samples in a predefined principal component space, providing a way to facilitate control of population stratification in joint analysis of multiple genetic datasets. Given a set of reference samples (for example, the 1000 Genomes Project samples), LASER can place sequenced or genotyped samples in the same ancestry coordinate space – even when samples are genotyped with different arrays, sequenced at only a few genes or the whole exome, or genome sequenced at different depths. To facilitate and simplify ancestry estimation using a shared coordinate space, we developed the LASER server, a web-based ancestry estimation tool with build-in ancestry reference panels for different geographic regions. The LASER server has a user-friendly web interface for job submission and monitoring and generates interactive web-based visualization of estimated ancestries. We parallelized the computations by adapting LASER's implementation to the MapReduce paradigm so that our server can deliver results in a timely fashion even for large datasets. As a result, the LASER server allows samples from different sources to be mapped to a shared ancestry coordinate space. Using these coordinates, samples can be precisely ancestry matched across studies to help identify opportunities to increase the study sample without introducing population stratification. The server can be accessed at http://laser. sph. umich. edu.

Unified tests for fine scale mapping and identifying sparse high-dimensional sequence associations. *S. Cao[1,2], H. Qin[2,3], A. Gossmann[2,4], H. Deng[2,3], Y. Wang[1,2,3].* 1) Department of Biomedical Engineering, Tulane University, New Orleans, LA; 2) Center for Bioinformatics and Genomics, Tulane University, New Orleans, LA; 3) Department of Biostatistics and Bioinformatics, Tulane University, New Orleans, LA; 4) Department of Mathematics, Tulane University, New Orleans, LA.

Motivation: In searching for genetic variants for complex diseases with deep sequencing data, genomic marker sets of high-dimensional genotypic data and sparse functional variants are quite common. Existing sequence association tests are incapable to identify such marker sets and individual causal loci, although they appeared powerful to identify small marker sets with dense functional variants. In sequence association studies of admixed individuals, cryptic relatedness and population structure are known to confound the association analyses. **Method:** We here propose a unified test (uFineMap) to accurately localize causal loci and a unified test (uHDSet) for identifying high-dimensional sparse associations in deep sequencing genomic data of multi-ethnic individuals. These novel tests are based on scaled sparse linear mixed regressions with Lp ($0<p<1$) norm regularization. They jointly adjust for cryptic relatedness, population structure and other confounders to prevent false discoveries and improve statistical power for identifying promising individual markers and marker sets that harbor functional genetic variants of a complex trait. **Results:** Under a wide range of simulated scenarios, the proposed tests appropriately controlled Type I error rate and appeared more powerful than several existing prominent methods. We illustrated their practical utilities by the applications to DNA sequence data of Framingham Heart Study for osteoporosis. The proposed tests identified 11 novel significant genes that were missed by the prominent famSKAT and GEMMA. In partiicular, four out of six most significant pathways identified by the uHDSet but failed by famSKAT have been reported to be related to BMD or osteoporosis in the literature.

1376F

Evidence for Further Colorectal Cancer Susceptibility Genes in Addition to the Mismatch Repair Genes and *MUTYH*. *M. Jenkins[1], A. K. Win[1], J. G. Dowty[1], A. C. Antoniou[2], A. Lee[2], G. G. Newcomb[11,12], J. L. Hopper[1], R. J. MacInnis[1,3].* 1) Centre for Epidemiology and Biostatistics, The University of Melbourne, Carlton, Australia; 2) Centre for Cancer Genetic Epidemiology, Department of Public and Primary Care, University of Cambridge; 3) Cancer Epidemiology Centre, Cancer Council Victoria, Melbourne, Victoria, Australia; 4) Oncogenomics Group, Genetic Epidemiology Laboratory, Department of Pathology, The University of Melbourne, Parkville, Victoria, Australia; 5) University of Colorado School of Medicine, Denver, Colorado, USA; 6) Molecular Genetics Laboratory, Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, Minnesota, USA; 7) Department of Preventive Medicine, Keck School of Medicine and Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, California, USA; 8) Lunenfeld Tanenbaum Research Institute, Mount Sinai Hospital, University of Toronto, Toronto, Ontario, Canada; 9) University of Hawaii Cancer Center, Honolulu, Hawaii, USA; 10) Department of Medicine, Division of Oncology, Stanford Cancer Institute, Stanford University, California, USA; 11) School of Public Health, University of Washington, Seattle, Washington, USA; 12) Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, Washington, USA; 13) Centre for Public Health Research, Massey University, Wellington, New Zealand; 14) Department of Health Science Research, Mayo Clinic Arizona, Scottsdale, Arizona, USA.

Background: Familial aggregation of colorectal cancer is probably due to multiple susceptibility genes, perhaps acting in conjunction with shared lifestyle risk factors. The aim of this paper was to investigate the genetic models that can best explain familial colorectal cancer not due to the DNA mismatch repair (MMR) genes or *MUTYH,* and to accurately estimate the mutation carrier frequency in the population*.* **Methods**: We studied 5,744 colorectal cancer cases (probands) who were recruited from population cancer registries from the US, Canada and Australia between 1997 and 2012. Blood samples taken from the probands were analysed for mutations in MMR genes and *MUTYH*. We investigated major gene models (dominant, recessive, general), polygenic models, and mixed models (both major gene and polygenic) by analysing information on cancer history in first-degree relatives and on the mutation status of the probands using the pedigree analysis software MENDEL. We estimated the simultaneous effects of MMR genes (*MLH1, MSH2, MSH6, PMS2*), *MUTYH*, a sixth hypothetical gene GENE6, and a polygenic effect. The models were assessed by likelihood comparisons and by comparison of the observed numbers of mutations and affected relatives with the predicted numbers. **Results**: The best-fitting model was mixed dominant model with an age-dependent polygenic standard deviation on top of the five known genes. Under this model, the estimated mutation frequency for GENE6 was 0. 10% (95% confidence interval [CI], 0. 02% – 0. 54%) and the relative risk for GENE6 mutation carriers was 31. 1 (95% CI, 11. 6 – 83. 4). The standard deviation of the polygenic component was 1. 81 (95% CI, 1. 05 – 3. 12) for age <40 years, 0. 96 (95% CI, 0. 51 – 1. 82) for age 40-49 years, 0. 68 (95% CI, 0. 34 – 1. 34) for age 50-59 years, 0. 89 (95% CI, 0. 52 – 1. 51) for age 60-69 years, and 0. 72 (95% CI, 0. 40 – 1. 28) for age ≥70 years. The estimated population allele frequency (%) was 0. 026 (95% CI, 0. 020 – 0. 034) for *MLH1*, 0. 018 (95% CI, 0. 013 – 0. 024) for *MSH2*, 0. 066 (95% CI, 0. 044 – 0. 098) for *MSH6*, 0. 070 (95% CI, 0. 047 – 0. 104) for *PMS2*, and 1. 11 (95% CI, 0. 95 – 1. 30) for *MUTYH*. **Conclusions**: These findings suggest that it is more likely that the remaining familial aggregation of colorectal cancer is due to a major gene on top of many low-risk variants than due to many low-risk variants alone. We have also provided accurate estimates of the carrier frequency of a MMR gene and *MUTYH* in the population.

Methods for detecting modifier genes responsible for phenotypic heterogeneity. *J. C. Carlson[1], E. J. Leslie[2], J. R. Shaffer[3], H. Schwender[4], M. A. Taub[5], I. Ruczinski[5], J. C. Murray[6], T. H. Beaty[7], M. L. Marazita[2], E. Feingold[3,1].* 1) Biostatistics, University of Pittsburgh, Pittsburgh, PA; 2) Oral Biology, University of Pittsburgh, Pittsburgh, PA; 3) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 4) University of Dusseldorf; 5) Biostatistics, Johns Hopkins University, Baltimore MD; 6) Bill and Melinda Gates Foundation; 7) Epidemiology, Johns Hopkins University, Baltimore MD.

Phenotypic heterogeneity is a hallmark of common, complex diseases. Combining similar phenotypes for analysis is a common approach when it is hypothesized that they share a common genetic etiology. Alternatively, each of the phenotypes may have unique genetic susceptibilities and underlying pathophysiology. Or, phenotypes may share some genetic risk factors while others are modifier genes that define a particular subphenotype or a more extreme phenotype. We evaluated several different approaches for finding genes under these models, considering both population-based and family-based data. In particular, we compared a case-case analysis that compares subphenotypic groups to each other directly with more conventional heterogeneity tests. We applied these methods to a cohort of 1,409 case-parent trios with nonsyndromic orofacial clefts (OFCs) that were sequenced for 6. 3Mb surrounding GWAS regions. OFCs are known for their considerable phenotypic heterogeneity as there are prevalence biases relating to cleft type (i. e. , cleft lip, cleft lip and palate, cleft palate), gender, the side of the lip that is affected, and severity among affected individuals.

1378T

An effective approach to identify rare variants associated with common diseases utilizing large families. *J. Sul[1,2], S. Sunyaev[1,2].* 1) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Harvard University, Boston, MA 02115, USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA.

Majority of sequencing studies aiming at finding association of rare variants with complex traits use the case-control design. A number of new initiatives plan to sequence large numbers of well-phenotyped pedigrees. Family-based studies offer several advantages over case-control studies. First, genetic variants that are rare in the population may be enriched in certain large families, which allows family-based studies to achieve higher power in detecting associations of rare variants than case-control studies, as suggested in recent literature. Second, sequencing errors can be detected as Mendelian violations. This reduces erroneous calls made by NGS, and hence increases power of rare variant analysis by correctly calling rare variants. We present a new approach to detect rare variants associated with common diseases in large family collections. This method detects rare variants with the skewed segregation patterns with respect to the affected/unaffected status. To increase the statistical power, the proposed test combines multiple rare variants both by gene and across multiple families. The method can be applied to any set of pedigrees phenotyped for either a binary or a quantitative trait. It is equally applicable to affected-only pedigrees. This is in contrast with most of existing approaches that focus on small families and handle either binary or quantitative traits. Our method also handles pedigrees with missing founders. The proposed method achieves higher power than existing approaches, as shown in simulations. The power gain is especially profound for large families. We also demonstrate that many existing methods have inflated false-positive rates if founders of large families are not genotyped in the study. The new method handles missing founder genotypes without inflating false-positive rate.

1379F

A family-based rare variant association test for time-to-event data based on the frailty model. *W. Qi[1,2], W. Wang[3], A. Allen[1], Y. J. Li[1,2].* 1) Department of Biostatistics and Bioinformatics, Duke University Medical Center, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 3) Institute of Statistics, National Chiao Tung University, Taiwan.

Since the rise of next generation sequencing technologies, many gene-based association methods have been developed for testing rare variants for disease susceptibility or modifiers. There is a robust literature on gene-based rare-variant association methods for binary or continuous phenotypes that can be applied to either unrelated case-control or familial data. On the other hand, the development of gene-based association tests for time-to-event data drew less attention, particularly for family data. Examples of the time-to-event data in genetics research include adverse events in pharmacogenetics research and age at onset (AAO) of the disease of interest in disease gene mapping research. For instance, we have previously shown that AAO of Alzheimer disease is genetically controlled (Li et al. 2002). Here, we propose a family-based rare variant association test for time-to-event data. We adopted the framework of orthogonal model used in the QTDT method (Abecasis et al. 2000) to decompose the genotype score into between- and within-family genotype scores for each rare variant. It can be applied to families of any size, with or without parental information. To model the time-to-event data in family, we included vectors of between- and within-family genotype scores for all rare variants of interest, as well as other covariates of interest in the frailty model. We assume that the between- and within-family effects are random effects following normal distributions. To differentiate the effect sizes between variants, we incorporated weights on rare variants in the partial likelihood function. Multiple weighting schemes for rare variants were evaluated. Both likelihood ratio and variance-component score tests were derived to test the within-family effects of rare variants, which provide a direct estimate of association of rare variants. The property and performance of both tests were then evaluated by extensive simulation studies using SeqSIMLA program (Chung and Shih 2014) to generate sequence data in families.

1380W

An Approach to High resolution IBD mapping under a linkage peak. *J. E. Hicks[1,2], P. An[2], H. J. Abel[2], M. A. Province[2].* 1) Division of Biostatistics, Washington University School of Medicine in Saint Louis, Clayton, MO; 2) Division of Statistical Genomics, Washington University School of Medicine in Saint Louis, Clayton, MO.

With the availability of high-throughput sequencing, rare variants as one of the causes of common phenotypes is a popular theory in genetic epidemiology. These rare-variants are more likely to be found on long haplotypes within the population, which are identifiable with common tools such as GERMLINE and BEAGLE. Conventional linkage analysis considers identify-by-descent (IBD) states within observed pedigrees to identify relationships between genotype and phenotype. By incorporating IBD states between pedigrees, further information can be useful for localizing these rare variants, since some putatively "independent" pedigrees may actually share recent common ancestry for the causative rare alleles. In order to better leverage ancestral information in combination with linkage information, we defined a statistic to quantify IBD in these pedigrees as the number of alleles shared IBD among individuals, summed over all pedigrees. We applied this approach to the Long Life Family Study, a family-based cohort used to identify the genetic determinants of aging traits, consisting of 615 families spanning 4,694 genotyped participants. These individuals were genotyped on the Illumina Human Omni 2. 5 v1 chip. In a genome-wide variance components linkage screen for hemoglobin A1c (HbA1c) levels, a region on chromosome 2 showed significant evidence of linkage in the region 36,919,293-39,982,534 bp. Using 309 individuals selected for membership in pedigrees displaying strong linkage to HbA1c, higher resolution analysis was used to narrow down the linkage region. IBD segments between these individuals were identified as genome spans of over 500 kilobase where at least 1000 genotypes were identical-by-state and there was a marker density of at least 100 markers per megabase. Of 2,378 within-pedigree pairs of individuals, the maximal amount of sharing using our approach was 1,258 allele pairs at rs7576549, a SNP within the region identified by standard linkage analysis. This demonstrates the utility of high-resolution IBD segment mapping in refining signals from linkage analyses.

1381T

Linkage Analyses Reveals Significant Association for Myopia. *A. Musolf[1], C. L. Simpson[1], F. Murgia[1,2], L. Portas[1,2], J. E. Bailey-Wilson[1], D. Stambolian[3].* 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 2) Institute of Population Genetics, CNR, Traversa La Crucca, 3 - 07040 Reg. Baldinca, Li Punti, Sassari, Italy; 3) Department of Ophthalmology, University of Pennsylvania, Philadelphia, PA 19104, USA.

Myopia (nearsightedness) is a condition where overgrowth of the eye causes light to focus in front of the retina and instead of directly on it, leading to blurring of distant images. It is one of the most common causes of reduced vision worldwide, affecting 1 in 4 Americans and has reached epidemic proportions in some parts of southeast Asia. Genotypes from the Illumina Exome array were merged with prior microsatellite data from extended pedigrees with multiple individuals affected with myopia. These families come from three discrete populations: African-Americans, Ashkenazi Jews from New Jersey, and Pennsylvania Amish. Two-point and multi-point linkage analyses were performed on each family using both a general inheritance model and an inheritance model specific to each population using MCLink. Familywise two-point LOD scores of greater than 2 were observed at chromosomes 3, 4, 6, 10, 13 and 14 in individual Ashkenazi Jewish families. The two highest LOD scores were equal to 2. 9 and appeared in a nonsynonymous SNP in an exon of the SYNE1 gene on chromosome 6 in one family and an intronic microsatellite in the antisense RNA gene ZMIZ1-AS1 on chromosome 10 in another family. We also observed familywise two-point LOD scores greater than 2 in the Pennsylvania Amish on chromosomes 2, 3, 9, 15, and 16. The two highest scores were 2. 3 at an intronic microsatellite located in the MTMR10 gene on chromosome 15 in one family and 2. 2 at a microsatellite in an intergenic region on chromosome 10 in another family. Although no two-point LOD scores higher than 2 were observed in the African-Americans, these families were smaller and therefore less informative. Nonetheless, familywise two-point LOD scores of greater than 1 were seen on chromosomes 1, 2, 5, 8, and 20. The highest two LOD scores were 1. 52 at a microsatellite in a noncoding RNA gene on chromosome 4 and 1. 47 at an exonic nonsynonymous SNP in GALNT15 on chromosome 3. Multipoint linkage analyses are ongoing and will be presented, including HLOD scores calculated for each population group and across all populations. Overall, this work identifies multiple interesting linkage signals for myopia across three discrete populations, using both two-point and multi-point analyses. Many of these signals are located within genes, which may be promising candidates for further study.

Power of Single Extended Pedigrees to Classify Rare Variants of Uncertain Significance in BRCA1 and BRCA2. *B. H. Shirts[1], E. A. Rosenthal[2].* 1) Laboratory Medicine, University of Washington, Seattle, WA; 2) Genetics, Medicine, University of Washington, Seattle, WA.

Family based analysis of trait and locus cosegregation can be used to facilitate classification of rare variants of uncertain significance (VUS). Many VUS will only be present in a single extended pedigree. Genealogy and social networking resources have made identifying and collecting distant relatives more feasible, potentially increasing the power to classify a VUS as benign or pathogenic. Using simulated family data we sought to identify the family sizes and structures necessary for adequate power. We simulated pedigrees based on historical demographic data from the United States (USA) and China (CHI), which differ in family size and structure. Pedigrees were simulated to include probands similar in age and sex to those currently tested in genetics clinics. Each simulated pedigree contained all descendants of the proband's carrier great-grandparent. Phenotypes for each individual were sampled based on age, sex and carrier status. We simulated >1000 families for all eight scenarios defined by three categories: pathogenic or benign variant; BRCA1 or BRCA2; USA or CHI. We calculated proband adjusted likelihood ratios (LRadj) using linkage analysis, assuming gene specific age-based penetrance and an allele frequency of 0. 001. A VUS was considered likely pathogenic when LRadj > 20, and likely benign when LRadj < 0. 05, per International Association for Research on Cancer (IARC) recommendations. The power and type I error rates for correctly classifying a pathogenic variant were: USA BRCA1: 26%, 3%; CHI BRCA1: 41%, 4%; USA BRCA2: 22%, 2%; CHI BRCA2: 34%, 3%. The power and type I error rates for correctly classifying a benign variant were: USA BRCA1: 70%, 0%; CHI BRCA1: 79%, 0%; USA BRCA2: 60%, 0%; CHI BRCA2: 69%, 0%. The number of breast/ovarian cases in families with power to classify pathogenic BRCA1/2 variants in US families ranged from 3 to 23 (median 7). As expected, power was higher in larger families. Despite lower recent fertility, simulated families with CHI structure had higher power to correctly classify both pathogenic and benign variants in both genes, most likely due to rapid family growth in the early 20th century and the presence of a larger number of older relatives. Given the relative prevalence of pathogenic and benign variants, we show that VUS classification in BRCA1/2 will likely be possible in >50% of families with either CHI or USA ancestry when all descendants of a common carrier great-grandparent are included in the analysis.

1383W

Large-scale phenome-wide scan in twins using electronic health records. *S. Hebbring[1], J. Pathak[2], J. Mayer[3], Z. Ye[3], S. Schrodi[1].* 1) Center for Human Genetics, Marshfield Clinic, Marshfield, WI; 2) Health Sciences research, Mayo Clinic, Rochester, MN; 3) Bioinformatics Research Center, Marshfield Clinic, Marshfield, WI.

Challenges in modern population-based genomic research have resulted in a re-awakening of family-based studies. However, difficulties arise with identifying the most interesting diseases and families for family-based research. Use of large patient populations linked to an electronic health record (EHR) may alleviate such challenges. Using readily available EHR data, we identified two independent twin cohorts from Marshfield (MCTC) and Mayo Clinic (Mayo-TC) (total=28,888 twins). In both cohorts, we measured familial aggregation across the phenome defined by 5,598 phenotypes/ICD9 codes. Not surprisingly, the top associations in both cohorts included the phenotype defining twin births (V31; MCTC, Pχ1. 5E-587; Mayo-TC, Pχ2. 7E-359). Additional top associations were comprised of numerous perinatal phenotypes including those related to birth weight (e. g. , ICD9 765: MCTC, Pχ2. 2E-501; Mayo-TC, Pχ1. 5E-161) and jaundice (e. g. , ICD9 774: MCTC, Pχ1. 3E-338; Mayo-TC, Pχ5. 6E-133). It is not unexpected that infants born together will likely have the same gestation period, comparable birth weights, and similar infant-related co-morbidities. There were also numerous common phenotypes previously characterized with high heritability such as myopia (ICD9 367. 1: MCTC; Pχ9. 5E-101; Mayo-TC, Pχ6. 0E-61) and developmental delays (ICD9 315: MCTC, P=1. 8E-134; Mayo-TC, Pχ2. 9E-57). Likewise, there were numerous rare Mendelian diseases (e. g. , hereditary spherocytosis, sickle cell anemia, and thalassemia) that were associated in both cohorts. Based on a combined analysis, 1,406 of the 5,598 phenotypes were statistically enriched for concordance (P<8. 9E-6), many with unknown genetic etiologies. With our novel phenome-wide methodologies highly translatable to other EHR systems, and potentially to other familial relationships, this study may pave the way to biotechnologically smart EHR systems that integrate family data to predict, prevent, and treat many diseases for the advancement of “precision medicine. ” Lastly, this study provides an intriguing perspective for the future of genomic research. Specifically, the future when large patient populations with sequenced genomes are unified by familial relationships in an integrated EHR system with extensive phenotypic data.

1384T

Detection of Gene-Gene Interaction and Genomic Imprinting in Affected Sib Pairs. *C. C. Wu[1], S. Shete[2].* 1) Environmental/Occupational Health, National Cheng Kung University, Tainan, Taiwan; 2) Biostatistics, The University of Texas MD Anderson Cancer Center, Houston, Texas, USA.

Genomic imprinting is an epigenetic phenomenon, which results in 2 alleles at a locus being expressed differentially depending on the parental origin of the chromosome. Recent studies show that imprinted genes not only play important roles in development and placental biology before birth but also have major effects on postnatal stages on common diseases, including obesity, psychiatric disorders, and cancer. Genome-wide association studies have discovered several hundred genetic variants associated with common diseases; the efforts to map interacting genes have been less successful. In response, we proposed a method to detect gene-gene interaction effects in the presence of genomic imprinting. We extended our previous allele-sharing method and presented 3 mathematical two-locus models incorporating imprinting effects: additive, multiplicative, and general models. Our methods are model-free based on allelic identity-by-descent sharing by affected sib pairs. We used two-locus score method to assess the gene-gene interaction effects using affected sib pairs in the presence of imprinting effects. We further proposed to use a novel test to assess the gene-gene interaction and imprinting effects individually and jointly.

1385F

Association and Meta-analysis Methods for X Chromosome. *S. Feng[1,2], G. Pistis[3], C. Sidore[3], A. Mulas[3], M. Zoledziewska[3], F. Busonero[3], S. Sanna[3], F. Cucca[3], D. Schlessinger[4], G. Abecasis[1].* 1) Department of Biostatistics, Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI, USA; 2) 23andMe, 899 West Evelyn Avenue, Mountain View, CA 94041; 3) IRGB, Cittadella Universitaria di Monserrato, Monserrato, Cagliari, Italy; 4) Laboratory of Genetics, National Institute of Aging, Baltimore, MD, USA.

Variants and genes on the X chromosome account for 5% of the human genome sequence. Following our previous work on association and meta-analysis methods for autosomal genes, we propose a series of gene-level association tests including burden, variable threshold, and sequence kernel association tests for analysis of rare variants on chromosome X. We use a linear model with three variance components to take account autosomal, X chromosomal, and individual environment contributions to total variance, and allow estimation of empirical kinship matrix for both autosome and X chromosome when pedigree structure is not known or cryptic relatedness and population structure are a concern. By simulation, we show that all of our gene-level tests have type I error well controlled and that, in models that assume complete X-inactivation, samples of males provide more power to detect association with X-linked genes. Furthermore, for any given per allele effect size, power to detect X-linked alleles was larger than for autosomal alleles with the same effect sizes. Using the SardiNIA study, we examined association at X-linked variants on exome chip, showing that variants near *G6PD* are associated with multiple quantitative traits.

1386W

PSEUDOMARKER-WGS: Family-based association tests for whole genome sequence data. *T. Hiekkalinna[1,2], M. Perola[1,2,3], J. D. Terwilliger[1,4,5].* 1) Genomics and Biomarkers Unit, National Institute for Health and Welfare (THL), Helsinki, Finland; 2) Institute for Molecular Medicine Finland FIMM; 3) University of Tartu, Estonian Genome Center, Tartu, Estonia; 4) Department of Psychiatry, Department of Genetics and Development, Gertrude H. Sergievsky Center, Columbia University, New York, NY, USA; 5) Division of Medical Genetics, New York State Psychiatric Institute, New York, NY, USA.

In the past decade, the human genetics community has spent a huge amount of resources on attempting to identify genetic variants underlying common disorders in genome-wide association studies (GWAs) on large population based cohorts. The common-disease common-variant hypothesis was the motivation for this quest, suggesting that if we genotyped a sufficiently large number of SNP markers across the genome we would be able to identify allelic associations with any common variant influencing a given disease. However, the results to date have been in a way disappointing, with lots of SNPs showing correlations with such disease outcomes, but with miniscule effect sizes, even when combined. Researchers are now returning to family-based designs, noting that under every model considered, they provided higher power for gene mapping, with the reason for the shift to studying unrelated individuals having been motivated almost exclusively by cost and convenience of acquiring large samples. However, as the world moves closer to routine sequencing as part of normal health care to identify any of the hundred thousand or so variants known to outright cause Mendelian disorders, we will soon have data available from relatives sharing some disease once again, motivating a resurgence of interest in classical position cloning strategies based on family data, but adapted to the situation where we have full sequence data, rather than a sparse map of markers as inputs. Family data will be much more powerful, for obvious reasons, as it has been well known fact for several decades that it affected relatives are much more likely to share the same disease predisposing genetic variants than any pair of unrelated affected individuals from the population. In this post-GWAs era, whole genome sequencing (WGS) techniques will be used to generating a vast amount of data, including relatives, which will raise enormous computational challenges for human genetics researchers. We have developed a set of user friendly programs, PSEUDOMARKER-WGS, for analysis of massive amounts of sequence based data in family-based joint linkage and association mapping. Here, we will show the superior power of our PSEUDOMARKER-WGS approach to joint linkage and/or linkage disequilibrium analysis as compared with recently proposed and classical methods. Our PSEUDOMARKER method can analyze jointly extended pedigrees, sib ships, trios and unrelated individuals and it is therefore an optimal algorithm.

1387T

Statistical testing for rare variant associations using affected family members. *K. Lin[1], S. Zöllner[1,2].* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Modern sequencing technology allows investigating the impact of rare variant on complex disease. However, in a conventional case-control design, large samples are needed to achieve sufficient power for testing associations of suspected rare variants to complex diseases. In such large samples, population structure can cause spurious signals. One approach to overcome low power and population stratification is family-based study design since the count of risk variants can be enriched in a family containing multiple affected members with the same genetic background. However, existing family-based methods do not efficiently utilize the fact that rare risk variants are more likely to reside on identical-by-descent chromosomes shared among affected family members. Given many family studies have been generated and new studies are ongoing, there is need to develop powerful approaches to discover associations between rare variants and disease phenotypes in families. We propose a novel test for a sample of families. In each family, we first determine the chromosome transmission at the locus of interest for all family members. Since affected family members are more likely to share risk variants identical-by-descent, we propose to test if rare variants are shared more than expected given the known haplotype transmission and the founder genotypes. In addition, we develop imputation algorithm for families that founders are missing, so that this test can adopt a sample of families with arbitrary family structures. The proposed test is generally robust to population stratification since each family is a matched unit. Using simulations, we compare our method with existing methods for family-based data as well as the conventional case-control design. Considering different models from rare to common variants, we show that the proposed approach is especially more powerful than the conventional case-control design for rare variants; in the presence of allelic heterogeneity, the proposed test further increases the power. In sum, we propose a family-based test that efficiently uses sharing of rare risk variants to maximize the power for detecting rare variant associations.

1388F

A Quasi-likelihood Approach To Detect Transmission Bias Using Sibship Data. *H. S. Kulkarni, S. Ghosh.* Human Genetics Unit, Indian Statistical Institute, Kolkata, West Bengal, India.

The Transmission Disequilibrium Test (TDT) is a popular family based alternative to the population based case-control design as it protects against population stratification. The study of quantitative traits has gained prominence since most complex disorders are governed by quantitative precursors which contain more information on within genotype variability. There have been several extensions of the classical TDT procedure (Speilman et al. 1993) for quantitative traits based on logistic regression (Waldman 1999) and center adjusted logistic regression model (Haldar and Ghosh 2015). However, the TDT procedure is not a valid test for association in the presence of multiple sibs in a family as the marginal effect of linkage can result in transmission bias of an allele. We propose a modification of the classical TDT procedure based on the quasi likelihood approach (Wedderbur 1974) which is also equivalent to the generalized linear regression model (McCullagh and Nelder 1989) using a logit link function. The major advantage of the proposed method over the classical TDT is that it includes the covariance of the transmission status of alleles within a sibship induced by linkage. The regression parameter is estimated using generalized estimating equation (Gourieroux et al 1984; Zeger 1986). We perform extensive simulations under a wide spectrum of the genetic models and different distributions of the quantitative trait (normal, chi-square and Poisson). We compare the empirically power of our proposed test with the FBAT test for sibship data (Lake et al 2000). We observe that the proposed test yields comparable powers across different probability distributions. We also find that the quasi likelihood approach is more powerful than the FBAT test for sibship data.

1389W

Increased power for detection of parent-of-origin effects via the use of haplotype estimation. *R. A. J. Howey[1], C. Mamasoula[1,2], A. Töpf[1], R. Nudel[3], D. F. Newbury[3], S. E. Fisher[4,5], J. A. Goodship[1], B. D. Keavney[1,6], H. J. Cordell[1].* 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, NE1 3BZ, United Kingdom; 2) Institute of Health and Society, Newcastle University, Newcastle upon Tyne, NE2 4AX, United Kingdom; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN, United Kingdom; 4) Max Planck Institute for Psycholinguistics, Nijmegen, the Netherlands; 5) Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, the Netherlands; 6) Institute of Cardiovascular Sciences, University of Manchester, Manchester, M13 9NT, United Kingdom.

Parent-of-origin (or imprinting) effects relate to the situation where traits are influenced by the allele inherited from only one parent, with the allele from the other parent having little or no effect. Given SNP genotype data from case/parent trios, the parent-of-origin of each allele in the offspring can often be deduced unambiguously; however this is not true when all three individuals are heterozygous. Most existing methods for investigating parent-of-origin effects operate on a SNP by SNP basis and either perform some sort of "averaging" over the possible parental transmissions or else discard ambiguous trios. If the correct parent-of-origin at a SNP could be determined, this would provide extra information and increase the power to detect effects of imprinting. We propose making use of the surrounding SNP information, via haplotype estimation, to improve estimation of parent-of-origin at a test SNP for case/parent trios, case/mother duos and case/father duos. This extra information is then used in a multinomial modelling approach to estimate parent-of-origin effects at the test SNP. We show through computer simulations that our approach has increased power over previous approaches, particularly when the data consist only of duos. We apply our method to two real data sets and find a decrease in significance of p-values in genomic regions previously thought to possibly harbour imprinting effects, thus weakening the evidence that such effects actually exist in these regions, although some regions remained more significant than expected. Softwareis available at www. staff. ncl. ac. uk/richard. howey/emim.

1390T

The *LRRK2* gene is a shared genetic regulator among three clinically divergent common inflammatory disorders. *V. M. Fava[1,2], J. Manry[1,2], A. Cobat[1,2], M. Orlova[1,2], N. Van Thuc[3], N. Ngoc Ba[3], V. H. Thai[3], L. Abel[4,5,6], A. Alcaïs[4,5,6,7], E. Schurr[1,2], The Canadian Lrrk2 in Inflammation Team (CLINT) investigators.* 1) Program in Infectious Diseases and Immunity in Global Health, Research Institute of the McGill University Health Centre, Montreal, Canada; 2) The McGill International TB Centre, Human Genetics Department, McGill University, Montreal, Canada; 3) Hospital for Dermato-Venerology, Ho Chi Minh City, Vietnam; 4) Laboratory of Human Genetics of Infectious Diseases, Necker Branch, Institut National de la Santé et de la Recherche Médicale, Paris, France; 5) University Paris Descartes, Imagine Institute, Paris, France; 6) St Giles Laboratory of Human Genetics of Infectious Diseases, Rockefeller Branch, Rockefeller University, New York, USA; 7) Centre d'Investigation Clinique, Unité de Recherche Clinique, Necker and Cochin Hospitals, Paris, France.

Coding variants of *LRRK2* have been associated with Parkinson's Disease (PD) and Crohn's Disease (CD). Moreover, non-coding variants of *LRRK2* were associated with leprosy. Recently, we demonstrated that a previously reported association between leprosy and the *TNFSF15*/*TNFSF8* genes (also a CD susceptibility locus) was most likely due to patients suffering from type-1 reactions (T1R). This prompted us to investigate if *LRRK2* variants were primarily associated with T1R rather than leprosy. We tested the preferential *LRRK2* association with T1R over leprosy in a family-based design. For this, we matched two samples of 229 families each with divergent T1R affection status in their offspring. In set 1, patients suffered from leprosy and T1R while in set 2 patients only suffered from leprosy. By formally comparing the T1R-affected versus the T1R-free subset we were able to address the association of genetic markers with the T1R endophenotype. We genotyped 156 SNPs in a 500kb window overlapping the *LRRK2* and *MUC19* genes. Of the 156 variants, 36 were nominally significantly associated in the T1R-affected subsetand 20 of these showed significant evidence for heterogeneity between T1R and leprosy. The "M" allele of the M2397T coding variant was significantly associated with T1R only (P = 0. 008, $P\ het$ = 0. 01). Thesame allele is a risk factor for CD (P = 2. 6 e-15). The M2397T impacts LRRK2 turn over with the methionine variant showing a lower half-life in compare to the threonine. A second SNP, rs7970326, significantly associated with T1R (P = 0. 03, $P\ het$ = 0. 006) is a risk factor for PD (P = 1. 1 e-6). Next, we quantified *LRRK2* mRNA expression in a whole blood assay of 54 leprosy cases in presence and absence of stimulation with *Mycobacterium leprae* antigen. Among the SNPs associated with T1R, we identified a series of eQTLs in unstimulated but not in stimulated blood. In that instance, the eQTL rs10784470 G-allele is a risk factor for T1R (P = 0. 02, $P\ het$ = 0. 02) and Inflammatory bowel disease (P = 7. 9 e-6). The *LRRK2* expression for this SNP bin is altered in response to mycobacterium antigen. Our results link the *LRRK2* gene to the pathogenesis of three clinically distinct common inflammatory disorders of medical importance.

The use of composite bi-allelic markers revisited: Creating highly informative multi-allelic markers from SNP and next generation sequence data. *A. F. Wilson, T. -H. Schwantes-An, C. M. Justice, A. J. M. Sorant.* Genometrics Section, CSGB, NIH/NHGRI, Baltimore, MD.

The renewed interest in using linkage analysis to investigate the role of rare variants in family data is hampered by the fact that the bi-allelic single nucleotide variants (SNVs) available from SNP arrays and next generation sequence data are not, by themselves, very informative. In the era of short tandem repeat polymorphisms (STRPs), the informativeness of these multi-allelic markers, as measured by the Polymorphic Information Content (PIC) was substantially higher than that of even the most common SNPs, resulting in a high proportion of matings that were informative for linkage analysis. The lack of informativeness for SNPs can be ameliorated with the use of multipoint linkage analysis, although this can be computationally intensive. Before the STRP era, bi-allelic markers in multi-locus systems like the MN and Ss blood group systems were used to create composite markers with relatively high PIC levels, increasing the proportion of informative matings for linkage analysis. Wilson and Sorant [2000] showed that the use of composite bi-allelic markers can be nearly as powerful in detecting linkage compared to the use of multi-allelic loci or multipoint methods. For example, a two or three locus composite bi-allelic marker was nearly as powerful to detect linkage with sib-pair linkage analysis as a multi-allelic marker and the power to detect linkage with a four-locus composite marker was similar to that using a multipoint approach. In this study, the bi-allelic variants for the MN and Ss loci, glycophorin A (*GYPA*) and glycophorin B (*GYPB*), respectively, are used as a model for the selection of bi-allelic variants that can be used to create multi-allelic composite markers. *GYPA* and *GYPB* are known to be about 90 kb apart and separated by a recombination hotspot (recombination rate of about 25 cM/Mb). HapMap markers were used to identify recombination hot and cold spot regions over the entire genome. Pairs of common SNPs with a minor allele frequency > 0. 4 and separated by a recombination hot spot were selected as composite marker candidates. Four sets of composite markers were generated, one for each of the HapMap reference populations (CEU, YRI and CHB) and one over all three populations. On average, 2144 two-locus composite markers, separated by approximately 0. 5 Mb were selected. Lists of composite markers will be posted on the NHGRI web-site. These markers will be useful for linkage analysis.

1392W

Regional IBD Analysis (RIA): a new method for linkage analysis in extended pedigrees using genome-wide SNP data. *H. J. Cordell[1], J. Eu-ahsunthornwattana[1,2], R. A. J. Howey[1].* 1) Institute of Genetic Medicine, Newcastle University, Newcastle upon Tyne, NE1 3BZ, United Kingdom; 2) Division of Medical Genetics, Department of Internal Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Ratchathevi, Bangkok 10400, Thailand.

The study of rare variants has revived interest in linkage analysis. However, exact calculations for traditional linkage analysis are computationally impractical in large, extended pedigrees. Although simulation-based methods can be used, they require significant computation and are not exact. We propose Regional IBD Analysis (RIA), a non-parametric linkage method based on comparison of locally and globally estimated identity by descent (IBD) sharing in affected relative pairs (ARPs). In RIA, genome-wide SNP data are used to calculate the "global" expected IBD sharing probabilities for each ARP, against which a "local" set of IBD probabilities, estimated using SNP data within windows of pre-specified width, are compared. The global and local IBD probabilities are used to construct a non-parametric maximum likelihood statistic (MLS)-like test of linkage in each window. We illustrate our method with real nuclear-family data from a study of vesicoureteral reflux and simulated data based on large extended pedigrees from a study of visceral leishmaniasis. RIA successfully detected the linkage signals with significant reduction in computational time (e. g. 2 hours vs 66 hours on 3,626 individuals from 308 extended families, genotyped at 545,433 SNPs) compared to traditional methods. RIA should be useful in studies involving large extended families, in which traditional linkage analysis is not feasible. Additionally, because it does not rely on prior knowledge about familial relatedness, RIA has an additional advantage of being robust to pedigree misspecification and can be used even in the absence of pedigree information.

1393T

Using genealogy clusters to find high-penetrant disease variants in the Danish population. *A. Rosengren[1], A. Buil[1], M. Bertalan[1], JH. Thygesen[1], PB. Mortensen[2], C. Bøcker Pedersen[2], T. Werge[1], SSI, BROAD & iPSYCH investigators.* 1) Institute of Biological Psychiatry; Mental Health Services of Copenhagen, Copenhagen, Denmark; 2) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark.

The Danish genealogy of recent times is established using information from the national Danish civil registry system. The registry includes approximately 9 million people alive in Denmark from 1968 onwards, their birth year and place as well as legal links between parent and offspring. The connection of siblings of mothers born since 1935 is nearly complete. This allows us to construct meiotic clusters of up to 6 generations, and to define an index pedigrees as all individuals with whom an index person share a common ancestor in the genealogy. We identify index pedigrees for all subjects recorded with a diagnosis of mental disorders in near complete, nationwide Danish Psychiatric Central Research Register*. We estimate heritability across all index pedigree for mental disorders, separately and joined using the genealogy information as co-variance matrix. We use the heritability estimates to examine whether heritability estimates correlate with time and place of birth of the index person, structure of the index pedigree, and with sub-diagnostic phenotypes, e. g. age-at-onset, hospitalization, treatment outcome and comorbidity. Also, we use the complete dataset to derived powerful estimates of genetic correlations between disease phenotypes to obtain measurements of the shared genetic effects among mental disorders. In particular, we will use genotype data from the approx. 80,000 index persons genotyped in iPSYCH initiative^ to correlate local heritability estimates to the underlying genetic architecture (e. g. polygenetic inheritance, high-penetrant variants etc.) and to guide IBD and NGS initiatives for the discovery of high-penetrant disease variants. The study offers the first compilation of the 9 mio. individuals in the know Danish genealogy linking individuals affected with severe mental disorders. The results provide a unique resource for population-bases disease studies. ** The near complete, nationwide Danish Psychiatric Central Research Register contains more than 4mio. hospital contacts and 15mio observations of psychiatric nature divided on roughly 900,000 unique individuals in the period 1969-2013. ^ The iPSYCH initiative includes all individuals in the Danish population born 1981-2006 with a diagnosis of AUT, SCZ, ADHD, BPD, MDD or anorexia as well as a randomly selected population sample, in total more than 80,000 individuals.*

1394F

A two-stage rare variant association test for family data with quantitative traits. *Y. Jiang[1], Y. Ji[1], A. Sibley[1], Y. Li[1,2], A. Allen[1].* 1) Biostatistics and Bioinformatics, Duke University, Durham, NC; 2) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC.

Confounding due to population substructure is always a concern in genetic association studies. While methods have been proposed to adjust for population stratification in the context of common variation, it is unclear how well these approaches will work when interrogating rare variation. Family-based association tests are known to be robust to population stratification and have been well-developed, particularly for common variants. Here, we adopted the concept of the orthogonal model described in Abecasis et al. (2000) to decompose genetic effects into between and within-family components. While atest of the within-family component is robust to population stratification, this within-family test ignores between-family information potentially leading to a loss of power. We, therefore, propose a family-based two-stage rare-variant test for quantitative traits. We first construct a weight for each variant within a gene, or other genetic unit, based on score tests of between-family effect parameters. These weights are then used to weight the total within-family efficient score of all variants to form a score test of within-family effect parameters. Since the between-family and within-family tests are orthogonal under the null hypothesis, this two-stage approach can increase power while still maintaining validity. Using simulation, we show that this two-stage test can significantly improve power while correctly maintaining type I error. We further show that the two-stage approach maintains the robustness to population stratification of the within-family test and we illustrate this using simulations reflecting samples comprised of continental and closely related subpopulations.

1395W

Three networks comprised of both multiple sclerosis and obesity-associated genes demonstrate strong evidence of protein-protein interaction and significantly increase disease susceptibility: Results from the Kaiser Permanente MS Research Program. *M. Gianfrancesco[1], X. Shao[1], B. Rhead[1], L. Shen[2], H. Quach[1], A. Bernstein[3], C. Schaefer[2,4], L. F. Barcellos[1,2].* 1) Division of Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) Kaiser Permanente Division of Research, Oakland, CA; 3) Palm Drive Hospital, Sebastopol, CA; 4) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS) [MIM 126200] is an autoimmune disease that involves both genetic and environmental risk factors, such as early life obesity. However, the underlying biological mechanism mediating the association between obesity and MS has not been determined. The Disease Association Protein-Protein Link Evaluator (DAPPLE, v2. 0, Broad Institute) was utilized for bioinformatics analysis to examine whether protein-protein interactions exist between established genome-wide significant gene regions associated with both body mass index (n=97) and MS disease susceptibility (n=110). Gene sub-scores based on resulting protein networks were derived by summing the number of risk alleles across each representative gene within each network. Logistic regression was used to test for association between each network sub-score and MS susceptibility, controlling for smoking, education, year of birth, ancestry based on principal components analysis (EIGENSTRAT), and carrier status for *HLA-DRB1*15:01*, the strongest genetic risk factor for MS. Participants included non-Hispanic White members of Kaiser Permanente, Northern California (KPNC; 1,200 MS cases, 10,000 controls). Common and rare variant data for each candidate gene were obtained through whole-genome profiling and imputation. Results revealed significant evidence for direct and indirect protein-protein interactions (p<0. 001 and p=0. 01, respectively); of 99 total direct interactions observed, 22 were between obesity and MS genes. The interactions clustered into 13 networks; five were significantly associated with MS susceptibility in the KPNC dataset after controlling for covariates (p<0. 05). Three significant networks included both obesity and MS genes, with evidence of protein-protein interaction between *DMXL2* and *RAB3A* (odds ratio [OR] =1. 18, 95% CI 1. 10, 1. 27; p<0. 001), *NPEPPS* and *GBE1* (OR= 1. 07, 95% CI 1. 01, 1. 15; p=0. 04), as well as a network of 38 genes including *ERBB4*, *NEXN*, *NFKB1*, and *IL7R* (OR=1. 08, 95% CI 1. 06, 1. 10; p<0. 001). This study is the first to characterize complex gene contributions to MS susceptibility while accounting for other established genetic and environmental risk factors, and establishes the first evidence for potential underlying biological mechanisms between obesity and MS through bioinformatics analysis of protein-protein networks.

1396T

Sovereignty Hypothesis: Strong effect of HLA shared epitope alleles in developing risk for rheumatoid arthritis is due to massive gene-gene interactions. *L. Padyukov[1], L. Folkersen[2], K. Shchetynsky[1], S. Uebe[3], L. -M. Diaz-Gallo[1].* 1) Rheumatology Unit, Karolinska Inst, Stockholm, Sweden; 2) Department of Systems Biology, Technical University of Denmark, Kongens Lyngby, Denmark; 3) 3. Human Genetics Institute, Universitétsklinikum Erlangen, Erlangren, Germany.

Introduction. Rheumatoid arthritis (RA) is relatively common disabling systemic autoimmune disease characterised by join inflammation and destruction. A particular subset of *HLA-DRB1* alleles (*01, *04 and *10) with shared amino acid sequence, known as share epitope (SE), is the most important genetic contributor to the developing of anti-citrullinated protein antibody (ACPA) positive RA although the mechanism impelling such high effect is not clear. We hypothesize that the fraction of non-HLA SNPs with individually low contribution to the risk of RA are in interaction with HLA SE alleles and this "sovereign" is representing a sum effect, reflected in the high risk value of HLA in RA. **Methods.** We performed analysis of two independent RA cohorts from EIRA and NARAC studies with 2018 ACPA positive RA patients and 2273 healthy control individuals. Genome wide genotyping was previously performed on Illumina platform and imputation was based on 1000G reference. We compared group of SNPs with significant association with disease to non-associated SNPs. The interaction between SNPs and the SE alleles was calculated using the attributable proportion (AP) measure in GEISA and the distribution of the observed AP p-values was compared by the Kolmogorov-Smirnov (KS) test. **Results.** We found an enrichment of significant interactions between the SE and the group of SNPs associated with RA both in EIRA and NARAC cohorts. Statistical evaluation of distribution of AP p-values reveals significant difference between associated and not associated groups of SNPs (KS test: D=0. 29 for the EIRA cohort and D=0. 48 for the NARAC cohort, p<2. 2e-16 for both). The analysis of RNA expression in PBMC for *LINC00355* and *YTHDC2* genes (marked by proximal ~200Kbp SNPs), that are overlapping for interaction in both cohorts, indicates SE alleles dependent eQTLs, thus suggesting new candidate genes for functional study of RA in context of HLA. **Conclusion.** Our data is in favour of Sovereignty hypothesis suggesting that the high SE risk effect in ACPA positive RA could be at least in part attributed to its interaction with non-HLA genetic risk factors. A number of non-HLA genetic risk factors does not have visible effect on development of RA in absence of SE alleles and it could explain the difficulty in detection of the risk alleles and incompleteness of heritability picture of RA based on the univariate analysis of genetic variations.

1397F

Construction and inference of large-scale biological network using Gaussian graphical model. *W. Chen[1,3], Z. Ren[2], T. Wang[1], Y. Ding[3].* 1) Division of Pulmonary Medicine, Allergy and Immunology Children's Hospital of Pittsburgh of UPMC, Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Statistics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA.

The analysis of biological networks provides additional information to understand human diseases beyond the traditional analysis that focuses on single SNP, gene, or protein. Gaussian graphical model (GGM), a probability model that characterizes the conditional independence structure of a set of random variables by a graph, has wide applications in the analysis of biological network, such as inferring gene-gene interaction or comparing differential networks. However, existing approaches cannot perform formal statistical testing and are usually inefficient for high-dimensional data that include tens of thousands of variables. Recently, we proposed a novel regression approach to obtain asymptotically efficient estimation of conditional dependences between each pair of variables (Ann. Stat. 2015, 43(3)). To our knowledge, It is the first theoretical work that produces p-value and confidence interval of each edge simultaneously in the graph. In this project, we illustrate the application of this method on network analysis with a novel and fast algorithm to perform the asymptotic estimation of GGM without any approximation. In simulation study, we demonstrate that the algorithm is faster in several orders of magnitude than existing methods without losing any accuracy or efficiency. Then, we apply our method to two real data sets: the proteomic data from a study of Alzheimer's disease and the transcriptomic data from a study of childhood asthma. We estimate the global molecular interaction networks for disease and health samples. The results from interaction networks identify interesting protein-protein interactions that would be overlooked by marginal correlation analysis. The differential networks between cases and controls in asthma study show functional relevance to the diseases. In conclusion, we develop a statistically sound and computationally efficient approach for constructing Gaussian graphical model and making inference for high-dimensional biological data. The algorithm has been implemented in an R package.

Data-Driven Genetic Encoding: A robust approach for detecting diverse action in main effect models and genetic interactions. *M. A. Hall[1], J. R Wallace[1], S. S. Verma[1], Y. Bradford[1], S. Pendergrass[2], M. Brantley[3,4], M. Brilliant[5], L. Chen[6], J. Denny[7,8], R. Frost[9], M. G. Hayes[10], T. Kitchner[5], C. McCarty[11], B. Muller-Myhsok[12,13,14], P. Peissig[5], D. M. Roden[15], K. Van Steen[16], J. H. Moore[17], M. D. Ritchie[1,2].* 1) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Geisinger Health System, Danville, PA; 3) Department of Ophthalmology & Visual Sciences, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN; 5) Marshfield Clinic, Marshfield, WI; 6) Vanderbilt Institute for Clinical Translational Research, Vanderbilt University, TN; 7) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 8) Department of Medicine, Vanderbilt University School of Medicine, Nashville, TN; 9) Department of Genetics, Institute for Quantitative Biomedical Sciences, Geisel School of Medicine, Dartmouth College, Hanover, NH; 10) Division of Endocrinology, Metabolism, and Molecular Medicine, Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago, IL; 11) Essentia Rural Health, Duluth, MN; 12) Max Planck Institute of Psychiatry, Munich, Germany; 13) Munich Cluster for Systems Neurology (SyNergy), Munich, Germany; 14) University of Liverpool, Institute of Translational Medicine, Liverpool, UK; 15) Department of Medicine and Pharmacology, Vanderbilt University School of Medicine, Nashville, TN; 16) Department of Electrical Engineering and Computer Science, Montefiore, Belgium; 17) Institute for Biomedical Informatics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA.

Certain assumptions are made about the biological action of a SNP when choosing a traditional genetic encoding. For each encoding, risk incurred by one copy of the alternate allele in relation to two copies varies: the heterozygous genotype (HET) is coded to bear 0%, 50%, and 100% the risk of homozygous alternate (HA) for recessive (REC), additive (ADD), and dominant (DOM) encodings, respectively. However, the actual HET action for a given SNP may incur any portion of the risk of HA. Further, choosing just one encoding is not flexible to the diversity of action in biology; while running every encoding raises the multiple testing burden. We present a novel, robust alternative: the data-driven genetic encoding. Here, a HET value is assigned based on the action a SNP demonstrates in the data, derived by its DOM and REC effects, thereby providing an individualized encoding for every SNP. We compared power of this method to detect main effect and genetic interactions using a comprehensive combination of simulated genetic models and found the novel method to outperform the traditional methods for the highest number of underlying models across varying minor allele frequencies (MAFs). We additionally compared the method to the codominant (CODOM) encoding and found that in situations where CODOM loses power (for low MAF) our method retained sufficient power. We further tested our method with null and main effect-only simulated datasets and found that our method maintained a low false positive rate (FPR) for likelihood ratio test (LRT) p-value, while the ADD and DOM encodings demonstrated inflation (as high as 16% FPR). Finally, we applied our method using age-related macular degeneration (AMD) cases (2,167) and controls (10,986) derived from the Electronic Medical Records and Genomics (eMERGE) Network. We identified 438 SNP-SNP models that were significant when allowing for a 5% false discovery rate. One top model included genes that encode *CFH* and *C2*, both with previously reported involvement in AMD. Our results reveal that caution is needed when using the ADD and DOM encodings for interactions due to the inflation observed. Further, we demonstrate the utility of our novel encoding method at flexibly assigning action to individual SNPs, identifying interactions between SNPs with diverse action, and uncovering examples of SNP-SNP interaction in natural data.

Sparse Functional Structural Equations for Causal Genotype-Phenotype Network Analysis with Next-Generation Sequencing Data. *M. Rahman[1], P. Wang[2], L. Jin[2], M. Xiong[1].* 1) University of Texas School of Public Health, Houston, TX; 2) Fudan University.

Despite their differences in selection of specific methods for estimation, the widely used methods for genetic analysis of complex traits do not detect, distinguish and characterize the true biological, mediated and spurious pleiotropic effects and are unable to unravel causal structures among multiple phenotype and genotype variants. To overcome these limitations, we develop sparse structural equation models (SEMs) as a general framework for a new paradigm of genetic analysis of multiple phenotypes. To incorporate both common and rare variants into the analysis, we further extend the sparse multivariate SEMs to sparse functional SEMs. To improve computational efficiency and reduce data dimension, functional data analysis techniques and the alternative direction methods of multiplier (ADMM) are used to develop a novel sparse two-stage least square estimation method for the structure and parameter estimation of large SEMs. Borrowing causal information from the SEMs and maximizing the power of marginal association analysis, we developed a novel statistic for testing association of genetic variants with multiple variants. Using large scale simulations we showed that the true network structure can be accurately recovered by our models and the new statistics have higher power than the PCA-based statistics. The proposed method is applied to exome sequence data from the NHLBI's Exome Sequencing Project (ESP) with 11 phenotypes, which identifies a network with 140 genes connected to 11 phenotypes and 15 genes with pleiotropic genetic effects and demonstrates that the proposed statistic has smaller P-values than the PCA-based statistics for testing marginal associations.

1400F

Modelling the IGF-Axis as a gene-network to identify early predictors of elevated blood pressure in children and adolescents. *P. G. Parmar[1], C. E. Pennell[2], L. J. Palmer[3], L. Briollais[4].* 1) Department of Biostatistics and Epidemiology, Auckland University of Technology, Auckland, Auckland, New Zealand; 2) School of Women's and Infants' Health, The University of Western Australia, Perth, Western Australia, Australia; 3) School of Public Health, University of Adelaide, Adelaide, Australia; 4) Lunenfeld-Tanenbaum Research Institute, University of Toronto, Ontario, Canada.

Genes of the Insulin-like Growth Factor (IGF) network have been shown to be associated with blood pressure and cardiovascular health. We aim to further current knowledge relating to the molecular mechanisms underlying the developmental origins of hypertension by accounting for some genetic complexity of Systolic Blood Pressure (SBP) by modelling the IGF-Axis as a gene-network and provide insight for the early onset of hypertension in growing children. We applied the gene-network methodology from Tsonaka *et al* using longitudinal data on growth and SBP across childhood and adolescence (5-18 years) from the Western Australian Pregnancy and Birth Cohort (Raine) Study. We found 27 gene-gene interactions were significant at p<0. 05, three were present in children aged ≤15 years (males only), two of which did carry over into adolescence (IGF1-IGFBP4 and IGF2-IGFBP3, p<0. 0001). The remaining 24 interactions were present in children aged >15 years (15 in males and nine in females). Of those, nine were significant to p<0. 0001 (six in males and three in females). We then investigated the gene-network profile of those who were classified within the highest 5% of SBP measures recorded across childhood and adolescence. We identified again, noticeable sex- and time-specific effects. These extreme (high) SBP profiles were associated with the following interactions; for females (under the age of 15 years) IGFBP3-IGFBP4 (p=0. 0076), for females (aged over 15 years) IGF1-IGF2 (p=0. 0014), IGF1-IGFBP3 (p=0. 0039), IGF1R-IGFBP5 (p=0. 0036) and for males (aged over 15 years) IGF2-IGFBP1 (p=0. 0080). The results attained are reasonable and align logically with current literature, particularly as IGF1 has been previously linked to hypertension and IGFBP1 has been linked with both positive and negative associations to SBP and to well-known risk factors of cardiovascular diseases. We found that this gene-network is modified with age; this in itself may be due to many reasons such as diet, hormones and developmental growth over time, particularly post-puberty. Further investigation using this method in cohort and consortium data would be ideal to validate our findings, improve accuracy surrounding the estimates produced here, and further improve the power to detect complex interactions. Through characterizing the association between multiple genes and disease outcomes we will offer new insight into disease aetiology whilst providing tools for making individualized treatment decisions.

1401W

Genome-wide search for gene-gene interactions in asthma susceptibility. *W. Murk, A. DeWan.* Department of Chronic Disease Epidemiology, Yale School of Public Health, New Haven, CT 06510, USA.

PURPOSE: Asthma is a highly heritable, common complex disease. Although many studies have attempted to identify gene-gene interactions in this disease, such studies have typically been conducted by only considering a small number of candidate genes, and there have been few genome-wide searches for interactions. We aimed to conduct a genome-wide gene-gene interaction study for asthma susceptibility using data generated from the GABRIEL Consortium [1]. **METHODS**: Three sets of asthma case-control data were used: a screening dataset (N=1,625 subjects), a follow-up dataset (N=5,264 subjects), and a replication dataset (N=230 subjects). All possible pairwise interactions among 301,547 SNPs were evaluated in the screening dataset; those with a screening interaction p < 10^-5 were evaluated in the follow-up dataset. The most significant interaction in the follow-up was subjected to further analysis in the replication dataset. Interactions were assessed via logistic regression modeling. **RESULTS**: From N = 4. 6 × 10^10 interactions tested in the screening dataset, N = 3. 5 × 10^5 met criteria for follow-up. None of these interactions passed a strict significance threshold of p < 1. 4 × 10^-7 in the follow-up analysis. The most significant interaction in the follow-up (involving rs910652 and rs11684871) had an interaction p-value of 1. 7 × 10^-6. Interestingly, rs910652 is located within 78 kilobases of *ADAM33*, which is one of the most well studied asthma susceptibility genes. The significance of this interaction was confirmed (p = 0. 025) in the replication dataset. **CONCLUSIONS**: Using a genome-wide approach, we identified and replicated a gene-gene interaction in asthma that potentially involves a highly plausible risk locus. This study provides evidence that non-additive effects among SNPs contribute to asthma susceptibility. **REFERENCE**: [1] Moffatt et al. N Engl J Med 2010. 363:1211-21.

1402T

A novel gene-level test of association using common variants. *P. Nakka, B. J. Raphael, S. Ramachandran.* Brown University, Providence, RI.

Genome wide association (GWA) studies have been used widely to identify susceptibility loci for complex phenotypes under the hypothesis that single mutations of large effect generate a phenotype of interest. However, complex diseases and traits are known to exhibit genetic heterogeneity on multiple levels: 1) within a causal gene, the phenotype may be generated by multiple mutations; and 2) mutations in distinct genes within a pathway may interact to cause the disease state. In both cases, gene-level tests of association and pathway analysis are necessary to identify candidate variants for experimental validation. However, in order to carry out gene-level tests using common variants, the SNP-level *p*-values need to be combined into a gene-level score. Here we introduce a new method to calculate gene-level scores that are*p*-values, calculated analytically from a null chi-square distribution that captures linkage disequilibrium (LD) between SNPs in a gene. We compare our new approach to three commonly used methods: minSNP, in which the lowest SNP *p*-value in a gene is chosen to be the gene-level *p*-value; permSNP, which calculates an empirical *p*-value using case-control permutations; and VEGAS, which uses simulations from a multivariate normal distribution whose variance is the empirical LD among SNPs in each gene. These methods have substantial drawbacks that can affect downstream pathway analysis including gene length bias, imprecision and computational inefficiency. We find that our method is unbiased by gene length, produces *p*-values with higher numerical precision by as much as 10 orders of magnitude and runs twice as fast as VEGAS. We conduct simulations to assess the sensitivity and specificity of our method, and find that our method has 30% higher true positive rate than minSNP when the false positive rate is fixed at 1%. Pathway analysis using HotNet2 uncovers gene interaction subnetworks containing a significant number of associated variants in cases (*p*-value <0. 05) for three traits: Attention-Deficit/Hyperactivity Disorder (ADHD), Ulcerative Colitis (UC) and Waist-Hip Ratio (WHR). We find gene networks associated with UC and WHR that have been functionally validated and novel gene associations for ADHD, UC and WHR, which may point to the underlying biological mechanisms and present potential new drug targets. Using gene scores from our method in HotNet2 analysis uncovers significantly associatedgene networks that are missed by minSNP and VEGAS.

1403F

Causal gene-gene and gene-environment interaction network analysis- A new generation of genetic interaction studies. *M. Xiong[1], P. Wang[3,1], Y. Zhu[2].* 1) Dept Biostatistics, Univ Texas Hlth Sci, Houston, TX; 2) tulane university; 3) Fudan University, China.

Most genetic analyses of phenotypes have focused on analyzing single traits or, analyzing each phenotype independently. However, multiple phenotypes are highly correlated. It has been reported that genetic pleiotropic effects likely play a crucial role in the molecular basis of correlated phenotypes. Joint gene-gene (GxG) and gene-environment (GxE) interaction analysis of multiple complementary traits will increase statistical power to identify GxG and GxE interactions, and hold the key to understanding the complicated genetic structure of the complex diseases. Despite their importance in uncovering the genetic structure of complex traits, the current marginal approaches for interaction analysis cannot distinguish between direct and indirect interactions, which will decrease our power to unravel mechanisms underlying complex traits. To overcome these limitations, we propose to use directed acyclic graphs (DAGs) as a major concept and a general framework for interaction analysis of multiple phenotypes to change the paradigm of traditional association guided interaction analysis. An essential issue for using DAGs to study interaction of multiple phenotypes is how to accurately and efficiently estimate the structure of DAGs from observational data. Structure learning of DAGs has been shown to be NP-hard. To obtain the causal graph from observation data as close to the biological causal graph as possible, we propose "score and search"-based methods for exact learning causal graphs of interaction to find the best-scoring structures for a given dataset. We develop novel functional structural equation models as a tool for defining score function and formulate the exact learning causal graphs of interaction as an integer programming. We develop efficient branch and bound algorithm to solve the formulated integer programming. To evaluate the feasibility of the proposed methods for causal GxG interaction analysis of multiple phenotypes, the developed methods are applied to a sample of 1,011 European-Americans (EA) with complete exome sequencing and 11 phenotypes. We identify a causal network with 22 nodes and 62 directed edges in which 39 gene-gene interactions cause the variation of 11 phenotypes. We also identify a hub gene CSMD1 formed interactions with 6 other genes which affect 5 phenotypes. The developed concept of causal inference for GxG and GxE interactions of multiple phenotypes is novel and powerful.

Multivariate Functional Regression Models for Epistasis Analysis. *F. Zhang[1], D. Xie[3], M. Xiong[2].* 1) Hohai University, Changzhou, China; 2) University of Texas School of Public Health; 3) Hubei University of Chinese Medicine.

To date, most genetic analyses of phenotypes have focused on analyzing single traits or, analyzing each phenotype independently. However, joint epistasis analysis of multiple complementary traits will increase statistical power, and hold the key to understanding the complicated genetic structure of the complex diseases. Despite their importance in uncovering the genetic structure of complex traits, the statistical methods for identifying epistasis in multiple phenotypes remains "fundamentally unexplored ". To fill this gap, we formulate a test for interaction between two gens in multiple quantitative trait analysis as a multiple functional regression (MFRG) in which the genotype functions (genetic variant profiles) are defined as a function of the genomic position of the genetic variants. We use large scale simulations to calculate its type I error rates for testing interaction between two genes with multiple phenotypes and to compare its power with multivariate pair-wise interaction analysis and single trait interaction analysis by a single variate functional regression model. To further evaluate its performance, the MFRG for epistasis analysis is applied to five phenotypes and exome sequence data from the NHLBI's Exome Sequencing Project (ESP) to detect pleiotropic epistasis. A total of 136 pairs of genes that formed a genetic interaction network showed significant evidence of epistasis influencing five traits. The results demonstrate that the joint interaction analysis of multiple phenotypes has much higher power to detect interaction than the interaction analysis of single trait and may open a new direction to fully uncovering the genetic structure of multiple phenotypes.

Genetic interaction networks reveal novel Type 2 Diabetes networks in the Marshfield PMRP. *R. Li[1], L. Bao[1], S. Dudek[1], D. Kim[1], M. Hall[1], Y. Bradford[1], P. Peissig[2], M. Brilliant[2], J. Linneman[2], C. McCarty[3], M. Ritchie[1,4].* 1) The Pennsylvania State University, University Park, PA; 2) Marshfield Clinic, Marshfield, WI; 3) Essentia Rural Health, Duluth, MN; 4) Geisinger Health System, Danville, PA.

Type 2 diabetes (T2D) accounts for over 90% of all cases of diabetes and is rapidly increasing around the world. Previous efforts to identify the genetic architecture of T2D led by Genome-Wide Association Studies (GWAS) have identified numerous genetic variants associated with the disease; however, the marginal effects of detected variants only explain a small portion of the disease risk. Typically, association studies only consider one model at a time to discriminate disease and healthy individuals; in addition, genetic interactions are often unexplored. Here, we propose a new analysis approach that can identify different genetic interaction architectures for T2D and non-T2D individuals simultaneously. We first performed a GWAS on 3265 T2D samples obtained from the Marshfield Personalized Medicine Research Project (PMRP) to identify the most strongly associated genetic variants. Our GWAS results replicated many previously known associations including the *TCF7L2* gene and *Hippo signaling pathway*. Next, we used SNPs that are marginally associated with T2D ($p < 0.001$) to construct genetic interaction networks in T2D and non-T2D individuals simultaneously. To search for the optimal interaction networks of genetic variants, we used Grammatical Evolution Bayesian Network (GEBN) that uses an evolutionary algorithm to significantly reduce the computational burden associated with structure estimation of the network. As a result, GEBN can be easily scaled up to thousands of input variables. We separately applied GEBN to T2D and non-T2D individuals and discovered different interaction networks for the two subgroups. Functional analysis revealed that T2D and non-T2D networks are enriched for different genes, GO terms, and pathways. A few notable examples include *CYP7A1, a* gene that controls synthesis of cholesterol, enriched only in the non-T2D individuals and *biosynthesis of unsaturated fatty acids* pathway only identified in the T2D individuals. We then combined the interaction networks and top GWAS associations to perform discriminant analysis for the T2D and non-T2D samples. We achieved an average AUC of 81% using cross validation, which presents a significant improvement over methods that only consider marginal effects. By combining the distinct genetic interaction networks in T2D and non-T2D and GWAS associations through discriminant analysis, we were able to better model the disease risk and gain novel insights in understanding the genetic architecture of T2D.

1406F

Testing for gene-by-environment interaction using a kernel-based score test. *F. Chen, S. Wang, L. Li.* BioStat Solutions, Inc. , Frederick, MD.

Background: Gene-by-environment interactions play an important role in both observational and interventional studies for precision medicine. Environmental factors such as smoking, radiation exposure and drug treatment may possibly have an interactive effect with genes on disease predisposition or drug response. Kernel-based approaches have been developed to test for the aggregate effects of genetic variants, but few methods are available to analyze interaction effects of a genomic region with environment factors. **Methods:** A novel kernel-based linear score test has been developed using a variance component approach to test for the interaction between the aggregate effects of genetic variants and environment. Specifically, both main effect of a gene and its interaction with an environment risk factor were modeled as variance components. A score test was employed to test for the interaction effect. Different types of kernels (e. g. Gaussian, identity-by-state (IBS), weighted IBS) have been considered in this approach. Type I error and power related to each type of the kernels were assessed and compared against existing methods in a simulation study. The approach has been applied to data from a genome-wide association study. **Results:** The proposed approach has preserved type I error and could achieve reasonable power, especially in the case of small sample size. This approach also showed higher computational efficiency. **Conclusions:** The novel kernel-based approach tests for the interaction between aggregate effects of genetic variants residing in a genomic region and environmental risk factors. The proposed approach provides a powerful tool to understand gene-by-environment interaction in genome-wide association studies or sequencing studies.

Detecting Interactions By Leveraging Genetic Ancestry. *D. S. Park[1], E. Y. Kang[2], I. Eskin[3], C. J. Ye[1], H. Aschard[4], E. Eskin[2], E. Halperin[3], N. Zaitlen[1].* 1) UC San Francisco, San Francisco, CA; 2) UC Los Angeles, Los Angeles, CA; 3) Tel Aviv University, Tel Aviv, Israel; 4) Harvard School of Public Health, Boston, CA.

Genetic association studies in humans have focused primarily on the identification of SNP effects contributing to the additive component of heritability. There is growing evidence that both gene-gene and gene-environment interactions contribute significantly to phenotypic variation in humans and model organisms. In addition to explaining components of missing heritability, interactions lend insights into the biological pathways regulating phenotypes and improve our understanding of their genetic architectures. Identification of interactions in human studies has been complicated by the multiple testing burden in the case of gene-gene interactions, and the lack of consistently measured environmental covariates in the case of gene-environment interactions. To overcome these issues we conduct SNP-by-ancestry tests of interaction in admixed populations. We use genetic ancestry (χ) as a proxy for unmeasured environmental covariates as well as SNPs with different frequencies in the ancestral populations of the admixed individuals. Our method is best illustrated with an example. Consider the case of a gene-environment interaction for an environmental covariate E. If E is correlated with χ ancestry can serve as a proxy for E (even if E is unknown or unmeasured), and can be analyzed for interaction in lieu of E. Many environmental covariates, such as socio-economic status, have been shown to be correlated with genetic ancestry. Ancestry can also serve as a proxy in the identification of gene-gene interactions for SNPs highly differentiated between ancestral populations. These high Fst SNPs will be correlated with χ and the resulting interaction test will maintain a 5x10-8 burden. To prevent false positive interactions driven by differential LD between ancestral populations we include local ancestry in our model. We applied our method to gene expression data from African American individuals in Corriell and ImmVar (Ye *et al.* 2014), which use LCLs and CD14 cells, respectively. In Corriell we found 2 genes (ERBB4, SGCG) that had a genome-wide significant ($p < 5x10-8$) interaction signal and 3 genes (MICU2, HBA1, HSF2BP) that displayed a moderate interaction signal ($p < 5x10-6$). For ImmVar there were no genes passing genome-wide significance but MAP3K7 showed a moderate interaction signal ($p < 5x10-6$), which replicated in the Corriell cohort.

Extracting socioeconomic data from electronic health records for gene-environment studies of blood pressure. *B. Hollister[1], E. Farber-Eger[1], D. Crawford[3], M. Aldrich[1,4,5], A. Non[1,2].* 1) Vanderbilt Genetics Institue, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Anthropology, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology & Biostatistics, Institute for Computational Biology,Case Western Reserve University, Cleveland, OH; 4) Department of Thoracic Surgery, Vanderbilt University Medical Center, Nashville, TN; 5) Division of Epidemiology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

Socioeconomic status (SES) is a fundamental variable contributing to health, particularly when analyzing racial disparities in health. SES data are rarely included in genetic studies, due in part to the difficultly of collecting these data when studies were not designed for that purpose. The emergence of large clinic-based biobanks linked to electronic health records (EHRs) provides research access to large populations with longitudinal phenotypic and exposure data captured in structured fields as billing codes, procedure codes, and prescriptions. SES in the EHRs, however, is often not explicitly recorded in structured fields. Rather, SES data are recorded in the free text of clinical notes and the content and completeness of these data vary widely by practitioner. To enable gene-environment studies that consider SES as an exposure, we sought to extract SES variables from BioVU, the Vanderbilt University Medical Center biorepository linked to de-identified EHRs. We developed an index of SES using information available within the de-identified EHR, including broad categories of occupation, education, insurance status, and homelessness. We performed free-text search across 15,865 individuals (11,521 African Americans; 1,714 Hispanics, 1,122 Asians, and 1,412 others) in BioVU for 22 different categories (534 unique terms) to extract relevant SES data. We identified 14,186 individuals with education information (89%) and 14,523 individuals with occupation information (92%). Examples of information collected include years of education an individual received, degrees earned, and latest recorded occupation. Insurance status was found for 75% of the individuals, and the term homelessness was found in the EHR for 43% of the individuals. We are in the process of investigating how the extracted SES data contribute to hypertension through interactions with genetic variants previously associated with hypertension from the Illumina Metabochip in African Americans. The SES data extraction approach and index developed here will enable future EHR-based genetic studies to feasibly integrate SES data into statistical analyses. Ultimately, increased incorporation of SES measures into genetic studies and examination of gene-SES interactions will help elucidate the impact of the social environment on common diseases.

1409F

Using Bayes model averaging to identify GxE interactions in genome-wide association studies. *L. C. Moss, D. V. Conti.* Preventive Medicine, University of Southern California, Los Angeles, CA.

Genome-wide association studies (GWAS) typically search for marginal associations between a single nucleotide polymorphism (SNP) and a disease trait while gene-environment (GxE) interactions remain generally unexplored. Numerous approaches exist to test for GxE interaction for either a single SNP or in a GWAS context. More powerful methods beyond the simple case-control approach leverage either SNP marginal effects or case-control ascertainment to increase power. However, these potential gains are accomplished under certain assumptions and it is often unclear if these assumptions are applicable *a priori*. Here, we review GxE methods, such as the case-only approach and more recently proposed two-step approaches, and use simulations to highlight performance as a function of marginal and interaction effect sizes, direction of effects, and the correlation of the two factors in the source population. Substantial variation in performance across methods leads to uncertainty as to which approach is most appropriate for any given analysis. Bayes model averaging offers a statistical foundation for incorporating model uncertainty and we present a framework that: (1) balances the robustness of a case-control approach with the power of the case-only approach; (2) leverages marginal SNP effects; (3) allows for the incorporation of prior information; and (4) allows the data to determine the most appropriate model. Within a log-linear model, we average over the inclusion of parameters corresponding to the marginal SNP and GxE interaction effects and the G-E association in controls. The resulting method exploits the joint evidence for marginal SNP and GxE interaction effects while gaining power from a case-only equivalent analysis. We use single-SNP and GWAS simulations to demonstrate that this method detects SNPs within a wide range of scenarios with the potential for increased power over current methods. We show the potential for increased power particularly for small marginal and interaction effect size combinations in various directions using this method. We demonstrate the approach on a genomewide gene-environment scan for asthma and lung function in the USC Children's Health Study.

Integration of text mining and epistasis analysis identifies new genes underlying atopy. *P-E. Sugier[1,2], M. Brossard[1,3], A. Vaysse[1,4], C. Sarnowski[1,3], M-H. Dizier[1,4], M. Lathrop[5], C. Laprise[6], F. Demenais[1,4], E. Bouzigon[1,4].* 1) INSERM UMR946, PARIS, France; 2) Université Pierre et Marie Curie, Paris, France; 3) Université Paris Sud, Paris, France; 4) Université Paris Diderot, Paris, France; 5) McGill University and Genome Quebec Innovation Centre, Montréal, Canada; 6) Université du Québec à Chicoutimi, Chicoutimi, Canada.

A few genome-wide association studies (GWAS) of atopy defined by skin prick test reactivity to allergens have been conducted in population-based cohorts and have led to the identification of at most 10 loci. Investigation of complex mechanisms such as gene-gene interactions and integration of prior-knowledge based on PubMed literature, in order to limit the multiple testing burden, may contribute to uncover new susceptibility genes. To identify new genetic determinants of atopy, we conducted in the French EGEA discovery dataset with validation in the French-Canadian SLSJ dataset a GWAS followed by epistasis analysis between the gene containing the most significant GWAS signal and a set of genes filtered according to the following criteria: (1) genes harbouring at least one SNP reaching a threshold of 10-4 in the GWAS; (2) genes selected in (1) and showing significant relationship through text mining using GRAIL (Gene Relationships Among Implicated Loci) applied to PubMed abstracts. The GWAS of atopy conducted in 1,660 EGEA subjects (including 925 atopics) with replication in 1,194 SLSJ subjects (with 675 atopics) identified a single genome-wide significant signal (Pmeta=9. 4x10-9) within adhesion G protein-coupled receptor V1 gene (*ADGRV1*). Based on the EGEA discovery GWAS results, 32 genes with at least one SNP with P≤10-4 were selected for cross-gene SNPx-SNP interaction analyses with *ADGRV1*. When using this first filtering criterion, 81,730 SNPxSNP interaction tests were performed in EGEA of which 403 reached the threshold of 5x10-3 and were taken forward for replication in SLSJ. Meta-analysis of the outcomes from these two datasets showed three SNP pairs with PmetaINT≤10-4. The GRAIL approach applied to the selected genes identified a relationship (PGRAIL<0. 1) between *ADGRV1* and three genes (*DNAH5*, *CHD7* and *ATP8B1).* This allowed reducing the number of SNPxSNP interaction tests by 9-fold. The same three SNP pairs previously identified had PmetaINT≤10-4. One of these pairs at *ADGRV1* and *CHD7* (chromodomain helicase DNA binding protein 7) reached the threshold of 2x10-5, which corresponds to the multiple-testing corrected threshold based on the text-mining filtering approach. This study highlights that integrating text mining and epistasis analysis facilitates the identification of new susceptibility genes. Funding: ANR-11-BSV1-027, ANR-USPC-2013-EDAGWAS.

1411T

Pathway analysis of next generation sequencing data based on a linear score test. *S. Wang, L. Li.* BioStat Solutions, Inc. , Frederick, MD 21703, MD.

Background: Over the past decade, there has been much focus on pathway analysis, which utilizes prior biological knowledge on gene function and relationship between genes. Such information is potentially useful for a better understanding of etiology of human diseases or mechanism of action in drug response. While gene expression microarray data have often been used, recent techniques have been developed to make use of genotype data, like Genome-wide association (GWA) and next generation sequencing (NGS) analysis. Methods: Our pathway analysis approach is tailored to NGS data. This approach is based on kernel machines which are often used in sequencing analysis. The method considers a kernel that defines genetic similarity of two individuals based on both, sequencing data and biological pathway information, and then uses a linear score test to assess statistical significance of the pathway effect on the outcome of interest. Based on a similar kernel setup, the application was also extended to test gene-gene (GxG) interaction effects while accounting for the gene main effect. Sample size and power of the proposed methods were assessed through multiple simulation scenarios, and we also applied the approach to sequencing data to demonstrate its application. Results: Based on the simulation, type I error was well controlled and the relative power has been demonstrated through different simulation scenarios. Conclusion: Different kernel strategies were implemented to identify either GxG interactions or profound pathway effects, and the proposed approaches have been built into a high-throughput analytics platform for NGS data analysis.

1412F

A stochastic search algorithm for finding multi-SNP effects using nuclear families. *C. R. Weinberg, M. Shi, A. Wise, D. M. Umbach, L. Li.* Biostatistics and Computational Biology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Given that biologic systems typically involve failure-resistant redundancy, phenotypes such as birth defects may occur only through the joint effects of exposures and several genetic variants. Such joint effects tend to produce a weak signal in typical GWAS analyses that assess only single-SNP associations. We describe an approach that uses case-parent triads and applies an “evolutionary algorithm” to stochastically search the large sample space that includes all sets of size S of potentially-interacting SNPs. We assess the performance of our algorithm using simulated but realistic data from the dbGaP GWAS data on families with the birth defect oral cleft. We simulate specific multi-SNP causal effects and then try to recover those causative complexes *de novo*. Initial simulations using our method show promising results in scenarios that involve two sets of four interacting SNPs, against a background of random cases. We are applying the refined method, using the original cleft data to explore a large set of candidate SNPs for epistatic effects related to risk of oral cleft.

1413W

Detecting 3-way G x AGE x SEX interaction effects for obesity traits: Methodological evaluation of approaches and results from the GIANT consortium. *T. W. Winkler[1], A. E. Justice[2], M. Graff[2], L. Barata[3], M. F. Feitosa[3], I. M. Heid[1], K. E. North[2], I. Borecki[3], Z. Kutalik[4,5,6], R. J. F. Loos[7].* 1) Genetic Epidemiology, University of Regensburg, Regensburg, Germany; 2) Department of Epidemiology, Gillings School of Global Public Health, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina 27514, USA; 3) Department of Genetics, Washington University School of Medicine, St Louis, Missouri 63110, USA; 4) Department of Medical Genetics, University of Lausanne, 1005 Lausanne, Switzerland; 5) Swiss Institute of Bioinformatics, 1015 Lausanne, Switzerland; 6) Institute of Social and Preventive Medicine, CHUV-UNIL, 1010 Lausanne, Switzerland; 7) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA.

Overall and central obesity – as measured by body mass index (BMI) and waist-hip ratio adjusted for BMI (WHRa) - differ between men and women and change over time (e. g. following menopause in women). Previously, genome-wide association meta-analyses (GWAMAs) revealed hundreds of associated loci, but little is known about the genetic impact on the sex-specific change in obesity traits around menopause. Given two potential interaction factors (sex and age), it can be tempting to test 3-way G x AGE x SEX interactions genome-wide. However, we are lacking methods and software to identify such 3-way interactions. Therefore, we introduce a difference-of-difference (d-o-d) test that can be utilized to infer 3-way G x AGE x SEX interactions from GWAMAs stratified by AGE (cut-off at 50 years, i. e. average age of menopause onset) and by SEX. First, we performed exhaustive simulations and analytical computations to evaluate type 1 error and power of different approaches to identify d-o-d. We found that the genome-wide screen for d-o-d showed highest power for extreme 3-way interactions that involve opposite effects across AGE and SEX. We also found that filtering for a marginal joint two-degree of freedom association, i. e. , allowing for heterogeneity in genetic effects for one, but not for the other factor (e. g. same effect in men and women, but different across the age groups), followed by a test for d-o-d was best powered to identify biologically more plausible 3-way interactions. Examples of these are the 1-stratum (effect in one stratum, lacking in others) or the 3-strata (effect in three strata, lacking in one) interaction. Application of approaches to age- and sex-stratified GWAMA data (N > 320,000) for BMI and WHRa from the GIANT consortium did not identify any significant 3-way G x AGE x SEX interactions. Given the large power (> 80%) for extreme 3-way interactions, our analysis does not support existence of such loci. Power for biologically plausible 3-way interactions was limited (< 20%). Even larger sample sizes are required to identify such loci with sufficient power (e. g. , N > 750,000 to identify a medium-sized 1-strata interaction with 80% power). In summary, we recommend screening approaches to identify 3-way interactions and provide a software implementation in the freely available R package EasyStrata. We demonstrate that extremely large sample sizes are required to find biologically plausible 3-way G x AGE x SEX interactions for obesity traits.

1414T

Multivariate functional regression model for gene-gene interaction analysis of highly correlated gene expressions. *K. Xu[1], M. Xiong[1,2].* 1) 1. School of Life Sciences and Institutes of Biomedical Sciences, Fudan University, Shanghai, Shanghai, China; 2) 2. Human Genetics Center, Department of Biostatistics, the University of Texas School of Public Health, Houston, TX, USA.

Gene-Gene interactions are essential components of the genetic architecture of the gene expressions. But, gene-gene interaction analysis of gene expressions remains fundamentally unexplored due to great computational challenges and data availability. On the other hand, considering the fact that many biological synthetic process require the balanced expression of multiple genes, analyzing the regulation mechanism of highly correlated gene expressions is crucial. However, simultaneously analyzing gene-gene interactions for highly correlated gene expressions poses enormous challenges for methodologies and computations: 1) lack of methods for gene-gene interaction analysis of multiple gene expressions, 2) severe multiple testing, 3) heavy computation burden. To meet these challenges, we use multivariate functional regression method for testing gene-gene interaction and estimating its effect in regulating gene expressions. In this model, we take a gene as a basic unit of the interaction analysis which includes both common and rare variants. By thorough simulation, we demonstrate that this method can achieve the correct type 1 error and have a better strength to detect the interaction effect than the pairwise interaction analysis. The proposed methods are applied to the gene expression and next-generation sequencing data with the 360 European samples and 87 African Samples from the 1000 Genome Project. For the 242 genes in MAPK pathway which are shared in these datasets, we discovered 46 pairs of genes showing significant interaction effects (P-value < 1. 71×10-6) on the highly correlated genes in this pathway, in both European and African people. For further study, we are applying this method on the whole genome data.

1415F

A comparison of methods for inferring causal relationships between genotype and phenotype using multi-omics data. *H. F. Ainsworth[1], S. Y Shin[2], H. J. Cordell[1].* 1) Institute of Genetic Medicine, Newcastle University, Newcastle Upon Tyne, UK, United Kingdom; 2) MRC Integrative Epidemiology Unit (IEU), University of Bristol, Bristol, UK.

Many novel associations between common genetic variants and complex human disease have been successfully identified using genome-wide association studies (GWAS). However, a typical GWAS gives little insight into the biological function through which these associated genetic variants are implicated in disease. Indeed, rather than finding variants which directly influence disease risk, the variants implicated by GWAS are typically in linkage disequilibrium with the true causal variants. Understanding the causal role of the genetic variants in disease etiology and moving towards therapeutic interventions is not simple. Integration of additional data such as transcriptomic, proteomic and metabolomic data, measured in relevant tissue in the same individuals for whom we have genomic (i. e. GWAS) data, could potentially provide further insight into disease pathways. Yet, open questions remain on how to assess the causal direction of association between these variables.

We review currently available statistical methods for inferring causality between variables that use a genetic variant as a directional anchor. We consider Mendelian Randomisation, Structural Equation Modelling, a Causal Inference Test and several Bayesian methods. We present a simulation study assessing the performance of the methods under different conditions, assuming throughout that we have a single genetic variant and two phenotypic variants that are associated with one another, although the underlying causal relationship may vary. In particular, we consider how the causal inference is affected by the presence of common environmental factors influencing the observed traits.

1416W

Pathway Analysis of Genome-Wide Glaucoma Data. *J. N. Cooke Bailey[1], M. Butkiewicz[1], L. R. Pasquale[2, 3], M. A. Hauser[4, 5], R. R. Allingham[4], J. L. Wiggs[2], J. L. Haines[1], NEIGHBORHOOD Consortium.* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Ophthalmology Duke University Medical Center, Durham, NC; 5) Department of Medicine, Duke University Medical Center, Durham, NC.

Primary open-angle glaucoma (POAG) is a phenotypically and genetically complex neurodegenerative disease that is a leading cause of blindness worldwide. To better understand the disease mechanism and genetic architecture of POAG, we performed an intensive pathway analysis with the goal of elucidating potentially novel mechanisms of disease. We implemented an updated version of the Pathway Analysis by Randomization Incorporating Structure (PARIS) program, which bins variants based on linkage disequilibrium blocks of similar structure and size to assess cumulative effects across biological pathways. Utilizing genome-wide logistic regression results from the NEIGHBORHOOD Consortium meta-analysis of imputed GWAS data from 3,853 POAG cases and 33,480 controls, we interrogated four pathway databases: Kyoto Encyclopedia of Genes and Genomes (KEGG), Gene Ontology (GO), Reactome, and NetPath. Because PARIS minimizes multiple testing and type I error concerns through the use of empirical genomic randomization to estimate significance, we are not obligated to correct for every variant evaluated and therefore set a significance threshold of P<0. 0001. We additionally set the number of permutations to 10,000. Our preliminary analysis which was restricted to pathways containing at least 3 genes identified several pathways of potential involvement in POAG beyond those previously reported; this includes 3/26 NetPath, 30/293 KEGG, 123/1748 Reactome, and 677/12765 GO pathways. From NetPath, the signal transduction pathways IL9, IL1, and TNFalpha show particularly intriguing results as 6 IL9, 21 IL1, and 28 TNFalpha genes were individually associated with P<0. 001 with very little overlap between the significant genes defining each pathway. From KEGG, the pathways with the highest percentage of associated features and with no genic overlap were the phenylalanine, tyrosine and tryptophan biosynthesis and the spliceosome pathways. Identifying novel POAG pathways will help to define the underlying mechanisms of POAG by identifying proteins and molecular pathways that influence pathogenesis; this information can then be utilized to identify biomarkers for early molecular diagnosis and treatment and improve prevention strategies. This work was supported by NIH/NEIEY022305.

1417T

A Highly Adaptive Test for Gene- or Pathway-Multivariate Trait Associationwith Application to Neuroimaging Data. *J. Kim, W. Pan.* Division of Biostatistics, University of Minnesota, Minneapolis, MN.

Testing for genetic association with multivariate traits has become increasinglyimportant, not only because of its potential to boost statistical power, but alsofor its direct relevance to some applications. For example, there is accumulatingevidence showing that some complex neurodegenerative and psychiatric diseaseslike Alzheimer's are due to disrupted brain networks, for which it would benatural to identify genetic variants associated with disrupted brain networks. In spite of its promise, testing for multivariate trait associations is challenging:if not appropriately used, its power can be much lower than testing on each univariatetrait separately (with a proper control for multiple testing). Furthermore, differing from most existing methods forsingle SNP--multiple trait association, we consider gene- and pathway-basedassociation testing for multiple traits, due to well known genetic heterogeneity andsmall effect sizes of individual SNPs. Because the power of a test critically dependson several unknown factors such as the proportions of associated SNPs, genes andtraits among those tested, we propose a highly adaptive test that data-adaptivelydetermines some optimal parameters in the test to yield high power across a widespectrum of situations. We compare the performance of the new test with severalexisting tests using both simulated and real data. We apply the proposed test tostructural MRI data drawn from the Alzheimer's Disease NeuroimagingInitiative (ADNI) project to identify genetic variants associated withthe human brain default mode network (DMN).

Covariate-selection approach in Genome Wide Association Studies for multivariate data. *Y. A. Tsepilov[1,2], G. Kastenmuller[3,4], R. Wang-Sattler[5,6], K. Strauch[7,8], C. Gieger[5,6,7], Y. S. Aulchenko[1,2].* 1) Institute of Cytology and Genetics SD RAS, Novosibirsk, Russia, 630090; 2) Novosibirsk State University, Novosibirsk, Russia, 630090; 3) Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 4) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom; 5) Research Unit of Molecular Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 6) Institute of Epidemiology II, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 7) Institute of Genetic Epidemiology, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 8) Institute of Medical Informatics, Biometry and Epidemiology, Chair of Genetic Epidemiology, Ludwig-Maximilians-Universitét, Munich, Germany.

Genome-wide association analysis (GWAS) is one of the most popular methods of identification of alleles that affect complex traits. Recent accumulation of functional genomics data ("ome" data, e. g. transcriptome, metabolome etc) could give a new insight into the functional role of specific changes in the genome. Such data require special statistical methods for their analysis, as they are characteristically high dimensional and contain statistical interactions and functional relationships between individual components, which usually reflect biological interactions. Development of such methods is of current importance as the progress of molecular biology techniques marches on. We introduce a group of approaches to evaluate the impact of genetic variants to "omics" phenotypes with relatively high power and rather modest computational intensities. It is based on the idea that if biological pathways and relationships in data could be reconstructed, we can use the knowledge about biochemical neighbors for chosen trait and include this information into analysis of this trait. The sources of biological relationship information can vary: biological pathway databases or reconstructed net from the data. We assessed our approach using real population study data from big German study KORA (n=1,784, 2M SNPs) with measured metabolomics data (151 metabolites). For reconstruction of the pathways we used Gaussian Graphical Models (GGM) which was shown as effective tool for the unbiased reconstruction of metabolic reaction. Previously it was demonstrated that using GGM-driven ratios instead of all ratios leads to comparable power with much less computational expenses. Our approach as well has shown the comparable power with all ratio approach with computational complexity similar to the analysis of original concentrations only (n instead of n2). Moreover we generalized this method using shrinkage regularization (RIDGE and LASSO) for phenotypic correction with different types of penalization (penalties proportional to GGM distances and penalties proportional to real biochemical distances extracted from databases). Using these types of models decreases the phenotype variances and the noise driven by network influences between metabolites with the dissolution of induced signals and the improvement of actual associations that helps with further functional annotation.

Identifying ethnic-group and SNP interaction in meta-analysis for sequencing association studies. *S. Wu[1], H. Wang[1], C. Lin[2], D. Chen[1], C. Chang[1], C. Fann[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan, Taipei, Taiwan; 2) Graduate Institute of Life Sciences, National Defense Medical Center, Taipei, Taiwan.

Meta-analysis is a routine approach in genome-wide association studies to analyze data across studies to increase power. Although large sample sizes can help guard against false-negative and false-positive results, a major potential problem is that allelic heterogeneity across populations could lead to dramatic reduction of power in detecting true positive signals. Therefore, the issue of population heterogeneity can not be ignored in meta-analysis. Currently, a widely used approach for adjusting population stratification (PS) is EIGENSTRAT method based on principal component analysis (PCA). The method identifies several top principal components (PCs) and uses them as covariates to adjust for PS. However, it is difficult to quantify interaction between ethnic-group and SNP. Very few studies have discussed the impact of ethnic-group and only coded them as a moderator variable in meta-analysis. In this study, we proposed an approach that incorporated ancestry informative markers (AIMs) information for investigating heterogeneity among populations and constructed a meta-regression model using ethnic-group as a moderator variable to detect interaction between ethnic-group and SNP in meta-analysis. In order to discern the population-heterogeneity markers among populations, 1000 genomes datasets were used as reference to create a panel of AIMs. The population differentiation measure, FST, was calculated for each SNP. In order to evaluate the efficacy of our proposed method, two simulation data structures were considered: (i) European and Asian populations; (ii) American and European populations. A few parameters such as minor allele frequency, the difference between two populations, the effect size for different ethnic groups, sample sizes and the numbers of studies were assumed to calculate type I error and power using simulation study. In our results, we found that fewer than 100 SNPs would be sufficient to determine the most representative population-heterogeneity markers among populations. In conclusion, our proposed method increase both sensitivity and specificity and hence reduce heterogeneity in meta-analysis.

New disease susceptibility loci identified by a multiple SNPs interaction search in GWAS. *Y. Yasui[1], N. Sharafeldin[1], Q. Liu[1], S. Jabbari[1], L. Wang[2], C. Franco-Villalobos[1], S. Mahasirimongkol[3], H. Yanai[3, 4], K. Tokunaga[3].* 1) School of Public Health, University of Alberta, Edmonton, Canada; 2) College of Agriculture & Biotechnology, Zhejiang University, China; 3) Department of Human Genetics, School of International Health, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 4) Fukujuji Hospital, Japan Anti-Tuberculosis Association, Kiyose, Japan.

A typical genome-wide association study (GWAS) explores SNP-disease associations following the common practice of analysis of a single SNP at a time in association with disease. We focused here on examination of *SNP-set* interaction effects within-genes on disease risk. We applied logic regression to search for SNP-set interactions using data from the Wellcome-Trust-Case-Control-Consortium (WTCCC). The genotype cluster intensity plots were generated for SNPs of statistically significant genes to exclude false-positive associations. Plots were visually inspected one by one: this was necessary to remove the genes discovered due to genotyping errors. The majority of the discovery had to be removed from the list of significant genes if one SNP or more in the logic trees had a genotype call that appeared erroneous. Genes showing strong evidence of association were: 13 for bipolar disorder (BD), 16 for coronary artery disease (CAD), 15 for hypertension (HT), 72 for rheumatoid arthritis (RA), 105 for type 1 diabetes (T1D) and 19 for type 2 diabetes (T2D). The identified loci included almost all strong single-SNP signals reported by WTCCC. On average 51% of recently reported GWAS meta-analyses signals across the six diseases overlapped with our findings. The top significant genes were: *NFIA* with BD, *CDKN2B* and *TPH1* with CAD, *COL4A4* with HT, *BTNL2* with RA, and *TCF7L2* and *TMEM155* with T2D. Our approach demonstrates the confirmatory and discovery value of considering higher order SNP-set interactions in addition to the standard single-SNP analysis in GWAS.

A Statistical Approach for Testing Gene by Microbiome Interactions. *N. Zhao, M. C. Wu.* Public Health Sciences Division, Fred Hutchinson Cancer Research Center, Seattle, WA.

Although GWAS and next generation sequencing studies of human genetic profiles have helped elucidate the genetic component of complex traits and disease, a comprehensive understanding requires understanding the role of other risk factors, including the microbiome. Facilitated by sequencing technology, comprehensive profiling of the microbiome is now possible and has led to a range of traits being associated with microbiome composition. However, despite the importance of both microbiome and genotype as factors underlying many traits, there has been little work on assessing their joint effect. A problem of particular interest is identifying genetic variants that modify the effect of microbiome composition on traits and the discovery of genotypes for which the effect of microbiome composition is heterogeneous. Yet, how to test for statistical interactions between microbiome composition and genetic variants remains un-addressed. Therefore, we propose a new strategy for assessing the interaction between individual variants and microbiome using a regression based framework. In particular, following standard microbiome approaches, we encode microbiome as a matrix of pair-wise distances between individuals where the distance is defined based on a phylogenetically informed metric. The distance can then be transformed to be a kernel matrix of pairwise similarities between the individuals in the study. This, in turn, enables us to exploit the kernel machine framework (e. g. SKAT) to model the relationship between a quantitative trait and microbiome (modeled flexibly through the phylogenetically informed kernel), the main effect of a genetic variant, and their interaction. Modifications to the standard kernel machine framework are necessary to accommodate the dimensionality and complexity of microbiome composition data. Under this modified framework, we develop a score test for testing the interaction term. Simulations and real data applications show that our approach has reasonable power and correct type I error.

Efficient heritability partitioning via controlled down-sampling with the Haseman-Elston approximate regression. *X. Zhou.* Biostatistics, University of Michigan, ANN ARBOR, MI.

Although genome-wide association and sequencing studies have identified many SNPs associated with common diseases and complex traits, the biological mechanisms underlying these associations are largely unknown. Quantifying the proportion of phenotypic variance contributed by various SNP functional categories, or partitioning chip heritability, has thus become an initial important step towards understanding the molecular mechanisms of SNP associations. Here, we present a new method for such analysis. Our method builds upon the renowned Haseman-Elston regression for variance component estimation and requires only summary level statistics. More importantly, our method effectively uses only a small fraction of the sample (e. g. 1%), while still produces accurate results with only slightly increased confidence intervals (e. g. 10%). This allows our method to be efficiently applied to large scale association studies while producing calibrated test statistics. Compared with the competing approach (i. e. LD score regression), our method produces unbiased and more efficient estimator, has proper control for type I error in hypothesis test, and is faster. Using simulations and real data applications, we illustrate the benefits of our method and provide insights for the importance of several functional categories. The method is implemented in the GEMMA software package, freely available at www. xzlab. org/software. html.

Causal Genomic Network Analysis emerges as a New Generation of GeneticStudies of Complex Diseases. *Y. Zhu[1], P. Wang[2], J. Zhao[1], M. Xiong[2].* 1) Epidemiology, Tulane Univ Pub Health & Tropical Med, New Orleans, LA; 2) Division of Biostatistics, The University of Texas Health Science Center at Houston,School of Public Health, Houston, TX.

In the past decade, rapid advances in genomic technologies have dramatically changed the genetic studies of complex diseases. Genome-wide association studies (GWAS) have been widely used in dissecting genetic structure of complex diseases. However, numerous studies reported that the genetic loci identified by GWAS collectively explain only < 10% of genetic variation across the population. Although extremely large number of samples are collected and whole genome sequencing studies will be conducted very soon, which will lead to reducing he fraction of missing heritability, a large proportion of heritability will be still missing under the paradigm of single trait genetic analysis. The methods for heritability estimation and single trait genetic study paradigm are questionable. The heritability of individual phenotype cannot reveal complicated genotype-phenotype structure and is highly unlikely to fully capture the structure of heritability of multiple phenotypes. The concept of heritability should be extended from a single trait to multiple traits. The genetic studies of complex diseases also should be extended from a single trait analysis to multiple trait analysis. The popular methods for genetic studies of multiple traits are mainly based on correlation and association analysis. These methods cannot efficiently detect, distinguish and characterize the true biological, mediated and spurious pleiotropic effects. To overcome these limitations, we develop a directed acyclic graph (DAG)-based new framework and novel statistical methods for inferring causal networks of genotype-phenotypes with NGS data and detecting, distinguishing and characterizing the true biological pleiotropic, mediated pleiotropic and spurious pleiotropic effects of genetic variants. The propose methods for causal network analysis of genotype-phenotype were applied to two independent GWAS datasets: WHI (4382 samples and 742,996 SNPs) and ARIC (7756 samples and 780,062 SNPs). A total of 9,732 genes and 16 phenotypes shared in two datasets were used to construct causal genotype-phenotype networks. We identified 23 significantly connected to phenotypes in causal genotype-phenotype networks common in the WHI and ARIC studies. There were 13 edges directed from gene to phenotypes and 7 edges directed from phenotypes to phenotypes were common in the causal networks constructed by 23 genes and 16 phenotypes in the in the WHI and ARIC studies.

1424F

Genetic modifiers of immune reactivity to a human pathogenic mycobacterium. *J. Manry[1,2], Y. Nédélec[3,4], V. M. Fava[1,2], A. Cobat[5], M. Orlova[1,2], L. B. Barreiro[3,4,6], E. Schurr[1,2].* 1) Program in Infectious Diseases and Immunity in Global Health, the Research Institute of the McGill University Health Centre, Montreal, Quebec H4G 3J1, Canada; 2) McGill International TB Centre and Departments of Medicine and Human Genetics, McGill University, Montreal, Quebec H4G 3J1, Canada; 3) Sainte-Justine Hospital Research Centre, Montreal, Quebec H3T 1C5, Canada; 4) Department of Biochemistry, Faculty of Medicine, University of Montreal, Montreal, Quebec H3T 1J4, Canada; 5) Laboratory of Human Genetics of Infectious Diseases, Necker Branch, Institut National de la Santé et de la Recherche Médicale, U. 1163, Paris 75015, France; 6) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Quebec H3T 1J4, Canada.

Leprosy is a human infectious disease caused by *Mycobacterium leprae*. A strong host genetic contribution to leprosy susceptibility is well established. However, the modulation of the transcriptional response to infection and the mechanism of disease control are poorly understood. To address this gap in knowledge of leprosy pathogenicity, we conducted a genome-wide search for loci that are associated with transcript variation – expressed quantitative trait loci (eQTL) – before and after stimulation with *M. leprae* sonicate in whole blood cells from 54 unrelated leprosy patients from Vietnam. Among 12043 tested genes, we found 6787 as being significantly up- or down-regulated. Gene ontology (GO) enrichment analysis on differentially expressed genes (DEG) allowed us to confirm that the vast majority of significant enrichments were related to the immune response, including genes that had previously been associated with leprosy (e. g. *TNF* is in the top 15 of the most DEG). We then identified 36700 cis-eQTL for 818 genes, including 5784 for 33 genes associated with the “immune response” GO term. Interestingly, most of these “immune response” eQTL were eQTL for genes in the HLA region. In addition, we found 7814 eQTL as being specific to stimulated or to non-stimulated cells but not to both conditions. Of those, we found 336 response eQTL for genes associated with the “immune response” GO term including 265 for HLA genes. This finding is concordant with the results of our genome-wide association study, which had identified the HLA system as an important genetic risk factor of disease. The response eQTL correspond to regulatory variations that likely affect the interaction between human whole blood cells and *M. leprae* sonicate, and thus likely between the human host and *M. leprae* themselves. Remarkably, *ADCY3* – previously identified as a leprosy type-I reaction signature gene – was one of the genes presenting the highest number of response eQTL as well as one of the highest up-regulations of gene expression. Given their association with changes in the immune response to *M. leprae* sonicate, these response eQTL represent promising genetic candidates for susceptibility or resistance to leprosy and show the functional consequence of genetic risk factors for disease. Importantly, our study identified novel, hitherto unknown pathways of host responsiveness to *M. leprae* and substantially increases our understanding of leprosy pathogenicity.

1425W

A variable selection method for identifying complex genetic models associated with human traits. *E. R. Holzinger[1], J. Malley[2], Q. Li[1], J. E. Bailey-Wilson[1].* 1) National Human Genome Research Institute, NIH, Baltimore, MD; 2) Center for Information Technology, NIH, Bethesda, MD.

Purpose: Standard analysis methods for genome wide association studies (GWAS) are not robust to complex disease models (e. g. multivariable models with non-linear interaction effects), which likely contribute to the heritability of complex human traits. Machine learning methods, such as Random Forests (RF), are an alternative analysis approach that may be more optimal for identifying these effects. One caveat to RF is that there is no standardized method of selecting a set of variables with a low false positive rate (FPR) while retaining adequate power. **Methods:** We have developed a variable selection method called r2VIM. This method incorporates recurrency and variance estimation into RF to guide optimal threshold selection. We assess how this method performs in simulated SNP genotype data with a variety of complex effects (multiple loci with interactions and main effects). **Results:** Our findings indicate that the optimal selection threshold can identify interactions with adequate detection power while maintaining a low FPR in the selected variable set. For example, the optimal VIM threshold had an average detection power of 0. 80 and an average FPR of 0. 11 for a model with a two-locus interaction and no main effects (i. e. a purely epistatic model). However, the optimal threshold is highly dependent on the simulated genetic model, which is unknown in biological data. To address this, we permute the phenotype and re-run r2VIM to generate a null distribution of VIMs. The results from the permuted data are used to choose a selection threshold in the non-permuted analysis by comparing FPR estimates at different VIM thresholds, which does not require knowledge of the underlying genetic model. We tested the permutation method on an array of simulated data. Our initial results show that the best balance between FPR and detection power is produced by selecting the VIM threshold with an FPR of close to 0. 05 in the permuted data. Since our method is selection based (i. e. no modeling), we also implement a novel technique in r2VIM called “entanglement maps” to guide distinction of main effects versus interaction effects. We present visualizations of these results to further aid interpretation.

Bayesian Kernel Based Modeling and Selection of Genetic Pathways and Genes for Cancer. *Z. Wang[1], S. Chakraborty[2].* 1) BioStat Solutions, Frederick, MD; 2) University of Missouri, Columbia, MO.

Background: Much attention has been given recently to the development of analytical methods that utilize the large quantity of genetic information, which becomes available, thanks to advanced biological technologies. Most of the proposed methods look at the entire set of genes and their impact on a disease. Recently a new philosophy emerged which considers a combined genetic pathways effect on a disease. Under the new philosophy the objective is to identify the significant genetic pathways and the corresponding influential genes within a disease process. Method: A Bayesian kernel machine model which incorporates existing information on pathways and gene networks into the analysis of microarray data is developed to identify significant pathways and genes related to survival time. Each pathway is modeled nonparametrically using a reproducing kernel Hilbert space. Mixture priors on the pathway indicator variable and the gene indicator variable are assigned. An efficient Markov Chain Monte Carlo (MCMC) algorithm is developed to fit our model. Simulation studies and a real data analysis, using, van’t Veer et al. (2002) breast cancer microarray data, are used to illustrate the proposed method. Result: 9 out of 243 pathways are selected and 94 out of 4363 genes are selected by the model. Conclusion: This approach can be used to model both linear and non-linear pathway effects and can pinpoint the important pathways along with the active genes within each pathway. The model can use RNA sequencing data as input and it can be easily adapted to continuous or binary response variables.

Modified Random Forest Algorithm to Identify gene-gene Interaction in Case-Parent Trios Studies of Oral Cleft. *Q. Li[1], E. Holzinger[1], J. Hetmanski[2], M. Marazita[3], T. Beaty[2], J. Bailey-Wilson[1].* 1) Computational and Statistical Genomics Branch National Human Genome Research Institute National Institutes of Health 333 Cassell Drive, Suite 1200 Baltimore, MD 21224; 2) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 3) Department of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh PA, USA.

Non-syndromic cleft lip with or without cleft palate (CL/P) is a common birth defect with strong genetic components. Genome-wide association studies (GWAS) for CL/P have identified multiple genes as influencing risk of CL/P. The case-parent trio design has the advantage of controlling for population stratification and facilitates error checking. However, methods designed to test for gene-gene interaction using trio data are very limited. In previous work, we have modified the random forest (RF) algorithm to identify gene-gene interaction in trio data. Our modified random forest uses a sampling scheme with a regression-based splitting criterion to take into account the family relationship among the cases and ‘pseudo controls’ (genotypic combinations possible given the parental mating type). In this project, to further explore possible gene-gene interaction effects, we applied our method to case-parent trio data from a previous GWAS study of CL/P with multiple ethnic/racial groups from an international consortium. To control for the randomness in the search algorithm, we employed the ‘recurrency variable importance metric’ to finalize the list of top SNPs possibly involved in gene-gene interactions. We have applied our method to a subset of ~400 markers, including those belonging to WNT pathway and those with large marginal effects. Our method identified markers with large marginal effects, (in genes *IRF6* and *C1orf107* in the Asian trios; and in *hcG_1814486* and *UNC5C* in the European trios), as the top SNPs possibly involved in gene-gene interactions. We did not find any evidence of gene-gene interaction within the WNT pathway. We are currently applying this method to the entire genome-wide marker panel using these GWAS data, since this method has the potential to identify possible gene-gene interactions among markers without large marginal effects. The results will be compared with the results from another ensemble method, trioFS, which is part of the R package, trio.

Causal Inference for Integrative Analysis of Genetic and micro RNA variation. *P. Wang[1,4], X. Chen[2], V. Vladimirov[2], Y. Zhu[3], M. Xiong[1].* 1) University of Texas, School of Public Health, Houston, TX; 2) Virginia Commonwealth University, Richmond, VA; 3) Tulane Univrsity, New Orleans, LA; 4) Fudan University, School of Life Sciences, Shanghai, China.

The rapid development of genomics technologies including microarrays and next generation sequencing (NGS) has provided powerful tools for comprehensive analysis of genomes, including the expression of microRNAs, and sequence variations. These genome-wide profiles of the genetic aberrations could reveal the biomarkers for diagnosis and prognosis of diseases as well as mechanistic insights into disease development and progression. Recent efforts to establish the huge psychiatric genome compendium and integrative omics analyses, so-called "integromics", have extended our understanding on the genome, showing its daunting complexity and heterogeneity. However, the challenges of the structured integration, sharing, and interpretation of the big omics data still remain to be resolved. We often use correlations or mutual information between two genes and Gaussian undirected graphical models to construct co-expression networks as well as regression to identify eQTLs. Although association analysis and regression quite useful in genetic and epigenetic studies of mental disorders, they are difficult to unravel the mechanic mechanism of the complex diseases. To overcome these limitations, gene perturbations that exploit naturally occurring genetic variations can be used to learn causal genotype-micro RNA networks. We propose exact learning causal graphical models for genotype-micro RNA networks from both miRNA-seq and NGS genetic data. This will open a new avenue to use exact learning DAG for causal inference of genotype-micro RNA networks, which will lead to accurate estimation of causal effects of the genetic variants on micro RNA expressions and provide a powerful tool for drug target discovery and precision medicine. The proposed methods were applied to micro RNA and SNPs datasets from the Stanley Medical Research Institute (SMRI) of 58 samples. We first apply our method to each gene and 422 miRNAs and 666 genes passed the p-value threshold 3. 25e-6. Then we fit our model to the 422 miRNAs and the 666 selected genes and get inferred sparse miRNA causal network consisted of 809 nodes and 1391edges, among which 339 genes were significantly connected to micro RNA.

1429T

Comparison and optimization of different centrality measures algorithms used in human gene network analysis. *T. Zhang, J. P. Rice.* Dept of Psychiatry, Washington University in Saint Louis, Saint Louis, MO.

Four centrality measures are one of the important parameters utilized in gene network analysis: 1) Degree centrality which simply counts the number of interactions to a node; 2) Eigenvector centrality which ranks the nodes in a network based on its integrating neighbors; 3) Betweenness centrality where nodes which fall in the shortest path of other nodes have high betweenness, and 4) Closeness centrality which is related to the topology of the nodes in a network. Despite some early studies that utilize the simplest degree centrality measure, most of the recent research projects have implemented the eigenvector centrality measure, such as algorithms modified from Google PageRank algorithm, to evaluate the importance of a gene in a gene network. However, research questions such as to what extent these centrality measures can represent the functional significance of genes or whether any of these centrality measures outperformed others have never been seriously investigated. In this project, we aimed to conduct a study to compare the accuracy and efficiency of these four centrality measures. Two essential gene sets were obtained and served as "true answers" for algorithms comparison and machine learning data training. One gene set containing 1,528 protein coding genes was directly extracted from Online Gene Essentiality Database (OEGG). Another gene set including 1,174 genes was obtained through implementing a variant filtering strategy based on theExome Aggregation Consortium data (ExAc). A comprehensive human gene network which covered 90% of human protein coding genes were constructed based on protein-protein interaction data extracted from STRING, REACTOME and iRefindex. The network visualization and centrality measure calculations were performed using R package igraph. ROC curve was made to make comparison of the four algorithms. In addition, we constructed a logistic regression model to combine the four centrality measures in order to give a more accurate prediction of the functional significance of protein coding genes in the comprehensive gene network. The 10-fold cross-validation approach was used to assess the performance of the prediction model. Our results indicated that the combined centrality measure is more efficient in predicting the functional significance of a gene in a specific human gene network.

1430F

Differential expression of transcript isoforms in schizophrenia. *E. Drigalenko[1], W. Moy[2], J. Duan[2,3], H. Göring[4], P. Gejman[2,3], A. Sanders[2,3], Molecular Genetics of Schizophrenia (MGS) Collaboration.* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Psychiatry and Behavioral Sciences, NorthShore University HealthSystem, Evanston, IL; 3) Department of Psychiatry and Behavioral Neuroscience, University of Chicago, Chicago, IL; 4) South Texas Diabetes and Obesity Institute, University of Texas Health Science Center, San Antonio, TX.

Transcriptome sequencing (RNA-seq) enables investigation of differential expression of transcript isoforms and genes from subjects with or without illness. Transcript isoform expression level is arguably more biologically meaningful than overall gene expression level since the former often encode different proteins, which can have different biological function. Sensitivity may be improved by avoiding the summing over transcript isoforms needed for aggregate (gene level) analysis. We profiled the transcriptome (>9M total single-end RNA-seq reads per subject) in lymphoblastoid cell lines (LCLs) of 1,278 European ancestry subjects (550 cases and 728 controls) from the MGS collection. We used programs Tophat v2. 0. 12 and Cufflinks2 v2. 2. 1 for read alignment, transcript assembly, and quantification (FPKM) of each transcript isoform and gene. We restricted our differential expression analyses to the 108,346 transcripts and 21,215 genes from Gencode v. 20 annotation that showed detectable expression (FPKM>0) in at least 80% (1,022) of subjects. We used square root as the variance stabilizing transformation for the expression values, and then adjusted for covariates: sex, age, age2, ancestry (five genotypic principal components), LCL characteristics (viral load, growth rate, energy status), and RNA-seq batch. After inverse normalization of residuals, we evaluated the association of expression levels with schizophrenia status by multiple linear regression analysis (R v3. 02 program package). We found 1,265 transcripts and 1,252 genes to be differentially expressed by affection status (Bonferroni corrected p<0. 05). Of these transcripts, 1,015 were in genes also showing significant differential expression in the gene-level analysis, while 250 were in genes not showing significant differential expression. On the other hand, 447 differentially expressed genes (gene-level analysis) did not show differential expression at the transcript isoform level. Differential transcriptomic analyses at the gene and transcript isoform levels may complement each other, providing additional information for identifying disease-associated aberrant expression. We found a number of significant transcripts and genes in HGNC (HUGO Gene Nomenclature Committee) gene families, such as histocompatibility complex, histones, interferons, and interleukins. Many of the detected gene families are immune-related ones, consistent with previous large GWAS and expression studies.

A HMM-based method to harmonize discordant genotypes obtained from DNA sequencing and genotyping experiments in the same samples. *C. Low-Kam[1,2], D. Rhainds[1], I. Mongrain[1,3], M. -P. Dubé[1,2,3], J. -C. Tardif[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montréal, QC, Canada; 2) Faculty of Medecine, Université de Montréal, Montréal, QC, Canada; 3) Beaulieu-Saucier Université de Montréal Pharmacogenomics Center, Montréal, QC, Canada.

We introduce a new method to merge genotypes from two data sources at divergent locations. Our approach is motivated by a low-pass whole-genome sequencing (WGS) study of the French-Canadian population, where 2002 individuals were sequenced at 5. 7x coverage. In this study, we identified over 32 million variants, of which 51% were not previously reported in public databases. We evaluated our data by comparing the resulting sequences against ExomeChip genotyping data available in the same individuals. The overall genotyping concordance rates between both datasets are 99% and 87% when considering all genotypes or only heterozygous genotypes, respectively. These rates are encouraging because low-pass WGS is theoretically less accurate for heterozygous genotypes, and for rare variants, which are enriched on the ExomeChip. To the best of our knowledge, no method currently exists for merging our datasets at discordant positions. As the confidence is greater for the ExomeChip genotyping data, a reasonable approach would be to choose genotypes from the ExomeChip as the “true” genotypes. A more adaptive alternative consists in using linkage disequilibrium to derive the most likely genotype at each divergent location. We developed a bivariate Hidden Markov Model (HMM)-based framework that extends the imputation method of the software MaCH to output posterior genotype probabilities based on both datasets. Conditional independence properties allow accounting for neighbouring sites variation while remaining computationally tractable. The associated algorithm is implemented in C++. Preliminary results are promising: we tested our method on two datasets with distinct errors derived from the same simulated genotypes. Our method provides a compromise that outperforms the dataset with the lowest error rate. Although the algorithm works best to detect errors in homozygotes for the major allele, it is still able to correct errors in heterozygotes and homozygotes for the minor allele. Finally, the algorithm is robust to parameter initialization. Our methodology can be applied to any datasets where divergent genotypes are collected from two sources, on the same samples.

1432T

Imputing LoF variants in Finnish founder population using population-specific reference panels. *A. Sarin[1,2], I. Surakka[1], K. Karczewski[3], R. Durbin[4], D. MacArthur[3], V. Salomaa[2], A. Palotie[1,3], S. Ripatti[1,5] for SISu project.* 1) Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Broad Institute of MIT and Harvard, Cambridge, MA 02142, USA; 4) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge CB10 1SA, UK; 5) Department of Public Health, University of Helsinki, Helsinki, Finland.

It has been shown that population specific reference panel improves imputation accuracy especially for the rare and low frequency variants. In our study, we utilized low-coverage whole genome sequencing (WGS) and whole exome sequencing (WES) based reference panels created from the Sequencing initiative Suomi (SISu; http://www. sisuproject. fi) data, and compared imputation accuracy of single nucleotide polymorphisms (SNPs) with MAF < 1% in a set of imputation reference panels that also included the publicly available 1000 Genomes panel. Our results show that the highest imputation accuracy in Finnish samples can be obtained by extending the WGS panel (3882 haplotypes) with the WES panel (3080 haplotypes). By using this combination in the imputation of Finnish Illumina HumanCoreExome data (N=10,489), we observed median squared correlation (r2) of > 0. 8 between true and imputed genotypes within 0. 1-0. 5% allele frequency range. Because of a genetic bottleneck in Finnish population approximately 100 generations ago, there is an enrichment of lost-of-function variants (LoFs) in 0. 5-5% allele frequency range compared to non-Finnish Europeans. We imputed 422 LoFs enriched in Finns and observed that 85% of them can be imputed with good quality (info > 0. 7) using a population based reference panel. A concordance analysis performed for a subset of the data (median MAF=1. 9%) showed that 93% of heterozygotes and 95% of the homozygotes for the minor allele could be captured by imputation while introducing 1. 4% of heterozygote and 0. 6% of homozygote false positives. Our results suggest that population specific, sequencing based reference panel allows better imputation of rare and low frequency variants and makes it possible to utilize the existing genome-wide association study (GWAS) chip data in fine-mapping and association screens of complex diseases and traits more efficiently. Because GWAS chip data is available for 60,000 Finns, there is a potential for novel discoveries. Currently, this is also a cost effective option while the field is moving towards large-scale sequencing studies.

Chinese population allele frequency estimations based on large-scale non-invasive prenatal testing samples. *H. Xu, F. Chen, X. Jin, Y. Zhang, H. Jiang, X. Xu.* BGI-Shenzhen, Shenzhen, China.

Allele frequency estimations in Chinese people were an important factor for the genetic map in Chinese population and other epidemiology studies including molecular prevalence of genetic diseases. Chinese Han populations in the 1000 Genomes Project released in 2012 have been the most widely-used database for variants especially SNPs in Chinese, providing an intact and precise map of genome variation in Chinese people and accelerating tons of Chinese population studies. With 90 Han people in China sequenced, the sampling proportion was quite small compared with billions of Chinese people and the estimated allele frequencies may be deviated from those of large-scale Chinese population due to sampling randomness. It was estimated that over 1,000,000 pregnant women took sequencing-based non-invasive prenatal testing for fetal aneuploides screening in China from January 2011 to June 2015. Low-coverage (~0. 1X) WGS strategy was mostly used in clinical labs in China, which presented a large-scale and randomly sampled population and constitutes significant genetic databases for Chinese populations with informative phenotypes including territory distributions, maternal age, nationality and regions. Till now, most population-based algorithms for allele frequencies computation were developed and validated in 30X WGS data but were not appropriate for low-coverage sequencing data. It was hard to discover population knowledge from such big but ultra-low coverage data which request specific models to deal with population SNP calling, demanding computational tools and mass storage. Here in this study we developed a maximum-likelihood method to estimate allele frequency in Chinese population and applied it to NIPT data in over 150,000 samples. A Chinese genetic map of over 150,000 Chinese people was built and the allele frequencies in the whole genome in the large-scale Chinese people were studied. We also analyzed prevalence of common single-gene disorders such as thalassemia, DMD, SMA and hearing loss in different regions in China from 2011 to 2015. Our findings were compatible with current epidemiology reports in Chinese populations and showed the pictures of molecular prevalence of genetic diseases in China. It was the greatest population studied with millions of orders of magnitude to our knowledge. Our studies improved the understanding of variants in Chinese populations, promoting more potential uses of NIPT samples in population genetics.

1434W

Joint whole-genome analysis of associations between host and hepatitis C virus diversity in a patient cohort. *V. Pedergnana[1], MA. Ansari[2,3], STOP-HCV Consortium[4], E. Barnes[3], P. Klenerman[3], C. Spencer[1].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Roosevelt Drive, Oxford. OX3 7BN; 2) Oxford Martin School, University of Oxford, 34 Broad Street, Oxford OX1 3BD; 3) Nuffield Department of Medicine, University of Oxford, Oxford OX1 3SY; 4).

Joint analysis of both human and viral genomes in the context of infection can inform on underlying molecular interactions and can be used to help patients and doctors make better decisions about treatment. The hepatitis C virus has a highly diverse RNA genome that is difficult to sequence. As part of the STOP-HCV consortium (www. stop-hcv. ox. ac. uk) we used a new, efficient, high-throughput method for sequence-specific enrichment and characterization of whole virus genomes capable of unbiased detection of virus variants to sequence the virus of 560 chronically infected patients. In parallel, we also genotyped over 800,000 SNPs in the patients' genome, using the Affymetrix UK Biobank array, and used statistical imputation to obtain data at over 10 million SNPs as well as classical HLA alleles. Perhaps for the first time, paired human genotyping data and novel whole-genome viral sequencing data allow a systematic study of the relationship between hepatitis C virus diversity and host genomics. We develop and apply a new statistical method to look for evidence that host genetics is associated with viral sequence motifs (so-called footprints) in patients infected with hepatitis C. Using an analysis adjusted for viral and human population structure, we inferred footprints of host immune pressures on the pathogen, including a strong signal of association at a previous described HLA-A footprint in the NS3 viral protein ($P < 10\text{-}13$). Using a Bayesian approach we combine evidence across multiple footprints (in the HLA, but also at other clinically relevant host genes and genome-wide) on the viral genome and relate the observations to gene function. Together these new approaches allow a joint assessment of clinically relevant genetic markers in both patient and pathogen, information that is going to be potentially readily available for clinicians in the new era of stratified medicine.

The KOPS Registry: A unique cohort for the study of the genetics of obesity and weight loss. *A. G. Comuzzie[1,2], R. Bastarrachea[1,2], J. Kent[1,2], M. Olivier[1,2].* 1) Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) TOPS Nutrition and Obesity Research Center, Texas Biomedical Research Institute, San Antonio, TX.

We have recently entered into a strategic alliance with the TOPS (**T**ake **O**ff **P**ounds **S**ensibly) organization to establish the TOPS Nutrition and Obesity Research Center in the Department of Genetics at Texas Biomedical Research Institute. TOPS was founded by Esther Manz in 1948 in Milwaukee, WI as a community-based support group for individuals seeking to loose weight. From an original membership of 3 (Mrs. Manz and two friends), TOPS has grown to over 180,000 active members with chapters all over the world, and has helped millions of people meet their weight goals over its 67-year history. A subset of the TOPS membership includes KOPS (**K**eep **O**ff **P**ounds **S**ensibly) members. These individuals have achieved their weight loss goals and have maintained this weight for more than a year. Currently there are 19,034 KOPS members in North America (320 in Texas, and 76 in the San Antonio metropolitan area) who have maintained their weight loss from 1 to 44 years. As part of our new alliance with the TOPS organization, not only will we have access to the general membership, but will be the repository for a KOPS database. As part of this initial effort, we are working with the San Antonio metropolitan area TOPS chapters to initiate data collection for the genomic characterization of the KOPS cohort. This unique resource of individuals who have not only achieved, but maintained significant weight loss, combined with similar data from those individuals who continue to struggle with weight loss and maintenance, will allow for the identification of the genetic contribution to weight loss success. For this study, we will begin by recruiting individuals that are members of TOPS chapters in the San Antonio region to identify both obese and formerly obese members. Given the ready abundance of highly palatable, and calorically dense foods, those individuals who can successfully loose excess weight, as well as maintain this loss in the presence of our modern obesogenic environment represent a unique population. For this initial phase of our study we will administer a survey form to capture eating behaviors and dietary preferences, along with other basic demographic parameters, and initial biological samples for DNA characterization. We will present demographics of our regional clubs and KOPS members, and preliminary results from our surveys to demonstrate the unique nature of this population-based resource.

1436F

A population-specific reference panel empowers genetic studies of Anabaptist participants through improved imputation and variant filtering. *L. Hou[1], R. L. Kember[2], J. C. Roach[3], J. R. O'Connell[4], D. W. Craig[5], M. Bucan[2], A. R. Shuldiner[4], F. J. McMahon[1].* 1) Human Genetics Branch, National Institute of Mental Health Intramural Research Program, Bethesda, MD; 2) University of Pennsylvania, Philadelphia, PA; 3) Institute for Systems Biology, Seattle, WA; 4) University of Maryland School of Medicine, Baltimore, MD; 5) Translational Genomics Research Institute, Phoenix AZ.

Genetic isolates are advantageous for genetic studies of complex phenotypes, owing to decreased genetic heterogeneity and enrichment of otherwise rare alleles. However, population-specific variants and linkage disequilibrium patterns may complicate association studies that rely on imputation at ungenotyped sites. Genetic drift may also confound attempts to filter variants against allele frequencies reported in general reference samples. Here we report the first population-specific reference panel drawn from people of Anabaptist ancestry and perform a preliminary assessment of the panel's value for sequencing studies. High-depth (>30x) whole-genome sequencing (WGS) data were generated on 265 individuals of Amish or Mennonite ancestry. We identified >12M single nucleotide variants (SNVs) and short indels, of which ~19% were novel. Genomes were phased with SHAPEIT2 and 120 unrelated individuals were extracted. To evaluate imputation accuracy, 80 individuals were selected at random as a reference panel while the remaining 40 were set aside as a test panel. In the test panel, genotypes on chromosome 1 were masked at all variable sites not represented on the Illumina Human OmniExpress SNP array. Masked sites were then imputed by IMPUTE2 against: 1) the Anabaptist reference panel, and 2) 100 CEU individuals from the latest 1000G reference panel. Imputation accuracy was measured as the squared correlation coefficient (r2) between imputed allele dosages and masked genotypes. Higher imputation accuracy was achieved with the Anabaptist reference panel, especially for SNVs with minor allele frequencies (MAF) <10%. The greatest advantage was observed for less common alleles. For example, alleles with MAF <1% were imputed at a mean r2of 0. 82 with the Anabaptist panel, vs. 0. 73 with the 1000G panel. At r2 > 0. 5, only 10% of SNVs with MAF <1% could not be accurately imputed with the Anabaptist reference panel, compared to 16% with the 1000G panel. To assess the value of the Anabaptist reference panel for filtering out common alleles, we performed exome-sequencing on 57 additional Anabaptist individuals and identified 1,321 functional coding variants that were uncommon (MAF<1%) in the 1000G and EVS panels. Of these ~28% were not uncommon in the Anabaptist reference panel, and ~2% were enriched >4-fold. In studies of population isolates like the Anabaptists, a population-specific reference panel can yield considerable benefits in rare variant imputation and filtering.

1437W

Measuring the value of GWAS results in a clinical trial setting. *P. Patil, J. Alquicira, J. Leek.* Department of Biostatistics, Johns Hopkins University, Baltimore, MD.

The catalog of published genome-wide association studies (https://www. genome. gov/26525384) represents over a decade of analysis and millions of dollars in research expenditures. One concern raised by both the research community and the popular press has been the relatively modest effect sizes detected from these studies. In this work, we undertake a repurposing of the GWAS catalog and apply a robust method from the analysis of clinical trials to assess the clinical value of the reported SNPs and associated odds ratios. We describe some of the nuances in the records for each SNP, including inconsistencies in reporting of odds ratios, sample sizes, and risk allele frequencies in the GWAS catalog. We present both manual and automatic cleaning and curation solutions that we employed to allow for a large-scale analysis of the catalog. We also present baseline covariate adjustment for treatment effect estimation, and how treating a SNP as a predictor of a phenotype can lead to estimator precision gain in a clinical trial setting. We report which SNPs identified through GWAS may offer a benefit if measured prior to a clinical trial for the phenotype of interest. Although the precision gains we see in most cases are small, these results represent a realistic usage of the information in the GWAS catalog toward true clinical value.

1438T

Equivalence tests for the analysis of genotyping data: Assessing equality of SNPs in study cohorts. *Z. Talebizadeh, H. Dai, A. Shah.* Children's Mercy Hospital and University of Missouri-Kansas City School of Medicine, Kansas City, MO.

Statistical testing is strictly based on null (Ho) and alternative (Ha) hypotheses. The construction of statistical hypotheses will determine the interpretation of results. In most analyses of genotyping data or genome-wide association studies, the null hypotheses assume there is no association between SNP and phenotype. Rejection of null hypotheses will provide strong evidence to indicate the potential associations between SNP and phenotype. The aim of our study is to demonstrate the application of equivalence tests on genotyping data in situations that require testing the presence of equality instead of differences. A series of SNP data will be generated and tested for a hypothetical scenario; i. e. , rule out the impact of tested SNPs on a given comorbidity in a disease group, by demonstrating equality between corresponding means. The constructed Ho is: there is association between SNP and comorbidity in the patient population versus the Ha: there is no association between SNP and comorbidity in the patient population. An equivalence test is warranted to test the constructed hypotheses. Equivalence test has been widely applied in clinical trials to confirm the equivalency in drug efficacy (i. e. , bioequivalency), but rarely on genotype data. In this work we will discuss: 1) differences between equivalence test and differential test, 2) misuse of differential test for equivalence testing in the context of analyzing genotyping data, 3) minimal sample size to establish an equivalence limit. We will perform the empirical Monte-Carlo simulation to assess the Type I error and power for three equivalence tests, and compare them with commonly used differential tests, including Fisher's exact test, Chi-square test and Cochran-Mantel-Haenszel trend test. The impact of variables such as: allele frequency, sample size, and the number of tested SNPs on equivalence of cases and controls will also be assessed. We will perform extensive simulation study to illustrate that misuse of differential tests may cause bias in stating equality of SNPs between cohorts. For genotyping data and genome-wide association analysis, a limited number of equivalence tests are available as compared to very rich pool of differential tests. Our study will contribute to addressing this gap by providing a useful protocol, including examples, for application of such tests on genotyping data. More equivalence tests need to be developed to fulfill the needs of genotype testing analysis.

1439F

Integrating genome-wide meta-analyses of binary and continuous phenotypes. *R. K. Walters[1,2,3], PGC ADHD Workgroup, iPSYCH-SSI-Broad/MGH ADHD Workgroup, EAGLE Consortium.* 1) Analytic & Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Department of Medicine, Harvard Medical School, Boston, MA.

Complex disorders frequently have corresponding measures of continuous population variation in the phenotype that exist alongside the clinical diagnosis. By capturing sub-clinical variation, studying these continuous phenotypes can offer increased power to detect novel genetic variants linked to the disorder (e. g. Dupuis et al. , 2010 Nat Genet.). On the other hand, dichotomous case/control status may be easer to ascertain from e. g. diagnostic codes in electronic medical records, facilitating rapid sample collection and increasing power through larger sample sizes (e. g. Ripke et al. , 2013 Nat Genet.). Despite the close relationship between the phenotypes, however, it is not possible to directly combine results from these two study designs in meta-analysis due to the differing measurement scales. Therefore, we introduce a framework for jointly meta-analyzing GWAS of both dichotomous disease status and corresponding continuous measures of population variation. First, the GWAS results for the dichotomous phenotype are transformed to the scale of a continuous latent trait under the liability threshold model with appropriate adjustment for case/control ascertainment. Next, the relationship between this latent liability and the continuous phenotype is modeled based on the genetic covariance between the two traits and their respective heritabilities, which can be calibrated based on LD score regression (Bulik-Sullivan et al. , 2015 bioRxiv). Modeling the genetic covariance ensures that the results from different phenotypes are weighted appropriately even when the continuous phenotype is not directly a measure of liability for the dichotomous phenotype. The current work presents thorough simulation studies quantifying the expected increase in power from this joint meta-analysis and the influence of varying genetic architectures contributing to the genetic covariance. We then demonstrate the potential for this methodological approach to improve power for discovery of associated SNPs by integrating GWAS of (continuous) measures of symptoms of Attention deficit/hyperactivity disorder (ADHD; MIM 143465) from the Early Genetics & Lifecourse Epidemiology Consortium (EAGLE) with the latest GWAS of ADHD diagnosis from the Psychiatric Genomics Consortium (PGC).

1440W

Assessing models for genetic prediction of complex traits: visualization and quantitative methods. *S. A. Gagliano[1,2,3], A. P. Paterson[2,3,4,5,6], M. E. Weale[7], J. Knight[1,2,3,5].* 1) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 4) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 5) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 6) Epidemiology Division, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 7) Department of Medical & Molecular Genetics, King's College London, Guy's Hospital, London, UK.

Within the past couple of years several *in silico* models have been developed with the intention of predicting which genetic variants are more likely to contribute to the risk of a complex trait given their functional genomic characteristics. Several predictive accuracy measures have been used to assess the performance of these models, but there had been no comprehensive review as to which type of predictive accuracy measures and data visualization techniques are most useful in the context of genetic risk variant prioritization. We undertook such a review, comparing various measures, some of which include: receiver operating characteristic (ROC) curves, Mann-Whitney U test, histograms of classification probability, and the novel use of the quantile-quantile plot (PMID: 25997848). These measures have variable interpretability depending on factors such as whether the dataset is balanced in terms of numbers of genetic variants classified as risk variants versus those that are not. We applied these measures to six models from Gagliano et al. (PMID: 24844982). We found that p-values (from the Mann-Whitney U, the hypergeometric and the generalized Cochran-Mantel-Haenszel tests) were uninformative in determining the most accurate models because statistical tests do not explicitly measure class separation between the risk and non-risk variants. We conclude that the area under the curve (AUC) is a suitable starting place, and for models with similar AUCs, violin plots are particularly useful for examining the distribution of the risk probabilities. This investigation emphasizes the importance of: (1) visualizing the distributions of the probabilities, and (2) exercising caution when making conclusions about model performance based on p-values.

1441T

Measuring the rate and heritability of aging in Sardinians using pattern recognition. *D. Schlessinger[1], E. D. Sun[1], Y. Qian[1], G. R. Abecasis[2], F. Cucca[3], J. Ding[1], I. G. Goldberg[1].* 1) National Institute on Aging, Baltimore, MD. 251 Bayview Boulevard, Suite 100 Baltimore, MD 21224; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan Ann Arbor, MI; 3) Institute of Genetic and Biomedical Research, National Research Council, Monserrato, Cagliari, Italy.

It is widely accepted that individuals age at different rates. A method that measures physiological age independently of chronological age could therefore be a first step to reveal contributing mechanisms; but searches for individual biochemical markers of physiological age have had limited success. In this study, we rather assessed the extent to which an individual's chronological age could be determined as a composite score inferred from a broad range of biochemical and physiological data. Data were collected in a longitudinal population study in Sardinia. The study (the "SardiNIA" project at https://sardinia. irp. nia. nih. gov/) includes measures of environmental factors and family structures to facilitate both epidemiological and genetic analyses. We used pattern recognition and machine learning strategies on data for the 6,000 participants in the study, who range in age from 12 to 81. The best predictive models were determined from multiple combinations of dimensionality reduction, classification, and regression algorithms. They reached very strong correlations (R > 0. 9) between predicted and actual ages, and showed relative stability in successive visits of the same individuals (R>0. 5). We then defined an Effective Rate of Aging (ERA) for each participant, a continuous trait measured as the ratio of an individual's predicted value to his/her chronological age. The inference that individuals have a characteristic rate of aging is supported by findings that in the entire cohort, the inferred values of ERA showed genetic heritability of 40%. This has been sufficient to initiate genome-wide association studies that identify the effect of variants in genes affecting telomere length and metabolic activity on the rate of aging.

1442F

The Kaiser Permanente/UCSF Genetic Epidemiology Research Study on Adult Health and Aging: Imputing rare variants in ~100,000 individuals. *T. J. Hoffmann[1], Y. Banda[1], M. N. Kvale[1], L. Shen[2], E. Jorgenson[2], C. Schaefer[2], N. Risch[1].* 1) University of California San Francisco, San Francisco, CA; 2) Division of Research, Kaiser Permanente, Oakland, CA.

Rare genetic variants may be responsible for a significant amount of the uncharacterized genetic risk underlying many diseases. Since sequencing is still much more expensive than microarrays, an efficient approach to testing rare variants may be to impute them into very large existing genome-wide studies that have been genotyped via microarrays. Although many success stories of individual rare variants have emerged, such as the variant with MAF 0. 38% associated with sick sinus syndrom (Holm et al, 2011), or the HOXB13 G84E variant in this cohort (MAF 0. 17%) (Hoffmann et al, 2015), to name just a couple, it is still unclear how well imputation will work in general for rare variants. However, increasing reference panel size has made rare variant imputation more feasible. We explore here the effect of several different reference panels on imputation success using ~100,000 individuals genotyped at over 650,000 SNPs in the Kaiser Permanente Research Program on Genes, Environment and Health (RPGEH) Genetic Epidemiology Research on Aging (GERA) cohort. We find, for example, that when comparing the reference panel of 1,092 individuals from 1000 Genomes to the more recent release with 2,504 individuals, that there is little change in the ability to impute variants with frequency>1%, but we recover approximately twice the variants with frequency<1%. In addition, we also find that an extremely high proportion of variants that were removed for QC reasons were recovered by imputation, which may be a useful strategy to control for batch effects.

1443W

Heritability and genetic correlations among hormone and cytokine levels related to type 2 diabetes. *R. L. Hanson[1], E. J. Weil[1], J. M. Curtis[1], M. Walter[2], R. G. Nelson[1].* 1) Diabetes Epidemiology Clin Res, NIDDK, Phoenix, AZ; 2) Clinical Laboratory Core, NIDDK, Bethesda, MD.

Several hormones and cytokines have been described as related to type 2 diabetes and obesity, but there is little information on the extent to which they are influenced by genetic factors or on their genetic correlations with conventional metabolic variables. We used classical pedigree-based variance components methods to calculate heritability (h2) for hormone levels in 1088 nondiabetic American Indians in a family study. All individuals were examined after an 8-hr fast. Ten "extended" hormones/cytokines were measured: adiponectin, adipsin, amylin, C-reactive protein (CRP), glucose-dependent insulinotropic peptide (GIP), interleukin-6, leptin, plasminogen activator inhibitor-1, resistin and tumor necrosis factor α (TNFα). We also analyzed 8 "core" metabolic variables: body mass index (BMI), fasting glucose (FPG), hemoglobin A1c, fasting insulin, HDL cholesterol, triglycerides, systolic and diastolic blood pressure (SBP, DBP). Significant (P<0. 05) heritability, adjusting for age, sex and ancestry, was observed for all "extended" variables with h2 ranging from 36% for TNFα to 86% for resistin. All "core" variables, except DBP (h2=0) were significantly heritable, and h2 ranged from 27% for fasting glucose to 57% for BMI. We conducted bivariate analyses of the covariance among relatives to partition the phenotypic correlation (rP) between "extended" and "core" variables (except DBP) into genetic and environmental sources (rG,rE). Of the 70 variable pairs 51 had significant phenotypic correlations with |rP| ranging from 0. 06-0. 59. Among these 51 variable pairs, |rG| ranged from 0. 01-0. 71 and |rE| from 0. 02-0. 60; on average 40% of the correlation was due to shared genetic factors. The strongest rG were: 0. 71 for leptin-BMI, 0. 66 for insulin-leptin, 0. 60 for CRP-BMI and -0. 59 for GIP-glucose; the strongest rE were 0. 60 for resistin-BMI and -0. 55 for resistin-HDL. These analyses suggest that many hormones/cytokines related to type 2 diabetes are substantially influenced by genetic factors and that many of these genetic factors partially overlap with those that influence conventional metabolic variables. Further molecular genetic studies of these hormones may help clarify the etiology of type 2 diabetes and obesity.

1444T

A simple yet accurate correction for winner's curse can predict signals discovered only in larger genome scans. *S-A. Bacanu, T. B. Bigdeli, D. Lee, B. P. Riley, V. Vladimirov, F. H. Ayman, K. S. Kendler.* VIPBG, Virginia Commonwealth University, Richmond, VA.

Genome-wide/sequencing scans, henceforth denoted as genome scans, discovered/will discover numerous genetic variants significantly associated with various phenotypes. However, while significant signals explain only a small fraction of the variation for most traits, variants with smaller signals explain a much larger part. To extract the signals of all magnitudes from a genome scan, we propose a very simple method for accurately estimating the mean of all (normally distributed) genome scan statistics (Z-scores). Given that adjusting for winner's curse (multiple testing) is difficult for all normally (χ^2) distributed statistics but simple for their p-values, we propose a two-step procedure which we denote as **F**DR **I**nverse **Q**uantile Transformation (FIQT). First, adjust the p-values for multiple testing using a False Discovery Rate (FDR) approach. Second, estimate the mean of Z-scores as having i) magnitude obtained by back-transforming the adjusted p-values to a (upper tail) standard normal quantile and ii) sign of the original statistics. When compared to competitors, e. g. Empirical Bayes and tail adjustment methods, FIQT has very good performance in terms of (i) squared error loss, (ii) fraction of the explained variability in true Z-score means and iii) computational efficiency. We show that FIQT applied to the first Psychiatric Consortium (PGC) schizophrenia cohort can be used to predict with reasonable accuracy a non-trivial fraction of the 108 regions harboring signals in the second PGC schizophrenia cohort. Finally, we suggest further improvements to FIQT by taking into account the noncentrality/mean of χ^2 statistics for i) the entire genome scan or ii) functionally relevant subsets.

1445F

Study the effects of multiple mediators using DNA methylation. *J. Shen, X. Lin.* Department of Biostatistics, Harvard TH Chan School of Public Health, Boston, MA.

With development of genetic and genomic technologies, it is of increasing interest in biomedical and epidemiological studies to explore the biological mechanism on how an exposure variable affects behavioral or disease outcome. Mediation analysis provides a powerful tool to identify the intermediate genes and biological pathways that mediates the disease causing process. Epigenetic studies for complex diseases have shown that the effect of exposure variables are more likely to be mediated in a collaborative fashion through multiple probes in a region, e. g. , CpG islands or shores, or methylation sites from several genes, e. g. , a genetic pathway or network. Rather than examining a single mediator, it is more desirable to investigate the mediation effect of multiple methylation sites simultaneously, while taking into account correlation among these mediators. We propose a test for the overall indirect natural effect for a group of mediators using the difference in coefficients approach. We employ kernel machine based approach to account for potential interactions and nonlinearity among mediators. A Wald type test is developed with a simple estimator for the variance when comparing coefficients from different models. The performance of the method is evaluated with simulation studies under various correlation structures of the mediators. The proposed test is then applied to the Normal Aging Study to investigate the effect of smoking on coronary heart disease that mediated by the methylation level on genome-wide CpG sites.

1446W

Genetic susceptibility to higher insulin secretion is associated with obesity. *J. N. Todd[1,2,4], C. M. Astley[1,4], J. N. Hirschhorn[1,3,4], J. C. Florez[2,3,4].* 1) Medicine-Endocrinology, Boston Children's Hospital, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) Harvard Medical School, Boston, MA.

High glycemic index diets have been associated with obesity in population studies. It has been theorized that carbohydrate-driven insulin secretion mediates weight gain by driving hunger and caloric intake. In fact, insulin secretion measures (*e. g.* insulin levels 30 minutes after an oral glucose load, first phase insulin) corresponded with weight loss on a low-glycemic diet and future weight gain in observational studies. To better understand the causal relationship between insulin secretion and obesity, we undertook a bi-directional Mendelian randomization analysis using polygenic instruments of both traits. In Mendelian randomization, genetic predictors of an exposure of interest (*e. g.* insulin secretion) are used to identify the association between that exposure and the outcome (*e. g.* obesity) not confounded by shared causes (*i. e.* unmeasured confounders). This same analysis is undertaken using genetic predictors of obesity to assess for reverse causation on insulin secretion. In this way, bidirectional Mendelian randomization can help tease out both the presence and direction of causal effect that contribute to observed correlations between two traits. Using summary statistical data from publicly available genome-wide association studies, we found that a genetic risk score of loci associated with glucose-stimulated insulin secretion at genome wide significance correlated with increased BMI; this was true whether we used SNPs identified by 30-minute insulin levels with or without adjustment for BMI (beta= 0. 089 and *P*=8. 6x10-7, beta=0. 061 and *P*=3. 5x10-6, respectively). Conversely, there was no relationship between a genetic risk score comprised of SNPs associated at genome-wide significance with BMI and 30-minute insulin levels (beta= 0. 005 and *P*=0. 80). This analysis provides evidence that higher levels of glucose-stimulated insulin secretion may play a causal role in obesity.

1447W

Genetic determinants of Multiple Sclerosis susceptibility in US minority populations. *A. Beecham[1,2], L. Amezcua[3], N. Isobe[4], P. Manrique[1], B. T. Lund[3], A. Levy[3], D. Conti[5], G. Beecham[1,2], P. De Jager[6], S. Delgado[7], J. Oksenberg[4], J. McCauley[1,2], International Multiple Sclerosis Genetics Consortium.* 1) John P. Hussman Institute for Human Genomics, Miller School of Medicine, University of Miami, Miami, FL, USA; 2) Dr. John T. Macdonald Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Department of Neurology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 4) Department of Neurology, University of California at San Francisco, San Francisco, CA, USA; 5) Department of Preventative Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 6) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, MA, USA; 7) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA.

Multiple Sclerosis (MS) exhibits variable prevalence across populations, with European populations having a higher prevalence than either Hispanic or African. In addition to environmental influences, this observation could be partly due to a greater genetic risk in European populations. Genetic association studies in individuals of European descent have identified 110 established MS risk variants in 103 discrete loci outside of the Major Histocompatibility Complex. Our goal was to determine whether these 110 variants also confer risk for MS in genetically admixed samples from Hispanic and African American populations. Targeted genotyping was performed using an Illumina ExomeChip+ BeadChip, inclusive of a dense set of markers within 1Mb of the 110 variants as well as ancestry informative markers (AIMS). Separately in the Hispanic (1056 cases and 1232 controls) and African American (1319 cases and 1173 controls) samples, logistic regression was used to test for an association of the additive genetic effect of each variant on MS risk after controlling for global and local ancestry. Global ancestry proportions of European, African, and Asian admixture were computed by ADMIXTURE with 12,073 AIMS. Local ancestry proportions for each of the 110 variants were computed with RFMix after first phasing the haplotypes within 1 MB of the 110 variants using Beagle. Additionally, a combined genetic risk score for the 110 variants was calculated using odds ratios previously published in studies of European populations, and an association between MS and the risk score was assessed. The genetic risk score was significantly higher in MS cases than controls in both samples (one-sided p=2. 08E-30 in Hispanics and p=2. 93E-14 in African Americans). In Hispanic cases, 94 of 107 of the risk variants had over-representation of the same allele as seen in European cases (40 demonstrating one-sided p < 5. 0E-02), while in African American cases only 78 of 107 of the risk variants had over-representation of the same allele (20 demonstrating one-sided p < 5. 0E-02). A greater proportion of the 110 variants show over-representation of the European risk allele in Hispanic MS cases than in African American MS cases. This could be due in part to the increased European admixture at these loci in Hispanics as compared to African Americans. A more in depth look at the local ancestry at these loci will provide further insight into the ancestral origin of these risk alleles.

Comparisons of Genetically Inferred and Self-reported Race/Ethnicity in US Adults: Results from the National Epidemiologic Survey on Alcohol and Related Conditions – III. *H. Zhang, J. Jung, R. Goldstein, B. Grant.* NIH/NIAAA, Rockville, MD.

Race and ethnicity are widely used in epidemiologic studies. Accuracy of race/ethnicity classification therefore has important implications for the interpretation of findings. Information on race/ethnicity is typically acquired through self-report. Therefore, it is necessary to assess the validity of self-reported race/ethnicity using genetic data. This study evaluated the consistency between genetically inferred and self-reported race/ethnicity in 15,578 samples collected from the National Epidemiologic Survey on Alcohol and Related Conditions-III (NESARC-III). Self-reported race/ethnicity consisted of: non-Hispanic white, black, Asian, Native Hawaiian/Other Pacific Islander (NHOPI), American Indian/Alaska Native (AIAN); Hispanic; and multiple-race. To infer genetic race/ethnicity, we included 924 samples from 11 Hapmap3 populations, 940 individuals from 51 populations of the Human Genome Diversity Panel and 347 individuals from four 1000-genome project as reference populations. First, we applied PLINK software to generate genome-wide IBS estimates between 15,578 NESARC-III and 2,211 reference samples at shared 10,612 common SNPs. Then, we produced multidimensional scaling plots for visual examination of genetically inferred race/ethnicity. We segmented our samples into 11 genetically inferred groups: European American, Middle East, African American, West African, East African, East Asian, C. S. Asian, Native American, Hispanic, Native Hawaiian/Pacific Islander, and multiple-race. Finally, we used kappa statistics to gauge agreement between self-reported and genetically inferred race/ethnicity. Overall consistency between self-reported and genetically inferred race/ethnicity was excellent (χ=0. 83, 95% CI 0. 82-0. 84). Non-Hispanic whites, blacks and Asians had the highest agreement (consistency rates: 96. 9%, 94. 7%, 90. 3%, respectively). Consistency among Hispanics was fair, with 72. 9% of self-reported Hispanics classified as Hispanic by genetic analysis. Consistency rates were 12. 5% for AIAN and 45. 2% for NHOPI. Self-reported and genetically inferred race/ethnicity agreed well, especially for US whites and blacks. Although the data sources agreed well among Asians, this group is highly heterogeneous. Agreement was fair among Hispanics, mainly because both genes and culture strongly affect self-identification as Hispanic. Improvements are needed to the classification of race in AIAN and NHOPI, among whom consistency rates were lower. .

A New Approximate Bayesian Computation (ABC) framework based on Local Ancestry to Infer Admixture Events. *M. H. Gouveia[1], T. P. Leal[1], F. S. G Kehdy[1], G. S. Araújo[1], W. C. S Magalhães[1], M. R. Rodrigues[1], G. B. Soares-Souza[1], A. R. Horimoto[2], M. L. Barreto[3], A. C Pereira[2], M. F. Lima-Costa[4], B. L. Horta[5], M. O. Scliar[1], E. Tarazona-Santos[1].* 1) UFMG-Brazil, Belo Horizonte, Minas Gerais, Brazil; 2) Instituto do Coração, Universidade de São Paulo, 05403-900, São Paulo, São Paulo, Brazil; 3) Instituto de Saúde Coletiva, Universidade Federal da Bahia, 40110-040, Salvador, Bahia, Brazil; 4) Instituto de Pesquisa Rene Rachou, Fundação Oswaldo Cruz, 30190-002, Belo Horizonte, Minas Gerais, Brazil; 5) Programa de Pós-Graduação em Epidemiologia, Universidade Federal de Pelotas, CP 464, 96001-970 Pelotas, RS, Brazil.

Numerous methods have been developed to infer, by genomic data, admixture parameters (APs) such as admixture times and/or the strength of admixture events. However, none of these methods use as direct information, the chromosomal segments of continuous specific ancestry (CSSA), also called admixture tracts. The CSSAs lengths are very informative about the time when the admixture event happened, whereas the recombination process fragments the CSSAs in lengths smaller and smaller over time. We implemented a new Approximate Bayesian Computation (ABC) approach based on local ancestry to infer historical APs, conditioning on a model of pulses of immigration. The main steps of this approach are: (1) generation of an informative prior distribution of admixture parameters for each pulse, conditioning on the estimated total continental ancestry; (2) simulation of CSSA lengths, based on the prior distribution; (3) computation of the distance between the simulated and observed CSSA lengths distributions; (4) estimation of the posterior distribution of the admixture parameters for each pulse by retaining the simulated CSSA lengths distributions that are more similar to the observed distribution. We simulated CSSA lengths in accordance to the Brazilian demographic history of three pulses (18-16, 12-10 and 6-4 generations ago) of tri-hybrid admixture. This demographic model conciliates statistical complexity and the real history of admixture. Interestingly, ABC results show that the observed low Native American ancestry was mostly introduced in different regions of Brazil soon after the European Conquest of the Americas, which is consistent with the posterior depletion of the Native American population in Brazil. Also, we inferred a predominantly earlier European colonization in the Northeast (Salvador) versus a more recent immigration in Southeastern and Southern Brazil (Bambuí and Pelotas), consistently with historical records. Conversely, African admixture showed a decreasing temporal trend shared by the three studied populations. Currently, we are improving our ABC framework by testing other demographic models with more than three admixture pulses an implementing validation tests. We are also inferring the admixture dynamic of the 1000 genomes admixed populations (Afro Americans -ASW, Colombians - CLM, Mexicans - MXL, and Puerto Ricans - PUR)and other admixture Brazilian (Southeast) and Peruvian (Quechuas) populations from Tarazona-Santos group LDGH dataset.

1450T

Demographic inferences from 447 complete human genome sequences from 148 populations worldwide. *M. Metspalu[1], L. Pagani[2], D. Lawson[3], A. Kushniarevich[1], R. Mägi[5], L. Saag[1], A. Eriksson[4], A. Manica[4], T. Kivisild[2], International Collaboration effort of the Estonian Centre for Genomics.* 1) Estonian Biocentre, Tartu, Estonia; 2) Department of Biological Anthropology, University of Cambridge, Cambridge, United Kingdom; 3) Heilbronn Institute, School of Mathematics, University of Bristol, Bristol BS8 1TH, UK; 4) Department of Zoology, University of Cambridge, Cambridge, UK; 5) Estonian Genome Center, University of Tartu, Tartu, Estonia.

Complete high coverage individual genome sequences carry the maximum amount of information for reconstructing the evolutionary past of a species in the interplay between random genetic drift and natural selection. Here we use a novel dataset of 447 human genomes sequenced at 40X on the same platform (Complete Genomics) and uniform bioinformatic pipelines. Based on SNP-chip data we generally chose three samples to represent each population of interest. We cover a wide range of mostly Eurasian populations with additional populations from Oceania, South America and Africa. Here we describe the dataset in terms data quality and new recovered genetic variation that originates predominantly from previously subsampled continental regions. Using MSMC, D-statistics and Finestructure we have shown that peopling of the World from Africa is best explained by at least two migration waves (See Lawson et al abstract nr …). Here we expand on these conclusions by investigating short IBD segment sharing patterns using diCal, Hapfabia etc. We also disentangle split times involving the two migrations out of Africa (OoA), by running MSMC separately on genome chunks derived from OoA1 and OoA2. We also present detailed regional population histories in reconstructions of past dynamics of effective population size and population split times.

1451W

Reconstructing the Genetic History of Indigenous Caribbean Populations. *T. Schurr[1], J. Benn Torres[2], M. Vilar[3], C. Melendez[4], G. Torres[2], J. Gaieski[1], M. Stevenson[5], R. Bharath Hernandez[6], Z. Browne[5], W. Waters[5].* 1) Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Anthropology, University of Notre Dame, Notre Dame, IN; 3) Science and Exploration, National Geographic Society, Washington, DC; 4) Liga Guakia Taina-Ke, Humacao, Puerto Rico; 5) The Garifuna Heritage Foundation Inc. , Kingston, St. Vincent; 6) Santa Rosa First Peoples Community, Arima, Trinidad.

In collaboration with the Garifuna/Kalinago of St. Vincent, the First People's Community of Arima, Trinidad, and Taíno descendant communities in Puerto Rico, we are conducting an anthropological genetic study of the prehistoric and historic settlement of the Caribbean. Using genetic data generated with the GenoChip, we are evaluating hypotheses concerning the original settlement of the Greater and Lesser Antilles, as well as the expansion of Carib and Awakan-speaking populations into this region over the past few thousand years. Our initial results suggest that the Greater Antilles were colonized by indigenous populations from South America and possibly Mesoamerica, whereas the Lesser Antilles were settled by only South American groups. In addition, while sharing some indigenous mtDNA (maternal) and Y-chromosome (paternal) lineages in common, populations from the Greater and Lesser Antilles otherwise appear to be largely genetically distinct from each other. Autosomal SNP data from these indigenous Caribbean communities further expand our understanding of the genetic contributions from African, European and South Asian populations since European contact. Overall, this study demonstrates the region's first peoples' ongoing legacy in shaping the genetic diversity of contemporary Caribbean populations.

Strong selection at MHC in Mexicans since admixture. *Q. Zhou[1,2,3], L. ZHAO[1,2], Y. GUAN[1,2,3,4].* 1) USDA/ARS Children's Nutrition Research Center, Houston, TX; 2) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 3) SCBMB, Baylor College of Medicine, Houston, TX; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Mexicans are recent admixture of Amerindians, Europeans and Africans. We performed local ancestry analysis of Mexican samples from two genome-wide association studies obtained from dbGaP and discovered that at the MHC region Mexicans have excessive African ancestral alleles compared to the rest of the genome, which is the hallmark of recent selection for admixed samples. The estimated selection coefficients are 0. 07 and 0. 09 for two datasets, which put our founding among the strongest known selections observed in humans, namely, lactase gene in northern Europeans and sickle-cell allele in Africans. Inaccurate Amerindian training samples was a major concern for the credibility of previously reported selection signals in Latinos. Taking advantage of the flexibility of our statistical model, we devised model fitting method that can learn Amerindian ancestral haplotypes from the admixed samples, which allow us to infer local ancestries for Mexicans using only European and African training samples. The strong selection signal at MHC remains without Amerindian training samples. One wonders why such a strong selection signal was not discovered by 1000 Genomes project in their analysis of Mexican samples using other competing local ancestry inference models. Our simulation studies suggested that the approach adopted by 1000 Genomes admixture analysis group, which used consensus estimates from four methods, is perhaps to blame. Finally, we pointed out that medical history studies suggested such a strong selection signal is plausible in Mexicans.

1453W

Genetic origins and admixed ancestry characterization of Japanese people. *W. Ko[1,2], K. Higasa[3], M. Narahara[2], F. Matsuda[3], R. Yamada[2].* 1) Faculty of Life Sciences and Institute of Genome Sciences, National Yang-Ming University, Taipei, 112, Taiwan; 2) Statistic Genetics, Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, 606-8507, Japan; 3) Human Disease Genomics, Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, 606-8507, Japan.

A modern human population found at a certain geographic location is often descended from multiple ethnic groups owning to the complex migration history of human expansion. In Japan, although it has been studied extensively over the past decades, the genetic origins of Japanese people remain controversial. Current genetic evidence supports a dual model which suggested that the Japanese people are constituted mainly by an early settlement of human populations during the Upper Paleolithic period (*i. e. ,* Jomon people) followed by an admixture event with the people migrated from the Korean peninsula around 2300 year ago (*i. e. ,* Yayoi people). However, the genetic origin(s) of the native Jomons remains unclear. Tracing the genomic signatures of admixture history can not only reveal the unknown human migration events but also provide critical information that can facilitate the genetic profiling of disease susceptibility, which is critical for the success of personalized medicine. Here, we analyzed a combined dataset of the whole genome SNP genotyping data from 2,277 individuals sampled globally across >100 populations for a total of 19,290 SNPs (after intersecting the two datasets). We performed principle component analysis to project individuals onto a series of orthogonal axes to reveal the genetic structure among diverse ethnic groups. After separating the genetic components contributed from the populations representing the Yayoi, we identified several candidate populations that share common non-Yayoi ancestry with the modern Japanese people. Our results suggest that the genetic origins of Jomons may consist of multiple migration events from both Southeast and Northeast Asia. Surprisingly, we also identified an additional migration wave from the Hmong population. We assigned local ancestry (LA) on the phased chromosomes of the mainland and Okinawa Japanese by performing RFmix (which used the identified candidate ancestral populations to infer the LA tracts in admixed chromosomes by finding the most likely sequence of ancestries through maximum a posterior estimation). Because an ancient population admixture would allow more recombination events to break LA tracks into shorter segments than a recent admixture event, our results of the LA track-length distributions differ significantly between the Yayoi, Hmong, and Jomon ancestries (in descending order), suggesting that the Hmong migration may have occurred before the Yayoi migration.

1454T

The genetic structure of the Saudi Arabian population. *H. Al-Saud[1], SM. Wakil[1], BF. Meyer[1], M. Falchi[2], N. Dzimiri[1].* 1) Genetics Department, King Faisal Hospital and Research Centre, Riyadh, Saudi Arabia; 2) Department of Twin Research and Genetic Epidemiology, King's College London, London, United Kingdom.

Saudi Arabia is the largest Gulf Cooperation Council (GCC) country. Its population consists of different tribes that originated in the northern, western, eastern, middle and south regions of Saudi Arabia, respectively. Due to political and cultural reasons, there has historically been very limited admixture between different tribes. People from the different Saudi tribes then migrated from Saudi Arabia, contributing to foundation of the populations now inhabiting other Gulf countries. Few population genetics research projects have been conducted on this highly consanguineous population that has been shown to have one of the highest prevalence in the world of recessive disorders and common metabolic diseases, especially diabetes. It is therefore important to identify the genetic substructures of the Saudi population, both to help in tracing the migratory genetic flows that contributed to other Gulf populations, and to permit designing of efficient genetic studies aimed at the identification of risk factors underlying common and rare diseases in the GCC countries. We carried out the largest population genetic study in Saudi Arabia to date, by genotyping 2,150 Saudi nationals sampled from different regions of Saudi Arabia using Axiom GWH-96 Array (Affymetrix) arrays. Model-based and model-free clustering were applied to these data, including in our analyses data on eight populations (encompassing Europe, America, Oceana, East Asia, Central South Asia, Middle East, Africa and Qatari populations) from the Human Genetic Diversity Project (HGDP) data set. We identified clear clustering of the Saudi samples into different subgroups, with some tribes showing similarity with both Central East Asian (Kalash Pakistan, Balochi Pakistan, Sindhi Pakistan, Makrani Pakistan and Brahui Pakistan subpopulations) European (Orkney Islands Europe, Russian Europe and Russian Caucasus subpopulations) and Qatari populations, while other tribes appear to show specificity of background. These data strongly support the presence of genetic stratification within the Saudi population, and suggest the presence of subgroups that are characterized by a unique genetic background different from other Arabian populations. Our findings constitute a valuable resource for the investigation of both general and population-specific genetic risk variants associated with different disorders in this population.

Recent genetic history of Denmark. *G. Athanasiadis[1,2], F. G. Jørgensen[3], J. Cheng[1,2], P. C. Kjærgaard[2,4], M. H. Schierup[1,2,5], T. Mailund[1,2].* 1) Bioinformatics Research Centre, Aarhus University, Aarhus, Denmark; 2) Centre for Biocultural History, Aarhus University, Aarhus, Denmark; 3) Tørring Gymnasium, Tørring, Denmark; 4) Department of Culture and Society, Aarhus University, Aarhus, Denmark; 5) Department of Bioscience, Aarhus University, Aarhus, Denmark.

Purpose. - Denmark has strong historical bonds not only with Norway and Sweden, but also with Western and Eastern Europe through a series of invasions, conquests and alliances. In addition, within Denmark, industrialization in the second half of the 19th century led to considerable migration from the countryside to the cities. In this work we explore the extent to which such distant and more recent historical events left their mark on the genetic structure of the current Danish population. *Methods.* - We ran an extensive genetic analysis on the *Where Are You From?* data set of ~600 students from 36 high schools across Denmark. Each student provided a saliva sample for DNA analysis and completed an online questionnaire about family origin, education level and basic biometrical data. All participants gave their informed consent and the Ethical Committee of the University of Aarhus approved the study. Genotyping was outsourced to 23andMe and more than 500,000 SNPs were available for analysis. After merging our data with data from POPRES, we ran PCA and ADMIXTURE to detect genetic structure. For more fine-grain effects, we identified each individual's closest genetic relatives through IBD tract sharing and calculated the geographic distance between the individual's place of birth and the weighted average geographic coordinates of their closest relatives. Finally, we explored population structure within Denmark as the result of recent admixture with adjacent populations by use of an IBD-based local ancestry method (i. e. "chromosome painting"). *Results.* - Although Denmark forms a distinguishable cluster from neighboring countries in the PCA plots (compatible with isolation-by-distance), no stong structure was observed within the country. Similarly, ADMIXTURE revealed high levels of homogeneity in the Danish samples compared to other North European countries. However, we did observe significant correlation between PC1 (south-north orientation) and average grandparental geographic coordinates rotated clockwise at ~30°. Also, the IBD-based geographic correlation analysis revealed that Danes tend to live near their closest genetic relatives at a median distance of 100 Km - significantly closer than the random expectation. Finally, chromosome painting revealed strong genetic influence from neighboring Nordic (Sweden and Norway) and Germanic (Germany and Holland) countries and negligible influence from Finland, France and Portugal.

1456T

Assessing the benefits of priors that encourage sparsity for estimating ancestral admixture from genome-wide data. *P. Carbonetto, Y. Wang, K. Noto, M. Barber, J. Byrnes, R. Curtis, K. Chahine, J. Granka, E. Han, A. Kermany, N. Myres, C. Ball.* AncestryDNA, San Francisco, CA.

Several recent papers have demonstrated the benefits of using sparse matrix factorization techniques---sparse factor analysis and non-negative matrix factorization---to infer population structure from genetic polymorphism data. The primary strength of sparse matrix factorization is its flexibility; it can capture a wide range of population structure scenarios, and can do so in a way that often has a natural interpretation. For example, sparse matrix factorization is able to recapitulate a mixture of continuous and discrete population structure, whereas other methods, such as PCA and STRUCTURE, cannot do this. However, we have found that this flexibility can come at a cost: in realistic demographic settings, it incorrectly predicts individual admixture proportions. We hypothesize that this is because sparse matrix factorization does not completely specify an admixture model. Motivated by this, we propose a model-based approach, building on ADMIXTURE, that encourages sparsity in the admixture proportions (or "loadings"). We encourage sparse estimates by introducing an exact L0-norm penalty term in the cost function that penalizes non-zero admixture proportions, then we iteratively solve for the model parameters using a hybrid EM algorithm. This penalty can also be interpreted as a prior on the number of ancestral populations contributing to an individual's genome. We explore the behaviour of penalized and unpenalized admixture estimates in data from the Human Genome Diversity Project. Although the idea of encouraging sparse admixture estimates has been suggested previously, to our knowledge the features of this approach have not been empirically assessed in real genetic data from human populations.

1457W

Whole Genome Sequence Identity by Descent Segment Sharing Across Diverse Populations. *N. Chambwe[1], D. E. Mauldin[1], J. G. Vockley[2], J. E. Niederhuber[2], I. Shmulevich[2], J. C. Roach[1].* 1) Institute for Systems Biology, 401 Terry Ave, North, Seattle, WA 98103; 2) Inova Translational Medicine Institute, Inova Health Systems and Inova Fairfax Medical Center, 3300 Gallows Road, Falls Church, VA, 22042.

The identification of shared genomic segments that are identical by descent (IBD) within pedigrees is a useful tool for human genetics. Firstly IBD analysis is important for determining loci implicated in the inheritance of mendelian traits. Secondly, IBD segments form the basis of relationship detection for algorithms such as Estimation of Recent Shared Ancestry (ERSA). Population haplotype diversity at a particular locus strongly influences the likelihood that a pair of individuals is identified as IBD at that locus, as do technical factors such as mappability of short reads to a reference genome. The statistical properties of IBD sharing at particular locations can vary highly, both due to population genetics and technical influences. Technical influences gain in relative importance for shorter IBD tracts, which can be identified by WGS but are not generally identified by older methodologies. To best evaluate the significance of candidate loci and relationship estimations, these locus-specific statistical properties of IBD blocks must be understood and evaluated in a control dataset. Extensive IBD analyses have been carried out using genotyping data generated from microarray platforms. However, whole genome sequencing (WGS) surveys IBD with greater precision and with markers that have distinct statistical properties from those in genotyping panels. Statistical properties of IBD sharing have yet to be fully explored with data generated from WGS. In order to determine IBD segment sharing from WGS data, we applied Inheritance State Consistency Analysis (ISCA) to more than 5000 individuals from diverse populations (INOVA Genomes). These data were generated using DNA from peripheral blood samples sequenced on the CGI and Illumina platforms. We describe global properties of IBD segments such as the segment length distribution and compare differences across populations and phenotypic categories. IBD segment sharing across populations largely agrees with expectations from population structure. We observed that the proportion of the genome with shared IBD1/IBD2 segments was higher between individuals from non-African populations. Increased variability in haplotype diversity across the genome correlates with both long and short IBD segments. This largely agrees with previous findings using genotyping platforms for long IBD segments, but extends the observation to shorter IBD segments we are able to detect with WGS data.

Characterizing Brazilian sickle cell anemia patients. *P. RS. Cruz[1], G. Ananina[1], M. A. C. Bezerra[3], A. S. Araujo[3], W. M. Avelar[4], A. C. Amato-Filho[4], F. Cendes[4], F. F. Costa[2], M. B. Melo[2].* 1) Center of Molecular Biology and Genetic Engineering (CBMEG), University of Campinas, Campinas, São Paulo, Brazil; 2) Hematology and Hemotherapy Center/HEMOCENTRO, University of Campinas, Campinas, São Paulo, Brazil; 3) Hematology and Hemotherapy Center of Pernambuco/HEMOPE, Recife, Pernambuco, Brazil; 4)) Neuroimaging Laboratory, Department of Neurology, University of Campinas, Campinas, São Paulo, Brazil.

Sickle cell anemia (SCA) is a devastating condition that affects millions and lacks a safe drug therapy. More than 500,000 newborns worldwide are thought to be affected a year. James B. Herrick reported SCA for the first time in 1910 and by the year of 1949 was the first so called molecular disease to have its mechanism unveiled. Before modern medical care, sickle-cell heterozygotes (*HbAHbS*) had the highest fitness in malaria-endemic regions, since they have a lower susceptibility to host *Plasmodium malariae*relative to the *HbA* homozygote and tend not to develop sickle-cell complications. *HbS* mutation is assumed to have arisen multiple times around 5 kya. Present haplotypes are named after their putative geographical origin (Benin, CAR or Bantu, Cameroon, Senegal and Arab) and contribute to the overwhelming phenotypic heterogeneity observed in SCA. African American is the best-studied population in respect to SCA, whereas Brazilian population is poorly described and differs from the American in origin. Slaves brought into the United States originated mainly from Central West African ports, where the Benin haplotype prevails, while the 2. 4 million African Negroes transported to Brazil, from 1701 to 1843, was predominantly from Angola, Congo, and Mozambique, areas where the CAR haplotype is more frequent. We propose, then, to characterize the Brazilian patients regarding ancestry. Ninety SCA patients were recruited at two Brazilian centers: HEMOCENTRO (Campinas, SP) and HEMOPE (Recife, PE), along with 62 *HbAHbA* allegedly healthy individuals. This study is in accordance to the Basic Principles of the Declaration of Helsinki. The genotyping protocol was carried out using Affymetrix SNP Array 6. 0 (Affymetrix Inc. , CA, USA). We filtered SNP and samples data using PLINK for probes with acceptable contrast quality (QC > 0. 40). Population structure and admixture were analyzed applying EIGENSOFT and ADMIXTURE software, along with HapMap reference populations. We found that SCA patients are more proximate to African origin (by both Fst values and ancestral composition) and that*HbS*haplotype shows linkage disequilibrium consistent with recent selection. As the next step we will further dissect chromosome 11 ancestral haplotypes in fine resolution and scan for positive selection signals. Inferring demographic and ancestral history in Brazilian SCA will provide valuable knowledge on the underlying phenotype.

1459W

Ancient European haplotype enrichment in modern Eurasian populations. *D. Harris[1], T. O'Connor[2].* 1) Graduate Program in Molecular Medicine, University of Maryland School of Medicine, Baltimore, MD; 2) Institute for Genome Sciences, Program in Personalized and Genomic Medicine, Department of Medicine, University of Maryland School of Medicine, Baltimore, MD.

The diversification of modern European populations is a fascinating puzzle that has recently advanced due to the sequencing of ancient European genomes. We analyzed 732 modern West Eurasian individuals using three ancient samples coming from the Lazardis et al. Human Origins Array dataset. Specifically, we determined ancient European haplotype enrichment by calculating pairwise differences (PWD) between each ancient European individual and modern Western Eurasian individuals in 50 SNP blocks. Modern Western Eurasians had the fewest PWD across all population groups with the farming Stuttgart individual and had the most PWD with the Loschbour and Motala12 hunter-gatherer individuals confirming Lazardis et al. observation that modern Europeans are more similarly related to ancient individuals coming from a farming community. We selected SNP blocks, for gene ontology enrichment analysis through the use of GORILLA, based on 1) the 10% of regions with greatest differences of PWD between groups, and 2) the 10% of those regions from the first criterion that most closely correlated with the geography of those groups. Most SNP blocks positively correlated to PC1 (latitude) and PC2 (longitude), therefore we focused on outliers that negatively correlated to biogeography. For SNP blocks that negatively correlated to PC1; "regulation of chondrocyte development", "androsterone dehydrogenase activity", and "antigen processing and presentation of endogenous peptide antigen" had the highest enrichment score in the comparison of the Stuttgart, Loschbour, and Motala12 individuals, respectively. Interestingly, the "alpha-beta T cell receptor complex" and "interleukin-17 receptor activity" (including CD3D,E,G and IL17RC,E) were enriched in the Loschbour and Motala12 comparisons of SNP blocks that were positively correlated to PC2. In addition, the Stuttgart individual had the lowest PWD disparity between all modern populations for the SNP blocks that contain the IL17R and CD3 genes, which potentially indicates selection acting on these immune system haplotypes from the Stuttgart individual consistent with the Stuttgart farmer and modern Europeans' continual close interaction with animals and zoonotic disease exposure. In conclusion, our approach of calculating PWD in small SNP blocks supported prior conclusions made by Lazardis et al. and illuminated small genomic haplotypes that are of importance to the evolution of modern West Eurasian populations.

1460T

Refining the South Asian origin of the Roma people. *B. Melegh[1,2], Zs. Banfai[1,2], M. Kayser[3], B. Melegh[1,2].* 1) Medical Genetics, University of Pecs, Pecs, Hungary; 2) Szentagothai Research Centre, University of Pecs, Pecs, Hungary; 3) Department of Forensic Molecular Biology, Erasmus University, Netherlands.

Purpose: Historical and linguistic studies have suggested that Roma people, living mainly in Europe, migrated into the continent from South Asia about 1000-1500 years ago. Genetic studies, based on the examination of Y chromosome and mitochondrial DNA data, confirmed these findings. Recent genetic studies based on genome-wide Single Nucleotide Polymorphism (SNP) data further investigated the history of Roma and, among many other findings, suggested that the source of South Asian ancestry in Roma originates mainly form the Northwest region of India. **Methods:** In this study, using also genome-wide SNP data, we attempted to refine these findings using significantly larger amount of European Roma samples. We also had the opportunity to use more data of distinct Indian ethnic groups, which provided us a higher resolution of the Indian population. The study uses several ancestry estimation methods based on the algorithmic method principal component analysis and model-based methods that apply Bayesian approach and uses Markov chain Monte Carlo or maximum likelihood estimation. **Results:** According to our analyses, Roma showed significant common ancestry with Indian ethnic groups of Jammu and Kashmir, Punjab, Rajasthan, Gujarat, Uttarakhand states, e. g. with Kashmiri Pandit, Punjabi, Meghawal, Gujarati and Tharu. However, we found strong common ancestry with Pashtun and Sindhi, ethnic groups living in Pakistan. Populations of Northeast India have also strong common ancestry with Roma. These ethnic groups are Brahmin, Kshatriya, Vaish. **Conclusion:** We can conclude, that Northwest India plays an important role in the South Asian ancestry of Roma, but they have similarly strong ancestry with some Pakistani ethnic groups and we can find populations in the east region of North India, which also could function as a source of Indian ancestry of Roma. However, ethnic groups of the southern region of India do not show strong relationship with Roma people, living in Europe.

1461W

Admixture and ancestry patterns of three Brazilian quilombo remnants communities. *C. T. Mendes-Junior[1], D. M. Salvanha[2], R. Z. N. Vêncio[2], L. M. Garrido[3], H. Krieger[3], E. C. Castelli[4], A. L. Simões[5], E. S. Andrade[5].* 1) Departamento de Química, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, SP, Brazil; 2) Departamento de Computação e Matemática, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, SP, Brazil; 3) Departamento de Parasitologia, Universidade de São Paulo (ICB-USP), São Paulo, SP, Brazil; 4) Departamento de Patologia, Universidade Estadual Paulista (FMB-UNESP), Botucatu, SP, Brazil; 5) Departamento de Genética, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil.

The Brazilian population results of the admixture between European, African and Amerindian populations. Complex historical factors have generated variables proportions of ancestry contribution between individuals and between different admixed populations. This study aimed to describe the admixture and ancestry patterns of three quilombo remnants populations from Brazil, Gaucinha (GAU, n = 14), Mimbó (MIB, n = 15) and Sítio Velho (STV, n = 15) and of an urban population, Teresina (TES, n = 15). Data from seven population samples from the HapMap Project (CEU, CHB, JPT, ASW, LWK, MKK, YRI, all with n = 15) were used as reference. Brazilian samples were genotyped for around 250 thousand SNPs using the GeneChip® Human Mapping 250K Nsp Array I - Affymetrix®. A set of 409 Ancestry Informative Markers (AIMs) was selected from panels described in the literature. Of these AIMs, 35 were present in the SNP array. Genetic distance (*FST*) estimates were performed using the Arlequin software. Global ancestry was estimated using ADMIX95, ADMIX 2. 0 and Structure 2. 3. 4 softwares. This latter was also used to evaluate population structure and individual ancestry. *FST* did not reveal significant genetic differences between the three quilombos. Nevertheless, they differ considerably in their proportions of ancestry composition, which were consistent among the three methods performed. Therefore, only the values generated from Structure are presented here. GAU and MIB presented low European contribution (0. 167 and 0. 185, respectively). GAU presented an African contribution of 0. 479, while in MIB was of 0. 600. Besides, GAU showed a higher Asian/Amerindian contribution (0. 354) than MIB (0. 215). The African contribution in STV was similar to that of GAU, while the Asian/Amerindian contribution was close to that of MIB. The European contribution in STV is much higher (0. 344) than in GAU and MIB. A possible explanation is that the founders of STV came from wider areas with diverse populations while in GAU and MIB they were direct descendants of black people already present in the region. TES presented different patterns in comparison with the three quilombos, with low values of African ancestry (0. 221) and high European ancestry (0. 546), as expected for an urban population. The individual genetic ancestry and genetic differentiation estimates corroborate all these results. FINANCIAL SUPPORT: FAEPA (Grant 1394/2011), CAPES, FAPESP (2013/15447-0) and CNPq/Brazil (309572/20142).

1462T

Sex-Biased Admixture in the Americas. *S. Musharoff[1], C. R. Gignoux[1], S. Shringarpure[1], M. A. Taub[2], T. O'Connor[3], R. A. Mathias[4], C. D. Bustamante[1], K. C. Barnes[4], CAAPA Consortium.* 1) Genetics, Stanford University School of Medicine, Stanford, CA; 2) Department of Biostatistics, Johns Hopkins University, Baltimore, MD; 3) University of Maryland School of Medicine, Baltimore, MD; 4) Division of Allergy & Clinical Immunology Department of Medicine, Johns Hopkins University, Baltimore, MD.

We studied sex-biased population histories from **C**onsortium on **A**sthma among **A**frican-ancestry **P**opulations in the **A**mericas (CAAPA) high-coverage whole genomes (~30x depth). CAAPA comprises 673 individuals who are African-American, African, Afro-Caribbean (Barbados, Jamaica), or Latin-American (Colombia, Brazil, Puerto Rico, Honduras, Dominican Republic). X chromosomes show a decrease of European ancestry as estimated with ADMIXTURE, consistent with a history of European male-driven colonization. CAAPA Latin Americans have female-biased Native American ancestry (5. 36% mean excess X-chromosomal), male-biased European ancestry (1. 36% mean excess autosomal), and female-biased African ancestry (6. 72% mean excess X-chromosomal). Some CAAPA African-descent populationshave never been studied genetically. The Garifuna from Honduras have very little autosomal European ancestry (2. 2%) but high Native American ancestry (16. 6%). The Afro-Brazilians from Condé have a high proportion of African ancestry (50. 5%). The Cartagena Colombians (from one of two slave ports in South & Central America) have more African ancestry than the TGP Colombians (CLM): on average CAAPA individuals have 31. 1% autosomal and 29. 7% X-chromosomal African ancestry and TGP CLM have 7. 7% and 6. 8%, respectively. Y and MT haplotype analysis support the above sex-biased admixture findings: Afro-Caribbeans have African mitochondria, Latin Americans have a mix of African and Native American mitochondria, yet both groups have mostly European Y chromosomes. We identify three Native American Y haplotypes in the Honduran Garifuna only, highlighting their unique history. Unexpectedly we identified a new subgroup of MT-E1a1a that suggests a connection with the Malagasy slave trade. We apply a novel method to infer sex-biased demography during specific time epochs to autosomal and X-chromosomal site frequency spectra. CAAPA Latin Americans show evidence for a female bias over a longer time scale, male-biased bottlenecks Out-of-Africa and into the Americas, and male-biased admixture events. We analyze ancestry tracts with the program TRACTS to estimate timings and magnitudes of sex-biased admixture events. Overall, our findings recapitulate the complex history of the Americas and highlight key differences between populations based on their local admixture histories. As this is the first time some of these unique populations have been studied, this represents a valuable population and medical genetic resource.

1463W

A novel approach to developing an ancestry informative marker panel for individual identification and population admixture characterization based on common population-specific SNPs. *D. Sengupta[1], A. Choudhury[1], M. Ramsay[1,2].* 1) SBIMB, University of the Witwatersrand, Johannesburg , South Africa; 2) Division of Human Genetics, National Health Laboratory Service and School of Pathology, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Background: Most ancestry informative marker (AIM) panels to date have been based on allele-frequency differences between populations. An alternative approach is to use population specific SNPs that are observed primarily in a single population. SNP array platforms used for GWAS and fine mapping have had a euro-centric sampling bias, and therefore have not been ideal to clearly differentiate diverse global populations or admixture at the level of the individual. The availability of large scale whole genome sequence data in recent years has made it possible to explore the potential for the design of an AIM panel based on population specific genetic variation. **Methods:** We have designed an AIM panel based on common (MAF greater than0. 05) population specific (CPS) SNPs identified from the 1000 Genomes Project (Phase 1) data. The CPS-SNP set for each population was LD pruned and a sub-set of SNPs representing the population a given number of times was identified using a novel iterative-masking algorithm. **Results:** The performance of the CPS-SNP AIM panel was evaluated by testing the accuracy of ancestry prediction for individuals from population studies with whole genome datasets including Complete Genomics, 1000 Genomes Project (Phase 3, including new populations) and individual genomes in the public domain. Despite being based on low coverage sequence data, the panel of 3,158 CPS-SNPs was able to efficiently identify the probable ethno-geographical origin of individuals, including some that were not represented in the design set. The predictions from frequency based AIM panels are probabilistic and require integration of population genetic data and computational analysis like PCA for ancestry inference. The major advantage of our approach is that the predictions are deterministic and no additional data integration and computational analysis are required. Moreover, the CPS-SNP AIM panel is modular and the size of the panel can be scaled down (or up) by including only SNPs for the ancestry components that are expected to be seen in study participants, or by including AIMs for additional parental populations. **Conclusions:** This approach shows promise for implementation in precision medicine, GWAS, forensics and individual identification. The inclusion of key populations representing Southeast Asia, Oceania and southern Africa, more high coverage data and more efficient algorithms in the panel design would significantly enhance the panel.

The Demographic Patterns Revealed by New World African Diaspora Genome. *W. Song[1], R. A. Mathias[2], K. C. Barnes[2], T. D. O'Connor[1], CAAPA Consortium.* 1) Medicine, University of Maryland, Baltimore, MD; 2) Medicine, Johns Hopkins University, Baltimore, MD.

One of the great interests in human genetics research is to understand human population structure, demographic patterns, and evolutionary history. New World populations, such as African Americans and Latino Americans with African ancestry, provide good examples for studying large migration and admixture events in recent human history. Three questions in particular are: 1) where did different sources of admixture come from, 2) when did admixture happen, and 3) what is the difference among subpopulations. To answer these questions we will make use of the *Consortium onAsthma among African-ancestry Populations in the Americas (CAAPA),* which contains high coverage (~30× depth) whole genome sequence data of 952 individuals of African ancestry. These individuals were selected from populations in North and South America, the Caribbean and continental Africa to form a large spectrum of New World African Disapora. We merged all CAAPA data with 1963 individuals from the publically available Human Origins genotype data. After filtering rare variation (MAF < 5%), there are 389,397 SNPs in autosomal chromosomes left for the analysis of population admixture in this work. The filtered SNPs are first phased using Shapeit with the reference panel from 1000 Genomes Project. PCA-based local ancestry estimation on the CAAPA dataset is performed with PCAdmix, using the continental reference samples from Human Origin dataset. Ancestry-specific PCA (ASPCA) Analysis of PCAmask, in which ancestry specific regions from Europeans, Africans, and Native Americans are masked in PCA with sub-continental reference panels, reveals that the European ancestry in these New World African Diaspora populations comes from two main parts of Europe: Northwest (English/French) and Southwest (Spanish). We use Malder and Tracts to identify the timing of admixture in these populations. The African and Native-American ancestries admix with each other about 13-16 generations ago and later European ancestry entered into these populations 6-8 generations ago. We show that the origin and time of European introgression are different between New World African ancestry populations. Our results clearly reflect the ancestry patterns of African admixed populations in America and provide a general pipeline to study the evolutionary history of other New World populations.

1465W

The genetics of Bene Israel from India reveals both substantial Jewish and Indian ancestry. *Y. Waldman[1,2], A. Biddanda[1], N. R. Davidson[1], P. Billing-Ross[1], M. Dubrovsky[3,4], C. L. Campbell[5], C. Oddoux[5], E. Friedman[3,4], G. Atzmon[6,7], E. Halperin[2,8,9], H. Ostrer[5,10], A. Keinan[1].* 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Molecular Microbiology and Biotechnology, Tel Aviv University, Tel Aviv, Israel; 3) Danek Gertner Institute of Human Genetics, Chaim Sheba Medical Center, Tel-Hashomer, Israel; 4) Sackler School of Medicine, Tel Aviv University, Tel Aviv, Israel; 5) Department of Pathology, Albert Einstein College of Medicine, Bronx, NY; 6) Departments of Medicine and Genetics, Albert Einstein College of Medicine, Bronx, NY; 7) Department of Human Biology, Faculty of Natural Sciences, University of Haifa, Haifa, Israel; 8) The Blavatnik School of Computer Science, Tel Aviv University, Tel Aviv, Israel; 9) International Computer Science Institute, Berkeley, CA; 10) Department of Pediatrics, Albert Einstein College of Medicine, Bronx, NY.

The Bene Israel Jewish community from West India is a unique population whose history before the 18th century remains largely unknown. Bene Israel members consider themselves as descendants of Jews, yet the identity of these ancestors and the time of their arrival to India are unknown, with speculations on arrival time varying between the 8th century BCE and the 6th century CE. Their genetic history remains similarly vague: Previous genetic studies showed that most Jewish Diasporas share ancestry that can be traced back to the Middle East, in accordance with historical records. An exception is the analysis of Bene Israel, for which previous studies did not find clear evidence for Jewish ancestry and stressed instead their similarity to Indian populations (with the exception of a suggestive Middle-Eastern link of the Y haplogroups in a set of four individuals). A challenge to the analysis of Bene Israel is the complex genetic structure of Indian populations, which are the result of ancient admixture of two ancestral populations, one of which more closely related to Eurasians and, hence, Jewish populations. Here, we characterize the genetic history of Bene Israel by collecting and genotyping 18 individuals from the population. Combining with 438 individuals from 32 other Jewish and Indian populations, and additional individuals from worldwide populations, we conducted comprehensive genome-wide analyses based on FST, PCA, ADMIXTURE, identity-by-descent sharing, admixture LD decay (ALDER), haplotype sharing (GLOBETROTTER), and allele sharing autocorrelation decay, as well as contrasted patterns between the X chromosome and the autosomes. Putting the results together point to Bene Israel individuals resembling local Indian populations, while at the same time constituting a clearly separated and unique population in India. They share genetic ancestry with other Jewish populations to an extent not observed for any other Indian population. We show that Bene Israel is an admixed population with both Jewish and Indian ancestry, with the genetic contribution of each of these ancestral populations being substantial. The admixture took place in the last millennium, about 19-33 generations ago. It involved Middle-Eastern Jews and was sex-biased, with more male Jewish and local female contribution. It was followed by a population bottleneck and high endogamy, which has led to the increased prevalence of recessive diseases in this population.

The Population Structure of Nunavik Inuit People. *S. Zhou[1,2], P. Xie[1], L. Xiong[3], A. Ambalavanan[1], CV. Bourassa[1], A. Dionne-Laporte[1], D. Spiegelman[1], PA. Dion[1,4], GA. Rouleau[1,4].* 1) Montreal Neurological Institute, Montreal, QC, Canada; 2) Department of Medicine, Faculty of Medicine, Université de Montréal, Montréal, QC, Canada; 3) Centre de recherche, Institut universitaire en santé mentale de Montréal, QC, Canada; 4) Department of Neurology and Neurosurgery, McGill University, Montréal, QC, Canada.

Nunavik Inuit, descendants of the Thule people who migrated from the west of Northern Canada at approximately 1,000 AD, are now the inhabitants of 14 villages across the north of Quebec. Previous studies and evidences suggested that contemporaryNunavik Inuit came from a small founder population, and their genetic profiles have shown to undergone selection to adapt to the cold climate and has therefore been uniquely preserved. However, genome-wide investigation have yet to be conducted on this group of people to explore their specific genetic background. Here we used high density bead array to genotype Inuit individualsfrom 13 Nunavikvillages, and compared their genetic patterns with those of aboriginal peoples from Americas, arctic populations from Siberia and Alaska, multiple Asian populations and French-Canadians also in Quebec. We further used exome sequencing on a selected individuals to provide additional population specific information in order to complement our findings. In result, principal component analysis (PCA) and Admixture suggested that Nunavik Inuit have extremely distinctive ancestral profiles compared to any world-wide populations, including other Canadian aboriginals as well as Siberians which commonly believed to share the same ancestors of Inuit. Increased runs of homozygosity (ROH) and elevated coefficients of inbreeding (*F*st) suggested that Nunavik Inuit have a significant amount of isolations and low gene flow in their populations, which further correlated with our findings that certain genes, such as *CPT1A* and its family members in the lipid metabolism pathway, are strongly selected for their unique adaptation to the environment. Our results provide important inputs to the studies of Nunavik Inuit susceptible diseases, it is also noteworthy that the population's unique genetic structure may help the disease gene discovery for certain complex disorders.

1467W

A genetic and socio-economic study of mate choice in Latinos reveals novel assortment patterns. *J. Y. Zou[1,2], D. S. Park[3], E. G. Burchard[3,4], D. G. Torgerson[3,4], M. Pino-Yanes[3,4], Y. S. Song[5,6,7], S. Sankararaman[8], E. Halperin[9], N. Zaitlen[3,4].* 1) Microsoft Research, Cambridge, MA; 2) Department of Biological Engineering, Massachusetts Institute of Technology, Cambridge, MA, USA; 3) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA, USA; 4) Department of Medicine, University of California, San Francisco, CA, USA; 5) Computer Science Division, University of California, Berkeley, CA, USA; 6) Department of Statistics, University of California, Berkeley, CA, USA; 7) Department of Integrative Biology, University of California, Berkeley, CA, USA; 8) Department of Genetics, Harvard Medical School, Boston, MA, USA; 9) Blavatnik School of Computer Science, Tel Aviv University, Tel-Aviv, Israel.

Understanding the patterns and drivers of nonrandom mating in human populations has important implications for genetics and medicine as well as for economics and sociology. Previous studies have provided evidence for assortative mating in diverse populations and have suggested that genetic assortment is significantly smaller than educational assortment in non-Hispanic whites. Nevertheless, there remain important open questions regarding assortment patterns (especially in non-European populations), the relationship between assortment based on genomic factors and socio-economic factors (such as income), and biological mechanisms driving such assortment. In this work we addressed these questions by jointly analyzing detailed socio-economic attributes and high-quality genotype data associated with large cohorts of Mexicans and Puerto Rican individuals sampled from multiple geographic locations. To quantify genomic assortment in the absence of parental genotypes, we developed a novel computational method, ANCESTOR, to accurately infer the genomic ancestry (fraction of the genome derived from European, Native American and African ancestries) of each parent from the offspring's genotype. We applied ANCESTOR to our richly phenotyped Latino cohorts. In ethnically homogeneous Latino communities, we quantified genomic ancestry as a key axis of assortment. Partners are much more likely to share similar genomic ancestries than random individuals. Consistent with this, partners are more closely related—equivalent to between third and fourth cousins in Mexicans and Puerto Ricans—than expected based on random mating. Our analysis showed that socio-economic factors only explain a small portion of the genomic ancestry similarity between partners. Strikingly, after normalizing by population background, partners are more similar in genomic ancestries than in education levels. We found that Puerto Rican couples are especially correlated in genes involved in facial development (above and beyond genome-wide similarities), suggesting that similarity at these genes represents an axis of assortment. We replicated our findings across multiple locations. Our analysis integrated population genomics with quantitative social sciences to address fundamental questions about mate selection.

Population Structure Analysis of Few Northwest Punjabi Populations based on Microsatellites and Alu Insertion Elements. *M. Kaur, B. Doza.* Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

Introduction: It is noteworthy that Punjabi population exhibit higher genetic affinity with Central Asia, Middle East and European populations due to previous episodes of foreign migrations and invasions. Furthermore, regional conversions from different castes occurred during the period of Islamic dominance. The present study was aimed to to analyze the genetic structure, relationship and gene flow in five endogamous population groups, based on microsatellite loci and Alu insertion elements. **Methodology:** A total of 751 subjects, (154 Jat Sikh, 148 Mazhbi Sikh, 151 Brahmin, 148 Ramdasia and 150 Muslim) were recruited from the Northwest Punjab. Two kinds of markers; microsatellite and Alu insertion elements were used to analyze the genetic structure and relationships among five studied population groups. The genotypes thus obtained were subjected to extensive statistical analyses **Results:** Significant deviations from HWE were observed in almost all the populations and all the loci. In the present studied populations the genetic diversity (DST) was almost similar, except for Muslim population group. Significantly low coefficient of determination (FST) was observed among the five studied population groups. The genetic distance, genetic identity, AMOVA, structure, phylogenetic, principal component, multidimensional scaling and centroid analyses revealed similar results. In the entire analyses the Brahmin and the Mazhbi Sikh formed same cluster, while Jat Sikh and Ramdasia were placed close to their cluster, whereas, Muslim population group maintained the genetic distance from all the other population groups. **Conclusions:** Overall, a low level of genetic differentiation, observed in the studied population groups, especially, Jat Sikh, Mazhbi Sikh, Brahmin and Ramdasia, indicates that genetic drift might have been small or negligible in shaping the genetic structure of the Northwest Punjabi populations. The work provides the evidence that for populations living in same geographic contiguity, ancestry is the governing factor in genetic differentiation. Some amount of affinity with the European, Central Asian and Middle East populations could be attributed to many Islamic invasions from Middle East and Central Asia, specially Iran and Iraq, and the various religion conversions during the expansion of Islamic faith into the Indian sub-continent.

1469W

A new population structure analysis approach specifically designed for whole genome sequence data. *M. Robinson[1], W. S. W. Wong[2], B. D. Solomon[2,3], J. G. Vockley[2,3], I. Shmulevich[1], G. Glusman[1], J. E. Niederhuber[2].* 1) Institute for Systems Biology, Seattle, WA 98109, WA; 2) Inova Translational Medicine Institute, Inova Health System, 3300 Gallows Road, Falls Church, VA 22042; 3) Department of Pediatrics, Virginia Commonwealth University School of Medicine, 1201 E Marshall St, Richmond, VA 23298.

We developed a new approach to population structure analysis that recognizes differences between closely related populations better than standard methods involving principal component analysis (PCA) followed by k-means clustering. We find that PCA's normalization overweights common variants. We developed a novel method, Scaled Singular Value Decomposition (SVD), that weights variants equally and takes full advantage of the rarer variants now observable by whole-genome sequencing (WGS). As a result, population structure within continents is clearly resolved. Scaled SVD also facilitates analysis of admixture by locating variants as well as samples on the same principal components. Furthermore, k-means clustering ignores the ordered nature of principal components and the hierarchical structure of populations. We thus developed abcTree, a top-down hierarchical clustering algorithm specifically intended for population structure identification. abcTree employs adaptive Bonferroni correction to resist over-interpreting population structure. We evaluated our new methods (separately and in combination) on two large WGS cohorts: the 2504 samples (26 ascertained populations) of the 1000 Genomes Project, and an ethnically diverse cohort of 3483 founders from family trios in Northern Virginia, acquired by the Inova Translational Medicine Institute (ITMI, www. inova. org/itmi). The ITMI cohort is annotated with a rich set of multi-omic and phenotypic data, and metadata including self-reported country of birth. We analyzed multiple sets of variants, including common variants sampled from a genotyping array and variants of all frequencies randomly sampled from WGS data. In all combinations, Scaled SVD and abcTree separated samples better than PCA and k-means clustering. For the 1000 Genomes cohort, our method better recapitulated the annotated populations. For the ITMI cohort, the clusters corresponded better with self-reported country of birth. Precise identification of a patient's population of origin enables improved care via better diagnosis of inherited diseases and assessment of disease risks. It also increases power in genome-wide association studies (GWAS). We anticipate that these improvements in population structure analysis will be increasingly valuable as whole genome sequencing enters clinical practice. .

1470T

PCA-seq: Population Structure Inference with Rare Variants from Sequencing Data. *T. Thornton, J. Kirk.* Department of Biostatistics, University of Washington, Seattle, WA.

Advancements in high-throughput sequencing technologies have allowed for unprecedented insight into the vast amount of rare variants across the human genome. Recent studies have found that rare variants are likely to show greater geographic clustering than common variants, and also may provide a powerful resource to delineate fine-scale patterns of population structure. In recent years, principal components analysis (PCA) has been the prevailing approach for population structure inference (and correction) with common variants from high-density single nucleotide polymorphism (SNP) genotyping data. Widely used PCA-based methods, such as EIGENSTRAT (Price et al. , 2006),however, may not give reliable population structure inference when applied to sequencing data with rare variants due to the genetic relatedness matrix (GRM) that is used in standard PCA approaches becoming unstable with low frequency variants. Here, we propose PCA-seq, a new PCA-based approach for population structure inference with rare variants from sequencing data. PCA-seq uses a modified GRM in a PCA, where this GRM can appropriately incorporate low frequency variants, as well as common variants, allowing for robust inference on population structure. In simulation studies, we demonstrate that PCA-seq provides a substantial improvement over PCA with EIGENSTRAT for inference on population structure with rare variants. We further demonstrate the utility ofPCA-seq in an application to sequencing data from the 1000 Genomes Project wherePCA-seqidentifies different patterns of population structure for rare variants and common variants.

Population analysis of INDELS markers in a sample of individuals from Santander, Colombia. *N. A. Trujillo, C. I. Vargas, A. Castillo, A. M. Gil, A. L. Pico.* Santander, Universidad Industrial de Santander, Bucaramanga, Santander, Colombia.

Nowadays, the insertion-deletion markers (INDELs) have been the focus of several researches, because this type of polymorphism has interesting features like low mutation rates and multiplexing capability, which makes these markers more suitable to investigate population admixture events. In the same way, the study of genetic diversity in admixed populations as Colombia, it is quite important because it can reveal different aspects associated with the history of each individual, being important for different application fields such as clinical and forensic genetics. According to this, the aim of this work was to determine the genetic structure of a population group from the six regional provinces of Santander, Colombia through the typing of 38 autosomal markers (INDELs), expanding the knowledge of the genetic history in our country. We analyzed a total of 500 unrelated individuals, who were genotyped for 38 Indels by multiplex PCR. In order to increase the information related to these markers, we reported allele frequencies, and genetics parameters such as heterozygosity, Hardy Weinberg equilibrium, genetic distance and linkage disequilibrium were evaluated in the population. Additionally, we performed an analysis of individual ancestry proportions using reference samples from European, African, Asian and Hispanic populations by Fondevila M. *et al*, 2012. In the Hardy Weinberg test, we did not obtain statistically significant differences in 32 markers of 38 INDELs analyzed in the population of Santander (P > 0. 01). The populations represented in the six regional provinces presented a high genetic diversity intragroups, which ratified the high variability between individuals. Also, the results revealed a highly diverse genetic composition from all continental populations as it was expected. With this study, it is expected to generate new knowledge about the genetic composition of the population in Santander from each marker typified. In addition, the database reported by this project will be the first obtained for our state, and it will generate new knowledge to the genetic history of Colombia. Also, these markers will constitute a valuable tool for the analysis of important aspects such as ancestry and the possible association of some Indels with a greater predisposition to the development of complex genetic diseases in our population. **Key words:** Insertion-deletion polymorphisms, human identification, Santander, population structure, admixture.

Personalized genomic medicine challenges due to ancestry: disparities in the African Diaspora. *M. D. Kessler[1], M. Taub[2], R. Mathias[2], K. Barnes[2], L. Yerges-Armstrong[1], T. D. O'Connor[1], CAAPA Consortium.* 1) University of Maryland, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD.

Health disparities in personalized genomic medicine can create both economic and interpretive difficulties in treating underrepresented minorities. This is especially true in clinical genomics, where most previous studies have been focused on European ancestry individuals. Using 642 whole genome sequences from the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) project, which represents an essentially healthy cohort coming from many groups of the African Diaspora, we evaluate typical filters and databases used in personalized genomic medicine. The ANNOVAR program was used to annotate variants for ClinVar and Human Gene Mutation Database (HGMD) information, allele frequencies, protein function, and 11 in silico predictions of deleteriousness. We excluded any variant with an MAF > 0. 05 in ANY of the 1000 Genome super populations or in the Exome Sequencing Project, as well as variants that were called deleterious by at least 2 in silico predictors. We find that likely-pathogenic variants and variants of unknown significance have a strong positive correlation with African ancestry (r = 0. 990, p < 10-10 and r = 0. 995, p < 10-10 respectively). We also find that pathogenic pre-filtered variants in HGMD are strongly positively correlated with African ancestry (r = 0. 992, p < 10-10), but this correlation disappears with filtering. ClinVar does not have a significant pre-filtered correlation, but when filters are applied, a significant negative correlation appears (r = -0. 639, p = 0. 008). In addition, ClinVar's correlation has changed over time amidst monthly updates, with the most extreme switch happening between March and April of 2014 (r = 0. 733 to r = -0. 683). By starting with April's variant list, and selectively including/excluding SNPs differing between April and March depending on their correlation values and significance, we identified 68 SNPs as the major drivers of the correlation pattern. Using the most recent version of ClinVar, we calculated per gene correlations to identify a subset with the strongest signal, and note them as those that require particular care in clinical analysis due to their large ancestry-related bias. We do not find that these genes are enriched for Mendelian, GWAS catalogue, or X-linked genes. These results also have important financial implications in clinical genetics, with ancestry impacting both variant validation and clinician variant review.

1473W

Percent African admixture is associated with telomere length in a healthy adult population. *L. R. Yanek[1,2], K. R. Iyer[1], M. A. Taub[3], D. Vaidya[1,2,3], B. G. Kral[1,2], L. C. Becker[1,2], M. Armanios[1], D. M. Becker[1,2,3], R. A. Mathias[1,2,3].* 1) Medicine, Johns Hopkins University, Baltimore, MD; 2) GeneSTAR Research Program, Johns Hopkins University, Baltimore, MD; 3) Public Health, Johns Hopkins University, Baltimore, MD.

Africans and African Americans (AA) have been shown to have longer leukocyte telomere length (LTL) than persons with European ancestry (EA), but the extent to which this is a function of a finer scale of admixture (i. e. percent African ancestry) remains unknown. We examined whether the percentage of African admixture is associated with telomere length in 283 healthy subjects (average age = 42. 3, age range = 21-80 years, n female = 161; n AA = 127). Telomere length was calculated from whole genome sequence (WGS) data (>30x coverage on the Illumina HiSeq platform) for 7 contiguous repeats of the telomere motif (TTAGGG or CCCTAA) using the approach of Ding et al (2014). Admixture was estimated using 50,000 LD-pruned SNPs in STRUCTURE using three ancestral groups to calculate the % African and % European ancestry. Standard linear models were used to evaluate the association between telomere length and admixture estimates. In the AAs, average African ancestry was 80% (range: 45-98%) and average European ancestry was 20% (range: 2-55%). In the EAs average European ancestry was 99% (range: 72-99%) and average African ancestry was 1% (range: 0. 01-19%). As previously observed, an overall comparison between the two groups reveals longer telomere length in AAs than EAs (84364 vs 78560 kb, p=0. 0008). On a continuous scale, % of African ancestry was significantly correlated with telomere length (r=0. 22, p=0. 0002). Furthermore, in AAs, there is a strong association between % African ancestry and telomere length (each percent increase in African admixture was associated with an increase in telomere length of 6284 kb, p=0. 0036). Given minimal variation in the EAs, there is no observed association with % African ancestry and telomere length in this group (p=0. 1552). We confirm the prior observations that telomere length is different between AAs and EAs, and show here that within African Americans the % of African admixture is a significant predictor of telomere length. Future studies of racial differences in telomere length may need to account for differences in the proportion of African ancestry among subjects, particularly within African Americans.

1474T

Comparative analysis of transcriptome of different neurons in the human brain. *L. Yang, B. Su.* State Key Lab of Genetic Resource and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, China.

Von Economo neurons(VENs) are specialized projection neurons with a characteristic spindle-shaped soma and thick basal and apical dendrite. VENs are distributed in only a few brain areas associated with intelligence and emotion. Humans have larger cell body and greater number of VENs than non-human primates. It was speculated that the emergence of VENs may be correlated with primate brain evolution and origin of human intelligence. However, the functional role of VENs remains elusive. Using laser capture microdissection and RNA sequencing, we analyzed the transcriptomes of VENs and three non-VEN types of neurons. We identified a set of VEN specific or preferential expression genes, which serves as important candidates for dissecting VENs' function and their potential contribution to the origin of human intelligence.

Sequence and Amplicon Diversity Among Chimpanzee Y Chromosomes. *M. T. Oetjens[1], F. Shen[1], Z. Zou[2], J. M. Kidd[1,2].* 1) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI, 48109, USA; 2) Department of Computational Medicine and Bioinformatics, University of Michigan Medical School, Ann Arbor, MI, 48109, USA.

The male-specific region of the Y chromosome is a unique resource for tracking the history of populations due to the lack of recombination. Y chromosomes are also enriched for large, nearly identical repetitive regions known as amplicons which harbor many of the genes essential for spermatogenesis. In humans, copy-number variation of specific amplicons has been demonstrated. Sequence diversity on the unique segment of the MSY is greatly reduced compared to the autosomes, an observation consistent with the action of strong purifying selection. Similar studies of Y-chromosome diversity in other primate species have been limited. Here, we analyze 9 chimpanzee (representing three subspecies: Eastern, Western, and Nigerian-Cameroon) and two Bonobo male whole genome sequences (WGS) produced by the Great Apes Genome Project to assess nucleotide and ampliconic copy number diversity across the *pan* lineage. To assess nucleotide diversity, we applied a series of filters designed to remove regions of high-self identity such as the ampliconic tracts and heterochromatin from our callset. In total, we identified 23,946 SNVs (without human) across 4. 2 million callable sites. Comparisons with autosomal, X chromosome, and mitochondrial sequences from the same samples indicate that nucleotide diversity on the chimpanzee MSY is reduced relative to neutral expectations. Consistent with purifying selection, we observed a significant bias in synonymous over non-synonymous variants (p = 1. 60 x 10-5; Fisher's Exact Test) in single copy X-degenerate genes. We applied Quick-mer, a novel pipeline for paralog-specific copy-number analysis based on exact kmer matches to assess the ampliconic diversity among chimpanzees. We observe that the copy number of Y chromosome amplicons is variable amongst chimpanzees and bonobos and identify several lineage-specific patterns. The inferred copy number of testis-expressed genes varies by population, which may reflect underlying selection specific to chimpanzee subspecies and bonobos. For example, we find *TSPY* to range in copy number between 9. 2 (Western Chimpanzees) and 32. 1 (Bonobos) and *DAZ,* 1. 76 (Easterns) - 4. 11 (Westerns). Recurrent switchpoints of copy-number change along the ampliconic tracts across chimpanzee populations were also observed, which may be the result of localized genome instability or selective forces. These results support the hypothesis that strong purifying selection is inherent to the MSY in the *pan* and *homo* lineages.

Trends in DNA methylation with age replicate across diverse human populations. *S. Gopalan[1], O. Carja[2], M. Fagny[3,4], E. Patin[3,4], M. S. Kobor[5], H. Fraser[6], A. Froment[7,8,9], M. Feldman[6], L. Quintana-Murci[3,4], B. M. Henn[1].* 1) Department of Ecology & Evolution, Stony Brook University, Stony Brook, NY, United States; 2) Department of Biology, University of Pennsylvania, Philadelphia, PA, United States; 3) Department of Genomes and Genetics, Human Evolutionary Genetics, Institut Pasteur, 75015 Paris, France; 4) Centre National de la Recherche Scientifique, URA 3012, 75015 Paris, France; 5) Centre for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, BC, Canada; 6) Department of Biology, Stanford University, Stanford, CA, United States; 7) Institut de Recherche pour le Développement, 75006 Paris, France; 8) Muséum National d'Histoire Naturelle, 75005 Paris, France; 9) Centre National de la Recherche Scientifique, UMR 208, 75005 Paris, France.

The process of aging is associated with marked changes in patterns of genomic DNA methylation, including a global loss of methylation with increasing age. Several specific CpG sites also exhibit linear changes in their DNA methylation levels with chronological age. Futhermore, it has been demonstrated that methylation data from a relatively small number of CpG sites can accurately predict an individual's chronological age. So far, however, models of DNA methylation and aging have primarily focused on European and North American populations. The substantial genetic diversity and environmental variation that exists among human populations has not been explicitly accounted for, and its effects on the process of epigenetic aging process remain unknown. In this study, we investigate DNA methylation trends in two African hunter-gatherer populations from two tissue types, blood and saliva (n = 181): the Baka pygmies from the Central African forests of Cameroon and the Πιτι K-homani San from the Kalahari Desert in South Africa. We conducted an epigenome-wide association study on each population to identify CpG sites where methylation levels exhibit a significant and linear association with age. We confirm that a CpG site in the promoter of the gene ELOVL2 exhibits a significant and remarkably congruent relationship with aging when compared to previously studied European populations. We further identify significant hypomethylation with age at a CpG site in the promoter the D-aspartate oxidase gene (DDO). Expression of DDO has previously been found to increase with age in several species. We also test the performance of a previously published age prediction model to estimate chronological age in diverse populations and from different tissue types. We find that several age-related CpG sites replicate consistently across populations, demonstrating their utility as accurate biomarkers for age with potential applications in the fields of forensics and genomics. These results demonstrate how the differences in epigenome-wide trends across ethnic groups may provide important insights into the phenomenon of epigenetic aging in humans.

On estimating the shared genetic basis of complex phenotypes between populations. *B. C. Brown[1], N. Zaitlen[2].* 1) Department of Computer Science, UC Berkeley, Berkeley, CA; 2) Department of Medicine Lung Biology Center, UC San Francisco, San Francisco, CA.

Many phenotypes vary dramatically in their distributions around the world, and the extent to which these differences are driven by genetic rather than environmental factors is unknown. In this work we develop a framework for estimating the correlation of causal variant effect sizes between two populations (χ_g) from summary statistics. When χ_g=1 all causal variants between populations have the same effect size and when χ_g=-1, all have opposite effect sizes. This estimate therefore encapsulates the extent to which gene-gene, gene-environment, or other modifiers alter effect sizes between populations. Previous approaches to this problem (Yang et al 2013 NG) rely on linear mixed models and have three disadvantages. First, they require access to primary genotypes and phenotypes. Second, these methods are computationally expensive. Finally, they estimatethe correlation of allele-frequency normalized effect sizes(χ_z), or more intuitively, the correlation of the variance explained per causal variant. While our framework can also estimate χ_z, interpretation of this statistic is difficult; even when all causal SNPs have identical effect sizes variations in allele frequencies will give χ_z<1. Our method is based on maximizing the likelihood of $\chi_g$given the observed summary statistics and genotype covariances computed from a matched reference panel. We show that the joint distribution of the summary statistics is multivariate normal and that a dramatic speed-up can be had by using only the diagonal elements of the covariance matrix, resulting in an estimator that can be fit in time of order NM, where N is the reference panel sample size and M is the number of SNPs. Our framework can also estimate the total heritabilityof a phenotype in each population and the co-heritabilitybetween two phenotypes in one population, thus providing novel estimators of those quantities from summary statistics, and extends naturally to partitioning by functional category. We have shown via extensive simulation over real genotypes in two populations that our estimator of $\chi_g$is unbiased with reasonable standard error: with 50k individuals and 50k SNPs the standard error is 0. 090. Furthermore, our heritabilityestimator has half the standard error of LD score regression (Bulik-Sullivan 2015 NG): 0. 039 vs 0. 084 at the same number of SNPs and individuals, facilitating application to smaller regions. Finally, our method is robust so assuming only a small fraction p<1 of the SNPs are causal.

mQRF: A random forest model on meQTL detection by using chromatin states, haplotype structure and chromatin interaction information. *Y. Liu[1,2], M. Kellis[1,2].* 1) MIT, Cambridge, MA; 2) Broad Institute, Cambridge,MA.

mQRF: A random forest model on meQTL detection by using chromatin states, haplotype structure and chromatin interaction informationYaping Liu, Manolis KellisCSAIL in MIT, Broad Institute of MIT and Harvard, USADNA methylation, as an essential epigenetic mark, plays a critical role in gene regulation possibly via interactions with genetic variants, transcription factors and other epigenetic marks. Recent advances in Epigenome Wide Association Study (EWAS) provide the opportunities to study these interactions in order to fully understand the function of DNA methylation. One of the important steps to decipher the mechanism of genetic influences on DNA methylation is the detection of methylated quantitative loci (meQTL) using accurate and highly sensitive computational methods. The methods currently used to discover meQTL, however, are directly adapted from expression quantitative loci (eQTL) detection methods. Here, we explored the variety of relationships between SNPs, methylation and gene expression in different chromatin environments, which indicated that it is important and necessary to design a specific method for meQTL detection. meQTLFinder, a random forest model present here, incorporated biological information associated with DNA methylation and greatly increased the power on meQTL detection even in a limited sample size. mQRF quantitatively identified the relationship between genetic variation and DNA methylation, DNA methylation and enhancer, DNA methylation and gene expression in different chromatin states among different tissues by using Roadmap Epigenome project datasets. DNA methylation values from microarray or next generation sequencing studies were further normalized based on different chromatin states, sequence context and reference tissue type. A generalized linear model widely used in eQTL studies was applied to calculated association significance level between SNP variation and CpG methylation level. Later, normalized Hi-C contact frequency and haplotype structure between meQTL was also incorporated into the training set of mQRF's random forest model to increase the power of weak associated meQTL detection. Grant support from NIH-1U01HG007610-01.

The genomic and epigenomic properties of sexual dimorphism in human meiotic recombination. *C. Bhérer, C. L. Campbell, A. Auton.* Department of Genetics, Albert Einstein College of Medicine, Bronx, NY.

Sexual dimorphism in meiotic recombination is widespread across species. In humans, males tend to have significantly lower recombination rates than females over the majority of the genome, but the opposite is true close to the telomeres. These broad-scale differences have been known for decades, and yet little is known about the fine-scale differences between the sexes and the factors influencing them. Based on recombination events inferred from pedigree data consisting of more than 100,000 meioses, we have constructed sex-specific genetic maps at a previously unachievable resolution. Compared to previous maps, our maps display an improved correlation to LD-based maps and improved localization of events to hotspots of recombination. Using wavelet analysis, we characterize the sexual dimorphism in recombination across different scales and its relationship to genomic and epigenomic features. We show that the variation in female and male rates are highly correlated over a range of scales, and investigate the genomic features associated with the differences. Interestingly, male recombinogenic regions are more strongly associated with certain repeat elements and epigenetic marks, implying that male and female hotspots may be differently regulated by the hotspot localizing protein PRDM9. Finally, fine-scale analysis of genomic regions with a significantly higher rate in female than male and vice-versa further revealed a number of genomic features enriched in dimorphic regions compared to matched non-dimorphic regions. These findings provide potential clues to the origins of sexually dimorphic recombination rates.

Insights into meiotic recombination from characterization of non-crossover and crossover events in a mouse humanized at PRDM9. *R. Li, N. Altemose, E. Bitoun, AG. Hinch, E. Hatton, P. Donnelly, G. Zhang, B. Davies, SR. Myers.* Wellcome Trust Center for Human Genetics, Oxford University, Oxford, United Kingdom.

Meiotic recombination is initiated by programmed DNA double strand breaks (DSBs), repairing as crossovers (COs) or non-crossovers (NCOs). Although most DSBs resolve as NCOs, some basic properties of these events remain uncertain, because NCO tracts are often short and so difficult to detect. In mice and humans, many DSBs occur in hotspots positioned by the DNA-binding protein PRDM9, although >30% of human crossovers occur outside known hotspots. To study PRDM9 alleles from both species, we crossed and sequenced transgenic *M. m. domesticus* (B6) mice humanized at PRDM9, with wild-type *M. m. castaneus* (CAST) mice, which have a high SNP density relative to B6. We identified 81 NCO and 106 CO events in four F2 progeny, whose chromosomes are mosaics of the CAST and B6 genomes due to maternal and paternal recombination. All NCOs comprised simple unbroken tracts of SNPs, implying complex NCO is very unusual, despite recent human results. We estimate a mean NCO tract length of only 34 bases, with an approximately 10:1 NCO to CO ratio in meiosis. Remarkably, almost all NCOs and CO's overlap DMC1 or H3K4me3 ChIP-seq peaks from F1 males, which mark DSBs and PRDM9 binding sites respectively. Therefore few or no truly female-specific recombination hotspots exist and previous apparent "non-hotspot" recombination (e. g. in humans) may reflect variation at hotspots or PRDM9, or insufficient power. Most NCO events occurred very near to PRDM9 binding motifs: up to 69% actually contain the motif, and NCO conversions show a GC-bias. The CAST PRDM9 allele shows dominance over the human allele for both CO and NCO events but nevertheless humanization reprograms recombination sites. CAST-controlled NCOs preferentially occurred on the B6 chromosome, but human PRDM9-controlled NCOs did not explained by CAST PRDM9 binding motif erosion on the CAST background, and implying no strong meiotic control of the number of DSB's occurring on individual chromosomes exists. Surprisingly, two >8kb deletions (one genic) found in individual F2 mice are both near (<2kb) human hotspots. Although recombination proceeds normally, in general, at humanized hotspots, it may therefore be that introducing the human allele, which has evolved outside the mouse genome, increases the frequency of such rearrangements.

1481W

Estimating Rates, Tract Lengths and Contributing Factors to Non-Allelic Gene Conversion. *A. Harpak[1], X. Lan[2], J. Pritchard[1,2].* 1) Biology, Stanford University, Stanford, CA; 2) Genetics, Stanford University, Stanford, CA.

Gene conversion is the unidirectional transfer of genetic sequence from a "donor" to an "acceptor". In one of its modes, Non-Allelic Gene Conversion (NAGC), the donor and the acceptor are homologous sequences in different genomic loci. The parameters dominating NAGC are poorly understood. For example, estimations of the rate of NAGC empirical studies range across 7 orders of magnitude. This is despite the fact that interlocus gene conversion has been implicated as the cause of various genetic diseases and may be an important factor in the concerted evolution of many human gene families. Recent tandem gene duplications are of focal interest in studying NAGC as this process is contingent on high sequence similarity between donor and acceptor. In this work, we estimate the rates of NAGC in humans and other primates using ~700 pairs of recent tandem duplicates. For this purpose, we align families of duplicates across humans and 4 other primates. We then use the patterns of sequence divergence to estimate the rate and tract length distribution of NAGC with two independent methods. In the first method, we consider correlation in divergence patterns between two nucleotides in the same gene. The rates of mutation and NAGC determine the levels of divergence expected. The physical distance between the pair of nucleotides determines the probability that a NAGC event would cover both nucleotides, resetting divergence in the two concurrently. Using this model, we estimate the set of parameters that maximize the composite likelihood of the observed divergence patterns across all pairs of nucleotides in all gene families. In the second method, we make explicit use of the fact that a NAGC event would change the genealogy of the affected region across the gene family in primates. Genealogies may vary along the gene sequence, and the rates of transitions between genealogies are determined by the rate and length scale of NAGC. We construct a Hidden Markov Model where observed states represent observed divergence levels and hidden states represent underlying genealogies. This method also outputs a map of putative NAGC events across recent duplicates. We regress the density of NAGC events to various genomic features to reveal features putatively driving accelerated NAGC rates. This work contributes precise, cross validated estimates of the rate and length distribution of NAGC, suggests factors enhancing NAGC and measures its effect on human genetic variation.

Geometry of ancestral links: Pathogenic clues. *M. Jeanpierre.* Genetics, Hopital Cochin, Paris, France.

Inferences about negative selection can provide important information about the probability of a given variant being the cause of a genetic disease. This is particularly important for non-coding variants, for which it is difficult to carry out functional tests. Recent variants are generally considered much more likely to cause disease than very old. As rare variants may or may not be deleterious, frequency is only a very approximate indicator of pathogenicity. The shape of the genealogy for a particular variant may, theoretically, represent the effects of positive and negative selection more accurately than frequency alone. The algebraic description of haplotype patterns according to any topology of graphs representing genealogical trees is possible, but the resulting expressions rapidly become unbound, even for simple graphs with only a few branches, as the number of terms is approximately proportional to the factorial of the number of branches. We therefore need to break this problem down into simpler, more tractable questions. The distribution of nodes along the branches from a common ancestor is shaped by selection and could be represented graphically. The resulting representation of the true complexity would be easier to understand than that conveyed by bulky algebraic expressions. This approach is more efficient than a two-step strategy beginning with the construction of a large set of possible trees and followed by attempts to make sense of the resulting forest of probable trees. Isolated variants considered separately are rarely correlated with large effects, intervals containing clusters of variants may be more meaningful. Due to the many biases involved, length-biased sampling and related questions must be taken into account in the set of functions defining the distribution of haplotype sizes for any type of genealogy.

1483W

Whole genome sequences are required to fully resolve the linkage disequilibrium structure of human populations. *R. J. Pengelly, W. Tapper, A. Collins, S. Ennis.* University of Southampton, Southampton, United Kingdom.

Introduction: An understanding of linkage disequilibrium (LD) structure in the human genome underpins much of medical genetics, and provides a basis for disease gene mapping and investigation of biological mechanisms such as recombination and selection. Whole genome sequencing (WGS) provides the opportunity to determine LD structure at maximal resolution. **Methods**: We generated LD maps according to the Malécot-Morton model as implemented in LDMAP. We then compared maps produced utilising high depth whole-genome sequencing (WGS) data with LD maps produced utilising the array-based HapMap dataset, for representative European and African populations. **Results**: Maps derived from the WGS data achieve much greater resolution of LD structure (~ 5 fold), which translates to improved utility. The improved resolution allows the reduction in size of candidate regions flanking GWAS signals by 17%. The absence of ascertainment bias in WGS genotyping improves the population representativeness of the maps, and highlights the extent of uncaptured variation present in African populations using array genotyping methodologies. This uncaptured variation is a key reason for the poor reproducibility of GWAS results in African populations. Given the extended time to an effective population bottleneck for African populations, larger sample sizes and higher marker densities are required to fully resolve the LD structure. As such, we are currently generating maps from larger datasets, for release as a resource to the community. **Conclusions**: Array-based LD mapping is unrepresentative of actual LD structure, particularly in African populations. The Malécot-Morton model provides a highly efficient means of quantifying LD, and WGS LD maps will provide a rich resource for medical genetics, as well as for recombination biology. This work is funded under the UK Biotechnology and Biological Sciences Research Council (BBSRC) 'Sparking Impact' scheme.

Regulation of crossover placement in human meiotic recombination. *C. L. Campbell[1], N. A. Furlotte[2], N. Eriksson[2,3], D. Hinds[2], A. Auton[1].* 1) Department of Genetics, Albert Einstein College of Medicine, Bronx, New York 10461; 2) 23andMe Inc. , Mountain View, California 94043; 3) Present address: Coursera, Mountain View, California 94041.

Recombination is a key step in meiosis, serving multiple functions. Crossing over between homologous chromosomes shuffles existing genetic variation, while failure of the chromosomes to synapse and recombine can lead to nondisjunction and aneuploid gametes. Recent studies have shown that the placement of crossovers is under careful regulation, but despite this, displays tremendous variability between males and females in the location and frequency of recombination throughout the genome. To further address sex differences in recombination we conducted a pedigree analysis using 4,209 human families obtained through a research agreement with the personal genomics company 23andMe. From this, we are able to observe 18,302 meioses; 9,152 from females and 9150 from males. We find that males have a higher hotspot usage than females, a 4. 6% increase. We find that the number of crossovers rises sharply in older mothers, in support of previous reports of a maternal effect of crossover count. Finally, we estimate the level of crossover interference, a phenomenon that acts to ensure even spacing of recombination events. Males show a stronger overall strength of interference, while in females, a greater proportion of events escape this effect and this proportion increases with maternal age. This suggests that crossover placement appears to become increasingly deregulated in older mothers.

Inferring the parental haplotype source of germline-transmitted de novo duplications from population genotype data. *Y. Liu[1,2], S. Vattathil[1,2,3], L. Huang[2], X. Xiao[4], R. B. Scharpf[5], C. Huff[1,2], I. Ruczinski[6], S. Arur[7], T. H. Beaty[8], P. Scheet[1,2].* 1) Graduate School of Biomedical Sciences, University of Texas at Houston Health Science Center, Houston, TX, USA; 2) Dept. of Epidemiology, University of Texas MD Anderson Cancer Center, Houston , TX, USA; 3) Dept. of Genome Sciences, University of Washington School of Medicine, Seattle, WA, USA; 4) Center for Genomic Medicine and Department of Community and Family Medicine, Geisel School of Medicine at Dartmouth, Hanover, NH, USA; 5) Dept. of Oncology, Johns Hopkins Unviersity, Baltimore, MD, USA; 6) Dept. of Biostatistics, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 7) Dept. of Genetics , University of Texas MD Anderson Cancer Center, Houston , TX, USA; 8) Dept. of Epidemiology, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA.

De novo germline-transmitted duplications arise during gamete formation (possibly driven by meiotic recombination) and represent the genesis of a genetic polymorphism that has been associated with both complex and Mendelian forms of human disease. The formation of this type of duplications could be divided into two categories, i. e. , there are two possible sources for the extra copy of DNA in the offspring: the parent in which the duplication arose either (1) transmitted one copy from each homologous chromosome ("tri-allelic", arising from inter-chromosomal recombination), or (2) transmitted two identical copies from a single chromosome ("bi-allelic", arising from intra-chromosomal recombination). Here we apply a novel statistical model to two large population family-based genetic datasets to estimate the relative contributions of these two processes to the origins of copy number duplications. One dataset contains 2078 trios from a study of craniofacial abnormalities and the other contains 1346 trios from a study of autism. In our procedure, we first use trios to identify *de novo* duplications in offspring. We then check for consistency among plausible combinations of transmitted haplotypes and observed SNP array data (genotypes implied by the "B allele" frequencies, BAFs) for the offspring (duplication carrier), assuming empirically informed distributions for the BAFs in regions of duplication. Our preliminary results from both datasets indicate a tendency for duplications to derive from the same parental chromosome (bi-allelic), however the proportions differ between data sets (55%, 89%) warranting further investigation. Interestingly, we found examples in both datasets with evidence of a crossover event within the de novo duplication, thus part of the duplicated region manifests as tri-allelic and part as bi-allelic. Our analysis present the first population-level investigation into a phenomenon critical to the generation of this specific form of genetic polymorphism.

Pleiotropic constraint in the Human Transcription Factor Network. *K. Chesmore, J. Bartlett, C. Cheng, S. Williams.* Genetics Dept, Dartmouth College, Hanover, NH.

It has long been argued that pleiotropy can constrain gene evolution. We can now investigate the pleiotropic mechanisms that drive such constraints because of the recent expansion of large-scale molecular data. No class of genes has been more thoroughly characterized than transcription factors due to the efforts of the ENCODE consortium. Here we examine constraints on the human transcription factor network as a function of the number of partners with which each protein and protein domain interacts. We show not only increased evolutionary constraint with an increasing number of molecular partners, but also as a product of each domain's role. Additionally, we show that as the number of protein-protein interacting domains increases for a given transcription factor, the constraint on each domain decreases. In summary, we demonstrate that not only does pleiotropy, as defined by the number of molecular partners, constrain protein evolution in general, but that the constraints differ by functional role.

The birth of a human-specific neural gene by incomplete duplication and gene fusion. *M. L. Dougherty[1], X. Nuttle[1], B. Nelson[1], J. Huddleston[1,2], O. Penn[1], M. Y. Dennis[1], L. Harshman[1], K. Penewit[1], F. Antonacci[3], M. Malig[1], K. Munson[1], M. Duyzend[1], E. E. Eichler[1,2].* 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Howard Hughes Medical Institute, Seattle, WA; 3) Université degli Studi di Bari, Bari, Italy.

The human-specific gene *HYDIN2* was generated by an interchromosomal duplication event that copied 360 kbp of the large ciliary protein-encoding gene *HYDIN* (hydrocephalus-inducing) from chromosome 16q22. 2 to 1q21. 1, a hotspot for genomic rearrangements. The segmental duplication, however, included neither the promoter and first five exons nor the final two exons of the original progenitor gene, leading to speculation that the duplicate may not produce a functional protein product. We coupled RT-PCR with long-read (SMRT) sequencing of cDNA to characterize transcription at this locus. 5' RACE indicated a transcription start site outside of the duplication, and by targeting the duplication boundaries, we observed fusion products on both the 5' and 3' ends of the segmental duplication as well as extensive splicing diversity. A novel promoter and first exon were acquired by an adjacent duplication block and fusion transcripts with an *NBPF* core duplicon are observed downstream. This juxtaposition of duplications leads to a new potential translation start site and long open-reading frame consistent with the emergence of a novel human-specific gene. Expression profiling by RT-PCR and RNA-seq confirmed a neural-specific expression pattern distinct from the ancestral locus. Interestingly, we also find evidence of accelerated amino-acid replacements for both *HYDIN* and *HYDIN2* indicative of potential subfunctionalization of both copies after duplication. By comparing the 360 kbp duplication block to homologous primate sequence, we were able to date the duplication event to 3. 1 million years ago (+/- 0. 5 mya). Despite its recent origin, the duplication is nearly fixed for copy number in the human species (99. 9%). We surveyed a diversity panel of 2134 human genomes and found only one individual with a diploid copy number <4 for both paralogs. This is especially striking in light of the susceptibility of the 1q21. 1 region to extensive deletion and rearrangement. These data suggest a model of rapid gene innovation by gene fusion of adjacent segmental duplications, altered tissue expression, and subfunctionalization of *HYDIN* and *HYDIN2* during the transition from australopithecines to the genus *Homo*.

An unsteady molecular clock in primates. *P. Moorjani[1,2,5], CE. Amorim[1,5], P. Arndt[3], M. Przeworski[1,4].* 1) Department of Biological Sciences, Columbia University, New York, NY, USA; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Max Planck Institute for Molecular Genetics, Berlin, Germany; 4) Department of Systems Biology, Columbia University, New York, NY, USA; 5) Contributed equally.

Evolutionary events, such as the human-chimpanzee speciation or human migration Out-of-Africa, are usually dated under the assumption of a "molecular clock"—a constant rate of substitutions per unit time. Although this assumption is central to our understanding of the chronology of human evolution, its validity remains unclear. Among mammals, for example, it is well known that there exists substantial variation in substitution rates, potentially due to differences in their generation times or other life-history traits. To characterize the effect in primates, we analyzed genome-wide autosomal data from 12 primates. Focusing on putatively neutral sites and accounting for possible effects of methylation and biased gene conversion, we found that substitution rates in Old World Monkeys are ~30-40% higher than in apes. Rates vary even among apes: the gorilla branch ~6-10% longer than the human one. Importantly, the extent of rate variation differs among mutation types, with both transitions and transversions at CpG sites exhibiting a more clock-like behavior. As a result, not only the total rate, but the mutational spectrum is evolving among primates. This indicates that the molecular clock in primates is unstable and suggests that events in primate evolution are most reliably dated using CpG sites. We present updated divergence times in light of these considerations.

1489W

Long-term survival of duplicate genes despite absence of subfunctionalized expression. *X. Lan[1], J. K. Pritchard[1,2,3].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Biology, Stanford University, Stanford, CA; 3) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

Gene duplication is a fundamental process in genome evolution. However, young duplicatesare frequently degraded into pseudogenes by loss-of-function mutations. One standardmodel proposes that the main path for duplicate genes to avoid mutational destructionis by rapidly evolving subfunctionalized expression profiles. We examined this hypothesisusing RNA-seq data from 46 human tissues. Surprisingly, we find that sub- or neofunctionalizationof expression evolves very slowly, and is rare among duplications that arosewithin the placental mammals. Most mammalian duplicates are located in tandem andhave highly correlated expression profiles, likely due to shared regulation, thus impedingsubfunctionalization. Moreover, we also find that a large fraction of duplicate gene pairsexhibit a striking asymmetric pattern in which one gene has consistently higher expression. These asymmetrically expressed duplicates (AEDs) may persist for tens of millionsof years, even though the lower-expressed copies tend to evolve under reduced selectiveconstraint and are associated with fewer human diseases than their duplicate partners. Wesuggest that dosage-sharing of expression, rather than subfunctionalization, is more likelyto be the initial factor enabling survival of duplicate gene pairs.

1490T

The effect of life history on the rate of the molecular clock and implications for great apes. *G. Amster, G. Sella.* Columbia University, NY.

Estimates of species split times in the great ape phylogeny rely on the molecular clock. The estimates have recently been nearly doubled, because pedigree based estimates of the mutation rate approximately halved previous estimates based on fossil calibration. These revisions, however, rely on assuming a constant mutation rate per generation, which appears inconsistent with our current understanding of mutation in hominins, and might also be inconsistent with the fossil record. Here we show that less naïve models of the molecular clock that account forlifehistoryfactors and our current knowledge about their effects on mutation rates suggest a potentially large increase in estimates of split times. Notably, moderate differences in generation time between the sexes, changes in male puberty age, and to a lesser extent, changes in the rate of germ cell division during spermatogenesis, would have had a substantial effect on the rate of substitutions in great apes. We also show thatlifehistorycould help explain the observed ratios of X to autosomes divergence in great apes, and suggest modifying inferences based on this ratios in other taxa.

1491W

Linked selection dominates the genomic landscape of Great Apes. *A. Woerner[1], K. Veeramah[2], M. Hammer[3].* 1) Genetics GIDP, University of Arizona, Tucson, AZ; 2) Dept of Ecology and Evolution, Stony Brook, NY; 3) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tucson, AZ.

Early studies that have attempted to utilize putatively neutral loci in the genome for demographic inference have focused on pseudogenes, introns, and repetitive elements such as Alus. More recent studies have attempted to reduce the impact of directional and purifying selection as well as background selection and genetic draft by finding loci that are either in regions of low gene density and high recombination rate, or are at a maximal distance from genes in genetic units. However nucleotide diversity not only reduced near genes across great apes, but also near noncoding conserved elements. Because ~5% of primate genomes are composed of evolutionarily conserved elements, with ~2/3 of these elements being noncoding, skews in diversity in regions in linkage with such elements has large effects on genomic patterns of nucleotide variation. Here, we show that the combination of multiple conserved noncoding elements has more of an influence on nucleotide diversity than the distance to the nearest gene. Using an approach that models the combined effects of linkage to coding and noncoding elements, we predict levels of polymorphism on both the autosomes and the X chromosome for humans, chimpanzees, bonobos and gorillas. Based on our predictions we identify loci that are “effectively neutral” across various ape taxa. Using the relationship between diversity and the local recombination rate as a proxy for the effects of directional selection on neutral sites, we show that unlike other loci in the genome, our effectively neutral loci show no significant correlation between the local recombination rate and diversity. We conclude that “neutral” sequence is extremely rare in the genome. Finally, we use these neutral regions to estimate the relative effective population size of the X chromosome vs. the autosomes in African and non-African human populations, and in gorillas, chimpanzees and bonobos.

1492T

The genetic handicap principle: a severely deleterious mutation can be tolerated if the genome-wide mutation load is sufficiently low. *K. Popadin[1,2], S. Peischl[3], R. Sailani[4], A. Letourneau[1], F. Santoni[1], M. Garieri[1], S. Nikolaev[1], D. Meyer[5], L. Excoffier[3], S. E. Antonarakis[1].* 1) University of Geneva Medical School, Department of Genetic Medicine and Development, Geneva, Switzerland; 2) University of Lausanne, Center for Integrative Genomics, Genopode Building, Lausanne, Switzerland; 3) Institute of Ecology and Evolution, Computational and Molecular Population Genetics (CMPG), Bern, Switzerland; 4) Stanford University, Stanford School of Medicine, Stanford, CA; 5) University of Sao Paulo, Department of Genetics and Evolutionary Biology, Sao Paulo, Brazil.

Every human genome harbors hundreds of slightly-deleterious mutations. Even though most of these mutations individually have a small effect, their cumulative effect (mutation load) could substantially reduce the fitness of an individual. Here we investigate an interaction between a severely deleterious mutation and the mutation load, formulating the genetic handicap principle: an individual bearing a severely deleterious variant (i. e. a genetic handicap) is viable only if the genome-wide mutation load is sufficiently low. We develop a population-genetic model, which predicts that live-born individuals carrying a handicap mutation (causing, for example, 50-90% probability of miscarriage) show a reduction (5-20%) in their number of slightly-deleterious mutations as compared to controls.

To test this prediction, we used data on trisomy of chromosome 21 (T21), a frequent chromosomal abnormality in humans which is associated with high miscarriage rates. Three lines of evidence support the view that live-born T21 individuals have passed through the strong embryonic selection and thus have decreased load of slightly-deleterious mutations.

First, on chromosome 21 there is a deficit of homozygotes for rare derived alleles in the T21 cohort (N=338), suggesting a selection against homozygotes for deleterious variants.

Second, the T21 cohort on chromosome 21 shows an excess of loss-of-expression (LOE) regulatory variants, which are considered to be compensatory under the condition of trisomy, and deficit of gain-of-expression (GOE) regulatory variants, which are considered to be deleterious under the condition of trisomy, consistent with embryonic selection in favor of LOE and against GOE variants.

Third, assuming that each gene has an optimal expression level and all deviations from the optimum are deleterious, we compared inter-individual variation in fibroblast expression level between live-born T21 individuals (N=8) and controls (N=8) and revealed whole-transcriptome decreased variation in expression level in T21 cohort, driven mainly by dosage-sensitive genes, considered to be the most important for the health of an embryo. This can reflect a potential selection against T21 fetuses with non-optimal pattern of expression.

We conclude that the negative fitness consequences of severe mutations such as trisomy can be partially compensated by a reduced genome-wide load of slightly-deleterious mutations.

1493W

Prevalence of Ebola viral entry resistance in a diverse population. *P. F. Cherukuri, T. Vilboux, P. Kothiyal, A. Black, G. Eley, K. C. Huddleston, R. K. Iyer, B. D. Solomon, J. G. Vockley, J. E. Niederhuber.* Inova Translational Medicine Institute, Inova Health System, Falls Church, VA. USA.

Whole-genome sequencing (WGS) is fast evolving into a population genetics tool to estimate effect of sequence variants on human health and fitness. However, predicting the role of variants that confer protection remains challenging. Given this, we hypothesized that use of large population datasets and integrative-omics data would delineate role of protective variants. To test this hypothesis, we used variants ascertained by WGS in specific genes that confer resistance to Ebola viral entry and pathogenesis. Methods: We performed trio-based WGS on individuals enrolled in various clinical protocols, primarily as part of a broad study on use of population-based genomic sequencing. As a pilot study we performed WGS on 3,536 ethnically diverse individuals who are prospectively followed as part of a clinical/genomic study. WGS was performed on Illumina platform. Each individual's ancestry was defined by pairwise Pearson Correlation Coefficient based hierarchical clustering using 1000 Genomes Project defined population genotype markers and matching self-identified ethnicities. Variants in genes (e. g. *NPC1*) known to play key roles in viral attachment and entry into human cells were evaluated for variant burden. Additional genes within the viral entry pathway with no clear known role in uptake of viruses were used as controls. Results were compared to frequencies in public exome databases. Additionally, RNASeq was performed on 237 individuals to test for gene-expression patterns for loss–of-function variants. Results: We screened the WGS data for heterozygous variants with predicted large functional effect in the gene set. Specifically, we prioritized variants that resulted in evolutionarily unanticipated missense, frame-shift, splice-site altering or protein truncating mutations. We identified 69 novel variants (not in dbSNP), of which 7 were missense and 4 protein truncating in *NPC1* in heterozygous state, compared to 3 missense variants in control gene dataset. RNASeq allele-specific measurement of truncated products showed skew in distribution of reads at heterozygous sites compared to normal controls, suggesting non-sense mediated decay of truncated message. From this, we predicted that 0. 11 - 0. 37 % of our diverse population would have resistance to Ebola virus based on the identified variants. Though there are obstacles in interpreting WGS data, our pilot study on viral entry resistance serves as an example of role of integrative-omics in population genetics.

1494T

Chromosome-wide scan to identify rapidly mutating Y-STRs. *T. Willems[1,2], M. Gymrek[1,2,3,4,5], Y. Erlich[2].* 1) Computational and Systems Biology Program, MIT, Cambridge, MA USA; 2) New York Genome Center, New York, NY USA; 3) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA USA; 4) Broad Institute of MIT and Harvard, Cambridge, MA USA; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA USA.

Precise estimates of the time to the most recent common ancestor play a pivotal role in various Y chromosome applications. These include tracing patrilineal surnames and anthropological statuses and discriminating between individuals for forensic analyses. Current tests rely on a few dozen Y-chromosome short tandem repeats (Y-STRs) due to their relatively high mutation rates. However, these tests would be substantially improved by incorporating additional rapidly mutating Y-STRs. Unfortunately, identification of these loci is encumbered by the high cost and low throughput of the traditional method for estimating Y-STR mutation rates, which involves collecting and genotyping tens of thousands of father-son pairs using capillary electrophoresis. To address these limitations, we developed a novel mutation rate estimation method that leverages the advent of population-scale whole-genome sequencing datasets and bioinformatics tools capable of genotyping STRs. Our approach constructs a phylogeny using Y-SNP genotypes, overlays WGS-based STR genotypes and utilizes message passing and numerical optimization to converge to the maximum likelihood mutation model. In addition, our approach has the added benefit of considering a range of mutation models that allow for multistep mutations and length constraints. Using in-depth simulations, we confirmed that our method correctly accounts for PCR stutter artifacts and obtains unbiased mutation rate estimates across all considered mutation models. Application of the method to data from the 1000 Genomes project resulted in estimates for nearly 350 Y-STRs, representing the largest such set to date. Comparison of these estimates with those from father-son studies indicated a high degree of concordance for loci that have been previously characterized. In addition, we identified over 100 previously uncharacterized Y-STRs with mutation rates greater than 10-3. 5. Altogether, our study provides a broadly applicable method for estimating Y-STR mutation rates from whole-genome sequencing cohorts and vastly expands the number of identified Y-STRs with high discriminative power.

1495W

The Qatari Genome: A Population-Specific Tool to Facilitate Precision Medicine in the Middle East. *KA Fakhro[1,2], MR Staudt[3], F Agosto-Perez[3], TL Vincent[3], A Robay[1], JA Malek[1], R Badii[4], A Al-Nabet Al-Marri[4], C Abi Khalil[1], D Stadler[5], M Zirie[6], A Jayyousi[6], J Salit[3], JG Mezey[3, 7], RG Crystal[3], JL Rodriguez-Flores[3].* 1) Weill Cornell Medical College in Qatar, Doha, Qatar; 2) Sidra Medical and Research Center, Doha, Qatar; 3) Department of Genetic Medicine, Weill Cornell Medical College, New York, New York; 4) Laboratory Medicine and Pathology, Hamad Medical Corporation, Doha, Qatar; 5) Weill Cornell Medical College in Qatar, Doha, Qatar; 6) Department of Medicine, Hamad Medical Corporation Doha, Qatar; 7) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

Precision medicine will be driven by the sequencing of humans from a wide geographical representation, for which accurate variant calling and personalized interpretation will be critical to deciphering relevance to individual health. In this study, the value of having a geographically appropriate reference genome is shown for both calling accuracy and bioinformatic analysis, by building a population-specific reference genome (QTR1) for the indigenous Arab population of Qatar. This reference was constructed by leveraging allele frequency data from exome and genome sequencing of 1,158 Qataris (0. 4% of population), and tested by aligning the exome and genome of an "n+1" individual sequenced on four platforms to both the standard GRCh37 reference genome and QTR1. Using a population-centric reference reduced the number of variants called in exomes by 14% and genomes by 23%, dramatically improving calling efficiency and cost of storage and analysis as sequencing cohort sizes grow. Furthermore, when analyzing variants linked to disease or pharmacogenetic phenotypes in the entire Qatari cohort, we observed that 295 of 2,330 (12. 6%) were in fact the major allele in Qataris, and may have been incorrectly classified as being deleterious alleles using a standard genome interpretation workflow based on GRCh37. We also refined automated annotation with manual curation to identify 198 Mendelian conditions with known disease-causing mutations observed in Qataris. By comparison to three large publically available exome databases, 26 conditions appear with causative allele frequencies highest in Qataris, including diseases with known elevated incidence in this population such as homocystinuria (CBS [MIM 613381]) and cystic fibrosis (CFTR [MIM 602421]), or favorable conditions such as hyperalphalipoproteinemia (APOC3 [MIM 107720]). Consistent with high consanguinity rates in Qatar, individuals homozygous for rare recessive mutations are observed despite the small sample size, including diseases such as ectodermal dysplasia (KRT85 [MIM 602767]), retinitis pigmentosa (RP1 [MIM 603937]), and arterial tortuosity (SLC2A10 [MIM 606145]). Notably, only a minority of all discovered mutations presented here are currently on the Qatari national newborn screening panels. We will provide this allele frequency data and the QTR1 reference sequence as open access tools for use in precision medicine in Qatar and in ethnically similar populations in the Arabian Peninsula.

1496T

Association of polymorphism *ADIPOQ* rs2241766 (45 T/G) and *ADIPOQ* rs1501299 (276 G/T) with obesity in breast cancer patients. *A. Mendez-Hernandez[1], R. PEREZ-MORALES[2], M. GALLEGOS-ARREOLA[3], J. ESPINOSA-FEMATT[1].* 1) DEPARTMENT OF RESEARCH, UNIVERSIDAD JUAREZ DEL ESTADO DE DURANGO, GOMEZ PALACIO, DGO. , MEXICO; 2) DEPARTMENT OF MOLECULAR BIOLOGY UNIVERSIDAD JUÁREZ DEL ESTADO DE DURANGO, Gómez PALACIO, DGO; 3) LABORATORY OF MOLECULAR GENETICS, DIVISION OF MOLECULAR MEDICINE, CIBO, IMSS, GUADALAJARA, JAL.

Background: Obesity is both a known risk factor for development of breast cancer and a negative prognostic factor among women with breast. Adipokines as adiponectin are produced in adipose tissue including mammary fat. Polymorphisms in the gene encoding adiponectin (*ADIPOQ*) have been associated with a decrease in the levels of this hormone, promotion and evolution of breast cancer. *ADIPOQ* rs1501299 genotype G/G and rs2241766 T/T are associated with decreased adiponectin levels, obesity, insulin resistance and breast cancer. Therefore our aim is to evaluate the association of polymorphisms *ADIPOQ* rs2241766 (45 T/G) and rs1501299 (276 G/T) with obesity in patients with breast cancer. Methods: DNA genomic of 301 samples (UMAE, HOSPITAL OBSTETRICS AND GYNECOLOGY, CMNO, IMSS) was included in the study. The *ADIPOQ* rs2241766 (45 T/G) and rs1501299 (276 G/T) genotyping was determinate by Taqman® probe and allelic discriminated was determinate by StepOne software v. 2. , of Applied Biosystems. The association was determinate by odds ratio (OR). Results: the genotype *ADIPOQ* rs2241766 T/G was associated with overweight and obesity [OR = 2. 53 (95% C. I. = 1. 13 - 5. 64), p = 0. 01] in patients with breast cancer, while the adipoq rs2241766 G/G genotype was found as a protective factor to overweight and obesity [OR = 0. 48 (95% I. C. = 0. 23 to 0. 98), p = 0. 04], no association was found with polymorphism rs1501299 (276G/T). Conclusion: the *ADIPOQ* rs2241766 (45 T/G) may be an indicator of risk for overweight and obesity and explain the possible mechanism of obesity in the progression of breast cancer in our population.

1497W

Exploring variation in mosaicism and the mutation rate over time in the mammalian genome. *S. J. Lindsay, M. E Hurles.* Human Genetics, Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom.

It is currently challenging to study heterogeneity in gametogenesis and mutation rate variation at different stages of the reproductive cycle explicitly in humans. Therefore, we have designed and carried out an experiment in order to investigate these attributes in laboratory mice. We surveyed the variance in contemporaneous gametes and the influence of parental age at set time points on the mutation rate by generating a tissue bank from the pups in consecutive litters between two reciprocal crosses (129S χ(B6 χ| B6 χ(129S χ) over their fertile lifespan. By whole genome sequencing, *denovo* mutation discovery and validation from multiple pups from the first and last litters produced by the same breeding pairs, we were able to investigate the age effect in the maternal and paternal lines. We found that laboratory mice display a broadly similar trend in paternal age effect as humans, although there is a degree of variance within each litter. Through further deep sequencing of validated *denovo* mutations in different tissues and multiple pups from the same litter, as well as their parents, we were also able to study germline and somatic mosiacism in the parents and offspring, offering insights into rate mutation rate variation between individuals over time.

1498T

A genome-wide association study revealed an association between HLA locus and positivity of rheumatoid factor in Japanese patients with rheumatoid arthritis. *T. Hosozawa, K. Ikari, A. Taniguchi, H. Yamanaka, S. Momohara.* Institute of Rheumatology, Tokyo Women's Medical University, Tokyo, Shinjuku, Japan.

Background. Many studies show that numerous genetic factors are associated with the onset of rheumatoid arthritis (RA). While the diagnostic utility and specificity of anti-cyclic citrullinated peptide antibodies for RA are the focus of many recent studies, we concentrated on another important diagnostic marker associated with RA disease activity and joint destruction, rheumatoid factor (RF). RF is an autoimmune antibodyrecognizing the Fc fragment of IgG, which has been used for more than half a century to diagnose RA. The genetic background of RF-positive RA patients is still not clear. The purpose of this study was to identify genes related to RF using a genome-wide association study. **Methods**. The present study was part of a Japanese RA cohort project established by the Institute of Rheumatology, Rheumatoid Arthritis (IORRA). DNA samples of 2423 Japanese RA patients were obtained from the IORRA DNA collection. SNP genotyping was performed using the Illumina HumanOmni2. 5 Exome-8 BeadChip. Quality control of the genotype data and analyses were performed using PLINK2. We then compared RF-positive and RF-negative for each SNP using the chi-square test. **Results**. All SNPs that satisfied the genome-wide significance level of $p<5. 0\times10\text{-}8$ were located in the Human leukocyte antigen (HLA) region of chromosome 6, which includes the HLA-DRB1 gene. Our result suggests that HLA polymorphisms are associated with RF-positive status in RA patients. Further studies using HLA imputation tools are required to confirm these results.

1499W

Contributions of short tandem repeats to the phenotypic variation and heritability of a simulated gene expression trait. *E. C. Glassberg[1], Y. Erlich[2,3], M. Gymrek[3,4,5,6], M. Feldman[1], J. Pritchard[1,7,8].* 1) Department of Biology, Stanford University, Stanford CA; 2) Department of Computer Science, Fu Foundation School of Engineering, Columbia University, New York NY USA; 3) New York Genome Center, New York, NY USA; 4) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA USA; 5) Broad Institute of MIT and Harvard, Cambridge, MA USA; 6) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston MA USA; 7) Department of Genetics, Stanford University, Stanford CA USA; 8) Howard Hughes Medical Institute, Chevy Chase MD USA.

An important aim of statistical genetics is to determine the genetic architecture of complex traits; however, for many complex traits studied to date, a large proportion of the heritability appears to be missing. One explanation for this missing heritability is that variants that are poorly tagged by the common SNPs used in current association studies, such as short tandem repeats (STRs), make significant contributions to phenotypic variability. STRs are highly polymorphic in humans, many STRs are known to have functional consequences, and linkage between STRs and common SNPs is estimated to be lower than between pairs of SNPs at comparable physical distances. Further, STR length variation has recently been shown to influence the expression of genes in *cis* (Gymrek et al 2015). As a result, STRs may play an important role in the determination of human complex traits. Further, due to the high mutation rate and multi-allelic nature of STR variation, current association studies are underpowered to detect the effects of STR alleles on complex traits. Therefore, causal STR variants may contribute to missing heritability. However, the different mutational profiles of SNPs and STRs affect both the expected contributions of each class of variant to phenotypic variation and our power to detect associations between variable loci and a trait of interest. Here, we compare a simple, two-phase model (from diRienzo et al 1994) of mutation and phenotypic effect of an STR locus on a simulated gene expression trait to an analogous, infinite sites model for SNPs, combined with a model for selection on gene expression. Simulating Wright-Fisher sampling, we explore (i) the amount of phenotypic variation produced by SNP and STR loci at various levels of mutation, phenotypic effect, and selection, and (ii) the ease with which causal associations are detected under various parameter sets. This work provides insight into the dynamics of selection on functional STR loci and the mutational and selection regimes in which STR variants contribute to missing heritability.

1500T

Human Mitochondrial Indel Discovery via *de novo* Assembly and its Applications. *M. Su[1], N. Stoler[2], B. Arbeithuber[3], B. Rebolledo-Jaramillo[2], W. Guiblet[4], K. D. Makova[1], A. Nekrutenko[2].* 1) Department of Biology, Penn State University, University Park, Pennsylvania, USA; 2) Department of Biochemistry and Molecular Biology, Penn State University, University Park, Pennsylvania, USA; 3) Institute of Biophysics, Johannes Kepler University Linz, Linz, Austria; 4) Integrative Biosciences, BioInformatics and Genomics Program, The Huck Institutes of the Life Sciences, Penn State University, University Park, Pennsylvania, USA.

Mutations in mitochondrial DNA (mtDNA) in human contribute to a number of severe genetic diseases, including LHON (Leber's hereditary optic neuropathy) and MELAS (mitochondrial encephalomyopathy lactic acidosis and stroke-like episodes), which are transmitted and observed in maternal lineages. The mutations in mtDNA are manifested as not only point mutations but also insertions/deletions (indels). Due to insufficient DNA repair and a toxic environment rich in radical oxygen species, the mutation rate of mtDNA is estimated to be ~10 times higher than that of nuclear genome. The presence of more than one mtDNA variant within an individual is called heteroplasmy. Analyzing 39 healthy mother-child pairs from central Pennsylvania, we have recently shown that on average a person carries 1-2 heteroplasmic point mutations in the mtDNA of blood or buccal cells, and one in eight mothers carries a disease-associated mtDNA mutation as a heteroplasmy. These findings drew our attention to the identification of indels in mtDNA, where they are common in low complexity regions (i. e. repetitive sequences). However, detecting low frequency indels is a challenge as they are often obscured by read alignment artifacts. In this study, we developed a new indel discovery method using *de novo* assembly. Experimental validation of indels was performed using droplet digital PCR and duplex sequencing. We discuss the identification of indel sites, the mutation rate of indels, the biological importance of indel mutations, and the applications of indel discovery analysis.

1501W

An overview of the *HLA-C* promoter and 3'untranslated region variability and haplotype structure. *E. C. Castelli[1], I. O. P. Porto[1], T. H. A. Lima[1], J. Ramalho[1], R. V. Buttura[1], M. A. Paz[1], L. P. Felício[2], C. T. Mendes-Junior[3], L. C. Veiga-Castelli[4], E. A. Donadi[4].* 1) School of Medicine, UNESP - Univ. Estadual Paulista, Botucatu, São Paulo, Brazil; 2) Federal University of Goiás (UFG), Goiânia, Goiás , Brazil; 3) Departamento de Química, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, São Paulo, Brazil; 4) Division of Clinical Immunology, School of Medicine of Ribeirão Preto, University of São Paulo - USP, Ribeirão Preto, São Paulo, Brazil.

The *HLA-C* gene seems to be the most unusual among the classical class I genes of the Major Histocompatibility Complex (MHC). Besides presenting a reduced variability and decreased expression when compared to *HLA-A* and *HLA-B*, its encoded molecule is able to interact with a series of receptors of the KIR family (Killer cell Immunoglobulin-like Receptor) responsible for inhibitory signals to Natural Killer cells and it is the only classical MHC gene expressed at the cytotrophoblast during pregnancy. *HLA-C* is the least explored among the MHC classical class I genes, in part because histocompatibility laboratories generally evaluate only *HLA-A* and *HLA-B*, and usually only the segment encoding the peptide-binding site is explored. Here we explore the variability and haplotype structure of the *HLA-C* promoter segment within 600 bases before ATG and the entire 3' untranslated region (UTR), from the stop codon to the end of the 3'UTR segment (616 bases), considering 100 individuals from the Southeast Brazil (São Paulo State). For this purpose, a next-generation sequencing strategy was developed coupled with bioinformatics approaches to enhance the mapping quality of HLA-related sequences. Considering the promoter segment, 34 variable sites were detected, with 32 found at least in two samples and 21 were already described by the official HLA database (IMGT/HLA). These variable sites were arranged into 16 haplotypes, five of them counting for more than 70% of all promoter sequences. For the 3'UTR segment, 47 variable sites were detected, all presenting polymorphic frequencies and arranged into 22 haplotypes, in which seven count for more than 75% of all the 3'UTR sequences. The promoter and 3'UTR nucleotide diversity was 0. 016828 and 0. 021434, respectively, what is close to the value observed for the *HLA-C* coding segment considering data from the 1000Genomes Project (0. 025024), but much higher than the one described for the entire human genome (0. 00075). Considering that polymorphisms at the promoter and 3'UTR segments might affect the binding of transcriptional factors and specific microRNAs, respectively, it is possible that these frequent and divergent haplotypes might be associated with different expression profiles and might be affected by different microRNA subsets. Finally, the *HLA-C* promoter and 3'UTR are highly polymorphic and should be considered for functional and clinical studies.

1502T

Characterization of the microsatellite mutation process at every locus in the genome. *M. Gymrek[1,2,3,4], T. Willems[4,5], N. Patterson[2], D. Reich[2,6,7,9], Y. Erlich[4,8,9].* 1) Harvard-MIT Division of Health Sciences and Technology, Cambridge, MA USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA USA; 4) New York Genome Center, New York, NY, USA; 5) Computational and Systems Biology Program, MIT, Cambridge, MA USA; 6) Department of Genetics, Harvard Medical School, Boston, MA USA; 7) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA USA; 8) Department of Computer Science, Fu Foundation School of Engineering, Columbia University, New York, NY, USA; 9) Equally supervised this work.

Microsatellites, or short tandem repeats (STRs), are comprised of repeating motifs of 1-6bp that span over 1% of the human genome and contribute to over 40 Mendelian disorders. These loci are prone to polymerase slippage during replication, resulting in mutation rates that are orders of magnitude higher than those of point mutations, conferring high evolvability. Revealing the mutation process of STRs is important to address questions in medical genetics, forensics, and population genetics. However, most studies of microsatellite polymorphism have focused on a highly ascertained set of loci that are extraordinarily polymorphic and easy to genotype, providing biased mutation models. Here, we harnessed novel bioinformatics tools and an analytical framework to estimate the mutation rate at each STR in the human genome. First, we used our lobSTR algorithm to generate the most comprehensive microsatellite polymorphism dataset to date, consisting of nearly 1. 5 million loci across 300 samples sequenced to high coverage by the Simons Genome Diversity Project. These samples originate from diverse genetic backgrounds and maximize our power to observe STR evolution across a wide range of time scales. Genotypes show more than 93% concordance with capillary electrophoresis panels and accurately recover population structure. Next, we developed an analytical model of the microsatellite mutation process that imposes a length constraint on allele size and shows greater consistency than traditional stepwise models with empirical data. Our model allows us to obtain maximum likelihood estimates of mutation rate and length constraint parameters at each microsatellite in the dataset by correlating genotypes with local sequence heterozygosity across the 300 samples. We extensively tested this model on simulated and observed genotypes and accurately recovered mutation rates for markers with published de novo rates. Applying our method at each STR locus in the genome, we find that nearly all loci show evidence of a length constraint, and a subset of microsatellites show extremely high mutation rates of 10-2/locus/generation. We used this call-set to analyze sequence determinants of microsatellite variation, assess patterns of variation in coding regions, and scan for microsatellites under selective pressure.

1503W

Gender-based differences on SNP polymorphisms in candidate genes to obesity: study of the general Mexican Mestizo population. *E. A. Hernández-Tobías[1], R. Camacho-Mejorado[1], C. Santana[2], G. Noris[2], L. Torres-Sánchez[3], M. A. Meraz-Ríos[4], R. Gómez[1].* 1) Departamento de Toxicología, Cinvestav-IPN, Mexico City , Distrito Federal , Mexico; 2) Laboratorio Biología Molecular Diagnóstica, Querétaro, Qro. , Mexico; 3) Instituto Nacional de Salud Pública, INSP, Cuernavaca, Morelos, Mexico; 4) Departamento de Biomedicina Molecular, Cinvestav-IPN, Mexico City, Mexico.

Obesity is a complex multifactorial trait associated with lifestyle and environmental factors, whose rates have risen significantly in the last few decades, reaching pandemic proportions worldwide. Recent studies support that heredity factors are a cornerstone in the development of obesity, which is genetically heterogeneous. Given the complex character of this trait, the identification of genetic markers is an active area of research for further preventive diagnosis and optimal treatment. However, remarkable discrepancies have been found among diverse research groups, related to ethnicity differences. In addition, population-based studies suggest a clear physiological difference between men and women such as disparity in fat distribution, causing differences in incidence and progression of disease, consequently, gender may be a confounder factor. Hence, it is important to know the genetic frequencies in the general population to validate possible associations in further case-control studies. Using a multiethnic population from Central Valley of Mexico, 200 men and 200 women (400 chromosomes), we studied eleven SNPs within or near of six candidate genes for obesity that regulate process such as: adipogenesis (PPARG, PGC1A), inflammation (ADIPOQ and CDH13), lipid storage (LYPLAL1) and overeating disorders (MC4R), through allelic discrimination assays by quantitative PCR. Our results showed that all loci presented similar genetic distributions between sexes, except rs1501299 and rs864265 located on ADIPOQ gene and rs2820446, near LYPLAL1 gene. Regarding ADIPOQ gene, a higher proportion of homozygous state was observed in men than women (~ 0. 78 vs. ~ 0. 54; P = 0. 001). In contrast, the heterozygote state for LYPLAL1 was more prevalent in women than men (~ 0. 60 vs. ~ 0. 1; P = 0. 018). We further analyze Hardy-Weinberg equilibrium for each gender, finding departures in ADIPOQ-rs1501299 and LYPLAL1-rs2820446 only in men, characterized by an excess of homozygotes (*Fis* = 0. 425 and 0. 850 respectively, P < 0. 0001). Results suggest that sex differences in obesity and other comorbidities related to inflammation may have an important genetic regulation background, reflected by differences among sexes in the general population. Thus, we suggest that further studies should consider this information to undertake their predict disease risk with the same accuracy for men and women. *Project supported by funds provided by Kellogg's Nutrition and Health Institute (to R. Gómez).* .

1504T

Influence of deleterious and disease variants on gene expression in human populations. *D. Lu, C. Zhang, K. Yuan, L. Tian, M. Shi, Y. Yuan, S. Xu.* Partner institute for Computational Biology, Shanghai, China.

Deleterious variants in human have been known younger than neutral variants of the same frequency, meanwhile, the age of gene origin is associated with gene expression level, gene haploinsufficiency and gene regulation. We hypothesized that expression levels have been regulated via the effective transcripts, which could make higher expression level on those genes with larger number of deleterious variants. Such 'genetic burden compensation', as we proposed, could affect the distribution of genes with higher expression level in human populations. Here we examined this hypothesis by assessing the number of deleterious variants of genes with different gene origin ages, and analyzing gene expression level based on transcriptomic data and genomic data obtained from the 1000 Genomes Project. Our results showed that the increased number of damaging mutations at younger genes have higher expression level. This observation has great implications as many human specific genes with young age might have played crucial roles during human speciation. We suggest the genetic burden compensation on such younger genes have paved a way and facilitated to human speciation and evolution.

The Impact of Promoter Polymorphisms on Infant Outcomes and Cytokine Concentration in Preterm Breast Milk. *K. L. Baumgartel[1], M. W. Groer[2,3], S. M. Cohen[1], D. Ren[4], D. L. Spatz[5], Y. P. Conley[1,6].* 1) Health Promotion and Development, University of Pittsburgh School of Nursing, Pittsburgh, PA; 2) College of Nursing, University of South Florida, Tampa, FL; 3) College of Medicine, University of South Florida, Tampa, FL; 4) Health and Community Systems, University of Pittsburgh School of Nursing, Pittsburgh, PA; 5) University of Pennsylvania School of Nursing, Philadelphia, PA; 6) Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA.

The immune protection offered through breast milk is especially important for preterm infants. Interleukins (ILs), found in breast milk but in varying concentrations, may provide preterm infants with protection against complications. The purpose of this study was to: 1) examine the relationship between maternal IL genotypes and weekly milk concentrations of IL4, IL6, and IL10, 2) describe the trajectories of milk IL change over the first three weeks postpartum, 3) examine whether maternal IL genotypes predict milk IL trajectories, 4) examine if weekly IL levels and/or IL trajectories predict infant outcomes, and 5) explore a relationship between maternal IL genotypes and infant outcomes. An ancillary study was conducted among mothers who delivered preterm infants (n=64) and maternal DNA was extracted from breast milk whey for genotyping using TaqMan. Trajectory modeling was used to identify IL subgroups. Subset analyses by ethnicity (Caucasian, African American, Hispanic) were performed. After controlling for gestational age at delivery and ratio of mom's own milk to total milk, maternal minor allele absence (MAA) was significantly associated with fecal calprotectin (FC) in Caucasians (rs1800795 p=0. 0222; rs1800796 p=0. 0158; rs1800872 p=0. 0196). There were significant associations in the total population between FC and rs1800795 GG genotype (p=0. 0213),rs1800871 TT genotype (p=0. 027), rs1800872 AA genotype (p=0. 0158), and rs1800896 AA genotype (p=0. 0045). There was an inverse trend toward significance among Caucasians between rs1800795 MAA and milk IL6 (p=0. 0966). Subsequently, there is a significant relationship between milk IL6 concentration and FC in Caucasians (p=0. 0290). Trajectory analyses resulted in linear group shapes, with two distinct subgroups in IL6, and three subgroups in both IL4 and IL10. SNPs were not associated with trajectory groups. IL6 group 1 membership was significantly associated with intraventricular hemorrhage (OR=6. 275, p=0. 0412), and there was a trend toward significance with FC (p=0. 0822). This study reveals an association between maternal IL SNPs and infant outcomes. This study also suggests that SNPs influence IL milk concentrations, and IL milk levels are associated with outcomes. Trajectory analyses revealed distinct linear-shaped IL milk groups at varying levels and group membership was associated with outcomes. More research is needed to determine clinically relevant milk IL levels and mechanisms for IL variability.

1506T

Profile of pathogenic alleles in healthy Lithuanian population. *V. Kucinskas, T. Rancelis, I. Domarkiene, E. Pranckeviciene, I. Uktveryte, L. Ambrozaityte.* Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Vilnius, Lithuania.

Introduction. Comparison of genomic variants identified in a particular exome/genome data with known variants of clinical significance is of key importance in diagnostics, prognostics and personal medicine. **Methods.** We analyzed 98 exomes of healthy Lithuanian individuals representing Lithuanian population. DNA samples extracted from venous blood were sequenced using SOLiD 5500 system according to the manufacturer's protocols (Life Technologies, USA). Functional annotation of genomic variants was performed using ANNOVAR including frequencies of genomic variants from 1000 Genomes project (1000G), ESP6500 project and ClinVar database. To compare alleles' frequencies exact Fisher test was used (α=0. 05). **Results.** Each individual exome was found to have 30k to 50k genomic variants. An average of 46 single nucleotide variants (SNV) per individual exome were assessed as pathogenic by ClinVar. 334 unique SNVs in 98 exome group were classified as pathogenic. Taking into account that all study individuals were healthy, they were subdivided into two groups: alternative allele carriers and homozygous for an alternative allele. Variants classified as pathogenic in individuals homozygous for an alternative allele were excluded from analysis (111 variants). Additionally, 46 variants were excluded due to high allele frequency (> 50%) in other populations. A number of pathogenic alleles had higher frequency in Lithuanian population compared to other populations. In a number of genes these pathogenic SNVs were identified: **Stargardt disease 1** (OMIM#248200) allele frequency in the Lithuanian population (LIT) 2. 6%, all populations' allele frequency from 1000G (ALL) 0. 3% (p=7. 993x10-4), European population from 1000G (EUR) 0. 4% (p=7. 165x10-3); **muscle AMP deaminase deficiency** (OMIM#615511) – LIT 7. 1%, ALL 1. 1% (p=7. 368x10-8), EUR 3. 7% (p=2. 607x10-2); **pigmented nodular adrenocortical disease** (OMIM#610475) – LIT 2%, ALL 0. 2% (p=9. 909x10-4), EUR 0. 5% (p=4. 163x10-2); **severe combined immunodeficiency disease** (SNOMEDCT#31323000) – LIT 5. 1%, ALL 0. 6% (p=1. 162x10-6), EUR 2. 2% (p=2. 286x10-2). **Conclusion.** Our identified distribution profile of genomic variants of high confidence in small Lithuanian population enriches current state of scientific knowledge and gives rise to the development of new diagnostic strategies. This study is part of the LITGEN Project (VP1-3. 1-MM-07-K-01-013) funded by the European Social Fund under the Global Grant Measure.

The effects of single nucleotide polymorphisms on the function of *HSPA1A*, a key regulator of the cellular stress response in humans. *R. M. Oliverio, K. Hess, M. C. Siracusa, N. Nikolaidis.* Biological Science, Center for Applied Biotechnology Studies, and Center for Computational and Applied Mathematics, California State University, Fullerton, Fullerton, CA.

An essential question in molecular evolution is how mutations enable organisms to adapt and survive their environments. At the cellular level, this same question relates to the ability of cells to adapt and survive stressful conditions, such as disease. Cellular adaptation to stress is regulated and maintained by the cellular stress response system. Molecular chaperones, and, in particular the 70-kDa heat shock proteins (Hsp70s) are key orchestrators of the stress response system, and alterations in their function have direct physiological consequences. Therefore, it is of vital importance to determine how natural mutations alter the function of these proteins and how such changes affect cellular and organismal adaptation. To answer these questions we tested whether natural single nucleotide polymorphisms (SNPs) found on *HSPA1A*, the major stress inducible Hsp70 gene in humans, alter protein function. Specifically, the wild-type human *HSPA1A* sequence was subcloned into mammalian expression vectors, and the mutated gene variants were generated using site-directed mutagenesis. We first determined whether any of these mutations affected the intracellular localization of HSPA1A within mammalian cells. These experiments were performed by tagging HSPA1A to GFP, and using fluorescent dyes to stain the nucleus, mitochondria, and lysosomes, to view where the proteins localized via confocal microscopy. These assays revealed that the mutants and the WT protein had similar subcellular localization. Next, we determined whether the mutations affected the ability of HSPA1A to prevent cell death by inhibiting the formation of protein aggregates caused by poly-glutamine carrying huntingtin proteins. This assay determined that two of the mutations caused increased cell death as compared to the WT, suggesting that some mutations alter the chaperone function of HSPA1A. Furthermore, live-dead assays showed that human cells carrying some of these mutations had significantly less resistance to heat stress than cells expressing the WT protein. Given that these natural variants are either population-specific or clinical we suspect that the observed functional differences alter the ability of cells, and the individuals carrying them, to cope with stress and adapt to environmental perturbations.

1508T

Whole-genome reference panel of Tohoku Medical Megabank Organization (ToMMo) and variant annotations. *Y. Yamaguchi-Kabata, N. Nariai, Y. Kawai, Y. Sato, K. Kojima, M. Tateno, F. Katsuoka, J. Yasuda, M. Yamamoto, M. Nagasaki.* Tohoku Medical Megabank Organization, Tohoku University, Aoba-ku, Sendai, Japan.

Although reports of common genomic variants and their frequencies are accumulating for various populations, many of low-frequency variants remain undetected or have unknown frequencies. A catalogue of genomic variants from whole-genome sequencing and estimates of variant frequencies for each population are needed to provide a foundation for genomic medicine. Tohoku University Tohoku Medical Megabank Organization (ToMMo) have sequenced whole genomes of 1,070 cohort participants, and constructed the whole-genome reference panel (1KJPN). We started partial public release of whole-genome Japanese reference panel, and opened a website “integrative Japanese Genome Variation Database (iJGVD; http://ijgvd. megabank. tohoku. ac. jp/)”. The current release of iJGVD provides SNV frequency data obtained from the 1070 individuals. The first release contains data of about 4,300,000 SNVs selected by the criteria: (1) they are on autosomes, (2) their minor allele frequency is greater than 5%, and (3) they have been reported in dbSNP138. This database can be used to search those SNVs and get their allele frequency with allele count, and the genome browser provides graphical views of the genomic location of SNVs with locations of known genes and other SNVs in dbSNP. Allele frequencies of SNVs in iJGVD were compared with those of SNVs in HapMap JPT (Japanese from Tokyo) individuals. The allele frequencies in the two populations were very similar. We are annotating variants of 1KJPN with biological and medical information, and identified overlaps between the SNVs and known pathological SNVs from the Human Gene Mutation Database (HGMD). We believe that our open variant data in iJGVD will be useful in medical genomics, especially for comparison of allele frequencies in iJGVD with those of the patient group for a target disease to identify disease-causing variants. Furthermore, information of pathogenic variants and their frequencies in the population will be utilized for comparison with those in other populations.

Novel validated Alu elements insertions from Mobile-Element Scanning. *J. Feusier, D. J. Witherspoon, W. S. Watkins, L. B. Jorde.* Human Genetics, University of Utah, Salt Lake City, UT.

Alu and LINE elements are retrotransposons that have been very active during recent human evolution. Specifically, the Alu Yb8 and Yb9 subfamilies account for about 1/3 of recent polymorphic Alu insertions in humans. It is likely that many thousands of Alu elements in human genomes have not been discovered yet. To address this issue, we captured Alu Yb8 and Yb9 elements from more than 400 members of diverse populations using Mobile-Element Scanning (ME-Scan), a multiplexed, targeted high-throughput sequencing method. ME-Scan uses primers specific to the Yb8/9 subfamily sequence to selectively amplify these families. We captured 15,911 insertions absent from the reference genome that were only present in one individual in the study and attempted to validate 60 of these insertions using locus-specific PCR. The evidence supporting each insertion is quantified by the number of supporting reads and by the number of predicted independent library capture events (number of molecules). We determined that 7 distinct molecules were representative of true positive insertion events. Additionally, we tested a set of high-quality insertions in exons and discovered that one individual had an Alu insertion event inside the second exon of *METTL20*. Specifically, the Alu element captured the first seven nucleotides of the exon as part of the target site duplication and inserted before the start of the exon. This exon capture event left the exon intact, but it may affect splice sites and disrupt protein translation. In conclusion, we identified and validated non-reference Alu elements in addition to discovering a rare insertion event inside of an exon.

Detecting signatures of positive selection associated with musical aptitude in the human genome. *I. Jarvela[1], X. Liu[2,5], C. Kanduri[1], J. Oikkonen[1], K. Karma[3], P. Raijas[4], L. Ukkola-Vuoti[1], Y-Y. Teo[2,5].* 1) Department of Medical Genetics, University of Helsinki, P. O. Box 63, 00014 University of Helsinki, Finland; 2) NUS Graduate School for Integrative Science and Engineering, National University of Singapore, Singapore 117456, Singapore;; 3) DocMus Department, University of the Arts Helsinki, P. O. Box 86, 00251 Helsinki, Finland; 4) Joensuu Conservatoire, Rantakatu 31, 80100 Joensuu, Finland; 5) Saw Swee Hock School of Public Health, National University of Singapore, Singapore 117597, Singapore.

Music perception and practice are complex cognitive functions of the human brain that are well preserved in human evolution. Musical aptitude is a common trait and the prerequisite for music perception and performance. Musical aptitude can be defined as the ability to understand and perceive the rhythm, pitch, timbre, tone duration, and the formal structure in music. Here, we have applied genomic and bioinformatic approaches to assign the regions of positive selection associated with musical aptitude in the human genome. We compared whole genome genotyping data of 647. 417 SNPs from the Illumina HumanOmniExpress 12 1. 0V SNP chip in 74 cases (mean age 44. 41 years, females N=36) and 74 controls (mean age 44. 99 years, females N=47) characterized for musical aptitude. Musical aptitude was defined using three music test scores, auditory structuring ability test (Karma Music test) and Carl Seashore's pitch and time tests, that formed a combined music test score; COMB (range 75-150) in this study. The mean COMB score was 137. 41 (range 125-148) for cases and 100. 30 (range 76-117) for controls. The definition of the phenotype was based on pattern recognition mimicking sound prototypes in songbirds combined with sensory capacities to detect pitch and duration. We assigned signatures of positive selection using three selection methods: haploPS, XP-EHH and FST. We show that regions under positive selection contain several genes affecting auditory perception, steroid hormone secretion, cognitive performance and memory and song perception and production of songbirds. Among them *VLDLR*, a target of human *FOXP2*, that is critical for human speech development. The selection region containing *GPR98* was identified with both haploPS and FST. *GPR98,* involved in inner ear development, is found to be under positive selection in songbird lineage, thus making it a plausible candidate gene for the evolutionary advantage of human musical aptitude. Moreover, *GPR98* is also associated with vision suggesting a common biological origin of sensory perception skills. Gene ontology classification of the identified genes by window statistics revealed the enrichment of genes responsible for inner ear development (GeneTrail2, Hypergeometric distribution test, fdr 0. 04). The findings are consistent with the evolutionary conservation of genes related to auditory processes and cognition and provide first empirical evidence for signatures of positive selection for musical aptitude.

1511W

Understanding high-altitude adaptations in Tibetans using population genetic and genetic association analyses. *C. Jeong[1], B. Basnyat[2], G. Childs[3], S. Craig[4], M. Neupane[5], D. Witonsky[1], C. Beall[6], A. Di Rienzo[1].* 1) Department of Human Genetics, University of Chicago, Chicago, IL; 2) Oxford University Clinical Research Unit, Patan Hospital, Kathmandu, Nepal; 3) Department of Anthropology, Washington University in St. Louis, St. Louis, MO; 4) Department of Anthropology, Dartmouth College, Hanover, NH; 5) Mountain Medicine Society of Nepal, Kathmandu, Nepal; 6) Department of Anthropology, Case Western Reserve University, Cleveland, OH.

Indigenous human populations in the Tibetan plateau are thought to be better adapted to their native environments than those of lowland origin, as reflected in their distinct physiological traits and their lower prevalence of high-altitude related diseases. However, the identity and impact of adaptive phenotypes are poorly understood beyond two candidate genes with signatures of positive selection and with functional involvement in hypoxia: *EGLN1* (egl nine homolog 1) and *EPAS1* (endothelial PAS-domain containing protein 1). To identify genetic variants, phenotypes, and environmental factors associated with high-altitude adaptations in Tibetans, we analyzed a cohort of 996 ethnic Tibetan women born and raised at altitudes (2,982-4,052 m) in Nepal, whose genotypes were determined over 660,000 loci. Phenotypes collected in the field include hemoglobin concentration (Hb), arterial oxygen saturation (SaO2), and fertility traits such as the numbers of pregnancies (PG) and live births (LB). Genome-wide significant associations (linear mixed model (LMM) $p \geq 4.40\times10\text{-}9$) were found between PG and LB and SNPs within *CCDC141* (coiled-coil domain containing 141). We could not detect a genome-wide significant association for either Hb or SaO2. However, association signals were present for candidate genes in Tibetans (*EPAS1* for Hb, LMM $p \geq 4.90\times10\text{-}5$; *HIF1A* for SaO2, LMM $p \geq 6.70\times10\text{-}4$) and for genes associated in other populations (*PRKCE* for Hb, LMM $p \geq 4.07\times10\text{-}4$), thus confirming a role for oxygen homeostasis systems in Tibetan adaptations. Interestingly, the *PRKCE* gene does not harbor signatures of positive selection, despite its physical position close to *EPAS1* and association with Hb. Next, we searched for genomic regions harboring signals of recent positive selection from multiple statistics, using 344 unrelated Tibetans. Both *EPAS1* and *EGLN1* show multiple signals, such as extreme allele frequency change, reduced haplotype diversity and excess haplotype sharing between high-altitude East Asian populations. We also found additional genes with multiple signals and potential functional implication for high-altitude adaptations, including *SLCO1A2*, *EP300* and *XYLT1*. Our study presents a multi-dimensional approach to understanding the genetic basis of human adaptations to local environments, incorporating both population genetic and genetic association analyses, as well as measures of short-term reproductive success.

1512T

A population genetics perspective on quantitative traits. *Y. B. Simons[1], K. Bullaughey[2], R. R. Hudson[2], G. Sella[1].* 1) Biology, Columbia University, New York, NY; 2) Ecology & Evolution, University of Chicago, Chicago, Illinois.

Genome wide association studies (GWAS) have begun uncovering the genetic architecture of a wide array of human quantitative traits, including morphological traits like height and BMI as well as complex diseases like schizophrenia and diabetes. Interpreting GWAS results in evolutionary terms can provide us with an unprecedented insight into the evolution of quantitative traits in humans and may help guide the design of future mapping studies. Evolutionary processes, such as mutation, selection, drift and pleiotropy, shape the genetic architecture of quantitative traits but very few existing models incorporate them in a way that's meaningful for GWAS interpretation. We extend Fisher's Geometric Model to quantitative variation and use it to obtain predictions of the genetic architecture of quantitative traits under different evolutionary scenarios. Under this model, we relate the phenotypic effects of variants to the selection acting upon them and we see that weakly and strongly selected variants are expected to carry more of the variance than nearly neutral sites and therefore be easier to detect in GWAS. However, variants under very strong selection would be too rare to be detected. Pleiotropy is represented by the dimensionality of the trait space and pleiotropic effects weaken the relationship between effect size and selection. The overall effect of pleiotropy on GWAS success is to effectively increase GWAS power. Our analysis suggests that the increase in GWAS success with increasing study size may be highly sigmoidal for some traits and that the increase may be quite dramatic once a large enough study size is reached. This model may provide the basis for using GWAS results to infer the strengths of evolutionary forces shaping quantitative traits in humans.

1513W

Global diversity in the TAS2R38 bitter taste receptor: revisiting a classic evolutionary PROPosal. *D. Risso[1,2], M. Mezzavilla[3], L. Pagani[2,4], A. Robino[3], G. Morini[5], S. Tofanelli[6], M. Carrai[6], D. Campa[6], R. Barale[6], F. Caradonna[7], P. Gasparini[3], D. Luiselli[2], S. Wooding[8], D. Drayna[1].* 1) National Institute on Deafness and Other Communication Disorders, NIH, Bethesda, MD 20892, USA; 2) Department of BiGeA, Laboratory of Molecular Anthropology and Centre for Genome Biology, University of Bologna, via Selmi 3, 40126 Bologna, Italy; 3) Institute for Maternal and Child Health - IRCCS "Burlo Garofolo", Trieste, Italy; University of Trieste, Trieste, Italy; 4) Division of Biological Anthropology, University of Cambridge, CB2 1QH, Cambridge, UK; 5) University of Gastronomic Sciences, Piazza Vittorio Emanuele 9, Bra, Pollenzo 12042, CN, Italy; 6) Department of Biology, University of Pisa, Via Ghini 13, 56126 Pisa, Italy; 7) Biological, Chemical and Pharmaceutical Sciences and Technologies Department, STEBICEF, Université degli Studi di Palermo, V. le delle Scienze, Edificio 16, 90128 Palermo, Italy; 8) Health Sciences Research Institute, University of California at Merced, 5200 North Lake Road, Merced, CA 95343, USA.

The ability to taste phenylthiocarbamide (PTC) and 6-n-propylthiouracil (PROP) is a classic polymorphic trait that is mediated by the *TAS2R38* bitter taste receptor gene. These taste phenotypes have been shown to be correlated with the ability to taste other taste-active compounds, as well as with food habits. Nonetheless, several features of its evolutionary significance and population dynamics are still unresolved. In particular, it is not clear why the worldwide frequency of the *TAS2R38* non-taster AVI haplotype is very high, almost equivalent to that of the taster PAV haplotype. While the long-standing hypothesis suggests that balancing selection has been acting on this locus, other theories have emerged more recently. We performed a detailed analysis of the *TAS2R38* gene and its surrounding regions in a sample of 5511 individuals belonging to 104 different worldwide populations. Our results show no departures from neutral expectations. This suggests that recent demographic events have had a major role in shaping the genetic diversity at this locus, suggesting a reconsideration of the classic hypothesis. We also hypothesize that interactions with the adjacent maltase-glucoamylase (*MGAM*) gene may have contributed to the current distribution of PAV and AVI haplotypes. One hypothesis is that the distribution of the uncommon *TAS2R38* AAI haplotype is interpretable as the product of a recent recombination event that occurred in Africa, after the Out Of Africa (OOA) event. Collectively, our results offer novel insights into the evolutionary history of the *TAS2R38* gene, showing a relaxation of the selective forces previously acting on this gene, and providing a new hypothesis for the observed present-day worldwide distribution of AVI and AAI haplotypes.

1514T

Clarifying the disputed role of *FOXP2* in modern human origins. *E. G. Atkinson, B. M. Henn.* Dept. of Ecology and Evolution, Stony Brook University, Stony Brook, NY.

Identified for its pivotal role in the development of spoken language, the *FOXP2* gene is also known for its controversial role in human evolution. Early genetic work identified a selective sweep for two derived amino acid substitutions in *FOXP2* during recent human evolution (within the past 200,000 years), supported in large part by detection of an extremely low Tajima's *D* value at the gene. When the genomes of other ancient hominids were found to contain the same fixed genetic variants, however, the conflicting timelines between the signals of selection obtained from the molecular sequence of the gene as compared to divergence time estimates between humans and other ancient hominid species were irreconcilable. Selection for these two amino acids thus appears not to be human-specific, yet many papers continue to work from a hypothesis of positive selection of *FOXP2* in humans. Here, we comprehensively re-analyze *FOXP2* with next-generation genomic datasets comprising hundreds of individuals and thousands of SNPs. Specifically, we test for fine-scale molecular patterns in the gene and between various human populations in order to resolve estimates of selection. We are unable to replicate the original negative *D* signal in the expanded human genomic datasets, despite having many more variants, more diverse individuals, and greater statistical power. We can, however, mimic the negative *D* result when running calculations on a subset of the HGDP genomic dataset with a sample of human populations comparable to the original work; i. e. one-third Africans and two-thirds individuals who underwent the Out-of-Africa expansion. The *D* signal thus appears to have been due to the pooling of Africans and non-Africans together for analyses, which increases the number of segregating sites relative to pairwise genetic differences. Such a result seems to have been an unintended consequence of a small sampling strategy. We apply additional selective sweep statistics and haplotype analysis to this locus to evaluate evidence for selection over the past 200,000 years, finding indications of balancing selection in Africans but not non-Africans. *FOXP2* does not appear to have undergone a recent selective sweep, as had been previously proposed.

1515W

Adaptation via gene flow in Africa: a novel approach using ancestry to identify regions of the genome under natural selection. *G. B. J. Busby[1], G. Band[1], Q. S. Le[1], E. Leffler[1], K. Rockett[1,2], D. Kwiatkowski[1,2], C. C. A. Spencer[1,2], MalariaGEN.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, OX3 7BN United Kingdom; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge. CB10 1SA United Kingdom.

Patterns of genetic diversity in human populations are the result of a complex demographic history, which is expected to shape variation across the genome, and natural selection, which acts at specific loci. By modelling haplotype similarity we describe shared ancestry within and between 58 worldwide populations with a focus on sub-Saharan Africa. Using a novel approach, we scan the genomes of individuals within these groups to identify loci where there is a significant deviation in local ancestry away from genome-wide expectations. Such signals may identify regions of the genome under natural selection.

Our approach identifies both known and novel beneficial loci that have been shared across populations by gene flow. For a West African pastoralist group called the Fulani, the region of the genome which has maintained the highest proportion of European ancestry contains the lactase persistance gene (*LCT*), and the region with the highest African ancestry contains the Duffy gene (*DARC*), mutations in which provide protection against *Plasmodium vivax* malaria. Across multiple African populations we identify other loci where natural selection has potentially changed the contribution of haplotypes from ancestral populations, including at the Major Histocompatibility Complex and at two loci known to be associated with malaria susceptibility: *ATP2B4* and *HBB*. We additionally see a ten-fold increase in hunter-gatherer ancestry at *SERPINB11* – a gene previously implicated as playing a role in host-parasite interactions – in the Fulani, who have historically hadlower levels of malaria than sympatric populations. Our observations are directly relevant to studies of disease genetics in Africa, and highlight an important – and general – role for gene flow in introducing new adaptations.

1516T

Joint Analysis of Natural Selection and Disease Association. *K. A. Hartman, R. D. Hernandez.* Biological & Medical Informatics, University California, San Francisco, San Francisco, CA.

Natural selection acts to promote genomic variants that drive phenotypic attributes that confer a fitness advantage or to remove those variants that are detrimental to fitness. Depending on the form of selection and the time since the selection took place, different signals will be left in the genomes of modern populations. The field of population genetics has developed a suite of genome-wide scans to detect these signals based on divergence between species or populations, rates of synonymous and nonsynonymous substitution, allele frequency distribution, and length of homozygous haplotypes. As natural selection can only act on genomic loci that cause fitness differences and as the genetic components of disease represent substantial phenotypic differences, it is reasonable to expect a large interplay between natural selection and disease. Indeed previous work showed Mendelian diseases are subject to greater than expected levels of purifying selection and that tag SNPs for a variety of complex diseases have greater than expected levels of background selection. This observation suggest that signals of selection can potentially aid the search for disease associated loci by identifying functionally important sites. We have developed a framework to jointly analyze natural selection and genome-wide association study (GWAS) statistics. The method identifies which signals of selection are predictive of associated sites for a particular phenotype and then uses these signals to refine phenotypic association. An intermediate result of the method is to identify the historical selection pressures that have acted on a particular phenotype. In order to validate the methodology, we have collected publicly available data from GWAS examining a variety of diseases and traits and evaluated signals of selection evaluated in the European populations of the 1000 Genomes Project. We use our framework for a joint analysis of GWAS and natural selection on each phenotype to predict additional sites that were not significant in the original studies and compare these predictions to sites found in replication studies. This framework is widely applicable to many traits, and can strengthen genome-wide associations to any phenotype likely to have a fitness effect.

1517W

Reintroduction of a Homocysteine Level-related Allele into East Asians by Neanderthal Introgression. *Y. Hu[1,2], Q. Ding[1,2], Y. He[2], S. Xu[2], L. Jin[1,2].* 1) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, School of Life Sciences, Fudan University, Shanghai, China; 2) CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences (SIBS), Chinese Academy of Sciences (CAS), Shanghai, China.

Here we present the analysis of Neanderthal introgression at the dipeptidase gene *DPEP1*. Neanderthal origin for the introgressive haplotypes was demonstrated using an established three-step approach. This introgression was under positive selection and reached a frequency of >50% in East Asians. This introgression introduced an allele (rs460879-T) into East Asians, and it was implicated with plasma homocysteine level in Filipino. However, the same allele was also found in non-East Asians, but not of Neanderthal introgression. It is likely that the functional rs460879-T was lost in East Asians, and was reintroduced through Neanderthal introgression. This study suggests that Neanderthal could reintroduce functionally important pre-existing allele into populations where the allele was lost, and shed new light on the understanding of the contribution of Neanderthal introgression to the adaptation of non-Africans.

1518T

OCA2 confers convergent skin lightening of East Asians during recent human evolution. *B. Su[1], Z. Yang[1,2], H. Zhong[3], J. Chen[4], X. Zhang[1], H. Zhang[1], X. Luo[1,2], S. Xu[5], H. Chen[6], D. Skin lightening among Eurasians is considered an adaptation to high latitude environments, likely occurred independently in Europe and eastern Asia due to convergent evolution. In Europeans, several responsible genes for lightening have been found, but for East Asians the situation remains elusive. We conducted a genome-wide comparison between dark-skinned Africans and Austro-Asiatic speaking aborigines and light-skinned northern Han Chinese, and identified a pigmentation gene *OCA2* showing unusually deep allelic divergence between them. An amino acid substitution (His615Arg) of *OCA2* prevalent in most eastern Asian populations, but absent in Africans and Europeans, was significantly associated with skin lightening in northern Han Chinese. Further transgenic and targeted gene modification analyses in zebra fishes and mice both recapitulated the phenotypic effect of the *OCA2* variant, resulting from a decreased melanin production. Our results indicate that *OCA2* plays a key role in the convergent skin lightening of East Asians during recent human evolution. .

Human nose shape differentiation is due in part to adaptation to local temperature. *A. A. Zaidi[1,2], P. Claes[3], B. C. Mattern[2], C. Hughes[4], M. D. Shriver[1,2].* 1) Genetics, Pennsylvania State University, University Park, PA, USA; 2) Department of Anthropology, Pennsylvania State University, University Park, PA, USA; 3) KU Leuven, ESAT/PSI - UZ Leuven, MIRC - iMinds, Medical IT Department, Leuven, Belgium; 4) Department of Anthropology, University of Illinois at Urbana-Champaign, Urbana, IL, USA.

The evolutionary reason for the differentiation of nose shape across human populations is an unsolved mystery. It has long been speculated that differences in nose shape among populations are temperature- and humidity-related adaptations to climate rather than being driven primarily by genetic drift or sexual selection. Functional studies of nasal morphology suggest that the nasal passage is useful in conditioning inspired air so as to prevent damage to the mucosal lining of the lungs. We are primarily interested in investigating whether local adaptation to climate is responsible for the divergence of nose shape across populations. We used a dense-correspondence quasi-landmark based method to quantify the three dimensional nasal shape of 459 individuals of West-African, East-Asian, Northern-European, and South-Asian ancestry. We then used Qst-Fst comparisons to show that the size and shape of the nares, as well as the surface area of the nose are more differentiated across populations than expected by genetic drift alone. Partial Mantel tests and spatial generalized linear mixed models show that both phenotypes are strongly correlated with temperature during the last glacial maximum and the Holocene after correcting for genetic distance, suggesting a role of temperature in the evolution of nose shape. We did not find significant correlations with humidity. In a sample of 486 individuals with mixed West African and European ancestry, we show that these traits are highly correlated with genetic ancestry. We further used a linear mixed model as implemented in the program GCTA to show that a set of ~500K autosomal SNPs explain a large proportion of the variance in nose shape in a sample of 1,721 individuals of European ancestry. These results suggest that both aspects of nose shape are heritable. Finally, we identified putative loci associated with nose shape in a sample of 324 individuals of mixed African and European ancestry and show that these loci exhibit signatures of accelerated evolution across populations. Our results provide strong support for the hypothesis that differentiation in nose shape across populations has been driven by local adaptation to temperature.

Identifying the target of selective sweep. *A. Akbari[1], G. Tesler[2], R. Ronen[3], Y. Lin[4], N. Rosenberg[5], V. Bafna[4].* 1) Department of Electrical & Computer Engineering, University of California San Diego, La Jolla, CA; 2) Department of Mathematics, University of California San Diego, La Jolla, CA; 3) Bioinformatics Graduate Program, University of California San Diego, La Jolla, CA; 4) Department of Computer Science & Engineering, University of California San Diego, La Jolla, CA; 5) Department of Biology, Stanford University, Stanford, CA.

Methods for detecting the genomic signatures of natural selection have been heavily studied, and have been successful in identifying many selective sweeps. For the vast majority of these sweeps, the favored allele remains unknown, making it difficult to distinguish carriers of the sweep from non-carriers. Because carriers of ongoing selective sweeps are likely to contain a future most recent common ancestor, identifying them may prove useful in predicting the evolutionary trajectory – for example, in contexts involving drug-resistant pathogen strains or cancer subclones. In this research, we start with the development and analysis of a new statistic, the Haplotype Allele Frequency (HAF) score, assigned to individual haplotypes in a sample. The HAF score naturally captures many of the properties shared by haplotypes carrying an adaptive allele. We provide a theoretical model for the behavior of the HAF score under different evolutionary scenarios, and validate the interpretation of the statistic with simulated data. We develop an algorithm (PreCIOSS: Predicting Carriers of Ongoing Selective Sweeps) to identify carriers of the adaptive allele in selective sweeps, and we demonstrate its power on simulations of both hard and soft selective sweeps, as well as on data from well-known sweeps in human populations.

We also investigate the problem of identifying the favored mutation itself, without using functional information. We developed a tool to reconstruct possible genealogical scenarios, using clusters of recurrent mutations as guides to ancestral conserved haplotypes. We use a novel algorithm to select conserved haplotype segments that best separate carriers and non-carriers identified by PreCIOSS. In simulations, and on real data-sets with known sites under positive selection, our tool is able to short-list the favored mutation with high sensitivity and specificity. Applying this method on a 600 kbp (163 sites) region including the lactase (LCT) gene region centered at the known favored mutation in European (CEU) population, we obtained a small list of 3 candidates that includes the C/T-13910 (rs4988235) mutation, for which the T allele was found to be 100% associated with lactase persistence in the Finnishpopulation. Similar results were observed for other selective sweeps including PSCA in African (YRI), and ADH1B and EDAR in Asian (CHB+JPT) populations from the Hapmap2 project.

A new measure of positive selection reveals genome-wide polygenic adaptation for complex traits in humans' recent evolutionary past. *E. A. Boyle[1,2], N. Telis[3], Y. Field[1,5], J. K. Pritchard[1,4,5].* 1) Genetics Dept, Stanford University; 2) School of Medicine, Stanford University; 3) Biomedical Informatics, Stanford University; 4) Biology Dept, Stanford University; 5) Howard Hughes Medical Institute.

Geneticists have long been stymied by the challenge of characterizing highly polygenic traits in human populations. While genome-wide association studies have permitted the profiling of more than 1,000 human traits in less than ten years, the implications of known or suspected SNP-trait associations have not been fully elucidated. Concurrently, other groups focusing on identifying how selection on genomic regions has shaped human evolution have struggled to identify the functional underpinnings of detected signal. While cases of selection acting outside the paradigm of hard sweeps are known in the literature, the relative dearth of such examples may suggest a gap unaddressed by current methods for detecting complex genetic adaptation. To investigate the potential contribution of polygenic, genome-wide adaptation in recent human history, we have developed a new metric – the Singleton Density Score – that aggregates signals of positive selection using singleton density across individuals within the Avon Longitudinal Study of Parents and Children (ALSPAC). We relate this novel metric to other genome-wide annotations and recapitulate prior work showing polygenic genetic architecture for height-favoring alleles in northern Europe. Finally, we apply this measure to over two-dozen other complex traits to quantify the effect of recent polygenic adaption on human quantitative traits in present-day populations and find evidence for selection acting to increase cranial size in Europeans' recent evolutionary history.

1522T

Estimating The Selective Effect For Each Gene Using Large Scale Population Data. *C. A. Cassa[1], D. M. Jordan[1], D. J. Balick[1], D. Nusinow[1], D. Beier[2], S. Sunyaev[1].* 1) Division of Genetics, Harvard Medical School/ Brigham and Women's Hospital, Boston, MA; 2) University of Washington, Seattle Children's Hospital, Seattle, WA.

Large sequencing datasetsenableunbiased queries into the significance and potential consequences of DNA sequence variation. Studies have assessed the functional importance of differential mutational load and the depletionof variants in genes. Here, we use the genome-wide distribution of expected and observed protein truncating variants (PTV) in a set of exomes to estimate the strength of selectionfor each gene. Next, we use this selective effect data to characterize the functional and clinical associations of genes throughout the spectrum of selective effects. We identify a set of understudied genes with high potential for developmental importance or essential function.

Characterization of the strength of selection (*s*) and dominance (*h*) coefficients for human genes is of great interest for evolutionary research and clinical interpretation. Estimates of these parameters in humans have proved elusive, as inference techniques used in other organisms generally require cross-breeding over several generations. Newly available large-scale population sequencing data provides insight into the selection that prevents PTVs from being observed in the general population. Using 60,706 patientexomeswithout severe Mendelian disorders from Exome Aggregation Consortium (ExAC), we use allele frequency information to estimate the strength of heterozygote selection in the form of the combined parameter s_het = *h*s*. Statistical power to infer these parameters in greatly increased by the simplifying assumption that all PTVswithin a given geneincur the same selective disadvantage,which should be particularly high in genes intolerant to such mutations. This allows us to treat PTVs in each gene as a single bi-allelic locus, where observations of PTVs throughout each gene are treated as multiple observations of the same PTV allele. We generally expect that mutations will enter the population in each gene at a localized rate of *U*, as estimated by a mutational model, and arefiltered by selection in proportionto their localized *hs* value. The forces of mutation and selection act against one another to generate and filter PTVs in each gene, and the ratio of these two values should be proportional to the observed number of PTV alleles in the population. For genes under extreme purifying selection (s~1), we can use the combined parameter *hs* to estimate the dominance coefficient *h*using the observed values of the mutation rate and variant frequencies for each gene.

1523W

The lingering load of archaic admixture in modern human populations. *K. Harris[1,2], R. Nielsen[2,3].* 1) Stanford University, Stanford, CA; 2) University of California Berkeley, Berkeley, CA; 3) Center for Bioinformatics, University of Copenhagen, Copenhagen, Denmark.

Founder effects and bottlenecks can damage fitness by letting deleterious alleles drift to high frequencies. This almost certainly imposed a burden on Neanderthals and Denisovans, archaic hominid populations whose genetic diversity was less than a quarter of the level seen in humans today. A more controversial question is whether the out-of-Africa bottleneck created differences in genetic load between modern human populations. Some previous studies concluded that this bottleneck saddled non-Africans with potentially damaging genetic variants that could affect disease incidence across the globe today (e. g. Lohmueller, et al. 2009; Fu, et al. 2014), while other studies have concluded that there is little difference in genetic load between Africans and non-Africans (e. g. Simons, et al. 2014; Do, et al. 2015). Although previous studies have devoted considerable attention to simulating the accumulation of deleterious mutations during the out-of-Africa bottleneck, none to our knowledge have incorporated the fitness effects of introgression from Neanderthals into non-Africans. We present simulations showing that archaic introgression may have had a greater fitness effect than the out-of-Africa bottleneck itself, saddling non-Africans with weakly deleterious alleles that accumulated as nearly neutral variants in Neanderthals. Assuming that the exome experiences deleterious mutations with additive fitness effects drawn from a previously inferred gamma distribution, we predict that the fitness of the average Neanderthal was about 50% lower than the fitness of the average human, implying the existence of strong selection against early Neanderthal-human hybrids. This is a direct consequence of mutation accumulation during a period of low Neanderthal population size that is thought to have lasted ten times longer than the out-of-Africa bottleneck (Pruefer, et al. 2014). Although our model predicts some transmission of deleterious Neanderthal variation to present-day non-Africans, it also predicts that many Neanderthal alleles have been purged away, depleting conserved genomic regions of Neanderthal ancestry as observed empirically by Sankararaman, et al. (2014). Our results imply that the deficit of Neanderthal DNA from functional genomic regions can be explained without the action of epistatic reproductive incompatibilities between human and Neanderthal alleles.

1524T

Pleiotropic effects of immune responses explain variation in the prevalence of fibroproliferative diseases. *M. Huang[1], SB. Russell[2], JC. Smith[3], JS. Trupin[4], SM. Williams[1].* 1) Department of Genetics, Geisel School of Medicine, Dartmouth College, Hanover, NH 03755; 2) Vanderbilt Genetics Institute, Division of Dermatology, Department of Medicine, Vanderbilt University, Nashville, TN 37091; 3) NHC Healthcare, Lewisberg, TN 37091; 4) 143 School St. Marshfield, VT 05658.

Many diseases are differentially distributed among human populations. Differential selection in ancestral environments that coincidentally predispose to disease can be an underlying cause of these unequal prevalence patterns. Some of the selected genes may be pleiotropic, affecting multiple phenotypes and resulting in more than one disease or trait. Patterns of pleiotropy may be helpful in understanding the underlying causes of an array of conditions in a population. For example, several fibroproliferative diseases are shown to be more prevalent and severe in populations of sub-Saharan ancestry. We propose that this disparity is due to selection for an enhanced Th2 response that confers resistance to helminthic infections, and concurrently increases susceptibility to fibrosis due to the profibrotic action of Th2 cytokines. Through an extensive review of the literature, we show higher relative frequencies of many fibroproliferative diseases in black populations than in white. We provide evidence that instead of conferring a selective advantage with respect to the specific disease, this pattern is best explained by selection for resistance to diseases caused by helminthic worms, prevalent in sub-Saharan Africa. Resistance to helminths is achieved by a shift in the immune system toward an enhanced Th2 immune response that coincidentally results in fibrosis. We show the allelic distributions of variants that affect Th2 response are almost universally consistent with this hypothesis. Furthermore, by comparing the differentiation between African and European populations with respect to Th2, Th1 and TGFB genes, we show that there is greater differentiation in variants in Th2 related genes compared to the genetic background between African and non-African populations, an observation consistent with selection favoring Th2 enhancement in Africa. In summary, we provide evidence that adaptation of the immune system has shaped the genetic structure of these human populations in ways that alter the distribution of multiple fibroproliferative diseases.

1525W

Signatures of positive natural selection targeting human microsatellites and estimation of relevant mutational and selective parameters. *R. Johnson[1], B. Payseur[2], R. Haasl[1].* 1) University of Wisconsin-Platteville, Department of Biology, 1 University Plaza, Platteville, WI, 53818; 2) University of Wisconsin-Madison, Laboratory of Genetics, 425-G Henry Mall, Madison, WI 53706.

Microsatellites are common genetic polymorphisms in which the copy number of a short nucleotide motif is variable. Although the vast majority of microsatellites are thought to evolve neutrally, variation at several microsatellites is implicated in human diseases including Huntington disease and Friedrich ataxia. Recent empirical data also suggest that some microsatellites possess adaptive repeat lengths, which have been selected for by positive natural or artificial selection. The goal of our research was to analyze candidate microsatellite loci in the human genome for signatures of positive natural selection. We genotyped 200 microsatellites in 200 human individuals from eight 1000 Genomes populations and applied a method based on approximate Bayesian computation (ABC) to infer neutral versus selective evolution. In cases where a model of positive selection was favored, we estimated the strength of selection and the mutational profile of the microsatellite. Here, we present the first results of our analysis, focusing on five microsatellite loci found in an intron or basal promoter of the genes *PAX3*, *GRIN2B, NOS2*, *SHBG*, and *EGFR*. In each case, we provide compelling evidence that the distribution of variation found at the microsatellite has been shaped by positive natural selection. Furthermore, through our joint inference of mutational and selective parameters, we demonstrate the complicated interplay of natural selection and mutation at these highly mutable variants. In particular, we show that the repeat length of adaptive alleles at a microsatellite locus affects the efficacy of positive selection as longer microsatellites tend to possess higher mutation rates, thereby generating less adaptive alleles with appreciable frequency.

1526T

Evolution of the 'fused' gene family's repeat region in primates. *V. Romero, I. Inoue.* Human Genetics, National Institute of Genetics, Mishima, Shizuoka, Japan.

Epidermal Differentiation Complex (EDC) on chromosome 1 is a dense cluster of genes expressed during the late differentiation of epidermis and is responsible for maintaining hydration and structure of skin. The cluster organization of this complex might suggest adaptation during evolution and is strongly associated with a variety of skin disorders. EDC includes the CE precursor family, S100A family and the 'fused' gene family. The 'fused' genes members are: Cornulin, Filaggrin, Filaggrin-2, Hornerin, Repetin and Trichohyalin. These genes have similar organization showing an initial S100 domain followed by a tandem repeat region and a C-terminal domain. In this study, we focus on the repeat region of each gene and the evolution pathway among Marmoset, Macaque, Baboon, Orangutan, Gorilla, Chimpanzee and Human. We demostrate that each member of the 'fused' genes is undergoing different selective pressure, which infers a complex model of adaptive evolution for the EDC. As an example, Filaggrin2/Filaggrin number of repeats varies between species; Human has 14, Chimpanzee 13, Macaque 14, Baboon 22 and Marmoset 8. The similarity between these repeats ranges from 70% to 100%. Phylogenic analysis separated all Marmoset-repeats apart, first repeats from all species, and then the rest of Macaque and Baboon, and Chimpanzee and Human pair together. Maximum-likelihood analysis detected positive selection in 7 codons of all branches, with each branch under different selective pressure and positive selection in 2 codons of the Marmoset-branch. We also inferred 15 duplications and 10 losses events by reconciling the gene tree with the species tree. Additional studies were performed with the rest of 'fused' genes.

1527W

Signals of Selection in Genes Associated with Autoimmune Diseases. *R. Rothwell[1], S. Zoellner[1,2], BRIDGES Consortium.* 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Psychiatry, University of Michigan, Ann Arbor, MI.

Recent epidemiological studies estimate autoimmune diseases collectively affect at least 5% of individuals worldwide. This group of diseases, including Crohn's disease, Celiac disease, multiple sclerosis, rheumatoid arthritis, lupus, spondyloarthropathy, type 1 diabetes, and ulcerative colitis, while presenting a wide range of symptoms, share multiple associated loci. In particular, there is substantial evidence for associations within loci of the major histocompatibility complex (MHC). The best characterization is for the human leukocyte antigen (HLA) loci, in which studies have implicated pathogen-driven balancing selection. Non-HLA shared loci, however, also show evidence of being directly causative in disease, though less is known of their evolutionary origin. Understanding this origin is important to developing the underlying genetic model of disease, therefore providing biological insights and leading to future medical interventions. It is also of interest to the general study of human evolution, exploring the process of adaption and the development of phenotypic diversity. One hypothesis is variants in these loci were previously selected for some protection from infectious diseases or offered some other evolutionary advantage. To assess this idea, commonly referred to as the "thrifty gene hypothesis", we use whole genome sequencing data to look for selection signals at previously implicated non-HLA autoimmune associated loci. The BRIDGES consortium dataset, one of the most extensive data sets to be used in sequencing scans, consists of 3765 European individuals sequenced to an average coverage of 9. 2x. Specifically, our analyses includes site frequency spectrum-based tests, (Tajima's D, Fay and Wu's H), linkage-disequilibrium based neutrality tests (extended haplotype homozygosity, integrated haplotype score), and inter-species neutrality tests (McDonald-Kreitman). We calculate these statistics in windows across the genome, generating an empirical distribution. To test for significance while accounting for population effects such as exponential growth, we compare the windows within our genes to this empirical distribution. We therefore conduct a comprehensive search for signals of previous positive selection, ongoing selection, and evolutionary adaptation, providing a complete description of the evolution of these autoimmune-associated loci.

1528T

Natural Selection on *HFE* in Asian Populations Contributes to Enhanced Non-heme Iron Absorption. *K. Ye[1], C. Cao[1], L. Xu[2], K. O'Brien[1], Z. Gu[1].* 1) Division of Nutritional Sciences, Cornell University, Ithaca, NY, USA; 2) Key Laboratory of Nutrition and Metabolism, Institute for Nutritional Sciences, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences and Graduate University of the Chinese Academy of Sciences, Shanghai, China.

HFE, a major regulator of iron (Fe) homeostasis, has been suggested to be under positive selection in both European and Asian populations. While the genetic variant under selection in Europeans (C282Y) has been relatively well-studied, the adaptive variant in Asians and its functional consequences are still unknown. Identifying the adaptive *HFE* variants in Asians will not only elucidate the evolutionary history and the genetic basis of population difference in Fe status, but also assist the future practice of genome-informed dietary recommendation. Using the HapMap Project data, we observed significant iHS values around *HFE* only in Asians, suggesting the presence of positive selection and population-specific selection pressure. We further identified a candidate adaptive haplotype that is common in Asians (52. 35-54. 71%) but rare in Europeans (5. 98%) and Africans (4. 35%). The T allele at tag SNP rs9366637 (C/T) captured 95. 8% of this Asian-common haplotype. FST statistics and differences of derived allele frequency (χDAF) for rs9366637 are significant between Asians and Europeans or Africans. Previous association studies have shown that the T allele of rs9366637 is associated with increased levels of circulating ferritin in women. We further showed that individuals carrying T/T or C/T at rs9366637 have significantly reduced *HFE* expression compared to C/C in lymphoblastoid cell lines from the Hapmap Project and in another four tissues/cells from GTEx, including lung, tibial nerve, EBV-transformed lymphocytes and prostate. As reduced expression of *HFE* theoretically would lead to enhanced non-heme Fe absorption, we hypothesized that the Asian-common haplotype of *HFE* was selected for enhanced non-heme Fe absorption in Asian populations, which has a long history of consuming plant-based Fe-poor diet. To test this hypothesis, we recruited 57 women of Asian descent and measured Fe absorption using stable isotopes in those homozygous at rs9366637, representing homozygous carriers (T/T) and non-carriers (C/C) of the Asian-common haplotype. We observed a 22% higher absorption in homozygous carriers compared to the non-carriers. Additionally, compared with a group of age-matched Caucasian women, Asian women exhibited significantly elevated Fe absorption after controlling for Fe status. Our results indicate population differences in Fe homeostasis and suggest that natural selection on *HFE* may have contributed to elevated Fe absorption in Asians.

1529W

Prevalence of an archaic high altitude adaptive *EPAS1* haplotype in the Himalayas. *Q. Ayub[1], S. Hackinger[1], T. Kraaijenbrink[2], Y. Xue[1], M. Mezzavilla[1], G. van Driem[3], M. A. Jobling[4], P. de Knijff[2], C. Tyler-Smith[1].* 1) Wellcome Trust Sanger Institute, Hinxton, Cambs, United Kingdom; 2) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 3) Institute of Linguistics, University of Bern, Bern CH-3012, Switzerland; 4) Department of Genetics, University of Leicester, Leicester, United Kingdom.

Genetic, biochemical and morphological changes have enabled humans to adapt to living at high altitudes in Asia, Africa and South America. High altitude adaptation in Tibetans is reportedly influenced by introgression of a 32. 7 kb long haplotype from the Denisovans, an extinct branch of archaic humans. This haplotype lies within the endothelial PAS domain protein 1 (*EPAS1*), a transcription factor acting in the hypoxia inducible factor pathway. A parallel study indicated that the same haplotype had probably entered the Tibetan population from the Sherpa, a high altitude adapted population from Nepal, thus suggesting that most likely the Denisovan introgression occurred in a population ancestral to the Sherpa and Tibetans. We genotyped 22 single nucleotide variants (SNVs) in this region in 1,550 Eurasian individuals, including 1,233 from Bhutan and Nepal residing at altitudes ranging from 86 – 4,550 m above sea level. Derived alleles for 5 SNVs (rs115321619, rs73926263, rs73926264, rs73926265, rs55981512) that characterize the core Denisovan haplotype (AGGAA) were present at high frequency not only in Tibetans and Sherpa, but also among many ethno-linguistic groups from Bhutan and Nepal. The frequency of the Denisovan core haplotype in these populations shows a significant correlation with altitude (Spearman's correlation coefficient = 0. 797, p-value 6. 996 x 10-12). The Denisovan derived alleles were also observed at frequencies of 3-14% in the 1000 Genomes Project African samples and an additional 10 East and South Asian samples shared the Denisovan haplotype that extends beyond the 32 kb region. These additional samples enabled us to refine the haplotype structure and identify candidate functional variants that might be driving the selection signal.

1530T

Genetic Basis of Polygenic Adaptation in Indigenous Siberian Populations Inferred using Exome Sequencing Data. *P. Hsieh[1], B. Hallmark[2], TM. Karafet[3], MF. Hammer[1,3], RN. Gutenkunst[1,4].* 1) Department of Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 2) Interdisciplinary Program in Statistics, University of Arizona, Tucson, AZ; 3) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tucson, AZ; 4) Department of Molecular and Cellular Biology, University of Arizona, Tucson, AZ.

Siberia is one of the coldest environments on Earth and has great seasonal temperature variation. Recent archeological studies indicate that humans have occupied Siberia for at least ~45,000 years, and persisted through the Last Glacial Maximum in North Eurasia. As early modern humans dispersed from their ancestral tropical African homeland into much cooler environments, long-term settlement in Siberia undoubtedly required biological adaptation to severe cold stress, dramatic variation in photoperiod, as well as limited and highly variable food resources. Humans are the only primate species other than the Japanese macaque that has adapted to boreal conditions—where temperatures remain far below freezing for more than half the year—pointing to intense selection pressures that likely drove the enhancement of physiological processes that generate and conserve heat. Physiological evidence, such as differences in basal metabolic rates and brown adipose tissue, suggests genetic adaptions in Arctic populations to life at high latitude. Because many of these physiological traits, including body mass and metabolic processes, are highly polygenic, we sought signatures of polygenic selection in Siberian populations. We sequenced exomes of individuals from two indigenous Siberian populations: the Nganasans (N = 21), who are the northernmost indigenous group in the world, and the Yakuts (N = 21), who live in the coldest regions on our planet. To detect polygenic selection, we performed gene-set enrichment analysis using pathways from the NCBI Biosystems database as well as a set of candidate genes that have been previously implicated in cold adaptation. The significance of the candidate gene sets for polygenic selection was assessed using whole-exome coalescent simulations to account for potential biases caused by demographic processes and heterogeneity in mutational and recombination rates across the entire genome. Our results thus give insight into the complex polygenic basis of adaptation to life in cold environments in human populations.

1531W

Population structure analysis in a Southwest American Indian population: potential for understanding natural selection in disease susceptibility. *P. Kumar, W-C. Hsueh, A. K. Nair, P. Piaggi, S. Kobes, R. L. Hanson, L. J. Baier.* Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ.

The high prevalence rates of type 2 diabetes and obesity in modern humans is a major health concern and have disproportionally affected specific populations including the Pima Indians of Southwest Arizona. It has been proposed that lifestyle changes have influenced evolutionary pressure on genes that regulate physiologic pathways which underlie complex genetic disorders including type 2 diabetes and obesity. Therefore, analysis of natural selection signatures may be important to understand the evolutionary processes and population specific differences in prevalence of certain metabolic diseases in different geographical regions. Here, we used genome-wide Affymetrix 6. 0 genotypic data from 73 unrelated full heritage Pima Indians (an estimated kinship coefficient < 0. 03 between any 2 subjects) and integrated these genotypes with genotypic data from 11 HapMap Phase III populations. Markers common to both datasets (N=355,000) were used for population genetic and natural selection analyses. Our principle component (PC) analysis separated Pima Indians from Europeans and East Asians at PC2 (4. 3%) and showed more closeness to East Asians. Population structure analysis using FRAPPE at K =4 (four population model) showed major components identifiable as Amerindian, European, East Asian and African across the populations. In Pima Indians, the major components were Amerindian 0. 91±0. 11 (mean±SD), European 0. 05±0. 10, and East Asian 0. 02±0. 01. The Amerindian component in the Mexican was 0. 39±0. 13. These analyses show that Pima Indian ancestry is majorly Amerindian and there is minimal admixture from other continental populations. Therefore selection signatures that underlie complex diseases common to this population may be unique as compared to other study populations. Additional analysis related to population differences, such as FST and long range haplotype analyses for recent selection events, is ongoing. Genes/regions identified by these methods will be tested for implication in disease processes in Pima Indians.

The recent production of population-scale genomic data offers an unprecedented opportunity to understand how natural selection has shaped human phenotypic variation within populations. Sardinia has a rich history of genetic studies driven by its relative isolation and high incidence of malaria, which was endemic there until eradication efforts in the 1940s. To identify signatures of recent positive selection in Sardinia, we use 23 million single nucleotide polymorphisms from low-coverage whole genomes of 3,514 Sardinians along with data from the 1000 Genomes project. Using haplotype (iHS, nSL), cross-population (Fst, PBS, XP-EHH), and site-frequency-spectra (CLR) based statistics we find many genetic variants show evidence of selection. To assess the significance of these selection statistics, we use an empirical null distribution generated from randomly chosen variants matched by minor allele frequency, local recombination rate, and background score. We also evaluate these statistics relative to a null, neutral model using a demographic history inferred from deeply sequenced Sardinian individuals. We show that selection statistics computed for outlier variants cannot be explained by neutral forces alone. By intersecting genome-wide-association study data for hundreds of traits in Sardinia with publicly available functional genomic databases we find that autoimmunity-related genes are significantly enriched for these putatively adaptive variants. Taken together, these results illustrate the importance of characterizing both the demographic history of and phenotypic variation within a population, and especially the utility of whole-genome-sequence data, when proposing and interpreting genetic signatures of positive selection.

Analyzing Nonsynonymous SNPs in their Protein Structural Context Reveals Novel Signatures of Population Differentiation in Humans. *R. M. Sivley[1,4], J. A. Capra[2,4], W. S. Bush[3,4,5].* 1) Department of Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Department of Biological Sciences, Vanderbilt University, Nashville, TN; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 4) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 5) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

The primary goal of this project is to integrate spatial and functional information from protein structures into population genetic analyses. The increasing availability of experimentally determined and computationally predicted protein structures provides a functionally relevant perspective from which to analyze whole-exome and whole-genome sequencing data. The spatial orientation of variants in 3D structures reflects their functional context and reveals relationships between variants that are distant in sequence, but nearby in structure. To enable this type of analysis, we first mapped 534,947 nonsynonymous SNPs (nsSNPs) from Phase 3 of the 1000 Genomes Project (1KG) to the affected amino acids in 4,965 biological assemblies from the Protein Data Bank. We found that for 59% of 1KG nsSNPs, the nearest nsSNP in structure differed from its nearest nsSNP in the genome. Heteromeric protein complexes accounted for 3. 7% of these nsSNPs, with the nearest nsSNP in structure located in another gene. To demonstrate the utility of incorporating structural information into genetic analyses, we performed a comprehensive scan for population differentiation in human protein structures. We estimated Wright's FST over nsSNPs within 10Å of each amino acid in each structure using the 1KG super-populations. We obtained an empirical p-value by shuffling nsSNP positions and recalculating each FST. We identified 1,791 proteins with structurally defined regions of significant ($p<0.05$) population differentiation, 256 of which were not detected by comparable sequence-based methods. Among the proteins with the most highly differentiated structural regions (FST>0. 05), we identified significant enrichment for several functional categories, most notably immune system response genes (BH adjP=0. 0365), suggesting that differences in pathogen exposure between human populations may have driven differentiation in coherent structural regions. These results highlight the extent to which protein folding affects the spatial proximity of variable amino acids, and demonstrate that considering these structural relationships enables the detection of novel signatures of population differentiation.

1534T

Novel probabilistically interpretable methods for identifying and localizing genomic targets of selective sweeps. *L. A. Sugden, S. Ramachandran.* Department of Ecology and Evolutionary Biology, Brown University, Providence, RI.

Human populations throughout the world have had to adapt to novel pathogens and environments; this adaptive evolution has shaped present-day genomes. Here, we introduce novel frameworks for detecting adaptive sweeps from *de novo* mutations that are easily extensible to detecting adaptive evolution from standing variation. While current methods for detecting adaptive mutations rely on single statistics that probe one of three major signatures of a sweep -- long-range haplotype blocks, changes in the site frequency spectrum, and population differentiation -- recently, composite methods have shown increased power by combining multiple statistics. However, these methods falter when a subset of their component statistics is undefined, as often happens with long-range haplotype statistics, and they yield scores that are fundamentally difficult to interpret. Our approach classifies local targets of selective sweeps within multiple populations in a way that combines multiple statistics, has an easy probabilistic interpretation, and deals naturally with undefined statistics. We introduce two classifiers that infer the probability that a new locus has undergone a sweep, based on distributions learned from demographic simulations. The first is a Naïve Bayes classifier, which assumes independence among component statistics, while the second uses a machine-learning tool called an Averaged One-Dependence Estimator (AODE) to allow for pairwise dependencies. In simulated data, we show that the Naïve Bayes classifier vastly outperforms state-of-the-art methods in detection and localization of sweep signals, in some cases reducing the number of false positive predictions by seven-fold. We show that this classifier performs particularly well when identifying completed sweeps and fast sweeps, which have great biological significance. For a subset of sweep parameters, the AODE further improves classification performance. In data from the 1000 Genomes Project, we show that both classifiers can detect known sweep targets, including the DARC locus in West Africans, the EDAR locus in East Asians, and the SLC24A5 locus in Europeans. We also show that the dependency structure implemented in the AODE is necessary for detection of some signals, including the CD36 locus in West Africans, which harbors malaria resistance alleles. Our methods produce fewer false positives and negatives compared to existing approaches, thus identifying promising targets for experimental validation.

1535W

Adaptation in global human populations has been hard, soft and polygenic. *Z. A. Szpiech[1], R. D. Hernandez[1,2,3].* 1) Department of Bioengineering and Therapeutic Sciences, University of California at San Francisco, San Francisco, CA 94158; 2) Institute for Human Genetics, University of California at San Francisco, San Francisco, CA 94158; 3) Institute for Quantitative Biosciences (QB3), University of California at San Francisco, San Francisco, CA 94158.

There is ample debate about the strength and mode of natural selection that has occurred in recent human evolution. This is particularly so for classical hard sweeps, during which an adaptive allele quickly drags a single haplotype to high frequency. An alternative model of adaptation involves soft sweeps, whereby multiple haplotypes are brought to high frequency (i. e. when a previously segregating neutral or slightly deleterious allele becomes adaptive in a new environment). Yet another alternative model includes polygenic selection, whereby complex phenotypes driven by multiple loci across the genome are selected. Here we develop new statistics designed to identify both hard and soft sweeps, by tracking the decay of homozygosity of the k-most frequent haplotypes away from a core locus. We evaluate our statistics with rigorous simulations under multiple realistic models of human demography and find that they have high power. We then integrate signals of selection across the genome to identify characteristic signals of polygenic selection. We apply our approaches to a large dataset of 1,728 unrelated individuals spanning 20 worldwide human populations from the 1000 Genomes Project. We find that a large number of novel regions consistent with soft sweeps, particularly in African populations, and instances of polygenic selection driving the regulatory architecture of several genes. We then use an Approximate Bayesian Computation framework to infer selection parameters for these regions.

1536T

A 3. 4-kb copy number deletion near *EPAS1* is significantly enriched in high-altitude Tibetans but absent from the Denisovan sequence. *S. Xu[1,2,9], H. Lou[1,10], Y. Lu[1,10], D. Lu[1,10], R. Fu[1,2,10], X. Wang[1], Q. Feng[1], S. Wu[3], Y. Yang[3], S. Li[4], L. Kang[5], Y. Guan[1,6], H. B. Peng[7], Y. J. Chung[7], L. Jin[3], B. Su[8], S. Xu[1,2,9].* 1) Max Planck Independent Research Group on Population Genomics, CAS-MPG Partner Institute for Computational Biology (PICB), Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai 200031, China; 2) School of Life Science and Technology, ShanghaiTec University, Shanghai 200031, China; 3) State Key Laboratory of Genetic Engineering and Ministry of Education (MOE) Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center of Genetics and Development, School of Life Sciences, Fudan University, Shanghai 200433, China; 4) School of Medicine, Xizang University for Nationalities, Xianyang 712082, Shaanxi, China; 5) Department of Biochemistry and Molecular Biology, Preclinical Medicine College, Xinjiang Medical University, Urumqi 830011, China; 6) Faculty of Medicine and Health Sciences, UCSI University, Kualal Lumpur Campus, Jalan Choo Lip Kung, Taman Taynton Vie, 56000, Cheras, Kuala Lumpur, Malaysia; 7) Integrated Research Center for Genome Polymorphism, Department of Microbiology, The Catholic University Medical College, Socho-gu Seoul 137-701, Korea; 8) State Key Laboratory of Genetic Resources and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming 650223, China; 9) Collaborative Innovation Center of Genetics and Development, Shanghai 200438, China; 10) These authors contributed equally to this work.

Tibetan high-altitude adaptation (HAA) has been studied extensively and many candidate genes have been reported. Subsequent efforts targeting HAA functional variants, however, have not been that successful; e. g. , no functional variant has been suggested for the top candidate HAA gene, *EPAS1*. With a method developed in this study, WinXPCNVer, we detected in microarray data a Tibetan-enriched deletion (TED) carried by 90% of Tibetans with 50% being homozygous for the deletion, in contrast to only 3% and 0%, respectively, in 2,792 worldwide samples (P<10-15). Long PCR and Sanger sequencing technologies were employed to determine the exact copy number and breakpoints of the TED in 70 new Tibetan and 182 diverse samples. The TED has identical boundaries (chr2:46694276–46697683; hg19) and is 80 kb downstream of *EPAS1*. Notably, the TED is in strong linkage disequilibrium (LD; $r2$=0. 8) with *EPAS1* variants associated with reduced blood concentrations of hemoglobin. It is also in complete LD with the 5-SNP motif, which was suspected to be introgressed from Denisovan, but the deletion itself is absent from the Denisovan sequence. Correspondingly, we detected footprints of positive selection for the TED occurring 12,803 (95% CI: 12,075–14,725) years ago. We further whole-genome deep sequenced (> 60x) seven Tibetans and verified the TED but failed to identify any other copy number variations with comparable patterns, giving this TED top priority for further study. We speculate that the specific patterns of the TED resulted from its own functionality in HAA of Tibetans or LD with a functional variant of *EPAS1*.

Purifying selection governs the evolution of the major chaperone sub-network in humans. *K. Hess, J. Ellis, N. Nikolaidis.* Department of Biological Science, Center for Applied Biotechnology Studies, and Center for Computational and Applied Mathematics, California State University, Fullerton, Fullerton, CA.

The cellular stress response (CSR) is one of the most conserved and universal mechanisms present in all species. The CSR allows organisms to adapt to their ever-changing environments and survive. The most important orchestrator of the CSR is a group of proteins called molecular chaperones, which regulate protein homeostasis and cell survival. Although the molecular chaperone networks are critical for cell health and disease, their evolution and function in humans remain largely unknown. Here we investigated the microevolution process of an important subset of the human chaperone network, composed by Hsp70s, Hsp40s, and BAGs, by analyzing single nucleotide polymorphisms (SNPs). The results show that first, in 92% of the genes the number of non-synonymous (ns) SNPs is higher than the number of synonymous (s) SNPs. Second, 65% of the genes had a significantly higher SNP density than the surrounding genes. Third, more than 80% of the genes had significantly higher SNP density within their exonic regions as compared to both intronic and un-translated regions. Fourth, the majority of genes contained more sSNPs than nsSNPs within known functional regions (domains), while the number of sSNPs is similar between domains and non-domain protein regions. Fifth, on average 50% of the genes contained a nsSNP on an amino acid position of known function. Sixth, calculations of synonymous and non-synonymous distances revealed the action of purifying selection, the intensity of which varied dramatically both between and within the gene families. To test the predicted effects of some of these nsSNPs we generated recombinant protein variants corresponding to the wild-type and mutated *HSPA1A*, the major human heat-inducible Hsp70 gene. We then used Isothermal titration calorimetry (ITC) and determined that most mutations only marginally altered the binding affinity to both nucleotide (ATP and ADP) and protein substrates. However, one mutation revealed significant alterations in the way the molecules interact and the reaction products are formed. Collectively, these results suggest that strong purifying selection due to functional constraints shaped the evolution of the major chaperone sub-network in humans. The nsSNPs, which are either predicted or showed to alter the function of a particular protein, may either represent adaptations to particular environmental pressures, disease states, or are mutations that have not been eliminated yet from the population.

1538T

Strong evolutionary constraint on human genes escaping X-inactivation is modulated by their expression breadth and level in both sexes. *A. Slavney[1,2], L. Arbiza[2], A. Clark[1], A. Keinan[2].* 1) Molecular Biology and Genetics, Cornell University, Ithaca, NY; 2) Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

In eutherian mammals, X-linked gene expression is normalized between XX females and XY males through the process of X chromosome inactivation (XCI). XCI results in silencing of transcription from one ChrX homolog per female cell. However, approximately 25% of human ChrX genes escape XCI and exhibit biallelic expression in female cells. The evolutionary basis of this phenomenon is not entirely clear, but high sequence conservation of XCI escapers across mammals suggests that XCI escape is a direct or indirect result of selection rather than neutral mechanisms (such as inefficient establishment or maintenance of XCI). This signal has been suggested to result from these genes' potential contributions to developmental and physiological sex differences, but XCI escape rarely introduces significant female expression biases, which renders this model a poor fit for most XCI escapers. Instead, we hypothesize that XCI escapers experience selection for high and/or broad gene expression in both sexes, which are strong predictors of reduced nucleotide substitution rates in mammalian genes. To test our hypothesis, we compared the extent of purifying selection and gene expression patterns between annotated human XCI escapers and X-inactivated genes. We used human polymorphism data from the Exome Sequencing Project (ESP) to estimate a mutation burden statistic that captures recent/weak purifying selection, and combined these data with divergences between the human and chimpanzee, orangutan, and macaque reference genomes to estimate the extent of ancient purifying selection using a McDonald-Kreitman framework. We calculated gene expression levels and breadth of ChrX genes using RNA-seq data from the Genotype-Tissue Expression (GTEx) consortium, which included expression data for 23 tissues in females and males. When we accounted for the functionality of each ChrX gene's Y-linked homolog (or "gametolog"), we observed that XCI escapers exhibit greater degrees of both recent and ancient purifying selection in the human lineage than X-inactivated genes. In support of our hypothesis, we also observed that they exhibit higher levels of gene expression, as well as broader expression across tissues, than X-inactivated genes, in both sexes. These results propose a significant role for gene expression in both sexes in driving purifying selection on XCI escapers, and emphasize these genes' potential importance in human disease.

1539W

Evolving ancestry: The shift in individual ancestry composition over time. *D. R. Velez Edwards[1,3], T. L. Edwards[2,3], T. L. McGregor[4].* 1) Department of Obstetrics and Gynecology, Vanderbilt University, Nashville, TN; 2) Division of Epidemiology, Department of Medicine, Vanderbilt University, Nashville, TN; 3) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 4) Department of Pediatrics, Vanderbilt University, Nashville, TN.

An individual's genetic ancestry can be estimated using ancestry-informative markers and subsequently assigning fractions of ancestry. Applications of this information include admixture mapping, controlling for population structure in association studies, and forensic/identification purposes. In observational studies and in clinical encounters, researchers and care providers frequently assign a single ancestry for each individual. We evaluated the genetic ancestry of individuals in a large cohort spanning over 100 birth years by evaluating ancestry informative markers and estimated proportions of racial ancestry with categorical race, as recorded in the electronic health record. Individuals included in this study are members of the BioVU repository, a cohort of DNA samples linked to deidentified electronic health records. Ancestry informative markers were extracted from the Illumina Infinium Human Exome Beadchip on 35,842 individuals. The data were evaluated using STRUCTURE software with the subjects from the 1000 Genomes Project, and the three ancestral clusters corresponding with African, European, and East Asian ancestry were further evaluated in our analyses. We observed that individuals identified as White in the electronic health record have become more genetically admixed over time. The mean fractions of European ancestry have decreased for all cohorts by decade of birth from over 98% through the 1980's to 95. 7% and 90. 0% for the cohorts born in the 2000's and 2010's, respectively. In addition, the number of individuals with less than 70% attributable to any single ancestry has been increasing over time. These data indicate that younger cohorts of individuals exhibit higher levels of heterogeneity than older cohorts, particularly within those identified as White. We also observed increasing heterozygosity over time, with more rapid increases in younger individuals, implying increasing rates of migration of alleles between racial groups over time. Investigators studying traits in younger cohorts should consider these increasing levels of admixture when developing study designs.

1540T

Estimation of inbreeding and substructure levels in African-derived Brazilian *quilombo* populations. *R. B. Lemes, K. Nunes, D. Meyer, R. C. Mingroni-Netto, P. A. Otto.* Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of São Paulo, Sao Paulo, SP, Brazil.

Over 3 million Africans were brought as slaves to Brazil during its colonial times. Many runaway, abandoned and freed slaves founded isolated communities (*quilombos*), that in the state of São Paulo are mostly located in its southern border (Vale do Ribeira). We assessed inbreeding and substructure levels from eight *quilombos* by means of analysis of genealogical and molecular data. In order to circumvent problems related to the paucity of historical records and to the heterogeneity of molecular sampling (performed in different groups of individuals with distinct purposes on different occasions), we developed or adapted methods for obtaining reliable estimates of these parameters, since these problems conferred an additional source of heterogeneity among loci and populations. Considering only individuals with more reliable information on his ascendants, from the genealogical analysis of about 2,000 individuals we got an average inbreeding coefficient **FG** = 0. 0025, a value considered low for isolates, but that is 3 to 4 times higher than the estimates for the overall Brazilian population or for the state of São Paulo. We also obtained estimates of the inbreeding coefficient **F** by analyzing a set of 16 microsatellite and 14 SNP autosomal loci (in about 600 and 300 individuals, respectively). Since on the long run **F**-values estimated from different loci are expected to be normally distributed around the average **F**-value for the same population, we developed a method to exclude outlier values exceeding the usual 95% range. The method averages the **F** values by the reciprocals of their variances, which we determined using a novel approximation. The results of this analysis, performed considering only individuals genotyped as to at least 90% of markers, showed that SNPs provide reliable **F** estimates (**F** = 0. 055 for the whole population), while microsatellites do not. Substructure analysis was performed using Wright's indices **FIT**, **FIS** and **FST**, whose statistical significance we tested using computer bootstrap procedures. The results showed that the levels of substructure of the communities here reported are very small, probably due to their proximity and to the migration levels among them over more than 150 years; therefore, the communities here reported can be considered as a single population aggregate. We also compared the estimates obtained using microsatellites to those using a large panel of SNPs, and discuss the possible causes of differences in estimates.

1541W

The Recent History of Human Population Size. *A. Rogers.* Anthropology, University of Utah, Salt Lake City, UT.

Current methods for estimating the history of population size have poor resolution in the recent past. I introduce here a method that combines information from linkage disequilibrium and from the site frequency spectrum. With samples of about 100 diploid genomes, it outperforms existing methods over the past few hundred generations. I validate the method against simulated data and use it with 1000-Genomes data, controlling statistically for the under-representation of rare variants low-coverage data. Results document post-Neolithic population growth in Europe.

1542T

Y-chromosome diversity suggests southern origin and Paleolithic backwave migration of Austro-Asiatic speakers from eastern Asia to the Indian subcontinent. *XM. Zhang[1], SY. Liao[2], XB. Qi[1], JW. Liu[1,8], J. Kampuansai[5], H. Zhang[1], ZH. Yang[3,4], B. Serey[6], T. Sovannary[6], L. Bunnath[6], H. Seang Aun[6], H. Samnom[7], D. Kangwanpong[5], H. Shi[3,4], B. Su[1,4].* 1) Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) School of Life Sciences, Anhui University, Hefei 230039, China; 3) Center for Primate Translational Medical Research, Kunming University of Science and Technology, Kunming 650500, China; 4) Yunnan Key Laboratory of Primate Biomedical Research, Kunming 650500, China; 5) Department of Biology, Faculty of Science, Chiang Mai University, Chiang Mai 50200, Thailand; 6) Department of Geography and Land Management, Royal University of Phnom Penh, Phnom Penh 12000, Cambodia; 7) Capacity Development Facilitator for Handicap International Federation and Freelance Research, Battambang 02358, Cambodia; 8) Kunming College of Life Science, University of Chinese Academy of Sciences, Beijing 100101, China.

Analyses of an Asian-specific Y-chromosome lineage (O2a-M95)—the dominant paternal lineage (60. 65% on average) in Austro-Asiatic (AA) speaking populations, who are found on both sides of the Bay of Bengal—led to two competing hypothesis of this group's geographic origin and migratory routes. One hypothesis posits the origin of the AA speakers in India and an eastward dispersal to Southeast Asia, while the other places an origin in Southeast Asia with westward dispersal to India. Here, we collected samples of AA-speaking populations from mainland Southeast Asia and southern China and then analyzed both the Y-chromosome and mtDNA diversities. Combining our samples with previous data, we generated a comprehensive picture of the O2a-M95 lineage in Asia, including both AA and Daic speaking populations. We demonstrated that the O2a-M95 lineage originated in the southern East Asia among the Daic-speaking populations ~20-40 thousand years ago and then dispersed southward to Southeast Asia after the Last Glacial Maximum before moving westward to the Indian subcontinent. This migration resulted in the current distribution of this Y-chromosome lineage in the AA-speaking populations. Further analysis of mtDNA diversity showed a different pattern, supporting a previously proposed sex-biased admixture of the AA-speaking populations in India.

1543W

Historical migrations and mating patterns affect the genetic landscape of the United States population today. *R. Curtis[1], J. Granka[2], J. Byrnes[2], E. Han[2], P. Carbonetto[2], Y. Wang[2], K. Noto[2], M. Barber[2], A. Kermany[2], N. Myres[1], C. Ball[2], K. Chahine[2].* 1) AncestryDNA, Ancestry, Provo, UT; 2) AncestryDNA, Ancestry, San Francisco, CA.

The population of the United States has been formed through a series of foreign migrations, rapid population expansion, and westward migration. However, not all regions of the US have grown in the same way. For example, according to US Census data, most southern states had a birthrate twice as high as states in the northern US during the 1860s, and foreign migration to the US after 1860 largely congregated in the northern states. To learn more about the genetic imprint of these historical differences, we consider inferred identity-by-descent (IBD) sharing patterns among 850,000 genotyped individuals in the AncestryDNA database who are living in the US today. Leveraging over 1. 5 billion pair-wise estimated IBD relationships, along with deep, annotated pedigrees, we use these IBD relationships to construct an IBD network between individuals. We identify two distinct regional patterns in the IBD network that are consistent with known history. First, we see disparity in the number of DNA connections between individuals living in different regions of the country. For example, a DNA sample from Alabama has, on average, nearly double the number of IBD connections as a DNA sample from New York, even though there are 4x more samples with birth locations in New York. Second, we identify, using associated pedigree data, sub-clusters in the IBD network where many individuals have descended from the same ancestor within the past seven generations. These descendant groups vary in size from 2 to over 120 descendants. Again, we find distinct regional differences in these groups. For example, shared ancestors with many identified descendants tend to hail from more geographically or culturally isolated regions of the country, or regions that have undergone rapid population growth. These patterns differ from what would be expected in a random sample from the database, and could be suggestive of certain founder individuals for some regional communities, i. e. people originating in French Quebec or Utah. In a final analysis, we examine the pedigrees in regions with high rates of IBD sharing. We find that individuals in these regions are more likely to share more than one common ancestral couple with their IBD connections, which might explain some of the regional patterns that we have observed. In summary, our analysis shows that IBD connection patterns in different regions of the US are consistent with historically documented mating biases.

Mitochondrial DNA analysis suggests a Chibchan migration into Colombia. *MC. Noguera[1,2], C. Anderson[4], D. Uricoechea[3], C. Durán[2], I. Briceño[2,3], J. Bernal[2,5].* 1) Medellín, Antioquia, Facultad de Ciencias de la Salud. Grupo Gisafaco. Corporación Universitaria Remington. Medellín, Antioquia, Colombia. Cll 51 51-27; 2) Pontificia Universidad Javeriana. Instituto de Genética Humana. Facultad de Medicina. Cra7 40-62 ed 32; 3) Grupo de Genética Humana, Facultad de Medicina, Universidad de La Sabana. Chía, Colombia. Km. 7, Autopista Norte de Bogotá. Chía, Cundinamarca, Colombia; 4) Department of Foreign Languages & Cultures, Universidad de La Sabana. Chía, Colombia. Km. 7, Autopista Norte de Bogotá. Chía, Cundinamarca, Colombia; 5) Universidad Tecnológica de Bolívar. Cartagena, Colombia. Carrera 21 #25, Cartagena, Bolívar.

The characterization of mitochondrial DNA (mtDNA) allows the establishment of genetic structures and phylogenetic relationships in human populations, tracing lineages far back in time. We analysed samples of mtDNA from twenty (20) Native American populations (700 individuals) dispersed throughout Colombian territory. Samples were collected during 1989-1993 in the context of the program Expedición Humana ("Human Expedition") and stored in the Biological Bank of the Institute of Human Genetics (IGH) at the Pontificia Universidad Javeriana (Bogotá, Colombia). Haplogroups were determined by analysis of RFLPs. Most frequent was haplogroup A, with 338 individuals (48. 3%). Haplogroup A is also one of the most frequent haplogroups in Mesoamerica, and we interpret our finding as supporting models that propose Chibchan-speaking groups migrated to northern Colombia from Mesoamerica in prehistoric times. Haplogroup C was found in 199 individual s (28. 4%), while less frequent were B and D, with 113 and 41 (16% and 6%) individuals, respectively. The haplogroups of nine (9) individuals (1. 3%) could not be determined due to the low quality of the samples of DNA. Although all the sampled populations had genetic structures that fit broadly into the patterns that might be expected for contemporary Central and South American indigenous groups, it was found that haplogroups A and B were more frequent in northern Colombia, while haplogroups C and D were more frequent in southern and south-western Colombia.

1545W

Ancient mitochondrial genetic diversity across time and space in the Iñupiat populations of North Alaska. *J. Tackney[1], A. M. Jensen[2,3,4], W. S. Watkins[5], E. Fair[1], J. Brenner-Coltrain[1], D. Anderson[6], D. H. O'Rourke[1].* 1) Anthropology, Univ Utah, Salt Lake City, UT; 2) UIC Science LLC, Barrow, AK; 3) Anthropology, Bryn Mawr College, Bryn Mawr, PA; 4) Anthropology, University of Alaska Fairbanks, Fairbanks, AK; 5) Human Genetics, University of Utah, Salt Lake City, UT; 6) Anthropology, Brown University, Providence, RI.

It is believed that Iñupiat/Inuit peoples are the descendants of a recent (~700 ybp) and rapid (<100 years) migration across the North American Arctic by the Neo-Eskimo Thule. Archaeological research, and reduced genetic diversity relative to Siberia, suggests a west-to-east migration. Modern arctic peoples also carry a restricted subset of Native American mitochondrial haplotypes, with clade coalescence dates within the Holocene. This supports origins from later migrations separate from the initial peopling of the Americas. Populations across the North Slope, the likely place of origin for the Neo-Eskimo, have been under sampled. Complete mitochondrial sequences are lacking, so clear links with extant mitochondrial diversity are difficult to make. We investigate two pre-contact archaeological sites with human burials. Nuvuk is a long-term Thule village at Pt. Barrow, AK. Radiocarbon dates on archaeological material suggest remains span from Early Thule to modern Iñupiat Eskimo. Igliqtiqsiugvigruaq, a more recent and interior Alaskan site, is located inside the boundary of Kobuk Valley National Park, adjacent to the Kobuk River. We selected three individuals from Nuvuk previously typed for variants associated with D4b1a2a1a(D3) and A2. The rib fragments were directly dated, with median intercept calibrated dates of 1269, 1313, and 1579 AD. We additionally selected three individuals from Igliqtiqsiugvigruaq previously typed as A2b. Radiocarbon, optically stimulated luminescence, and dendrochronology all indicate an age near the turn of the 19th century. Using a targeted mitochondrial capture method and Ion Proton next-generation sequencing, we sequenced high coverage full genomes. Our bioinformatics pipeline and variant calling with the Torrent Variant Caller is identical to current best-practices approaches. Our results allow phylogenetic refinement of haplotypes A2b and D4b1a2a1a, and respective clade coalescence dates. Our archeological and genetic analyses of ancient Iñupiat from two Alaskan North Slope sites demonstrate continuity between prehistoric Neo-Eskimo Thule populations and extant Arctic populations. This research was supported by NSF grants OPP-0732846, OPP-0637246 to DHO'R, OPP-0820790 to JBC, and PLR-1460387, ARC-0726253 to AMJ. Permissions were granted from the Barrow Senior Advisory Council, the Ukpeagvik Iñupiat Corporation, the Native Village of Barrow, the local community of Kiana, and the National Park Service.

Mitochondrial DNA Haplogroup C Phylogeny for Altaian Populations and its Implications for the Peopling of Siberia and the Americas. *A. Askapuli[1,3], M. C. Dulik[1], S. I. Zhadanov[1,2], L. P. Osipova[2], T. G. Schurr[1].* 1) Department of Anthropology, University of Pennsylvania, Philadelphia, PA 19104-6398, USA; 2) Institute of Cytology and Genetics, SB RAS, Novosibirsk 630090, Russia; 3) Center for Life Sciences, NLA, Nazarbayev University, Astana 010000, Kazakhstan.

Characterization of mitochondrial DNA at a genomic level is very important since it provides opportunities for more accurately estimating the timing and directionality of prehistoric human migrations from a maternal perspective. The Altai Mountains are located at the geographic center of the Eurasian landmass, and have been a hotspot of human activities since ancient times due to itsgeographic location and rich natural resources. Aiming to contribute to a better understanding of the prehistoric human expansions in Siberia and subsequent colonization of the Americas, we sequenced and characterized eighteen whole mtDNA genomes belonging to haplogroup C from Altaian populations. The sequenced Altaian mtDNAs represent all four subgroups of haplogroup C (C1, C4, C5, and C7), and two of them belong to C1a, the Asian sister branch of Native American C1. The Altaian whole mitochondrial sequences were analyzed together with 313 previously published haplogroup C sequences from different parts of the world. The analyses of whole mitochondrial genomes reveal that haplogroup C lineages in Siberia are distributed without any specific association with geography or language, and suggest northeastern Siberia as a place of origin for haplogroup C and its subbranches C1, C4, C5, and C7. The analyses also indicate that Native American haplogroup C types are distantly related with their Siberian sister branches. Given the distribution pattern of haplogroup C in Eurasia, the timing of expansions could be inferred from the age estimates of the lineages within haplogroup C. Age estimation of haplogroup C sequences in our data set via χstatistics shows that haplogorup C has a TMRCA of 31. 25 kyr (24. 13-38. 56), and its subbranches C1, C4, C5, and C7 have TMRCAs of 21. 64 kyr (16. 83-26. 55), 24. 88 kyr (16. 65-33. 41), 19. 76 kyr (13. 63-26. 08), and 27. 2 kyr (16. 69-38. 17), respectively. Still, it is almost impossible to pinpoint geographic origin of Native Americans and directionality of prehistoric migrations in Siberia with certainty. Based on the results of the current study, the Amur region in northeastern Siberia could be the geographic origin for ancestral Native Americans. In order to obtain clearer picture of human population movements in Siberia and the Americas from a maternal perspective, more mitochondrial genomes need to be sequenced, especially mitochondrial genomes belonging to the relatively diverse haplogroups C and D.

Structured mating and its genetic consequences in the multi-ethnic Kaiser Permanente (KP) Genetic Epidemiology Research on Adult Health and Aging (GERA) cohort. *Y. Banda[1], T. Hoffmann[1,3], M. Kvale[1], L. Shen[2], D. Ranatunga[2], E. Jorgenson[2], P. Kwok[1], C. Schaefer[2], N. Risch[1,2,3].* 1) Institute Human Genetics, University California San Francisco, San Francisco, CA; 2) Kaiser Permanente Northern California Division of Research, Oakland, CA; 3) Department of Epidemiology and Biostatistics, University of California, San Francisco, CA.

Population stratification is influenced by patterns of racial/ethnic/national endogamy versus exogamy, as well as ancestry-related assortative mating within racial/ethnic groups. We analyzed mating patterns and genetic ancestry between and within the European, East Asian, Latino, African American, and South Asian participants in the KP GERA cohort of 103,000 subjects. Of 7892 total spouse pairs identified from electronic records, 6785 were concordant for race/ethnicity (87 African American, 321 East Asian, 6225 European, 150 Latino, 22 South Asian), while 1087 were discordant. According to random mating, 2066 discordant pairs were expected. The largest excess of concordant pairs occurred within South Asians and African Americans, followed by East Asians and Latinos. In the principal components analysis of genetic ancestry in the concordant pairs, within the Europeans, Ashkenazi subjects formed a separate cluster and induced a modest correlation in PC1 and PC2 between the spouses (0. 36, P<1e-16 for PC1 and 0. 17, P<1e-16 for PC2). After removing the Ashkenazi subjects, the correlation between spouses for PC1 and PC2 fell to 0. 18 (P<1e-16) and 0. 12 (P<1e-16), respectively. The first PC corresponds to a northwest-southeast European cline, and the second PC to a southwest-northeast cline. For the East Asian pairs we observed a correlation of 0. 35 (P<1e-16) in PC1 (representing European versus East Asian ancestry) and a correlation of 0. 77 (P<1e-16) in PC2 (representing a north-south cline in East Asia). The correlation in PC1 largely reflects Filipino spouse pairs, while the high correlation in PC2 reflects extensive endogamy among East Asian nationalities. Among Latinos, we observed spouse correlations of 0. 25 (P=0. 0021) and 0. 24 (P=0. 0038) for the first and second PCs, reflecting European and African versus Native American ancestry, respectively. These correlations reflect both concordance of nationality and ancestry related assortative mating. For the African Americans, the correlation in PC1 was 0. 32 (P=0. 0026), representing African versus European ancestry. Genetic consequences of structured mating observed in this cohort were apparent in that SNPs that loaded most heavily on PCs reflecting genetic ancestry exhibited both an excess of homozygosity and linkage disequilibrium. The very complex nature of structured mating we observed suggests a need for its careful consideration when designing and interpreting population-based genetic studies.

Native Americans present a remarkable case study in human evolution and population genetics. They belong to one of the few extant human groups whose ancestors entered a vast uninhabited area over a relatively short interval and then apparently remained relatively isolated from other human groups for a considerable period of time before European contact. Their substantial cultural diversity, linguistic complexity, and biological variation has been the subjects of a plethora of studies, whose level of sophistication has consistently grown over the past 40 years, but to date has not yet seen a final consensus among the disciplines involved. After all these years, this debate is still ongoing among scientists regarding major issues such as the number of migratory events, the source populations and arrival timing, and the likely entry routes into the Americas. Even the archaeological evidence is inconsistent as the dating of skeletal remains and Clovis lithic artifacts yielded values of 13-14,000 years before present (YBP), while other archeological studies reported sites with dating to more than 33,000 YBP. The overall picture is gradually emerging much clearer and detailed thanks to the contributions provided by human genetics and genomics studies. The first pieces were provided by analyses of the so-called "classical" genetic markers; subsequent findings came from the phylogenetic surveys of uniparentally transmitted genetic systems, in particular from mitochondrial DNA; then in the last few years, further valuable details were delivered by a new phase characterized by ancient DNA analyses.

Here, we present a comprehensive, diachronic and comparative picture of the mitogenome variation along the double continent. More than 1600 entire mitochondrial DNAs from modern samples (were gathered from literature and unpublished databases and compared with ca. 90 novel ancient pre-European contact mitogenomes (mostly from North America) in order to reconstruct the migratory path(s) of ancient native populations and to evaluate the differential demographic impact of post-European contact in South and North America.

1549W

The relative effective population size of chromosome X and the autosomes along distinct branches of the human population tree. *L. Arbiza, A. Keinan.* Biological Statistics and Computational Biology, Cornell University, Ithaca, NY.

In recent years, many studies have focused on the effective population size of chromosome X relative to the autosomes. This comparison can be useful to reveal past demographic processes, differences in the histories of males and females, and the action of natural selection. We have recently shown how the ratio of nucleotide diversity between the two (X-to-Autosome ratio; X/A), when compared between pairs of populations (relative X/A), can be used to uncover sex-biased processes in human history. While this strategy serves to alleviate the response of genetic diversity to the influence of events in a time range that largely predates the split of the studied populations, a different and more natural approach to capture recent changes occurring after populations split can be formulated based on the differentiation of allele frequencies between populations, as commonly summarized by the FST statistic. Here, we consider population differentiation in humans, and extend beyond simple pairwise comparisons, using allele frequency differences across several populations to learn about the ratio of X-to-autosomal effective population size along distinct branches in the tree of human populations. We then test these for differences from the expectation of equal female-to-male breeding ratios, as well as differences between different branches. Using coalescent simulations of a variety of previously published human demographic models, we show that our approach is able to capture the ratio of interest and is more accurate than estimates based only on pairwise FST across all pairs of populations. We then turn to the latest data from the 1000 Genomes Project, controlling for the effect of uncertainty associated with low coverage sequencing, as well as the influence of linked selection (background selection or hitchhiking), all of which differentially affect the X chromosome and the autosomes. Estimating the X-to-autosomal effective population size ratio for branches leading to different 1000 Genomes populations, as well as for internal branches in the population tree, points to a higher female effective population size in African-specific population history, but not in non-Africans. More interestingly, we localize previously-debated observations to a significant increase in male effective population size on the branch leading to all non-African populations, suggesting male-biased processes associated to the Out-of-Africa event.

1550T

Accurate non-parametric estimation of recent effective population size from segments of identity by descent. *S. R. Browning[1], B. L. Browning[2].* 1) Dept Biostatistics, Univ Washington, Seattle, WA; 2) Dept Medicine, Medical Genetics division, Univ Washington, Seattle, WA.

Existing methods for estimating historical effective population size from genetic data have been unable to accurately estimate effective population size during the most recent past. We present a non-parametric method for accurately estimating recent effective population size using inferred long segments of identity by descent (IBD). We find that inferred segments of IBD contain information about effective population size from around 4 generations ago to around 50 generations for SNP array data and to over 200 generations for sequence data. In human populations that we examine, the estimates of effective size are approximately one-third of the census size. We estimate the effective population size of European-ancestry individuals in the UK 4 generations ago to be 8 million and the effective population size of Finland 4 generations ago to be 0. 7 million. Our method is implemented in the open-source IBDNe software package.

1551W

Past demography revealed from rare variants with population specific F_{ST} values. *J. Goudet[1,3], B. S. Weir[2].* 1) Department of Ecology and Evolution, Biophore, University of Lausanne, Lausanne, Vaud, Switzerland; 2) Department of Biostatistics, University of Washington, Seattle, WA; 3) SIB-Swiss Institute of Bioinformatics, Unil-Sorge, Lausanne, Vaud, Switzerland.

Statement of PurposeUnderstanding the past demography of humans is essential in many areas of human genetics, in particular because many demographic processes leave genomic signatures identical to those that can be left by selection. Computer intensive methods such as approximate Bayesian computation of exact likelihoods have been proposed to this end, but they have difficulty with the magnitude of current data. Instead, we propose the use of population specific FST values, and show that, in conjunction with the frequencies of derived alleles, these measures allow the recovery of several aspects of the past demography. Methods usedWe estimate population specific FST from the proportion of pairs of alleles within a population that are identical in state (ibs) relative to the unweighted proportion of ibs pairs of alleles between all pairs of populations within a study. For SNPs, we show the parametric form of population-specific FST as a function of the derived allele frequencies under classical models of population structure and we use computer simulation to verify our predictions. We use 1000 Genome Phase 3 data for African and South Asian samples to illustrate how the past demography can be recovered. Summary of resultsWe show, both in simulations and with 1000 genomes data, that population specific FST as a function of the derived allele frequencies shows the signature of past demographic events: a past population split such as South Asian splitting from African, followed by population expansion results in strongly negative FST for Africa, for SNPs with a low frequency of derived alleles, mirrored by strongly positive values for Asia. The negative FST values for rare variants reflects the lower matching across alleles within the African sample than between the African and South Asian samples, and this signal is missed by the usual population average FST. The following demographic estimates result: assuming an effective population size for Africa of 10,000 individuals, dispersal of 1,780 individuals out of Africa occurred 44,000 years ago (25 years/ generation); South Asia grew to 10,900 individuals 4,700 years ago, and Africa and South Asia kept exchanging seven migrants per generation during this time. These estimates, while in broad agreement with those already published, point to a more recent expansion from Africa.

1552T

Historical mating patterns in the U. S. revealed through admixture and IBD patterns from genome-wide data from over 800,000 individuals. *J. M. Granka[1], Y. Wang[1], E. Han[1], J. K. Byrnes[1], A. Kermany[1], R. E. Curtis[2], P. Carbonetto[1], K. Noto[1], M. J. Barber[1], N. M. Myres[2], C. A. Ball[1], K. G. Chahine[2].* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Provo, UT.

Within a diverse population like the United States, many individuals are admixed, with ancestry from many worldwide regions. Non-random mating and migration can result in non-random combinations of ancestries within admixed individuals (i. e. , certain sets of ancestries may be common, and others may be rare); such dynamics can also affect patterns of identity-by-descent (IBD) among admixed and non-admixed individuals. To shed insight into historical mating and migration, we study genome-wide genotype data of over 800,000 AncestryDNA customers, as well as a subset of over 400,000 born in the US. First, we use a supervised algorithm to estimate individuals' genetic admixture proportions across 26 global regions. We measure correlations between the estimated ancestries, and find certain sets of ancestries to frequently co-occur in individuals' estimates. Such relationships may reflect historical events; e. g. , the association between ancestry from the Americas and the Iberian Peninsula could reflect Colonial Era admixture. In addition to historical mating patterns, however, the admixture inference procedure and the delineation of global regions could also impact such correlations. To disentangle whether these trends could reflect mating patterns and preferences, we examine associations between the estimated ancestries of the parents of over 10,000 trios. Observed correlations agree with many of those identified within individuals, and potentially reflect more recent historical trends. Thirdly, we extend our study to IBD patterns in an inferred IBD network among genotyped individuals. Sub-clusters of the IBD network, which can often be annotated by ethnicity or historical US migration, are often inter-connected by bridging IBD connections; we highlight several connected sub-clusters in light of findings from genetic ancestry. Finally, we corroborate findings from these three analyses, as well as their potential timescales, by examining over 500,000 AncestryDNA customer pedigrees. Associations of country-level birth locations between pairs of couples support many of the non-random associations of ethnicities and IBD connections identified using genetic data. Many of the associations we observe reflect historical phenomena, and while not conclusive about their cause, suggest that many individuals with admixed ancestry, including those in the US, have present-day genetic signatures reflecting the migration and subsequent non-random mating of their ancestors.

1553W

Discovery of a previously unknown ancestral origin of the modern Taiwanese population that is distinct from the north-south gradient seen in other Han Chinese populations using the Taiwan Biobank. *C. W. Lin[1,2], C. H. CHEN[1,2,3,4], J. H. YANG[3], P. E. WU[1,2], C. N. HSIUNG[1,2], L. C. CHANG[3], J. CHANG[2], I. W. SONG[2], S. L. YANG[2], F. T. LIU[1,2], C. Y. SHEN[1,2,5].* 1) Taiwan Biobank, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) National Center for Genome Medicine, Academia Sinica, Taipei, Taiwan; 4) School of Chinese Medicine, China Medical University, Taichung, Taiwan; 5) College of Public Health, China Medical University, Taichung, Taiwan.

The aim of the Taiwan BioBank is to build a nationwide biomedical research database that integrates genomic profiles, lifestyle patterns, dietary habits, environmental exposure histories, and long-term health outcomes of 300,000 Taiwanese residents (representing almost 1. 5% of the Taiwanese population). We describe here results from 8265 samples that were genotyped using the Taiwan BioBank array, which was specifically designed for the Taiwanese population. After data quality control, genotype data for 589,016 single-nucleotide polymorphisms (SNPs) in 7203 unrelated individuals were denoted as TWB7203 and further analyzed. The 7203 individuals were clustered into three cline subgroups: 4. 5% were of northern Han Chinese ancestry, 77. 6% were of southern Han Chinese ancestry, and 17. 8% were an admixture of Han Chinese and a previously unknown ethnic group. This unknown group was genetically distinct from neighboring southeast Asian groups and Austronesian tribes, but was similar to the southern Han Chinese. Long-range linkage disequilibrium and flips of major alleles at about 400 SNPs across the major histocompatibility complex region suggested that the previously unknown group may have experienced evolutionary events different from those of the other southern Han Chinese. The difference was further supported by the unique pattern of body figures measures of this unknown group. Genome-wide summary statistics for the ethnic subgroups of TWB7203 were released through a publicly accessible web-based calculation platform, Taiwan View (http://taiwanview. twbiobank. org. tw/taiwanview/twbinfo. do), on which genome-wide association analyses can be performed using TWB7203 as the reference. The release of this large-scale population-level and subpopulation-level genomic information will greatly benefit human genetic research.

1554T

Estimation of growth rates for populations and haplogroups using full Y chromosome sequences. *F. L. Mendez, G. D. Poznik, C. D. Bustamante, 1000 Genomes Project Consortium.* Department of Genetics, Stanford University, Stanford, CA.

Evolutionary processes affecting a population influence gene genealogies across the genome. Coalescent theory provides the mathematical framework to connect realized genealogies to the underlying evolutionary processes. However, in most cases, information about the genealogies is obtained only indirectly through the observation of genetic variation. Therefore, in general, very limited information about any individual locus is available. As the longest non-recombining portion of the human genome, the Y chromosome accumulates mutations relatively quickly. When large amounts of sequence are used, the Y chromosome provides an unparalleled ability to resolve the structure and coalescence times of its genealogy. Because patterns of variation in the Y chromosome are only influenced by processes affecting men, they can be used to study both demographic and social phenomena. The 1000 Genomes Project includes whole Y-chromosome data from more than 1000 men and has an extensive representation of most lineages that have experienced recent massive expansions in size. Though the dynamics of population growth have likely changed over time, we are more interested in the growth rates at the times of these rapid expansions than on an average effect. To study this, we have developed a new method that takes advantage of the temporal resolution provided by Y-chromosome data and of historical data, while accounting for the uncertainties associated with the coalescent and mutational processes. We estimate the growth rates for several branches of the Y-chromosome tree, including those in Europe, sub-Saharan Africa and South Asia. We estimate that several lineages within the European R1b, sub-Saharan African E1b, and South Asian R1a haplogroups experienced growth rates of at least 20-60% per generation at the onset of their massive expansions, some 3-5 thousand years ago. These high growth rates are comparable to those experienced by human populations during the 20th century. However, we find that most observed genealogies are unlikely to be the result of whole population expansion or of natural selection.

1555W

Bayesian Nonparametric Inference of Population Size Changes from Sequential Genealogies. *J. Palacios[1,2,3], J. Wakeley[1], S. Ramachandran[2,3].* 1) Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Ecology and Evolutionary Biology, Brown University, Providence, RI; 3) Center for Computational Molecular Biology, Brown University, Providence, RI.

Sophisticated inferential tools coupled with the coalescent model have recently emerged for estimating past population sizes from genomic data. Accurate methods are available for data from a single locus or from independent loci. Recent methods that model recombination require small sample sizes, make constraining assumptions about population size changes, and do not report measures of uncertainty for estimates. Here, we develop a Gaussian process-based Bayesian nonparametric method coupled with a sequentially Markov coalescent model which allows accurate inference of population sizes over time from a set of genealogies. In contrast to current methods, our approach considers a broad class of recombination events, including those that do not change local genealogies and uses all sufficient statistics needed to estimate population size changes over time. First, we show that under the sequentially Markov coalescent model, the set of local Tajima's genealogies consisting of ranked tree shapes and coalescent times, are sufficient statistics for inferring the population size trajectory. Second, we show that our method outperforms recent likelihood-based methods that rely on discretization of the parameter space. We illustrate the application of our method to multiple demographic histories, including population bottlenecks and exponential growth. In simulation, our Bayesian approach produces point estimates four times more accurate than maximum likelihood estimation (based on the sum of absolute differences between the truth and the estimated values). Further, our method's credible intervals for population size as a function of time cover 90 percent of true values across multiple demographic scenarios, enabling formal hypothesis testing about population size differences over time. Using genealogies estimated with ARGweaver, we apply our method to European and Yoruban samples from the 1000 Genomes Project and confirm key known aspects of population size history over the past 150,000 years.

1556T

Modeling SNP array ascertainment with Approximate Bayesian Computation to improve demographic inference. *C. Quinto[1], A. Woerner[1], K. Veeramah[2], M. Hammer[3].* 1) Genetics GIDP, University of Arizona, Tucson, AZ; 2) Department of Ecology and Evolution, Stony Brook University, Stony Brook, NY; 3) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tucson, AZ.

Single nucleotide polymorphisms (SNPs) in commercial genotyping arrays have often been discovered by sampling a small number of chromosomes from a group of selected populations. This form of non-random ascertainment skews patterns of nucleotide diversity, and can affect population genetic inferences. In addition, the effect of ascertainment bias is particularly strong when the populations of interest are genetically distinct from the ascertainment panel. Although different methods have been proposed to take into account this bias, the challenge remains because the exact discovery protocols are not known for most of the commercial arrays.

In this work, we propose a demographic inference pipeline that explicitly models the SNP discovery protocol in an Approximate Bayesian Computation (ABC) framework. We simulate genomic regions according to a demographic model that includes Yoruba, Han Chinese and European individuals, and recreate the SNP distribution of a commercial chip (Affymetrix Axiom Genome-Wide Human Array) by varying the number of sampled chromosomes and the allele frequency cut-off in the given regions. We then calculate site frequency spectrum and haplotype based summary statistics obtained from both the ascertained and genomic data and infer the ascertainment and demographic parameters of the model using ABC. To validate this method, we simulate summary statistics with known parameter values and treat them as observed data. We are able to successfully recover the true parameter values from the simulations in the 95% High Posterior Density Interval. Finally, as proof of concept, we implement our pipeline to study a real example of admixture, likely affected by ascertainment bias. We model the admixture process in the Mexican population, replicating the SNP distribution given by the inferred ascertainment protocol. Ancestry blocks are identified in admixed whole genomes and its distribution is used to estimate the time and proportion of admixture in an ABC analysis. Our inference framework is applicable to studies when only SNP chip data of the populations of interest are available and will improve to accuracy of the demographic model inference.

1557W

Selective constraint and sex-biased demography of human populations from X chromosome-autosome comparisons. *M. H. Quiver[1], J. Lachance[1], K. Mullen[2], M. E. B. Hansen[2], M. A. Chen[2], P. H. Hsieh[3], K. R. Veeramah[4], S. A. Tishkoff[2].* 1) School of Biology, Georgia Institute of Technology, Atlanta, GA; 2) Departments of Biology and Genetics, University of Pennsylvania, Philadelphia, PA; 3) Department of Molecular and Cell Biology, University of Arizona, Tucson, AZ; 4) Department of Ecology and Evolution, Stony Brook University, Stony Brook, NY.

Because the number of X chromosomes differs for men and women, comparisons between sex-linked and autosomal genetic loci reveal sex-biased patterns of human demography. Using 44 high-coverage whole genomes from a diverse global set of 11 human populations we quantified the strength of selective constraint on different chromosomes, found evidence of sex-biased colonization, and determined whether recent migrations are matrilocal or patrilocal. Relative amounts of genic and intergenic diversity were similar across all studied populations regardless of subsistence pattern or geography. The strength of selective constraint on genes was greater for X-linked loci compared to autosomal loci - a pattern that is consistent with selection against deleterious recessive alleles. The ratio of X chromosome to autosome diversity (Q) was greater than the null expectation of 0. 75 for African populations and less than 0. 75 for non-African populations, with lower values of Q for populations located farther from Africa. This pattern is consistent with a male-biased serial founder effect model, and computer simulations suggest a plausible out-of-Africa bottleneck size of 320-340 males and 60-70 females. Using PSMC, we found evidence of large historic population sizes for West African Pygmies, but not Hadza or Sandawe populations. Genetic distances revealed female-biased gene flow between Hadza and Sandawe hunter-gatherers, between Maasai pastoralists and African farmers, and between Chinese and Japanese populations. We found evidence of male-biased gene flow between African farmers and hunter-gatherers, and between different African farmer populations. This calls into question the idea that patrilocality is coupled with the emergence of agriculture.

1558T

Genetic, Geographic and Cultural Reconstruction of an Ancient Endogamous Community. *D. K. Sanghera[1], A. Raina[2], C. E. Aston[1], D. D. Mascarenhas[3].* 1) Pediatrics, University of Oklahoma HSC, Oklahoma City, OK ,USA; 2) All India Institute of Medical Sciences, New Delhi, India; 3) Mayflower Organization for Research and Education, Sunnyvale, CA, USA.

The provenance of a rare R1a1 Y-haplogroup (Y-HG) subtype designated as 657A lies in proximity to anancient migration route running through Afghanistan but is largely absent from other geographic locations. A clan of 657A Brahmin “founder” family lineages within the Goud Saraswat community (GSB) in a town in Western India wasidentified in which 15 of 16 males from nine families were R1a1 Y-HG, including 10 who were 657A. TMRCAcalculations using pairwise comparisons to control cohorts suggested a probable migration history for this priestlysubgroup. To support this genetic narrative we present archeological, toponymic, numismatic, linguistic,iconographic, architectural, sociological and literary data. Specifically, in this study we test two main hypothesesregarding these 657A families: (1) Using Y-HG centroid analysis, chi-square analysis of TMRCA distributions andarcheological find-spots, and discriminant function analysis we show that the parental Z93 L342. 2 sub-clade in which657A occurs originated in West Asia and that 657A individuals migrated toward the southeast by a Bolan Pass routedistinct from the traditionally presumed route of “Vedic” ingress into the Indian subcontinent; and (2) Priestly 657Alineages in Western India retain distinct family practices with respect to literacy, religious practice and migration notshared by other more orthodox Brahmins of canonical geographic origin within the same community, despiteintermarriage. Long-term transmission of differentiated family practices within a single patrilineal endogamouscommunity has rarely been documented.

1559W

Unique autosomal STR heterogeneity among three traditional populations from historical Tibet. *T. Tsering[1], T. Gayden[2], S. Chennakrishnaiah[3], A. Bukhari[4], R. Herrera[5].* 1) Tata Institute of Fundamental Research, Mumbai, India, 400 005; 2) Department of Human Genetics, McGill University, Montreal, Canada; 3) Department of Experimental Medicine, McGill University, Montreal, Quebec, Canada; 4) College of Medicine, Florida International University, Miami, Florida, USA 33199; 5) Department of Molecular Biology, Colorado College, Colorado Springs, Colorado, USA.

Reaching an average altitude of more than 4000 meters above sea level, the Tibetan plateau is the highest and largest highland on the planet and is rightly called the ‘roof of the world’. It is bordered on three sides by huge cordilleras: the Kunlun, the Karakoram and the Himalayas. These three massifs along with high elevation have kept Tibet relatively isolated throughout its long history and prehistory. However, given its strategic location in Eurasia, the region also served as a corridor for human migrations, including the ancient Silk Road. While several studies on Tibetan populations have been previously reported, none of them have comprehensively characterized the genetic population structures of the three major culturally defined regions of historical Tibet: Amdo, Kham and U-Tsang. Thus, in this study, we genotyped 15 highly polymorphic autosomal STR loci using the AmpFLSTR Identifiler System in 338 unrelated individuals from Amdo (86), Kham (101) and U-Tsang (151). All of the analyzed loci were in agreement with Hardy-Weinberg equilibrium expectations, with the exception of the locus D19S433 in the Kham province. FGA is the most informative marker with the highest observed heterozygosity and gene diversity values across the three Tibetan populations. Conversely, TH01 is the least variable locus displaying the lowest values for the same two parameters. In addition, FGA displays four 2 bp microvariant alleles (20. 2, 21. 2, 22. 2 and 25. 2) that are distributed between U-Tsang and Kham populations but are completely absent in the Amdo people. U-Tsang displays the highest total numbers of alleles (139) trailed by Kham (130) and Amdo (128) groups. The allele frequency data from this study were compared to relevant global reference populations. Our results suggest that although these three Tibetan groups segregate within the cluster of the Himalayan populations in both the Correspondence Analysis (CA) plot and the Neighbor Joining (NJ) tree, they exhibit some degree of genetic differentiation among themselves. The genetic uniqueness of the three historically Tibetan populations is congruent with their characteristic dialect, culture and tradition. In conclusion, the 15 autosomal STR loci examined provides a significant dataset for forensic applications, parentage testing and population genetic studies.

Geographic patterns of Identify-by-descent recapitulate fine-scale migration history of the African Americans. *Y. Wang, M. Barber, J. Byrnes, P. Carbonetto, R. Curtis, J. Granka, E. Han, A. Kermany, N. Myres, K. Noto, C. Ball, K. Chahine.* Ancestry. com, San Francisco, CA.

African Americans constitute the third largest ethnic group in the United States. The population structure and migration history of this group has drawn great interest. Recently, Simon Gravel (Gravel et al. , ASHG 2014) presented a population genetics study using 6,000 genotyped African American samples, in which he and colleagues identified signature of recent south-to-north migrations, possibly due to an event known as The Great Migration. Unfortunately the signal they found was only marginally significant, likely due to a limited sample set size. Here we present a large-scale study of the African American migration history, using genotyping data from over 770,000 consenting AncestryDNA customers. First we predict the genetic ancestry of all samples using ADMIXTURE (Alexander*et al. ,*2009) with a high-quality reference panel of 3,000 samples. We select samples with estimates of more than 50% sub-Sahara African ancestry for further analysis. This leads to a subset of over 50,000 African Americans representing all 50 U. S. states. In a similar approach, we also select more than 600,000 samples with estimates of over 90% European ancestry. Examining the identity-by-descent (IBD) patterns among these African American individuals, as well as self-reported birth locations, we identify a clear south-to-north migration pattern, distinct from the east-to-west pattern present in individuals with primarily European ancestry. Furthermore, our analysis reveals three distinct migration routes by which African Americans left the South. The first route goes along the Atlantic coast from South Carolina to Pennsylvania and New England. The second route starts from Alabama and Mississippi and disperses into the Great Lakes region. And the last route extends from Louisiana and Texas to the west. These routes agree with historical records revealing three separate migratory patterns during the Great Migration. In contrast, we observe different patterns when we look at IBD shared between African Americans and European Americans. We find that African Americans tend to share more IBD with European Americans born in states, such as South Carolina, Georgia, Virginia and Louisiana, where the major transatlantic slave trade ports were located. Our results suggest a large part of the European-African admixture dates back long before the Great Migration.

Siberia and Western Russia are home to some of the least studied ethnic groups in the world, and their genetic history holds keys to understanding peopling of the world. We present whole-genome sequencing data from 28 individuals belonging to 14 distinct indigenous populations from that region. We used these datasets together with an additional 32 modern-day and 15 ancient human genomes to build and compare autosomal, Y-DNA and mtDNA trees and delineate genetic history. Our analyses uncover complex migratory processes that shaped the genetic landscapes in Asia and Europe. Admixture events between ancient Siberian groups resulted in distinct ancestries of nowadays Western and Eastern Siberians. Western Siberians share genetic affinity with modern Europeans. Both can trace their ancestry to the lineage of a 24,000-year-old Siberian Mal'ta boy. For Eastern Siberians, they have much weaker genetic affinity with Europeans and their ancestor separated from East Asians much later (approximately 10,000 years ago). Major migration wave from Eastern Siberians into Western Siberian groups occurred approximately 7,000 years ago, and it extended into Northeastern Europe. This is based on the admixtures we observed between Siberians and lineages represented by the 5,000-year-old hunter-gatherer Ire8 from Pitted Ware Culture excavated in Sweden, the 2,900-year-old Iron age Hungarian IR1 from the Mezocsat Culture, and modern-day northeastern Europeans. Our whole-genome data based on a broad sample of populations in Siberia and Western Russia provides new insights at a high-resolution into the genetic history of Eurasians.

1562T

Ages of mitochondrial DNA lineages coincides with the agriculture spread in Finland. *S. Översti[1], P. Onkamo[1], J. Palo[2].* 1) Department of Biosciences, PO Box 56 (Viikinkaari 5) FI-00014 University of Helsinki, FINLAND; 2) Laboratory of Forensic Biology, Department of Forensic Medicine, Hjelt Institute, PO Box 40 (Kytösuontie 11) FI-00014 University of Helsinki, FINLAND.

The current inhabitants of Finland in the Northeastern Europe are quite unique in terms of their genetic composition. Based on Y chromosomal and genome wide studies Finns differ from other European populations: especially the Y chromosomal diversity is reduced and distinctive. In contrast, Finnish mitochondrial DNA (mtDNA) haplogroup distribution is similar to other European populations. Mitochondrial genepool in modern Europeans is a mixture of Mesolithic hunter-gatherer associated haplogroups (U and V) and Neolithic associated farmer haplogroups (H, J, K and T). The frequency of hunter-associated haplogroup U in Finland is one of the highest in Western Eurasia. Also, it is more common in Eastern and Northern parts of the country while farmer haplogroups are more frequent in Southern and Western Finland. In this study we compiled a comprehensive data set of 833 modern Finnish complete mtDNA sequences from the public databases and utilized coalescent based Bayesian phylogenetic inference (BEAST v. 1. 8. 1) to perform fine resolution phylogenetic analyses on the sequences. We also exploited previously published radiocarbon dated ancient complete mtDNA sequences from Western Eurasia in our analysis as calibration points to the phylogenetic trees, enhancing their accuracy. Our results demonstrate that among Finns, many typically “European” haplogroups, both hunter-gatherer and farmer associated, actually comprise lineages specific for Finns. Several of these lineages, despite being rather common in present Finnish population, are virtually absent from other populations. Oldest of these haplogroups date back over 7,000 years, though most appear to be around 3,000-5,000 years old. This period temporally coincidences with the arrival and especially the spreading of the agriculture and Corded Ware culture in Finland. Age estimates are also concurrent with the arrival of another culture, the textile ceramics, into Finland from Volga region (main period of textile ceramics lies between 1,700-1,000 BC). According to these results there is distinct evidence that arrival of these cultural entities also influenced Finnish mitochondrial DNA pool and this impact is still visible in modern day Finns.

Fine scale population structure of Spain and the genetic impact of historical invasions and migrations. *C. Bycroft[1], C. Fernandez-Rozadilla[1,2], A. Carracedo[2], C. Ruiz-Ponte[2], I. Quintela-García[3], P. Donnelly[1,4], S. Myers[1,4].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford; 2) Galician Public Foundation of Genomic Medicine (FPG-MX)-Grupo de Medicina Xenómica-Centro de Investigación BioMédica en Red de Enfermedades Raras (CIBERer)-Universiy of Santiago de Compostela, Spain; 3) Grupo de Medicina Xenomica, Universidade de Santiago de Compostela, Centro Nacional de Genotipado - Plataforma de Recursos Biomoleculares y Bioinformaticos - Instituto de Salud Carlos III (CeGen-PRB2-ISCIII); 4) Department of Statistics, University of Oxford, 1 South Parks Road, Oxford, OX1 3TG, UK.

As well as being linguistically and culturally diverse, the Iberian Peninsula is unusual among European regions in that its demographic history includes a prolonged and large-scale occupation by people of predominately north-west African origin. Therefore, the Iberian Peninsula provides a unique opportunity for studying fine-scale population structure and admixture, and to test cutting-edge methods of detecting complex or subtle population genetic patterns. Previous studies using Y-chromosome, mtDNA as well as autosomal data have detected limited genetic structure in Iberia. However, powerful new methods and larger datasets mean it has recently become possible to detect and characterise genetic differentiation at a sub-national level. We performed the largest and most comprehensive study of Spanish population structure to date by analysing a dataset of ~1,400 Spanish individuals typed at ~700,000 SNPs. Using the fineSTRUCTURE method we detected striking and rich patterns of population differentiation within Spain, at scales down to tens of kilometres. Strikingly, the major axis of genetic differentiation in Spain runs from west to east, while conversely there is remarkable genetic similarity in the north-south direction. To infer details of historical population movements into Spain, we analysed Spain alongside a sample of ~6,000 individuals from Europe, North Africa, and sub-Saharan Africa. Across Spanish groups, we identify varying genetic contributions from north-west African ancestral populations, at times that all fall within the period of Islamic occupation. We also identify Basque-like admixture within Spanish groups to the south of the Basque-speaking region, implying southerly gene flow from this region. This analysis has revealed details of the strengths and weaknesses of different approaches to investigating population genetic history, as well as providing important new insights into the complex genetic history of Spain.

Polygenic Adaptation Regression Analysis. *Y. Field[1,2], N. Telis[3], E. A. Boyle[1,4], D. Golan[1,5], J. K. Pritchard[1,2,6].* 1) Genetics, Stanford University; 2) Howard Hughes Medical Institute; 3) Biomedical Informatics, Stanford University; 4) Stanford School of Medicine; 5) Statistics, Stanford University; 6) Biology, Stanford University.

Understanding how natural selection had shaped the existing genetic variation within humans is a major goal in population genetics. With the growing understanding that many human diseases and complex traits have a polygenic genetic architecture, it has been hypothesized that adaptation in recent human history might be largely polygenic as well. The increased frequency of many alleles associated with genetic basis for tall stature in northern Europe, has been the major supporting example for the polygenic adaptation model. However, beyond this outstanding example, the nature and extent of polygenic adaptation in recent human history is still poorly understood. Current methods for testing for polygenic adaptation, based on allele frequency differences between populations, do not account for the linkage disequilibrium between loci. In turn, there is no general framework available for testing for adaptation over one set of functionally related loci, while controlling for possible causal effects (on allele frequency differences) by other genetically-linked genomic features. For example, one would like to test for adaptation among known GWAS hits, controlling for the selection for height; or to test for selection within regulatory regions, controlling for possible selection on non-synonymous sites; or to control for admixture effects on allele frequency differences, etc. To address this need, we have developed POLARIS, a novel and general method for POLygenic Adaptation Regression analysIS. Our method is based on a multivariate normal model for the frequency differences between populations, which is structured to explicitly represent linkage disequilibrium, drift and annotation-dependent polygenic adaptation. The method allows to test, and control, for annotation-dependent effects on both the mean and variance of allele frequency difference, giving it a great flexibility to mix directed and undirected hypotheses. As we demonstrate with an initial analysis of publically available datasets, POLARIS opens the road for a richer and more extensive characterization of the nature and extent of polygenic adaptation in recent human history.

1565W

Patterns of IBD (identity-by-descent) sharing among 780,000 present-day Americans reveal geography and recent settlement history in the United States. *E. Han[1], R. E. Curtis[1], M. J. Barber[1], J. K. Byrnes[1], P. Carbonetto[1], J. M. Granka[1], A. R. Kermany[1], N. M. Natalie[1], K. Noto[1], Y. Wang[1], E. R. Battat[2], C. A. Ball[1], K. G. Chahine[1].* 1) AncestryDNA, San Francisco, CA; 2) History and Literature, Harvard University, Cambridge, MA.

The United States is often thought of as a new homogeneous population formed by mixture of different nationalities, ethnicities, and cultures. However, recent research shows that there is a distinct geographic distribution for ethnicity and isolation-by-distance models hold in the United States. We take over 780,000 genotyped individuals from the United States and identify over 600,000,000 segments of identity-by-descent (IBD). We recursively run the *Louvain community detection* method on the resulting IBD network (vertices are individuals and weighted edges are IBD connections among them). Finally, we annotate the network vertices with information from the corresponding individuals' pedigree data, which include the surnames, birth dates and locations of ancestors dating back hundreds of years. The result is a striking set of genetic clusters that reveal migrations and settlements over time, show the movement of groups within the United States, and identify groups of people connected to each other through ethnicity or culture. We are able to identify Asian, Jewish, and Latin American clusters spread over the Americas. We detect French Americans in Maine and Louisiana, Scandinavian Americans in Midwest, Irish and Italian American in urban areas, German Americans in Pennsylvania and Ohio, and English Americans in Northeast. We detect a Mormon migration to Utah and an Amish group in Pennsylvania. We identify more geographically isolated populations in the Cumberland Mountains. In the south, we identify African Americans and agricultural populations. Often, the groups we identify are associated with known migrations, and their movements are associated with known history of economic changes in various parts of the United States. For example, a large wave of German immigrants are known to have settled in Pennsylvania before 1780-1810, and tended not to move once they settled there. We detect not one but three distinct subgroups that settled in slightly different parts of Pennsylvania. We can trace their ancestry from different parts of Germany and Switzerland at that time and confirm it through aggregating estimates of their ancestry based on their genomes and common surnames found in their pedigrees. In summary, our analysis provides a significant insight into population structure in the United States which still remains distinct enough to identify only using patterns of IBD sharing among present-day Americans.

1566T

Identity by descent analysis reveals fine-scale population structure in Crete. *A. M. Plantinga[1], F. Tsetsos[2], P. Paschou[2], P. Drineas[3], B. L. Browning[1,4], G. Stamatoyannopoulos[5].* 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Molecular Biology and Genetics, Democritus University of Thrace, 68100 Alexandroupolis, Greece; 3) Department of Computer Science, Rensselaer Polytechnic Institute, Troy, NY; 4) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 5) Departments of Medicine and Genome Sciences, University of Washington, Seattle, WA.

The island of Crete is 160 miles long and 37 miles at its widest point. Despite its small area, Crete contains populations that historically have been relatively isolated due to Crete's mountainous topography. We hypothesized that this isolation would create detectable fine-scale population structure across Crete. To study this structure, SNP array data was collected for 129 subjects sampled from 17 regions of Crete. All individuals were at least 70 years old at the time of sampling and reported having maternal and paternal grandparents from the same region as the subject. We show that identity by descent (IBD) analysis, which detects chromosomal segments that are shared between individuals due to inheritance from recent common ancestors, reveals fine-scale regional relationships that are consistent with the geography and history of Crete. For instance, the amount of genetic material shared IBD between two populations decreases both with separation by mountains or other natural barriers and with increasing east-west distance. Expansion of the IBD analysis to include samples from other parts of Greece reveals close relationships between samples from West Crete and samples from the Peloponnese, which is northwest of Crete, and similarly close relationships between samples from East Crete and samples from the Dodecanese, which are northeast of Crete. These results indicate that IBD is a powerful way to detect genetic relationships between populations on a fine geographic scale.

1567W

The fine-scale genetic structure of the Japanese population: estimation of genetic materials derived from Asians and the basis of genetic differentiation. *F. Takeuchi[1], T. Katsuya[2], R. Kimura[3], T. Nabika[4], T. Ohkubo[5], Y. Tabara[6], K. Yamamoto[7], M. Yokota[8], WH. Saw[9], YY. Teo[9], N. Kato[1].* 1) Dept of Gene Diagnostics and Therapeutics, National Center for Global Health and Medicine, Tokyo, Japan; 2) Dept of Clinical Gene Therapy, Osaka University Graduate School of Medicine, Suita, Japan; 3) Department of Human Biology and Anatomy, Graduate School of Medicine, University of the Ryukyus, Nishihara-cho, Japan; 4) Department of Functional Pathology, Shimane University School of Medicine, Izumo, Japan; 5) Department of Hygiene and Public Health, Teikyo University School of Medicine, Tokyo, Japan; 6) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan; 7) Department of Medical Chemistry, Kurume University School of Medicine, Kurume, Japan; 8) Department of Genome Science, School of Dentistry, Aichi Gakuin University, Nagoya, Japan; 9) Saw Swee Hock School of Public Health, National University of Singapore, Singapore.

BackgroundJapan has often been viewed as a genetically homogenous country among Asians. Based on archaeological evidence, it is suggested that a modern Japanese population was formed by admixture of the Jomon and Yayoi peoples around 3000 years ago, yet genetic data supporting this is limited. In the recent methodological transition from GWAS to genome-wide sequencing, knowledge about the fine-scale genetic structure of Japanese is important as a signature of historical demographic events to avoid its potential for confounding disease association studies. **Methods**For 1,600 individuals comprising 200 each from eight geographical regions in Japan (seven regions in or close to the mainland of Japan plus Okinawa), we performed SNP genotyping with GWAS arrays and applied the fineSTRUCTURE algorithm that could capture fine-scale population structure based on haplotype coancestry to compute genetic clusters in the Japanese populations. Then, we estimated the ancestry of Japanese by referring to genome-wide SNP data for 25 Asian (non-Japanese) populations derived from the Asian Diversity Project. Moreover, we examined whether genetic differentiation between the regional clusters of Japanese could result from genetic drift or positive selection. **Results**We found that the genetic clusters computed solely based on SNP data could distinguish the eight geographical regions in Japan; and that the ancestry of Japanese was a mixture of Korean, Chinese and Southeast Asian populations, while the composition of three ancestries differed modestly between the regional clusters. Genetic diversity was most prominent between the Okinawa population and any of the mainland Japanese populations, in accordance with previous studies. Geographical genetic differences, although relatively weak in signal, were detectable across the chromosomes, and in a few instances they appeared to be under some positive selection. **Conclusion**Our data show that the fineSTRUCTURE algorithm allows for capturing fine-scale population structure among seven regions in or close to the mainland of Japan, which have not been distinguishable in previous studies using principal component analysis. The mainland Japanese populations are grouped into two super-clusters in addition to individual regional clusters. However, such geographical genetic differentiation is found to principally result from genetic drift and it may not appreciably confound disease association studies involving the mainland Japanese populations.

1568T

Recent polygenic adaptation in Europe. *N. Telis[1], E. A. Boyle[2,5], Y. Field[3,4], J. K. Pritchard[3,2,4].* 1) Biomedical Informatics, Stanford University; 2) Biology, Stanford University; 3) Genetics, Stanford University; 4) Howard Hughes Medical Institute; 5) Stanford School of Medicine.

Adaptive evolution in recent human history remains poorly characterized. Human population genetics has focused on strong selective sweeps. However, our understanding of other selective patterns and their effects on patterns of human genetic diversity is still limited. Although there is compelling evidence for recent selection pushing increased height in northern Europe, the literature is devoid of other strong notable examples of recent polygenic selective events. We develop a non-comparative scoring method for individual polymorphisms to detect signals of recent adaptation, based on using singleton density to approximate haplotype age. Simulations suggest that this method preferentially detects recent evolutionary events with several different sweep patterns. We apply this method to 1,600 individuals from the ALSPAC cohort and confirm known selection signals in Northern Europeans, as well as broader signals of polygenic selection. We investigate associations with these signals and demonstrate that these signals are robust to population allele frequency differences in Europeans. We use this method in combination with population allele frequency differences to identify novel signals of polygenic adaptation in modern Europeans.

1569W

Insights on modern human migration and rare variation spread using ten of millions of genealogical profiles. *M. Wahl[1], J. Kaplanis[2], A. Gordon[3], Y. Erlich[3, 4].* 1) Molecular and Cellular Biology, Harvard University, Cambridge, MA; 2) Whitehead Institute for Biomedical Research, Cambridge, MA; 3) New York Genome Center, New York, NY; 4) Department of Computer Science, Columbia University, New York, NY.

Investigation of recent human migration patterns via genealogical records provides a low-cost, medium-accuracy, and high-volume complement to genomic approaches. National and church population registers are renowned for their reliability regarding persons who live and die near their birthplace, but rarely track persons who undergo long-distance migrations. Familial records maintained by hobbyist genealogists are more likely to maintain this information, but may be partial or incorrect: these disadvantages are allayed by the rising popularity of tools to digitize, share, and compare family trees, increasing the number and accuracy of available data. Here we employ public records on over 43 million persons from the 1700s through the present day, obtained from the genealogical social network Geni. com, to study patterns of human migration from birth to childbirth and death. Fathers appear both more likely than mothers to raise children in their hometown and more likely to migrate unusually long distances before raising children. We find evidence for an east-west bias in migration both locally and at long distances. Dispersal of descendants of a common ancestor is examined as a function of average generations elapsed, ancestor's birth year, and proximity to the frontier of a human range expansion (viz. , colonization of the American West). We further simulate inheritance of hypothetical novel autosomal, Y chromosome, or mtDNA mutations from given ancestors to investigate typical distributions of carriers in the present day.

'Human Knockout Project' in a Pakistani population with high levels of consanguinity. *P. Natarajan[1,2], W. Zhao[3], A. Rasheed[4], S. Khetarpal[5], P. Frossard[4], E. S. Lander[2], S. Gabriel[2], M. J. Daly[2,6], J. Danesh[7], D. J. Rader[5,8], S. Kathiresan[1,2], D. Saleheen[3,4] on behalf of the PROMIS Investigators.* 1) Center for Human Genetic Research and Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA, USA; 2) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Center for Clinical Epidemiology and Biostatistics and Department of Biostatistics and Epidemiology, University of Pennsylvania, USA; 4) Center for Non-Communicable Diseases, Karachi, Pakistan; 5) Division of Translational Medicine and Human Genetics, Department of Medicine, University of Pennsylvania, USA; 6) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 7) Department of Public Health and Primary Care, University of Cambridge, UK; 8) Department of Genetics, University of Pennsylvania, USA.

Experimental disruption of both gene copies ("knockout") in model organisms has proven useful to understand gene function. Here, we leverage naturally-occurring null mutations and consanguinity in the human population in order to: 1) identify humans knocked out for genes; and 2) characterize the phenotypic consequences of complete gene disruption. We performed whole-exome sequencing in 7,078 individuals living in Pakistan, a region of the world with high levels of consanguinity, and tested whether knockouts differed from wild-type participants across a range of over 200 cardiometabolic traits. Among Pakistanis, the median excess homozygosity, as determined by the F inbreeding coefficient, was 1. 6%. 47,656 mutations were predicted to be null (nonsense, frameshift, or canonical splice-site) and we further filtered variants based on minor allele frequency, transcript position, splice sites, and conservation to identify 36,850 "high-confidence" null mutations across 12,131 autosomal genes. Across all participants, 961 distinct genes were completely disrupted by homozygous high-confidence null mutations. 1,306 participants (18. 4%) had at least one gene knocked out. Simulations using the excess observed autozygosity suggest that with the sequencing of ~200,000 Pakistanis, we can expect about 8,000 genes to be completed disrupted; this number is six-times larger than if a similar number of participants from an outbred population were sequenced. In a phenotypic screen, homozygosity for null mutations at *PLAG27* was associated with absent enzymatic activity of lipoprotein-associated phospholipase A2 in the blood; at *CYP2F1*, with higher plasma interleukin-8 concentrations; and at either *A3GALT2* or *NRG4*, with markedly reduced plasma insulin C-peptide concentrations. These observations provide a roadmap to understand the consequences of complete disruption of a large fraction of genes in the human genome.

Homozygous Loss of Function (HLOF) variants provide a valuable window on gene function in humans, as well as an inventory of the human genes that are not essential for survival and reproduction. All humans carry at least a few HLOF variants, but the exact number of inactivated genes that can be tolerated is currently unknown - as are the phenotypic effects of losing function for most human genes. Here, we make use of 1,432 whole exome sequences from five European populations to expand the catalogue of known human HLOF mutations; after stringent filtering of variants in our dataset, we identify a total of 173 HLOF mutations, 76 (44%) of which have not been observed previously. We find that population isolates are particularly well suited to surveys of novel HLOF genes because individuals in such populations carry extensive runs of homozygosity, which we show are enriched for novel, rare HLOF variants. Further, we make use of extensive phenotypic data to show that most HLOFs, ascertained in population-based samples, appear to have little detectable effect on the phenotype. On the contrary, we document several genes directly implicated in disease that seem to tolerate HLOF variants. Overall HLOF genes are enriched for olfactory receptor function and are expressed in testes more often than expected, consistent with reduced purifying selection and incipient pseudogenisation.

1572T

Harnessing the power of exome sequencing and isolated populations to identify risk factors for inflammatory bowel disease. *M. A. Rivas[1,2], C. Stevens[1], B. Glaser[3], I. Peter[4], G. As part of a broader collaborative network of exome sequencing studies, we developed a jointly called data set of more than 3500 Ashkenazi Jewish exomes and make publicly available a resource of site and allele frequencies, which should serve as a valuable reference for medical genetics in the Ashkenazi Jewish population. We developed a novel statistical framework for the analysis of isolated populations in order to identify and characterize alleles that are enriched through the bottleneck event. We apply this to this resource and previously described Finnish reference from the SISu Project and estimate that 13% and 19% of alleles present in Ashkenazi Jewish and Finnish samples are uniquely enriched in these populations by roughly 10x compared to the maximum frequency seen in all other population exome sequencing resources. Among these enriched alleles, in case-control analysis of Crohn's disease we find an unusual aggregation of novel distinct Ashkenazi Jewish associated alleles in *NOD2* (p. A612T, p=5. 5x10-9; p. A755V, p=0. 002; p. D357A, p=0. 003; p. P427L, p=0. 005) in addition to those previously reported as associated in *NOD2*. A major focus of the program is to identify protein truncating alleles that protect against the inflammatory bowel diseases. Protective loss-of-function variants hold particular promise for identifying potential targets of inhibition withhigher confidence in both safety and efficacy. We used the sequencing data to seek such variants in genes strongly implicated by GWAS. We discovered a novel protective association at a predicted protein-truncating mutation (p. Arg179Ter) in*RNF186*, a single-exon ring finger E3 ligase with strong colonic expression. This study presents an unprecedented opportunity to examine the role of rare variants and its contribution to inflammatory bowel disease predisposition. Initial findings from these studies will enable studies of the allelic associations across multiple phenotypes in large population cohorts, powerful in-depth characterization of the functional consequences, and deeper understanding of the allelic architecture in directly implicated genes from ongoing fine-mapping studies of common variant associations. .

1573W

Rare coding and regulatory noncoding variants in the Saguenay-Lac-Saint-Jean founder population. *A. Morin[1,2], T. Kwan[1,2], L. Létourneau[2], AM. Madore[3], K. Tandre[4], ML. Eloranta[4], M. Ban[5], M. Caron[1,2], G. Bourque[1,2], S. Sawcer[6], AC. Syvänen[6], L. RonnBlom[4], MG. Lathrop[1,2], S. Gravel[1,2], C. Laprise[3], T. Pastinen[1,2].* 1) Human Genetics, McGill University, Montréal, Quebec, Canada; 2) McGill University and Genome Québec Innovation Centre, Montréal, Quebec, Canada; 3) Département des sciences fondamentales, Université du Québec àChicoutimi Saguenay, Quebec, Canada; 4) Department of Medical Sciences, Section of Rheumatology, Uppsala University, Uppsala, Sweden; 5) Department of Clinical Neurosciences, University of Cambridge, Cambridge; 6) Department of Medical Sciences, Molecular Medicine and Science for Life Laboratory, Uppsala University, Uppsala, Sweden.

In the past few years, research has started to focus on delineating the whole genetic architecture of complex traits including very rare and singleton variations. We have developed ImmunoSeq: a custom capture panel that targets the exome region as well as noncoding regulatory regions of immune cells in order to study coding and regulatory noncoding variants in the context of complex traits that have an important immune or inflammatory component. The noncoding regulatory regions were selected base on DNase I hypersensitive sites (DHSs) mapping from a set of 12 different cell types available from ENCODE and NIH Roadmap epigenomics Projects. Asthma is one of the traits being examined using the Saguenay-Lac-Saint-Jean (SLSJ) asthma familial collection. The SLSJ region is located in northeastern Quebec and is known for its unique demographic history and founder effect, characterized by several population bottlenecks followed by rapid expansion. Since founder populations have smaller spectrum of rare variations but are enriched in rare and unique Loss-of-Function (LoF) variants, we aim to show the advantages of using the SLSJ population in the study of rare coding and noncoding regulatory variants in a complex trait. Rare variant distribution and characteristics of the SLSJ population (n=298) were compared to three other European populations from Sweden (n= 369), United Kingdom (n=264), and France (n= 96). We observed a lower number of low frequency and rare variants (MAF<5%) in the SLSJ compared to the other populations, which reflects the multiple bottlenecks in its history. A high proportion of rare variants unique to the SLSJ were observed (40%) that is increased when looking at selectively constrained (GERP++>=1) variants (55%). We also observed a larger proportion of variants that are common in the SLSJ but rare in the other populations. This is already known on the basis of rare disorders. As an example, the the *LRPPRC* mutation causing the Leigh syndrome French Canadian type has a carrier rate of 1 in 21 among inhabitants of the region, whereas it is extremely rare in other French populations. In the future, we will interrogate differences between coding and noncoding variants in the different populations as well as determine how much power we can gain using the SLSJ founder population in the study of rare variants in a complex trait.

1574T

Whole genome view of the Finnish bottleneck effects using 2926 whole genome sequences from Finland and UK. *H. Chheda[1], P. Palta[1], M. Pirinen[1], S. McCarthy[2], V. Salomaa[3], R. Durbin[2], T. Aittokallio[1], A. Palotie[1,4,5], S. Ripatti[1,2,6].* 1) Institution for Molecular Medicine Finland (FIMM), Helsinki, Finland; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, United Kingdom; 3) National Institute for Health and Welfare, Helsinki, Finland; 4) Program in Medical and Population Genetics and Genetic Analysis Platform, The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Department of Medical Genetics, University of Helsinki and University Central Hospital, Helsinki, Finland; 6) Public Health, University of Helsinki, Helsinki, Finland.

Lim et al (Plos Genetics 2014) showed recently that loss-of-function (LoF) and missense variants in 0. 5-5% frequency are enriched in Finnish population compared to Non-Finnish Europeans, providing an opportunity to study downstream effects of these variants in Finns. However this change in the frequencies may not be confined only to the coding region. To this extent we have studied the enrichment of variants in the Finnish population across the whole genome. To study the bottleneck effects across the whole genome, we analyzed single nucleotide variants (SNVs) from 1463 low coverage whole genome sequences both from Finland (~4. 6x) and UK (6x). These samples were processed together by the Haplotype Reference Consortium to harmonize the variant calls and minimize the batch effects. As observed previously, we see a 1. 34x enrichment of the LoF variants (p-valueLoF = 0. 056) in the 2-5% minor allele frequency (MAF) range and 1. 1x enrichment in the missense variants (p-valuemissense = 2. 95e-05). Further, we studied the enrichment of variants across the whole genome. We found significant enrichment in Finns in the MAF range from 0. 5-5%, with maximum enrichment in the MAF range of 2-5% (p-value = 6. 4e-323). We also see enrichment across different functional sub-categories in Finns with the highest enrichment observed for conserved regions (p-valueconserved_regions=9. 36e-24, p-valueTFBS=6. 02e-46, p-valuepromoter=1. 67e-11, p-valueenhancers=0. 001), although not as considerable as for the LoF variants. Furthermore, in the regulatory regions, rare and low frequency variants (MAF <= 2%) are enriched beyond expected bottleneck effects. When limiting the analysis to the 23,441 variants that were enriched at least 100x in Finns, genes in pathways related to neuron development, signal transductions and cation transport channels were observed to be significantly over represented after correcting for multiple testing. These results show that the enrichment of low frequency variants in founder populations is not limited to coding loss-of-function and missense variants, but are also observed in conserved regions and regulatory elements. This finding provides opportunities to study downstream health effects of these variants in founder populations with multiple bottleneck effects such as Finns outside of the coding regions.

1575W

A genetic population isolate in The Netherlands showing extensive haplotype sharing and long regions of homozygosity. *L. Olde Loohuis[1], M. Somers[2], M. Aukes[2], B. Pasaniuc[1,4], K. de Visser[5], R. Kahn[2], I. Sommer[2], R. Ophoff[1,2,3].* 1) Center for Neurobehavioral Genetics, University California Los Angeles, Los Angeles, CA; 2) Brain Center Rudolf Magnus, Department of Psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands; 3) Department of Human Genetics, David Geffen School of Medicine at UCLA, University of California Los Angeles, Los Angeles, CA, USA; 4) Department of Pathology and Laboratory Medicine, University of California Los Angeles, Los Angeles, CA, USA; 5) Department of General Practice, University Medical Center Groningen, University of Groningen, Groningen, The Netherlands.

Background Genetic isolated populations have features that may facilitate genetic analyses and can be leveraged to improve power of mapping genes to complex traits. Our aim was to test the extent a population with a former history of geographic isolation, and currently with one of the highest fertility rates in The Netherlands, shows signs of genetic isolation. **Methods** Genome-wide genotype data was collected of 72 self-reported unrelated individuals from this population as well as in sample of 104 random control subjects from The Netherlands. Additional reference data from different populations and population isolates was available through HapMap and the Human Genome Diversity Project (HGDP). We performed a number of analyses to compare the genetic structure between these populations. We calculated the pairwise genetic distance (Fst) between populations, examined the extent of identical-by-descent (IBD) sharing and estimated the effective population size. **Results** Genetic analysis of this population showed consistent patterns of a population isolate at all levels tested. We confirmed that this population is most closely related to the Dutch control subjects, and detected high levels of IBD sharing and runs of homozygosity at equal or even higher levels than observed in previously described population isolates. The effective population size of this population was estimated to be several orders of magnitude smaller than that of the Dutch control sample. **Conclusions** We conclude that the geographic isolation of this population combined with rapid population growth has resulted in a genetic isolate with great potential value for future genetic studies. .

1576T

Recessive disease gene mapping in India: extraordinary opportunities for understanding health and disease. *N. J. Nakatsuka[1], K. Thangaraj[2], P. Moorjani[1,3,4], A. Tandon[1,3], N. Patterson[3], L. Singh[2], D. Reich[1,3,5].* 1) Department of Genetics, Harvard Medical School, Boston, MA USA; 2) Centre for Cellular and Molecular Biology, Hyderabad, India; 3) Broad Institute of MIT and Harvard, Cambridge, MA USA; 4) Department of Biological Sciences, Columbia University, New York, NY USA; 5) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA USA.

Modern India is a region of remarkable cultural, linguistic, and genetic diversity with over 4,500 anthropologically well-defined groups. Large genetic differentiation has been observed between many of these groups, reflecting strong founder events with effects that have been preserved in some cases for thousands of years due to low genetic exchange between groups. We undertook a systematic survey to assess the strength of founder events in over 1200 individuals from over 230 Indian groups genotyped on Affymetrix (6. 0 and Human Origins) and Illumina (650K) arrays. These groups include tribes, castes, and religious groups with a wide-range of census sizes and spanned every state in India. We also analyzed Ashkenazi Jews and Finns, two groups known to have high rates of recessive diseases due to strong founder events. To determine the severity of founder events, we measured the total length of the genome inherited identical-by-descent (IBD) in each group. The data were phased with Beagle 3. 3. 2, and detection of IBD fragments was performed using FastIBD and GERMLINE. The HaploScore algorithm was used to filter out false positive fragments. To reduce the influence of recent consanguinity, we excluded closely related individuals detected by the presence of very long IBD segments. We quantified the IBD score for a group as the combined length of IBD segments between 3 to 20cM long, averaged over all pairwise comparisons within the group. We find that over 100 Indian groups in our dataset have founder effects stronger than in Ashkenazi Jews and Finns, including many groups with large census sizes (>1 million). This represents an extraordinary opportunity for biological discovery and potential reduction of genetic disease burden through mapping of recessive disease genes and prenatal counseling. Future work should focus on better characterization of the history and relationships amongst the founder events, as well as mapping variants associated with genetic diseases in the groups with the strongest founder events.

1577W

Using Y chromosome diversity to investigate the origin and the formation of the Taiwanese. *J. Loo, T. Wang, Y. Lai, M. Lin.* Medical Research, MacKay Memorial Hospital, New Taipei City, Taiwan, Taiwan.

Taiwanese comprise Aborigines and Non-Aborigines. The Aborigines are further divided into many Mountain tribes and Plain tribes. The Non-Aborigines are generally categorized as “Taiwan Han”, and are represented by two major populations: Minnan and Hakka. Actually, these groups can be specifically divided further into separate groups each having well characterized but independent profiles. From the article of Trejaut et al. 2014, the multidimentional scaling plot of Y-SNP frequencies displayed the relative position of Taiwanese relationship between themselves and other Asian populations (Figure 5). Interestingly, the Taiwan populations were located on a straight line, with Taiwan Mountain Aborigines on the one end, the Taiwan Plain Tribes in the middle, and Minnan, Hakka and Taiwan Coastal people on the other end. In a first stage we used BEAST package to compare the relationship of all Taiwan aboriginal Y haplogroup O1a1* (M214, M175, M119, P203) haplotypes with non aboriginal (Han) Taiwanese within the same haplogroup. Regrettably only five Y-STR loci could be used due to the vast diversity of typing methods between different laboratories. Several points are noticed:1) There are clades which are typically composed of haplotypes belonging to Taiwan Aborigines (*P*=0. 006);2) These clades are not unique as they can also be found among other Island Southeast Asian populations;3) Clades that are poor in aboriginal haplotypes represent Taiwan Han (*P* =0. 0029), Taiwan Coastal people (*P* <0. 0001), Northeast Asian and Northern Han (*P* =0. 0011);4) The distribution of Taiwan Plain Tribes haplotypes shows no difference between aboriginal and non aboriginal clades (p=0. 3629) which Beast indicate it might be recent admixture;5) While “Han” are represented by 4 points of divergence within the O1a1* Tree, the Taiwan aboriginal groups is represented by 29 divergence pointsConclusion: Based on the Y O1a1* haplogroup, the landscape of Taiwan Aborigines and Taiwan Non-Aborigines are different. And the formation of Taiwan Non-Aborigines is related to more recent migration of Northeast Asia. The second stage of this study will be to analyze other haplogroups (O2 and O3).

Characterization of 20,000 clinically relevant variants in 50,000 non-European individuals. *E. E. Kenny[1], C. R. Gignoux[2], S. A. Bien[3], N. Zubair[3], A. E. Justice[4], L. Fernandez-Rhodes[4], M. Graff[4], G. L. Wojcik[2], Y. Vaydylevich[1], G. M. Belbin[1], A. A Seyerle[4], J. M. Kocarnik[3], R. D. Jackson[5], J. Xing[6], F. Schumarcher[7], E. Stahl[1], J. L. Ambite[7], S. Buyske[6], C. Wassel[8], I. Cheng[9], L. A. Hindorff[10], T. C. Matise[6], R. J. F. Loos[1], C. Kooperberg[3], K. E. North[4], C. A. Haiman[7], J. Romm[11], C. D. Bustamante[2], C. S. Carlson[3], N. S. Abul-Husn[1].* 1) Icahn School of Medicine at Mt. Sinai, New York, NY; 2) Stanford University, Stanford, CA; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) University of North Carolina, Chapel Hill, NC; 5) Ohio State University, Columbus, OH; 6) Rutgers University, Piscataway, NJ; 7) University of Southern California, Los Angeles, CA; 8) University of Pittsburgh, Pittsburgh, PA; 9) Cancer Prevention Institute of California, Fremont, CA; 10) National Human Genome Research Institute, National Institute of Health, Bethesda, MA; 11) Johns Hopkins University, Bethesda, MA.

During the past decade major advances in deciphering the genetic basis of human disease have resulted in >6000 disorders that are now understood at a genetic level. However, the implementation of these findings into clinical care poses a difficult challenge. Vast quantities of rare variants in human populations make questions of causality, penetrance and expressivity for any particular variant difficult to ascertain. This problem is compounded by the recent observations from population genetics that rare variants are typically restricted to one or a few closely related populations, with implications that causal variants discovered in one population are unlikely to translate to another. Therefore, the characterization of clinically relevant variants (CRVs) in multi-ethnic cohorts is a critical step in advancing global genomic medicine efforts.

To address this, we generated a panel of 2,720 clinically relevant genes, including monogenic and polygenic disease genes, curated from ClinVar, HGMD, and OMIM in consultation with domain experts, and pharmacogenes from PharmGKB. Within these genes, we selected 15,000 variants previously classified as pathogenic, and 5,000 loss-of-function variants we classified as likely pathogenic extracted from a multi-ethnic panel of approximately 40,000 whole exome sequenced individuals. These variants were included on the Illumina Infinium Multi-Ethnic Genotype Array (MEGA) which was used to genotype 50,000 individuals, including African American, Afro-Caribbean, North, Central and South American, Japanese, and Native Hawaiian Islanders, as part of the Population Architecture using Genomics and Epidemiology (PAGE) Study. These data are linked to broad epidemiological trait and disease information, and a subset of 12,500 are linked to longitudinal electronic medical records (EMR).

We will present data on the frequencies of known and likely pathogenic variants, and will report phenotypic evidence to support causality and penetrance for a subset of CRVs segregating in PAGE. For example, we have already uncovered a skeletal dysplasia variant in *COL27A1* that is observed only in Puerto Ricans, and is in homozygosity in five individuals with extreme short stature (mean 4’ 2” females and 4’ 10” males). EMR data supports features of skeletal dysplasia despite a lack of diagnosis in those individuals. Follow up work will focus on characterizing other rare disease variants and uncovering monogenic forms of complex disease in this cohort.

Understanding germline mutation from multi-sibling families. *R. Rahbari[1], A. Wuster[1], S. Lindsay[1], R. Hardwick[1], L. Alexandrov[1], A. Dominiczak[2], A. Morris[3], D. Porteous[4], B. Smith[3], M. Stratton[1], M. Hurles[1], UK10K Consortium.* 1) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridgeshire, UK, CB10 1SA; 2) nstitute of Cardiovascular and Medical Sciences, College of Medical, Veterinary and Life Sciences, University of Glasgow, Glasgow, United Kingdom; 3) Medical Research Institute, University of Dundee, Dundee, United Kingdom; 4) Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, Scotland, United Kingdom.

Germline mutation is a driving force behind genome evolution, genetic variation and genetic disease. Despite recent focus on the germline mutation rate, there are some fundamental aspects of germline mutation that remain elusive. We investigated mutation rates, spectra, and timing by sequencing the genomes of multi-sibling families. We found that while the number of mutations in the child increases with paternal age in each family, the rate of this increase differs more than two-fold between families. We meta-analyzed the mutation spectra of 6,570 high confidence *de novo* mutations and found remarkable consistency of germline mutation spectra between the sexes, between families and at different paternal ages. Moreover, we noted that 3. 8% of de novo mutations per genome are germline mosaic in the parents, resulting in 1. 3% of mutations being shared between two or more siblings. The rate of sibling recurrence of *de novo* mutations varied significantly between families. Our data suggest that the mutation rate per cell division is higher during early embryogenesis and during proliferation of primordial germ cells, but is reduced three-fold during post-pubertal spermatogenesis. These findings have important consequences for the prediction of recurrence risks of genetic disorders caused by *de novo* mutations.

1580T

Most Rare and Common Variants in the *MAP3K1* Gene Have Neutral Phenotypic Effects. *M. Groden, J. Loke, K. Upadhyay, A. Pearlman, H. Ostrer.* Albert Einstein College of Medicine, Bronx, NY.

Gain-of-function (GOF) missense and splicing mutations in the *MAP3K1* gene cause 46,XY partial and complete gonadal dysgenesis by tilting the balance from the male to the female sex-determining pathways (Loke et. al. , Hum Mol Genet. 23:1073, 2014). Loss-of-function (LOF) mutations in *MAP3K1* while observed commonly in breast cancer (and other cancers) are rarely present in the germline state (only 1 stopgain, 1 frameshift and 1 inframe deletion and no splice or indels inframe insertions observed in the 1000 Genomes Project (1kG). Here, we used flow variant analysis (FVAs) to assess the phenotypic consequences of this stopgain and 14 rare and common missense variants of 24 observed in 1kG. Lymphoblastoid cells (LCLs) for these individuals (obtained from the Coriell NHGRI Catalog) were compared to LCLs with 5 known GOF mutations for MAP3K1 protein binding to RHOA, MAP3K4 and FRAT1 and phosphorylation of downstream targets, p38 and ERK1/2. The accuracy of the functional predictive algorithms (SIFT, Polyphen-2) was also compared to the observed molecular phenotypes. FVAs for the GOF variants showed increased phosphorylation of p38 and ERK1/2 and binding of cofactors (FRAT1, MAP3K4 and RHOA), and decreased binding of RAC1. The stopgain variant increased phosphorylation of ERK1/2, but not p38, and increased binding of RAC1 and RHOA. None of those effects was observed for the common or rare population ascertained variants. These phenotypic effects were not predicted by SIFT and Polyphen-2. We have extended the use of FVAs to demonstrate the phenotypic effects of LOF mutations in *MAP3K1*. Despite the common inference that most rare variants are deleterious, FVAs of rare missense 1kG *MAP3K1* variants demonstrated neither loss nor gain of functional effects. Computational classifiers over predicted the prevalence of deleterious variants in 20% of our sample demonstrating the utility of FVAs over these tools. Although physical phenotypes have not been associated with *MAP3K1* LOF variants, they may be subject to diminished reproductive fitness (negative selection) as occurs for GOF variants in this gene.

1581W

Rare variants – the key to decipher cryptic relatedness in diverse population structures. *A. C. Shetty[1], T. D. O'Connor[1,2] On behalf of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA).* 1) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD; 2) Program in Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD.

Background: Common variants have primarily been used to infer the structure of the human population. Using common variants, we have only been able to successfully discern the broad-scale patterns of population structure. Recent dramatic events of population expansion have resulted in humans harboring a vast number of rare variants that play an influential role in delineating fine-scale patterns of population structure, which when left unrecognized could lead to spurious results from association studies. **Hypothesis:** Rare variants are concentrated within regions of low nucleotide variability supporting the premise that they tag recent haplotypes in the population. **Methods:** Our study analyzed the genetic variation data from the latest phase III release of the 1000 Genomes Project (1KG) and 952 high coverage (~30x depth) whole genomes sequenced as part of the **C**onsortium on **A**sthma among **A**frican-ancestry **P**opulations in the **A**mericas (CAAPA) project. The genetic variants were categorized in different bins based on their derived allele frequency (DAF). We computed the average nucleotide diversity (ϖ) for each 10kb window in a 1Mb region flanking each variant. Separate ϖ values were computed for individuals possessing the variant (carriers) and individuals without the variant (non-carriers). The ratio of ϖ in carriers to non-carriers was computed for each 10kb window. **Results:** For rare variants (DAF $\leq$ 0. 05), ϖ values were lower in carriers than non-carriers. However, this lower ratio was only observed in the immediate flanking regions (~200kb to 350kb) from the variant. The ratio of ϖ in carriers to non-carriers gradually increased till no difference in ϖ values were seen between carriers and non-carriers as we moved further upstream or downstream from the variant. In addition, as the DAF increased from rare to more common variants, the difference in ϖ between carriers and non-carriers diminished. These results were consistent within the populations from 1KG as well as within the African-admixed CAAPA dataset. **Conclusions:** We were able to demonstrate that rare variants resided within genomic loci that posses lower nucleotide diversity in carriers than non-carriers. This correlation of derived allele frequency of genetic variation to genomic variability could help identify recently diverged haplotypes giving us insights into cryptic kinship in population samples and reveal signatures of fine-scale population structure in association analyses.

1582T

Path Analysis and Structural Equation Modeling for traditional cardiovascular risk traits in Punjabi adolescents. *S. K. Brar[1], B. D. Badaruddoza[2].* 1) Deptt of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Director, Aligarh Muslim University Murshidabad Centre, Murshidabad, WB.

The accuracy of different anthropometric and socio-economic lifestyle indices to predict cardiovascular diseases is still debated in adolescent age group and few data are available in state of Punjab in India. Keeping in mind, that the complex nature of all studied anthropometric and socio-economic lifestyle variables to evaluate the determinants of pre-hypertension and hypertension, the path analysis of structural equation modeling using Analysis of Moments Structures (AMOS 21. 0) model fitting program has been applied in the study consisting a total of 1530 adolescent boys and 1530 adolescent girls aged 10 to 18 years old. The study first tested the adequacy of hypothesized path model which contain the inter-correlated variables (such as BMI, waist circumference, WHR, sum of skinfolds, food habits, exercise, screen time and family status). Next, the study tested the relative strength of association of independent variables with SBP and DBP on the basis of the magnitude of path coefficients of regression, covariances and variance. The study adopted maximum likelihood estimation, 95% confidence limit and critical ratio in generating the estimate of path coefficients and its significance. The whole analysis confirmed that the waist circumference, BMI and family income status have significant contribution to increase blood pressure. The findings of the present study regarding effect of BMI, waist circumference, WHR, sum of skinfolds, food habits, exercise, screen time and family status on blood pressure are in an agreement with few other studies It is further established from estimates of covariances from path analysis that combination of BMI with waist circumference, waist circumference with sum of skinfolds, BMI with sum of skinfolds, exercise with family status and screen time with family status have significant association with elevated SBP and DBP. Whereas, impact of variances on SBP and DBP of all the studied variables have been found significant for path analysis model among both adolescent boys and girls.

Privacy leaks from genomic data-sharing beacons. *S. Shringarpure, C. Bustamante.* Department of Genetics, Stanford University, Stanford, CA.

A major goal of the human genomics community is to enable efficient sharing and analysis of genomic and phenotypic data to understand the genetic contributors of health and disease. The Beacon Project aims to simplify data sharing through a web service (“beacon”) that provides only allele presence information. Users can query institutional beacons for information about genomic data available at the institution. Queries are of the form ``Do you have a genome that has a specific nucleotide (e. g. ,`A’) at a specific genomic position (e. g. , position 1127 on chromosome 1)” and the server can answer “Yes” or “No”. We hypothesize that beacons are susceptible to re-identification attacks, i. e. , given a query individual’s genome, we can predict whether this individual was among the set of genomes used to create the beacon. This is troubling since beacons often summarize data characterized by having a particular disease. For instance, identifying that a genome is present in the beacon at a cancer research institute suggests that the subject has cancer. Thus, beacons can leak not only membership information but also phenotype information. We have developed a statistical test to predict whether a given individual genome is present in the beacon using only allele presence queries. For a simulated beacon with 1000 individuals, 5000 SNP queries are enough to detect membership in the beacon with 95% power and 5% false positive rate. For empirical evaluation, we set up a beacon using 65 CEU individuals from Phase 1 of the 1000 Genomes project. With just 250 SNPs, beacon membership can be detected with 95% power and 5% false positive rate. In existing beacons, we were also able to identify an individual from the Personal Genome Project using just 1000 SNPs. We used our framework to show that relatives can be detected in a beacon (in the simulated beacon, 40,000 SNPs allow detection of parents/siblings of the query individual). Our results are robust to sequencing errors and differences in variant calling. Our test is independent of allele frequencies. Including multiple populations in the beacon does not reduce the power of the test. Our results show that beacons can leak unintended phenotypic information about subjects if care is not taken to ensure privacy. We suggest ways of reducing re-identification risks, such as increasing beacon size or sharing only common variation. Our solutions will allow data sharing while simultaneously decreasing the risk of re-identification.

1584T

Using DNA methylation data to test heritability-based predictions of evolutionary models of aging. *C. Robins[1,2], A. McRae[3,4], J. Powell[3,5], P. Visscher[3,4], G. Montgomery[6], D. Cutler[1], K. Conneely[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA, USA; 2) Graduate Program in Population Biology, Ecology, and Evolution, Laney Graduate School, Emory University, Atlanta, GA, USA; 3) The Queensland Brain Institute, University of Queensland, Brisbane, QLD, Australia; 4) University of Queensland Diamantina Institute, University of Queensland, Translational Research Institute (TRI), Brisbane, QLD, Australia; 5) The Institute for Molecular Bioscience, University of Queensland, Brisbane, QLD, Australia; 6) QIMR Berghofer Medical Research Institute, Brisbane, Australia.

Evolutionary theories have proposed both adaptive and non-adaptive explanations for the existence of aging. Major hypotheses include the theories of: 1) mutation accumulation (MA), and 2) antagonistic pleiotropy (AP), with disposable soma (DS) as a special case of AP. MA suggests aging to be caused by deleterious late-acting mutations that have accumulated in the population over many generations as a result of a declining strength of selection. In contrast, DS suggests aging to be caused by random somatic damages that accumulate over the lifetime of an individual due to imperfect somatic maintenance and repair mechanisms resulting from the evolutionary optimization of energy allocation tradeoffs. Past empirical tests have supported aspects of each theory, but no consensus has been reached on their relative importance in explaining human aging. Here, we use DNA methylation as a biomarker of aging to test contrasting predictions of MA and DS at sites across the genome. Many widespread and robust DNA methylation changes occur with age. That is, numerous sites across the genome show consistently variable patterns of methylation between younger and older ages. Sites exhibiting this pattern of changing methylation with age are called age-differentially methylated (aDM). Many of these sites also show heritable patterns of methylation, where closely related individuals are more correlated in their methylation levels than unrelated individuals. These facts allowed us to devise a test that differentiates MA from DS. MA predicts that aDM sites will show increasing heritability of DNA methylation levels with age, while DS predicts the opposite. To test these contrasting predictions in genome-wide DNA methylation data we used variance components models in SOLAR to test if the heritability of methylation level at aDM CpG sites increased or decreased with age. DNA methylation was measured at >480K CpG sites in blood sampled from 610 individuals from 176 families from the Brisbane Systems Genetics Study (age range=10-75 years). After exclusion of probes containing SNPs, 51% of CpG sites were aDM (FDR<. 05) and 42% had heritable methylation levels. Of the ~85K aDM and heritable sites, <5 showed significant increasing heritability, while >2500 showed significant decreasing heritability with age. These results suggest the heritability of age-associated DNA methylation changes may be overwhelmingly consistent with DS.

The NHGRI Sample Repository: A Collection of DNA and Cell Lines for Human Genetic Research. *A. M. Resch, F. Rahimov, M. Berkowitz, L. Brown.* Coriell Institute for Medical Research, Camden, NJ.

The knowledge of the entire spectrum of genetic variation across ethnically diverse human populations is important for reconstructing human evolutionary history and understanding the genetic basis of human disease. Established in 2006, the mission of the NHGRI Sample Repository for Human Genetic Research is to provide high-quality human biospecimens for researchers and clinicians investigating human population genetics and disease. The NHGRI Repository offers DNA samples and cell lines from twenty-seven distinct populations that include samples used for the International HapMap Project, 1000 Genomes Project, Human Microbiome Project (HMP), and the Fosmid Library Collection for Analysis of Structural Variation. Currently the NHGRI Repository hosts over 3,700 unique cell cultures and DNA samples for the HapMap and 1000 Genomes collections, 298 unique DNA samples for the HMP collection, and 11 fosmid libraries. Whole blood samples were collected from anonymized and de-identified donors with broad consent for various studies, including DNA sequencing and genotyping, gene expression and proteomics. Epstein-Barr virus-transformed lymphoblastoid cell lines (LCLs) were derived from peripheral blood mononuclear cells (PBMCs) and genomic DNA was isolated from LCLs. Cell lines and DNA may be used by academic and commercial entities. In addition, the NHGRI Repository utilizes secure laboratory information management systems to monitor inventory and distribution of samples. Thus, by establishing and maintaining a centralized collection of human biospecimens, the NHGRI Repository provides a unique resource for human genetic studies. The full catalog can be accessed at https://catalog. coriell. org/1/NHGRI.

The effect of SNP array ascertainment bias on the distribution of runs of homozygosity lengths. *A. Gladstein[1], M. Hammer[2].* 1) Ecology and Evolutionary Biology, University of Arizona, Tucson, AZ; 2) Arizona Research Laboratories, Division of Biotechnology, University of Arizona, Tucson, AZ.

Background: Runs of homozygosity (ROH) are chromosomal segments of continuous homozygous sites that reflect the relatedness of an individual's ancestors. ROH are most often found using SNP genotyping arrays. ROH must be inferred indirectly since SNP arrays do not contain complete genomic information. Importantly, ROH can be incorrectly identified because of the underlying SNP array ascertainment bias. Ascertainment bias is the systematic deviation of population genetic statistics from theoretical expectations caused by sampling a nonrandom set of individuals or by biased SNP discovery protocols. Although SNP array ROH have been used in many demographic and disease studies, no work has assessed the impact of ascertainment bias on ROH identification.

Purpose: We develop a correction for the effect of ascertainment bias on the distribution of ROH lengths identified from SNP array data. We hypothesize that if a SNP array introduces ascertainment bias, on average, ROH identified from the SNP array will be longer than the true genomic ROH. Moreover, the difference between SNP array and genome ROH lengths will be a function of the genetic distance from populations used to discover the SNPs.

Methods: We simulate genomes using a two population split model and create pseudo SNP arrays from the simulated genomes. We find the ROH truth set from the simulated genomes and identify ROH from the pseudo array using PLINK. We also determine the most accurate PLINK parameters by comparing the pseudo array PLINK ROH to the truth set. We compare the distribution of the simulated genome and pseudo SNP array ROH lengths under increasing population divergence times. We determine a transformation, as a function of divergence time, that makes the distribution of pseudo SNP array ROH lengths closer to the true genome distribution.

Results: Under a null model of no ascertainment bias we found many PLINK parameter sets that produced similar distributions of ROH lengths to the simulated genome distribution. If we defined ROH as having a minimum length of less than 500kb, the default PLINK parameters were among the worst. Compared to the truth set, fewer and longer ROH were found from the pseudo array. We provide recommendations for the best PLINK parameters to accurately identify ROH from SNP array data and corrections to the distribution of ROH lengths based on the genetic distance between the study population and those used to discover the SNPs.

Anthropometric and cardiovascular trait variation among sub-Saharan African populations: the impact of subsistence practice and genetic ancestry. *M. E. B. Hansen[1], J. Lachance[2], S. Soi[1], L. Scheinfeldt[1], A. Ranciaro[1], S. Thompson[1], J. Hibro[1], S. A. Tishkoff[1].* 1) Genetics Dept, University of Pennsylvania, Philadelphia, PA; 2) School of Biology, Georgia Institute of Technology, Atlanta, GA.

The African continent is home to a diverse range of indigenous peoples that have adapted to a wide range of ecological environments and subsistence lifestyles. Many complex traits are expected to display variation between populations due to demographic history and/or adaptation to these diverse environments. In an effort to survey phenotypic variation in Africa and begin to understand the genetic and environmental factors that contribute to this variation, we have collected trait measurements on height (N~5000), BMI (N~5000), grip strength (N~2000), systolic and diastolic blood pressure (N~2000), and pulse (N~2000) from agricultural, pastoral, and hunter-gatherer communities across eastern and western sub-Saharan Africa. We present the observed variation in these traits between genders, across populations, and across subsistence practices. We find significant differences in trait values among these categories. A subset of 697 individuals were genotyped on the Illumina 1M-Duo SNP array. We performed a GWAS using a linear mixed model approach, and find that only height replicated GWAS top hits from non-African cohorts (p-value enrichment). To assess the impact of genetic ancestry and subsistence lifestyle on trait variation, we performed STRUCTURE analysis to determine ancestral cluster proportions, and fit both the mean effects and variance components for ancestry and subsistence category using linear mixed models. The fraction of variance explained by genetic ancestry is discussed, as well as the implications for future genotype/phenotype analyses within sub-Saharan Africa for these and related traits.

Splice site mutation in the key cytoskeletal gene *TLN1* causes systemic capillary leak syndrome in a first reported familial case. *D. Oz-Levi[1], V. Papadaki[2], R. Sion-Sarid[3], P. Nikolopoulou[2], T. Olender[1], S. Houri[3], V. Kostourou[2], D. Lancet[1].* 1) molecular genetics, weizmann institute of science, Rehovot, Rehovot, Israel; 2) Vascular Adhesion Lab, BSRC Alexander Fleming, 34 Fleming Str, Vari, 166 72 Athens, Greece; 3) Pediatric Intensive Care Unit, Wolfson Medical Center, Holon, Israel.

Systemic Capillary Leak syndrome (SCLS) is a rare disease characterized by life-threatening attacks of marked increase in capillary permeability, leading to plasma extravasation, vascular collapse and hypotensive shock, with roughly 150 isolated cases reported worldwide. We identified a first familial SCLS case, an Israeli family with ten affected individuals, showing suspected autosomal dominant inheritance with incomplete penetrance (Sion-Sarid R. et al 2010). The proband is a 14-year old boy with multiple attacks since the age of 5 months. His sister died of an acute attack at infancy. Exome sequencing on the proband and on an affected father's cousin yielded 37 candidate variants. We used our newly established variant interpretation tool VarElect (http://varelect. genecards. org/), to attain phenotype-dependent variant prioritization, leveraging the comprehensive information within the GeneCards Suite (http://www. lifemapsc. com/). Employing "capillary leak" as keyword, VarElect produced a prioritized list of contextually annotated genes, scored according to their likelihood to be disease related. The top candidate gene was *TLN1*, encoding Talin1, a cytoskeletal protein playing a key role in focal adhesion mechanosensory function, mediating the coupling of integrin b to actin filaments. The variant was A>G heterozygous substitution at a splice donor site (+2) of intron 54 (c. 7543+2A>G). cDNAs harboring the *TLN1* mutant allele show both skipping of exon 54, leading to an in-frame deletion of 21 residues, and retention of intron 54, that creates a premature stop codon. Talin1 coordinates endothelial dynamics, mediating microvascular remodeling, capillary contractility, and controlling of endothelial cell growth via VEGF and TGF-beta. These factors were found significantly elevated in SCLS serum of patients during an acute crisis. Such augmentation may provoke vascular leak symptoms by eliciting endothelial hyperpermeability. Transcriptome and proteome analyses on patient skin fibroblasts identified down-regulation of several immune genes, echoing previous reports on a connection of capillary leak to immunity. We hypothesize that the mutated protein could lead, perhaps via a dominant-negative model, to aberrant initiation of adhesion site assembly and endothelial dysfunction. Together with the observed increase in VEGF and TGF-beta, this suggests a model for SCLS pathogenesis, underlining a plausible molecular mechanism for this rare and precarious disorder.

Splice-EMASE: Quantifying allele-specific alternative splicing in diploid genomes. *N. Raghupathy, K. Choi, S. C. Munger, G. A. Churchill.* The Jackson Laboratory, Bar Harbor, ME.

Current RNA-seq analyses employ three separate pipelines to quantify gene expression abundance, Allele-specific gene expression (ASE), and alternative splicing from RNA-seq data. Gene-level abundance is estimated from alignment of all reads genome-wide, ASE is assessed by analyzing only reads that overlap known SNP locations; and alternative splicing is estimated by analyzing reads overlapping splice junction or exon-specific reads. Earlier, we developed computational tools; Seqnature and EMASE, to build individualized diploid genome using known phased genetic variations, perform personalized RNA-seq analysis using diploid transcriptome, and estimate allele-specific expression and gene expression simultaneously. Here we present Splice-EMASE, an extension of EMASE with splice-aware EM algorithm on diploid exons and junction alignment profiles. Splice-EMASE quantifies allele-specific alternative splicing in addition to ASE and total gene expression simultaneously. The EM algorithm probabilistically allocates both allelic and genic multi-mapping reads to estimate effective read counts at exons and splice-junctions. These effective exon and splice-junction read counts could be readily used to get allele/isoform/gene expression estimates. We demonstrate the utility of the approach by using simulated data and real RNA-seq data.

1590F

A system for gene ranking through variant annotation in Autism Spectrum Disorders. *E. Larsen[1], I. Menashe[2], M. Ziats[3], W. Pereanu[1], S. Banerjee-Basu[1].* 1) MindSpec Inc. , McLean, VA; 2) Department of Public Health, Faculty of Health Sciences, Ben Gurion University of the Negev, Israel; 3) Baylor College of Medicine, Houston, TX.

The search for genetic factors underlying autism spectrum disorders (ASD) has led to the identification of hundreds of genes containing thousands of variants that differ in mode of inheritance, frequency and function. These data are summarized in our Autism Database (AutDB; http://autism. mindspec. org/autdb/Welcome. do), a publicly available, curated, web-based, and searchable database for genetic variations associated with ASD. With the rapid pace of variant discovery in recent years, a major challenge in the field of ASD biology involves assessing the collective genetic evidence in an unbiased, systematic manner. Therefore, we set out to develop a scoring algorithm for prioritization of candidate genes based on the cumulative strength of evidence from each ASD-associated variant in AutDB. A total of 928 research articles from AutDB were analyzed to generate a dataset of 2187 rare variants and 711 common variants distributed across 461 ASD-associated genes. Each individual variant was manually annotated with 17 descriptors extracted from the original report, followed by score assignment using a set of standardized scoring parameters that are summed up to yield a single score for each gene in the database. There were remarkable variations in gene scores resulting in a log-normal distribution of scores with a mean gene score of 16. 65 ± 29. 57. Interestingly, there were 12 genes with scores deviating more than two standard deviations (SDs) from the mean score of all genes, with three high confidence genes (*SHANK3*, *CHD8*, and *ADNP*) with extremely high scores. Importantly, the gene scores generated by our approach were significantly correlated with the scores in the SFARI Gene scoring module (Spearman r = -0. 63; *P<0. 0001*) indicating a strong agreement between gene prioritization using our approach and the expert-mediated SFARI Gene scoring initiative. In this study, we provide a framework for assessment of diverse types of genetic variants associated with ASD. Using this model, we prioritize a set of genes with cumulative evidence that are likely to be important for defining the genetic risk architecture in ASD.

Typing of PRDM9 genotypic class from Next Generation Sequencing data in early onset childhood cancer. *A. Ang Houle[2], J. C. Grenier[2], V. Bruat[2], P. Awadalla[1,2,3].* 1) OICR, Toronto, Canada; 2) UHC Sainte-Justine Research Center, Montreal, Canada; 3) CARTaGENE, Montreal, Canada.

Recombination is the exchange of genetic information between homologous chromosomes during meiosis. The positions of recombination events cluster tightly together in recombination hotspots, which are determined in part by the DNA binding zinc finger domain of the rapidly evolving protein PRDM9. The repetitive microsatellite-like structure of the coding sequence of the ZnF array drives a constant generation of multiple new alleles in populations. Alleles of PRDM9 containing the *k*-ZnF have previously been associated with patients affected with childhood acute lymphoblastic leukaemia. PRDM9 alleles are notoriously difficult to type due to the repetitive nature of the ZnF arrays. Here, we propose a method to characterize alleles of PRDM9 from next-generation sequencing samples, by identifying the number of alleles containing a specific ZnF type. Our method is based on the correlation of profiles representing the counts of nucleotide sequences unique to each ZnF from ideal sets of short reads representing an allele pair and from the sequencing short reads of the sample. A scoring weight function is then applied to the top scoring correlations: the highest scoring genotypic class is deemed as predictive for the sample. We conduct a simulation analysis to examine the validity of the predictions obtained by our method with all pairs of known alleles, to compensate for the rarity of genuine samples containing some of the alleles, at varying coverage of next-generation sequencing data. We also confirm that the method can accurately genotype previously unobserved PRDM9 alleles by masking the ideal profiles containing corresponding alleles in the a priori given to the software. We also conducted a preliminary analysis to identify the PRDM9 *k*-ZnF genotype in cohorts of childhood cancers, including paediatric glioblastoma multiforme, which is characterized by the recurrent mutations in the histone H3, the target of PRDM9 epigenetic mark. This method opens the possibility of identifying associations between characteristics of PRDM9 alleles in other types of early onset childhood cancers, through a data-mining effort in public cancer databases.

A key challenge in genome interpretation and precision medicine is the lack of an extensive, high quality, ethnically-diverse collection of human genomes as a reference set. A prospective disease-causing variant that appears to be "rare" based on publicly available sequence may in fact be a polymorphism in an ethnic population under-represented in public databases. Resources such as the Exome Variant Server, the 1000 Genomes Project, and the Exome Aggregation Consortium have been immensely valuable to the community, and Kaviar combines such datasets into integrated allele frequencies, but public databases have not been funded to provide broad and deep ethnic representation. QIAGEN's Ingenuity Variant Analysis™ genome interpretation solution has been used to interpret hundreds of thousands of ethnically diverse human sequencing samples. However, these NGS datasets are private and most are never publicly released. The Allele Frequency Community (www. allelefrequencycommunity. org) has been formed to address this interpretation need. Community members have pooled extensive human exome- and genome-wide variant call datasets in a secure, anonymized, pooled fashion to create the largest integrated, freely-accessible, hosted community database of allele frequencies ever available. More than 100,000 human exome- and genome-wide variant call datasets, including over 13,500 whole genomes, are already included in the Allele Frequency Community. The database is richly ethnically diverse, representing over 100 countries of origin and has been shown in benchmarking studies to significantly decrease the false positive rate in disease causing variants identification. To enable this community resource to grow over time, users have the opportunity to opt-in to join the Allele Frequency Community and benefit from the extensive database, agreeing in return to allow their sequences to contribute to the database. Only anonymous, pooled allele frequencies are provided, protecting patient privacy. QIAGEN Bioinformatics agreed to host the content and make it available free of charge via its HIPAA and Safe Harbor compliant genome interpretation ecosystem, which includes QIAGEN's Ingenuity Variant Analysis, CLC Biomedical Research Workbench and Clinical Insight offerings. Application of this new resource to clinical sequencing cases will be presented.

Robust Classification of Protein Variation Using StructuralModeling and Large-Scale Data Integration. *E. H. Baugh[1,4], R. Simmons-Edler[1,4], C. L. Mueller[2,4,5], R. F. Alford[6], N. Volfovsky[3], A. E. Lash[3], R. Bonneau[1,2,3,4,5].* 1) Department of Biology, New York University, Manhattan (New York City), NY; 2) Computer Sciences Department, New York University, Manhattan (New York City), NY; 3) Simons Foundation, Manhattan (New York City), NY; 4) New York University Center for Genomics and Systems Biology, Manhattan (New York University), NY; 5) Simons Center for Data Analysis, Simons Foundation, Manhattan (New York University); 6) Department of Chemistry, Carnegie Mellon University, Pittsburgh, PA.

Existing methods for interpreting protein variation focuson annotating mutations as deleterious or neutral ratherthan detailed interpretation of variant effects and frequentlyuse only sequence-based or structure-based information. We present VIPUR, a computational framework seamlesslyintegrating sequence analysis and structural modeling(with the Rosetta protein modeling suite) to identify andinterpret deleterious protein variants. To train VIPUR,we collected 9,477 protein variants with known effectson protein function from multiple organisms and curatedstructural models for each variant from crystal structuresand homology models. VIPUR can be applied to mutationsin any organism's proteome with improved generalizedaccuracy and interpretability compared to other methods. We apply VIPUR to inflammation associated variantsand de novo mutations associated with autism spectrumdisorders, demonstrating the structural diversity of disruptedfunctional sites and improved interpretation of mutationsassociated with human diseases.

1594W

Big Data Warehouse for Large Scale Genomics. *B. Bernard[1], J. Slagel[1], S. Elasady[1], A. Black[2], G. Glusman[1], G. Eley[2], J. Vockley[2], I. Shmulevich[1], J. Niederhuber[2].* 1) Institute for Systems Biology, Seattle, WA; 2) Inova Translational Medicine Institute, Fairfax, VA.

Large-scale clinical genomics studies consisting of thousands of whole genome sequences require a system with the ability to analyze billions of unique variants over terabytes of data, generated with different technologies by disparate laboratories. Modern big data/cloud technologies, rather than traditional tab-delimited file-based approaches, are advantageous and increasingly necessary for scalable, high access genome analysis workflows and tools. Additionally, large collections of standardized annotations enable the evaluation and interpretation of genomic variation and improve the quality of analysis results. To this end we have developed a cross-platform, Hadoop-based system for distributed storage and query of annotations and large collections of genome sequences.

The system has been designed to integrate whole genome sequences from Illumina and Complete Genomics, with an extensible model for genomic data integration derived from multiple sequencing platforms. The genomic data model normalizes technical details such as variant call quality and no-calls; supports versioning and provenance of evolving annotation sources, genome builds, and sequences originating from different studies; and scales seamlessly to handle increases in content with minimal impact on performance. Over twenty annotation sources have been standardized, normalized, and integrated for deployment in several cloud-based or in-house platforms. These annotation sources are joined with sequencing data to support a variety of in-database analysis workflows and ad hoc queries, rather than static tab-delimited vcf files. Incremental and modular updates to the system are possible as new genome sequences are added to continuously growing collections and annotation sources are modified. Data replication of sequences and annotations, as well as indexing/partitioning schemes, are employed to enhance performance for scenarios ranging from deep analysis of family pedigree to association studies of large collections of genomes. Distributed queries can be coupled with parallel computation, for example with Python or R through industry standard APIs (e. g. , ODBC or GA4GH). As the use of genomics in the clinic grows, large scale, distributed, normalized data systems such as the one outlined here, will be imperative to continuously improve the accuracy and quality of personalized medicine.

1595T

Increased Statistical Power Using Informed Conditioning in Case-Control Studies. *M. Bilow[1], S. Eyheramendy[2], E. Eskin[1].* 1) UCLA, Los Angeles, CA; 2) Pontificia Universidad Católica de Chile, Santiago, Chile.

Genome-wide association studies (GWAS) have found thousands of associations between genetic variants and disease. Many of these studies have collected clinical phenotypes in addition to genetic data. Many of these clinical phenotypes correlate with disease status, and some genetic variants that affect disease have also been found to affect clinical phenotypes. Including multiple phenotypes in a single association test should make it easier to discover genes that affect clinical phenotypes and disease. As such, there is great interest in studying multiple phenotypes in a single GWAS. Unfortunately, most association tests used in GWAS in the literature analyze a single phenotype at a time. This is an inherently less powerful technique than joint analysis of multiple phenotypes when the genetic variant affects both case-control disease status and clinical phenotypes. A class of multivariate methods that combine multiple continuous phenotypes in a single association test have recently become more acknowledged within GWAS. However, it was shown recently that multivariate models can lose power in studies integrating continuous clinical phenotypes with discrete case-control data. Part of this loss of power is caused by multivariate models not fully Part of the reason for the loss of power is because individuals are selected to the study on the basis of their disease status. This results in a phenomenon known as selection bias, as selection of equal numbers of individuals affected by a rare disease and unaffected by the disease will oversample all of the factors that influence the disease's ontogeny. We present a novel technique that combines discrete case-control data with a continuous trait in a single multivariate model. This model, based on the liability threshold model, succinctly expresses an individual's likelihood of disease using a latent continuous variable and increases statistical power. We demonstrate the model increases statistical power in simulated data as well as data derived from the North Finland Birth Cohort dataset.

1596F

A resampling-based method for comparison of location parameters in multivariate datasets. *M. Borges[1,2], B. Carvalho[1,2], I. Lopes-Cendes[1,2].* 1) Department of Medical Genetics, State University of Campinas, Campinas, Sao Paulo, Brazil; 2) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas, São Paulo, Brazil.

Experiments involve analyzing differences between groups. Despite the simplicity of concept, such evaluation includes a series of hypothesis assessments. The most common characteristic under scrutiny is the theoretical distribution of the data. However, other technical details, particularly high dimensionality, play a significant role in hypothesis testing. Ideal statistical procedures for group comparison must be robust to departures of the standard normality assumption and provide means of handling highly dimensional datasets. Nonparametric methods make no assumptions about probability distribution of the data and are natural candidates for robust strategies. Permutation tests comprise a powerful class of nonparametric strategies called resampling-based methods. Using this method, we estimate the distribution of the statistic of interest under the null hypothesis (i. e. , no differences between the groups) by randomly shuffling the group memberships of the observations. This allows the researcher to perform hypothesis testing without distributional assumptions. Projection methods are natural choices to address high dimensionality and to provide simpler data visualization. We developed our own comparison method by combining multidimensional scaling (MDS) with permutation tests. Our strategy uses MDS to project the data onto lower dimensions, while preserving the distance between the data points. Using these projections, we determine the statistic of interest: Mahalanobis distance between the groups. The method empirically estimates the null distribution of the distances between the groups using permutation. The strategy uses this distribution to assess the evidences of differences between the groups. This method is available as an R function at https://goo. gl/tEftzz.

1597W

Multilevel Regression Approach for Cross-Platform Transformation of Gene Expression Data. *Y. Cheung[1], N. Dimitrova[1], W. Verhaegh[2].* 1) Clinical Informatics Services and Solutions Depart, Philips Research, Briarcliff Manor, New York, USA; 2) Precision and Decentralized Diagnostics Department, Philips Research, Eindhoven, Netherlands.

The dynamic ranges of gene expressions can vary considerably depending on the choice of profiling platform. As a result, prognostic gene signatures are usually platform-specific, and expression data generated by heterogeneous platforms in general cannot be directly combined for computational analysis, thus limiting the scope of use of legacy data and hindering the adoption of new profiling technologies. Specifically, tremendous resources have been spent on microarray studies, and it is desirable to transfer the knowledge and insights onto the new platform such as next generation sequencing. Towards the goal of cross-platform compatibility of gene expression data, we propose a generalized multilevel regression framework that efficiently transforms gene expression data from the original to the designated platforms over a wide dynamic range. It can be flexibly adapted for any platforms, and supports out-of-sample data transformation after model training. As a first implementation, we developed a two-level framework that transforms gene expressions from Affymetrix HT-HG-U133A microarray (log2RMA) to Illumina HiSeq 2000 RNA-Seq (log2 RSEM) platforms based on 545 TCGA samples that have data for both platforms. For each sample, on average the correlation between the two platforms is $r = 0.71$ and the fractional root-mean-square (rms) error is $erms = 0.36$. Using 100 samples for training, after two levels of regression, both average correlation and fractional rms error are significantly improved: $r = 0.966$ and $erms = 0.092$. Moreover, principal component analysis showed that the transformed samples merge very well with the true RNA-Seq samples without systematic bias.

1598T

An automatic next-generation sequencing analysis pipeline for family-based disease studies. *R. -H. Chung, W. -Y. Tsai, C. Y. Kang, P. J. Yao.* National Health Research Institutes, Zhunan, Taiwan.

For disease studies using next-generation sequencing (NGS) data, family design has become an attractive approach to identifying rare mutations that are enriched in families. Several family-based algorithms and tools are available for analyzing sequencing data in families with disease. Integrating these resources into an automatic analysis pipeline will significantly facilitate the analysis. However, current analysis pipelines for family data mostly focus on a specific function. Therefore, a pipeline which can accommodate different analysis strategies for family-based analysis is desirable. We developed an analysis pipeline, FamPipe, which can be applied to the analysis for Mendelian disorders or complex diseases. Identity-by-descent (IBD) sharing statistics or linkage LOD scores calculated using Merlin are incorporated in FamPipe to identify linkage regions. For Mendelian disorders, segregation scores, which account for sequencing errors, are calculated in FamPipe. A disease model identification (DMI) algorithm is developed to classify variants into different disease models based on the segregation scores. For complex disease studies, family-based association tests can be performed in the linkage regions or across the genome. Furthermore, two family-based imputation tools, Merlin and GIGI, are integrated in FamPipe. We used simulation studies to evaluate the sensitivity and specificity for the DMI algorithm, IBD sharing statistics and linkage LOD scores. We also used simulations to compare the performance between the two family-based imputation tools. The simulation results showed that the DMI algorithm achieved specificity and sensitivity of 100% in the presence of genotyping errors when analyzing 10 nuclear or extended pedigrees consisting of both affected and unaffected individuals. Simulation results also showed that the IBD sharing statistics can have higher sensitivity of identifying linkage regions than linkage LOD scores when there are only a few families available, but linkage LOD scores can be more powerful when 10 families were analyzed. Finally, GIGI had higher imputation quality scores (IQS) than Merlin for large pedigrees consisting of 69 individuals in each pedigree. Similar IQS were observed for GIGI and Merlin for imputing pedigrees each with 12 individuals. In conclusion, an NGS analysis pipeline with commonly used functions for family-based disease studies is developed, which will expedite the analyses of NGS data in families.

1599F

An automated, differences-based model for retrospectively applying dynamic annotation data to static whole exome sequencing result sets. *D. Corsmeier[1], P. White[1,2].* 1) The Biomedical Genomics Core & The Center for Microbial Pathogenesis, The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Pediatrics, College of Medicine, The Ohio State University, Columbus, OH.

The vast majority of causative variants in Mendelian diseases are believed to be in the coding regions of the genome. However, whole exome sequencing studies typically have a molecular diagnosis rate of 25%, suggesting that many genes underlying these diseases have yet to be found and demonstrating that novel disease-causing gene discovery is still dynamic and rapidly expanding. While the underlying genomic data is static, literature and databases are constantly growing and periodic review is likely to help diagnose numerous additional cases. Current approaches to variant annotation create a snapshot and make the process of retrospectively examining existing data cumbersome. As such, an effort to periodically update annotations and apply them to these data sets requires complete reanalysis, a method lacking efficiency and practicality. In an effort to overcome this problem, we have implemented an automated system to apply evolving variant annotation to an existing repository of human genomic data. As new pathogenic variants are discovered, the corresponding annotation data are extracted and queried against the genomic data with the goal of identifying previously undiagnosed patients whose genetic etiology is revealed by the new discovery. This differences-based approach minimizes both compute resources and the effort required to review the new results. The report constructed from these queries includes primary findings and incidental, medically actionable variants as defined by the American College of Medical Genetics and Genomics. To demonstrate the utility of our system we used exome data sets that included variants for which annotation had changed in recent updated annotation database releases. Highly optimized queries were utilized to examine genomic loci across a sample data repository for cases in which annotation data changed and a report was generated accordingly. This process ensures that novel gene discovery information relevant to an existing patient's health or treatment will not be delayed or overlooked entirely.

Gene and pathogenic variant discovery for Mendelian and Complex Familial Traits. *H. Dai[1], G. T. Wang[1], B. Peng[2], R. L. P. Santos-Cortez[1], S. M. Leal[1].* 1) Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Bioinformatics and Computational Biology, The University of Texas - MD Anderson Cancer Center, Houston, TX.

We provide methods and implementation of best practices to identify rare variants involved in the etiology of Mendelian and familial complex traits using next-generation sequence (NGS) data. We demonstrate through case examples, bioinformatics protocols to analyze exome and genome sequence data to elucidate pathogenic variants that are either *de novo*, underlie Mendelian phenotypes or complex traits with familial aggregation. We feature four types of commonly adopted study designs analyzing either genomes or exomes from (1) a single affected individual (2) multiple family members, (3) multiple families and (4) multiple unrelated individuals with a family history of disease. For each design we illustrate the procedures to integrate data from different sources, performing variant annotations, and selecting potentially pathogenic variants from single or multiple exomes based on several parameters, including but not limited to mode of inheritance, variant sharing among pedigree members, population minor allele frequency, functional annotation and prediction, linkage mapping data and variants/genes previously implicated in disease etiology. Case studies were novel pathogenic variants have been discovered for nonsyndromic hearing impairment, thoracic aortic aneurysms and dissections, autism, Moyamoya disease, otitis media and rare autosomal recessive traits such as achromatopsia and trichothiodystrophy are used to illustrate the protocols and best practices. . We have also developed an easy-to-use bioinformatics software, Variant Mendelian Tools (VMT), to implements the protocols which makes it possible for any researcher with NGS data to efficiently hunt down and identify pathogenic variants. VMT is designed to be flexible to accommodate regular updates from annotation databases and incorporation of new information from a variety of sources including public databases and in-house data, e. g. linkage regions. The analysis protocols we developed are distributed under the VMT platform which can be readily adapted and shared for a variety of projects, owing to the compact, human-readable syntax that VMT adopts. Our work is highly beneficial to clinicians and researchers who aim to identify pathogenic variants from NGS data but have minimal knowledge and experience in the use of Linux and programming languages, and/or in annotations and variant discovery using family data.

The ClinGen Interface for Curating the Clinical Validity of Gene-Disease Associations: Specifications and Implementation. *S. Dwight[1], T. P. Sneddon[1], K. Liu[1], K. Dalton[1], F. Tanaka[1], B. Hitz[1], E. Riggs[2], O. Birsoy[3], A. Buchanan[2], R. Ghosh[4], N. Strande[5], S. Plon[4], H. Rehm[3], C. Martin[2], J. Berg[5], J. Michael Cherry[1], ClinGen Resource.* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Geisinger Health System, Danville, PA; 3) Laboratory for Molecular Medicine, Partners Healthcare Personalized Medicine, Cambridge, MA; 4) Pediatrics-Oncology, Baylor College of Medicine, Houston, TX; 5) University of North Carolina, Chapel Hill, NC.

The Clinical Genome Resource (ClinGen) is a NIH-funded program dedicated to creating a curated database of clinically relevant genes and genomic variants to inform genome interpretation in a variety of clinical contexts. It is anticipated that clinicians, researchers, laboratories and patients will benefit from this resource. A key element of ClinGen is the development of a suite of user interfaces that will facilitate expert curation of genes and variants, their association with disease and their clinical actionability. Here we report the development of one such tool in this suite - the gene curation interface. This interface will facilitate the curation process and guide the curator in determining the strength of a gene-disease association using the clinical validity classifications developed by the ClinGen Gene Curation Working Group (GCWG). This standardized classification scheme for clinically relevant genes optimizes their inclusion on clinical genetic testing panels and clinical interpretation of test results. Evidence supporting or contradicting a gene's association with disease occurs through manual literature curation of clinical and functional evidence. The specifications for the gene curation interface were developed iteratively in close working collaboration with members of the GCWG. The interface supports consistent application of the clinical validity classifications via careful design of the curator workflow, meaningful relationships between captured evidence, ontologies and controlled vocabularies, and free text descriptions that allow curator expressivity. The design supports gene curation by both "community curators" and ClinGen approved curators, with final review by an Expert Reviewer associated with a specific ClinGen Clinical Domain Working Group. As such, the completed gene curation interface is designed to provide ClinGen supported curation of gene-disease relationships by the larger genetics community. Additionally, the evidence fields captured by the interface will support the clinical validity classification and the assimilation of supplementary knowledge associated with the gene or disease, such as specific phenotypes involved, demographics, segregation, methodologies, and implicated variants. All of this curated information will be made available and searchable through a public web portal at www. clinicalgenome. org.

1602F

Efficient testing of multiple phenotypes in genome-wide association studies. *L. Gai[1], E. E. Eskin[1,2].* 1) Computer Science, UCLA, Los Angeles, CA; 2) Human Genetics, UCLA, Los Angeles, CA.

Expression quantitative trait loci (eQTL) mapping has emerged as a powerful tool for finding genetic variation that affects gene regulation. However, the wealth of information available through eQTL mapping comes with a great computational cost, especially when in combination with more sophisticated statistical models as such as mixed models. Unlike traditional genome-wide association studies (GWAS) where only a few clinical phenotypes (such as disease status or a biomarker) are studied at a time, a single eQTL study may involve tens of thousands of gene expression phenotypes. Since eQTL studies are generally conducted by running an independent GWAS on each expression phenotype, this results in billions of tests. Some of these tests are redundant, as some subsets of the phenotypes are not actually independent. Here we present we present Rapid Association-testing for Multiple Phenotypes (RAMP), a novel method to reduce the number of tests required in eQTL studies by leveraging the correlation between phenotypes. We show that RAMP greatly reduces the number of tests required for eQTL studies while maintaining statistical power. Finally, we apply RAMP combined with Genome-wide Rapid Association Testing (GRAT), a method to reduce the number of SNPs sampled per phenotype, to discover biologically relevant markers in an eQTL dataset. RAMP will be made available in a future release of pyLMM, a linear mixed model solver.

1603W

In silico Construction of Personalized DNA Methylation Biomarkers. *E. Gatev[1,2], M. Park[2,3], L. McEwen[2], J. MacIsaac[2], M. Kobor[2,4].* 1) Bioinformatics, University of British Columbia, Vancouver, Canada; 2) Centres for Molecular Medicine and Therapeutics, University of British Columbia, Vancouver, Canada; 3) Population and Public Health, University of British Columbia, Vancouver, Canada; 4) Medical Genetics, University of British Columbia, Vancouver, Canada.

DNA Methylation variability across individuals can be exploited to construct personalized biomarkers for disease and risk. This requires the integration of genetic and DNA methylation data. The typical scenario of a limited number of observation poses several challenges, including over-fitting, perormance assessment and interpretability of the results. We offer a novel approach to the construction of personalized DNA methylation biomarkers, that addresses these challenges. Our approach is based on constructions of informative reduced representations of the multiple big “Omics” data, and their integration in a novel way. We use a three stage pipeline with genomic feature construction and selection, relevant DNA-methylation probe selection and data integration to demonstrate a proof-of-concept cortisol personalized biomarker in a small cohort of 187 individuals.

1604T

Leveraging tumor lineage trees to predict and genotype somatic structural variations using paired-end sequencing. *I. Hajirasouliha[1], F. Hormozdiari[2], V. Popic[1], Z. Weng[1], R. B. West[1], A. Sidow[1], S. Batzoglou[1].* 1) Stanford University, Stanford, CA; 2) University of Washington, Seattle, WA.

We present LAPSI (Lineage-Aided Maximum-ParsimonyStructural VariationInference), a novel method for detecting and genotyping somatic structural variations (SVs) in multiple whole-genome sequencing tumor samples, taken from a patient. In contrast to standard SV discovery approaches, which do not leverage phylogenetic information, LASPI makes use of the multi-sample lineagetree structurereconstructedfrom deep sequencing somatic SNV datasets using a specialized method suchas LICHeE [1]. We assume that lineage trees based on different somatic variant classes are almost identical, and demonstrate that leveraging lineage trees reduces false negatives in detecting and genotyping of SVs. Our method effectively pools samples that share a common ancestor in the tree and finds clusters of discordant reads that suggest the same SV breakpoint across these samples. Placement of SVs onto specific branches of the lineage tree resultsin amorecomprehensive roadmap of the tumor’s genome evolution that begins at the zygote. LAPSI utilizes a combinatorial optimization formulation with the objectiveof assigning optimal SV clusterstothe branches of the tree,such that only a small fraction of discordant alignments are not assigned to any SV clusters, while sub-clonal SVs are favorably selected. LAPSI allows mixed-lineage samples to be present in the model, which makes the problem computationally NP-hard, and employs an effective approximation algorithm,based on the greedy *maximum coverage* problem. We tested LAPSI on multi-samplebreast cancerdatasetsand their corresponding lineage trees [2, 3]. Our initial investigation of thesedatasetsdemonstratesthe great potential of this method for detecting and genotyping somatic SVs in cancer genomes. For example, by investigating potential SVs in one of the patients, we have found a set of ~300 novel somatic deletions which were not present in the Lymph sample of the same patient. This set contains several *subclonal* deletions (i. e. those only present in a subset of samples). Furthermore, we wereable to identify a small somatic inversion with a relatively high support, whichwasnot seen in Lymph. **References**[1] Popic et al. , Fast and scalable inference of multi-sample cancer lineages. *Genome Biol.* 2015. [2] Newburger et al. Genome evolution during progression to breast cancer. *Genome Res.* 2014. [3] Weng et al. ***Bior_annotate* and *VCF-Miner*: An annotation and visualization framework designed for a constantly evolving genomic landscape.** *S. Hart[1], P. Duffy[2], M. Meiners[2], D. Quest[2], A. Hossain[2], M. Kalmbach[2], J-P. Kocher[1].* 1) Health Sci Res, Mayo Clinic, Rochester, MN; 2) Department of Research IT, Mayo Clinic, Rochester, MN.

Keeping up with the rapid pace of development in genomics is a non-trivial task. New algorithms to get more data out of sequencing experiments are published every week and existing tools can be updated at any time. Annotating the variants requires combining data from disparate external and in-house annotation sources, or command-line tools. While some applications have been developed to automate the annotation and filtering of genomics variants, these systems are highly restrictive. Maintaining existing annotations or adding new annotations is dependent on the authors’ availability or willingness to do so. Many times annotation and filtering are often integrated into toolkits, but lose track of provenance for where the data actually originated and how it has been modified. Because the Variant Call Format (VCF) is the standard reporting output format for many next generation sequencing experiments, we used the specification to build a flexible framework for adding new annotation and tool sets with minimal coding effort. The new *bior_annotate* application automatically splits large VCF files into smaller chunks for array processing and has several built-in checks for data consistency. Configuration files allow users to point to the specific catalogs (or versions of catalogs) that are needed. Because it is written in BASH, new command-line tools are also easy to add as optional processing operations. The inputs are a set of configuration files and a VCF, and the output is an annotated VCF file. This VCF File can be uploaded to *VCF-Miner*, a graphical user interface that sorts, filters, queries, and exports tables from VCF files. This allows rapid automatic integration of new and existing annotations from the VCF to be available to the end users, who many times are not computational biologists. When combined, these two tools make the process of adapting to an ever changing environment a much more tractable and reproducible task.

1606W

EpiCenter2: a powerful tool for RNA-seq and ChIP-seq data analysis. *W. Huang, L. Li.* Biostatistics and Computational Biology, NIEHS, Research Triangle Park, NC.

Cost-effective RNA-seq has quickly become a popular method for studying gene expression and their regulation mechanisms. The development of analysis methods and tools, however, still lags far behind the need. In particular, sequencing is now being used for more complicated or more challenging studies, and existing tools are no longer sufficient for these new and more advanced applications. For example, many early tools, while effective when dealing with data with few replicates, cannot take full advantage of more recent sequencing data with more replicates and/or more complex experimental designs. To meet such computational challenges, we introduce a new tool, EpiCenter2, for analyzing both RNA-seq and ChIP-seq data from the latest sequencing technologies. EpiCenter2, while based on our previous work EpiCenter, uses a new statistical framework that can take advantages of more biological replicates and gives more accurate predication of differentially expression genes or epigenetic changes. Specifically, EpiCenter2 can employ permutation method to assess statistical significance of difference between two groups. In addition, EpiCenter2 supports visualization of read coverage maps of any specific region or gene, and can be used for three-group comparison analysis. EpiCenter2 has been extensively tested in-house for real data analysis. Tests on simulated sequencing data also suggest that EpiCenter2 is accurate and efficient. EpiCenter2 is implemented in both C++ and R codes, and is computationally efficient by supporting multiple-thread computing. EpiCenter2 will be publicly available upon it is released.

1607T

FOAM: avoiding misleading variants in genomic regions Frequently Observed As Mutated. *C. Humphries[1], T. Ferrah[1], V. Dhankani[1], B. Bernard[1], D. Mauldin[1], L. Hood[1], M. Robinson[1], N. Clegg[1], J. Roach[1], P. Kothiyal[2], G. Eley[2], J. Vockley[2], J. Niederhuber[2], I. Shmulevich[1], G. Glussman[1].* 1) Institute for Systems Biology, Seattle, WA; 2) Inova Translational Medicine Institute, Fairfax, Virginia.

A well-known problem in genome analysis is that certain genes recurringly appear to be mutated - regardless of the phenotype. These include genes with many similar pseudogenes, large gene families such as olfactory receptors or immune receptors, poorly annotated genes, long intercellular matrix proteins that are very tolerant of missense mutations, and genes with extremely long coding sequences. It is common practice to discount variants that occur within these 'usual suspect' genes. However, this approach may result in discarding true causative variants. We developed a new method to identify error-prone genomic regions rather than whole genes. These regions are Frequently Observed As Mutated (FOAM) in individual genomes; variants within them should thus be treated with special caution. We analyzed high quality (>40x) whole-genome sequence (WGS) data from 7,879 individuals, sequenced on the CGI and Illumina platforms for the Inova Translational Medicine Institute (inova. org/itmi) and the Institute for Systems Biology (familygenomics. systemsbiology. net). We collected a joint set of 24M singleton variants (each observed in just one genome) and defined FOAM regions by clustering the variants based on distance and variant density. The FOAM regions span ~8% of the genome and overlap ~3. 5% of UCSC annotated exons. As expected, telomeric and centromeric satellite sequences are enriched in FOAM regions, as are highly similar gene families like olfactory receptors. Likewise, genes with internal sequence repeats overlap FOAM regions. For example, a FOAM segment overlaps the last three exons of the *KANK1* gene (i. e. , the ankyrin repeat domains) whereas it did not overlap the other, non-repeat exons. We identified a set of SNPs listed in the GWAS catalog that correlate to overlap with FOAM regions. Additionally, a review of the literature revealed that GWAS SNPs in FOAM regions tend not to be replicable in independent follow-up studies. We further enumerated pathogenic variants in ClinVar that overlap FOAM regions and may require further evaluation. Filtering observed genomic variants in FOAM regions is a more precise method for studying common false-positive genes, and informs about problematic regions in otherwise trustworthy genes. Fine-grained annotation of variants in FOAM regions leads to fewer spurious findings — a particular concern in clinical settings.

1608F

FIRE: functional inference of genetic variants that regulate gene expression. *N. M. Ioannidis[1], J. Davis[1], N. B. Larson[2], A. French[2], S. K. McDonnell[2], A. J. Battle[3], S. B. Montgomery[1], S. N. Thibodeau[2], W. Sieh[1], C. D. Bustamante[1], A. S. Whittemore[1].* 1) Stanford University School of Medicine, Stanford, CA; 2) Mayo Clinic, Rochester, MN; 3) Johns Hopkins University, Baltimore, MD.

Whole-genome sequencing technologies are increasingly enabling studies of genetic variation in large numbers of healthy and diseased individuals. However, interpreting the clinical significance of variants identified in these studies remains a critical challenge that has motivated the development of a variety of computational tools to aid in pathogenicity prediction. Current pathogenicity prediction tools for noncoding variants are not designed to provide insight into the biological functions of these variants upstream of their effect on pathogenicity. One of the major potential functional effects of noncoding variants is regulation of the expression and splicing of nearby genes. Here we present FIRE (Functional Inference of variants that Regulate Expression), a new tool trained to recognize expression quantitative trait loci (eQTLs) that enables prioritization of noncoding variants by predicting their potential to regulate the expression of nearby genes. We developed FIRE by training a random forest to recognize cis-eQTL variants using data from the Geuvadis consortium study of gene expression in the lymphoblastoid cell lines (LCLs) of 373 individuals of European descent. We find that FIRE achieves significant separation of scores for eQTL and non-eQTL variants using predictive variant features such as sequence conservation, overlapping functional elements from ENCODE and Ensembl, and position relative to the nearest transcription start site and splice site. We also show that FIRE scores for eQTLs identified in Yoruban individuals are similar to those for eQTLs in individuals of European descent, suggesting that FIRE scores are predictive across populations. Finally, we show that FIRE scores are only slightly lower for eQTLs identified in an independent study of 471 prostate tissue samples than for eQTLs in LCLs, suggesting that FIRE scores are predictive across tissue types despite a small degree of tissue specificity in the genomic features that characterize regulatory variants. We plan to deposit FIRE scores for all variants into the Clinical Genome Resource (ClinGen) knowledge base, and we anticipate that these predictions will be useful in future studies of regulatory variation and for prioritizing the likely clinical significance of rare genetic variants identified in large-scale clinical sequencing studies.

1609W

Turning Publicly Available Gene Expression Data into Discoveries Using Gene Set Context Analysis. *Z. Ji[1], S. A. Vokes[2,3], C. V. Dang[4], H. Ji[1].* 1) Department of Biostatistics, Johns Hopkins University, Baltimore, MD; 2) Department of Molecular Biosciences, The University of Texas at Austin, Austin, TX; 3) Institute for Cellular and Molecular Biology, The University of Texas at Austin, Austin, TX; 4) Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA.

Gene Set Context Analysis (GSCA) is an open source software package to help researchers use massive amounts of publicly available gene expression data to make discoveries. Users can interactively visualize and explore gene and gene set activities in 25,000+ consistently normalized human and mouse gene expression samples representing diverse biological contexts (e. g. , different cells, tissues and disease types, etc.). By providing one or multiple genes or gene sets as input and specifying a gene set activity pattern of interest, users can query the expression compendium to systematically identify biological contexts associated with the specified gene set activity pattern. In this way, researchers with new gene sets from their own experiments may discover previously unknown contexts of gene set functions and hence increase the value of their experiments by making more discoveries. GSCA has a graphical user interface (GUI). The GUI makes the analysis convenient and customizable. Analysis results can be conveniently exported as publication quality figures and tables. GSCA is available at https://github. com/zji90/GSCA. This software significantly lowers the bar for biomedical investigators to use PED in their daily research for generating and screening hypotheses, which was previously difficult because of the complexity, heterogeneity and size of the data.

1610T

An automatic end-to-end solution for disease-causing variant detection in rare and hereditary diseases with a high case solve rate and a much reduced false positive rate. *A. Joecker[1], S. Shah[2], D. Basset[2], R. Yip[2], D. Richards[2], B. Oester[1], G. Eley[3], B. Solomon[3], J. G. Vockley[3].* 1) QIAGEN Aarhus, Aarhus, Denmark; 2) QIAGEN Silicon Valley, Redwood City, USA; 3) Inova Translational Medicine Institute, VA, USA.

Next generation sequencing technology has enabled identification of causal genetic variants underlying rare inherited diseases in a short time. However, data analysis and interpretation of the large amounts of data is still a bottleneck, as causal variants are often not detected or, when detected, may include false positives that need to be ruled out through additional experiments. We present here a new streamlined automatic solution workflow, which enables the detection and interpretation of causal variants from whole genome and whole exome data with a higher case solve rate and a much reduced false positive rate. The new solution combines new functionaltity of Biomedical Genomics Workbench (BxWB) with Ingenuity Variant Analysis to provide a streamlined end-to-end workflow from FASTQ files to disease-causing variants. In addition to the normal variant calling from data of mother, father and child, the new functionality in BxWB includes a back-check to create a list of all variants found in all three individuals to look up the mapped sequencing reads and identify missing variants. This approach reduces the false positive rate of the end result significantly as many potential *de novo* variants can be excluded as inherited. It also increases sensitivity particularly for variants with low coverage. When used together with QIAGEN's Ingenuity Variant Analysis, that integrates the Ingenuity Knowledge Base and HGMD, in an automatic workflow, the workflow not only identifies in almost all cases the disease-causing variants in the tested cases, but also significantly reduces the false positive rate. In this study, we analyzed 15 TRIOs from the INOVA clinic (www. qiagenbioinformatics. com/inovagenomes) using the new solution and will show the results of this experiment in detail.

1611F

HITseqClust: Analysis of HIV-1 Integration Targeting-sequencing (HIT-seq) data to identify gene clusters targeted by specific transcription factors. *R. C. Johnson[1], G. W. Nelson[1], M. C. Cam[2], X. Wu[3], S. H. Hughes[4].* 1) CCR Collaborative Bioinformatics Resource, Frederick National Laboratory, Frederick, MD; 2) CCR Collaborative Bioinformatics Resource, National Cancer Institute, Bethesda, MD; 3) Leidos Biomedical Research, Inc, Frederick National Laboratory for Cancer Research, Frederick, MD; 4) HIV Drug Resistance Program, National Cancer Institute, Frederick, MD.

Lens epithelium-derived growth factor (LEDGF) is a transcription coactivator that assists HIV integration into the host genome. It has been shown that HIV integration can be redirected by replacing the N terminus, which binds chromatin, with chromatin binding domains from other transcription factors. The use of HIV Integration Targeting (HIT-seq) can shed valuable light into the function of these factors. After HIV integration sites have been sampled by next generation sequencing the relative density of integration sites is calculated using a gaussian kernel density estimator, and genes with high a density of integrations sites are flagged for each transcription factor variant. Genes targeted by individual transcription factor variants or groups of transcription factor variants (clustered using a principal components analysis of integration density among all genes) are compared using a pathway analysis, with a focus on both gene sets similarly targeted and those differentially targeted by different transcription factor variants. We revisit a published data set looking at H3K4me3 interactions with TAF3 to identify groups of genes differentially targeted by wild type TAF3 or the M880A mutant of TAF3. We also present a subset of genes that are not differentially targeted by only one variant, but are strongly associated with both. HITseq is a highly specific method for identifying genes targeted by various transcription factors. The software presented here identifies genes targeted by various transcription factors and compares gene clusters targeted by different variants of these transcription factors as well as differences and similarities among cell lines treated with identical variants.

1612W

Model selection via iterative hard thresholding for genome-wide association studies. *K. L. Keys[1], G. K. Chen[2], K. L. Lange[1,3].* 1) Biomathematics, UCLA, Los Angeles, CA; 2) Biostatistics, USC, Los Angeles, CA; 3) Human Genetics, UCLA, Los Angeles, CA.

Genome-wide association studies (GWASes) examine genetic variation between two groups of patients distinguished by a measurable phenotype. Each patient is genotyped at several places on the genome, and the genetic variation between cases and controls is compared. Since GWASes were introduced in 2005, researchers have performed GWASes for hundreds of traits on thousands of individuals. GWASes produce massive quantities of data that present computational and model selection challenges to their analysis. Current statistical software performs penalized regression, such as LASSO or MCP, to select the handful of informative SNPs from the thousands of predictors. Unfortunately, these methods introduce SNPs whose spurrious relationships to the trait obfuscate its genomic underpinning. We exploit iterative hard thresholding (IHT) to effectively select with great confidence the genetic markers most informative for the trait. Our parallel implementation exploits GPUs and PLINK data compression to fit GWAS data in computer memory. By leveraging commodity laptop computer hardware, we enable GWAS analysis on desktop machines and discard the need for expensive supercomputing resources. We demonstrate algorithmic performance on both simulated and real GWAS data. Our tests suggest that IHT effectively controls statistical type I errors better than LASSO and MCP regression.

1613T

Automated Identification, Prioritization and Visualization of Large-Scale Genomic Data. *M. J. Kiel[1,2], N. Patel[1,2], R. W. Peng[3], S. Schwartz[2,3], M. S. Lim[1,2,4], K. S. J. Elenitoba-Johnson[1,2,5].* 1) Department of Pathology, University of Michigan, Ann Arbor MI; 2) GENOMENON, Ann Arbor MI; 3) AlfaJango, Ann Arbor MI; 4) Department of Hematopathology, University of Pennsylvania, Philadelphia PA; 5) Center for Personalized Diagnostics, University of Pennsylvania, Philadelphia PA.

The tertiary component of genome sequence analysis requires identification of informative disease-gene-mutation associations for extraction of clinicobiological meaning from patient data. The accuracy and efficiency of tertiary analysis is limited by inaccessibility and non-uniformity of this information in both public databases and primary articles. To overcome these limitations, we have developed MASTERMIND - asuite of novel analytic tools that dramatically reduces the time and effort required to organize and integrate genomic information from any data source including millions of full-text scientific articles and dozens of heterogeneous variant databases. To comprehensively interrogate genomic data from both structured and unstructured databases, an automated querying architecture was designed using customized open-source analytics engines and a combination of publicly available and custom-developed APIs. Curated lists of diseases and gene transcriptswith synonyms comprising 11. 7K and 50. 9K total entrieswere used as initial query parameters. Custom-designed algorithms were used to generate comprehensive mutation query lists comprising602M total entriessorted by biological outcomeand used assecond-tier queries. Using titles andabstracts of 24M primary articles, we identified 909K putative disease-gene associations which we then confirmed by automated scanning of5. 8M full-text articles to comprehensively identify all disease-mutation citations within each article. Integrated metadata for each finding was used to prioritize disease-gene-mutation associations in accordance with the abundance and quality of supportingevidence. To facilitate rapid comprehension, theseassociationswere then organized withina singular graphical UIwith display of all relevantinformation from the primary source material used to drive data prioritizationincluding interactive access to annotated full-text articles. This method of rapidly assimilatingdisease-gene-mutation-associations for displaywas reproduced for several additional structured databases including ClinVar. In summary, MASTERMIND rapidly and comprehensively interrogates, organizes and displaysgenome data and has promising applications in expediting tertiary analysis of human genome sequencing data in clinical assays of individual patients.

1614F

SoloDel: A probabilistic model for detecting low-frequent somatic deletions from unmatched sequencing data. *S. Kim[1], J. Kim[2], H. Nam[3], S. Kim[2], D. Lee[4].* 1) SMRI, Rockville, MD; 2) Yonsei University College of Medicine, Seoul 120-752, Korea; 3) Gwangju Institute of Science and Technology, Gwangju 500-712, Korea; 4) KAIST, 291 Daehak-ro, Yuseong-gu, Daejeon 305-701, Korea.

Finding somatic mutations from massively parallel sequencing data is becoming a standard process in genome-based biomedical studies. There are a number of robust methods developed for detecting somatic single nucleotide variations (SNVs). However, detection of somatic copy number alteration (SCNAs) has been substantially less explored and remains vulnerable to frequently raised sampling issues: low frequency in cell population and absence of the matched control samples**.** We developed a novel computational method SoloDel that accurately classifies low-frequent somatic deletions from germline ones with or without matched control samples. We first constructed a probabilistic, somatic mutation progression model that describes the occurrence and propagation of the event in the cellular lineage of the sample. We then built a Gaussian mixture model to represent the mixed population of somatic and germline deletions. Parameters of the mixture model could be estimated using the expectation-maximization (EM) algorithm with the observed distribution of read-depth ratios at the points of discordant-read based initial deletion calls. Combined with conventional structural variation caller, SoloDel greatly increased the accuracy in classifying somatic mutations. Even without control, SoloDel maintained a comparable performance in a wide range of mutated subpopulation size (10% to 70%). SoloDel could also successfully recall experimentally validated somatic deletions from previously reported neuropsychiatric whole genome sequencing data.

1615W

FMAP: Functional Mapping Analysis Pipeline for Comparative Metagenomics and Metatranscriptomics. *J. Kim[1,2], M. Kim[1,2], A. Koh[2,4,5], Y. Xie[1,2,3], X. Zhan[1,3,6].* 1) Quantitative Biomedical Research Center, University of Texas Southwestern Medical Center, Dallas, TX; 2) Harold C. Simmons Comprehensive Cancer Center, University of Texas Southwestern Medical Center, Dallas, TX; 3) Department of Clinical Sciences, University of Texas Southwestern Medical Center, Dallas, TX; 4) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX; 5) Department of Microbiology, University of Texas Southwestern Medical Center, Dallas, TX; 6) Center for Genetics of Host Defense, University of Texas Southwestern Medical Center, Dallas, TX.

FMAP is an open-sourced stand-alone functional analysis pipeline for analyzing whole metagenomic and metatranscriptomic sequencing data. FMAP assembles a publically available UniProt reference database, which improves the sequence alignment outcome compared with other existing pipelines. Integrated statistical analysis procedures can identify differentially abundant genes and enriched functional pathways between sample groups. These results can be easily visualized through heatmaps and functional pathway diagrams. In addition, FMAP provides novel operon-level analysis in order to better interpret microbial functions.

1616T

Improving haplotype phasing accuracy using many short IBD segments. *A. Kleinman, E. Durand, C. McLean.* 23andMe, 899 West Evelyn Ave. , Mountain View, CA 94041.

Haplotypes are required for many genetic applications, such as imputation and fine mapping. Here we present Origin, a novel method for leveraging IBD data to improve phasing accuracy. Origin calculates the most likely haplotype matches for every IBD segment spanning a genomic region and integrates switch error predictions from all IBD segmentsusing a weighted voting method. We extracted over 350,000 individualsfrom the 23andMe dataset. We phased all individuals with Finch, a modification of the Beagle phasing algorithm that separates the haplotype graphconstruction and phasing steps. We then computed IBD across all pairs of individuals using GERMLINE, used HaploScore to filter out false-positive segments, and then ran Origin using this data to rephase. We assessed phasing accuracy by comparing Finch andOriginphasing to the gold-standard trio phasing in 3,000trio children. Origin decreased the global switch-error rate by 25-30%, with increased IBD coverage corresponding to better performance gains. The algorithm can be easily modified to run on genotypes phased and IBD calculated by other methods, and so is widely applicable to population-scale datasets.

coalescentSTR: a statistical approach for short tandem repeat number estimation based on coalescent theory from high-throughput sequencing data. *K. Kojima[1], Y. Kawai[1], N. Nariai[2], T. Mimori[1], T. Hasegawa[1], M. Nagasaki[1].* 1) Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 2) Institute for Genomic Medicine, University of California San Diego, San Diego, United States.

In the estimation of repeat numbers in a short tandem repeat (STR) region from high-throughput sequencing data, two types of approaches are usually considered: approaches counting repeat patterns in sequence reads aligned to the region and paired-end read based approaches that consider the difference between the insert size inferred from each aligned read pair and its actual size. Although the former approaches can estimate repeat numbers accurately, STR regions with the size more than the sequence read length cannot be handled. On the other hand, the latter approaches can handle STR regions longer than the length of sequence reads. However, the accuracy of repeat numbers estimated with the latter approaches is not high, compared with those with the former approaches. Thus, we propose a statistical approach named coalescentSTR that considers the unobserved genealogy of multiple individuals and estimates their repeat numbers from paired-end read distances. The genealogy is represented by coalescent trees sampled from phased genotypes around a target STR region with Markov chain Monte Carlo. By propagating belief of repeat numbers from insert size data in the sampled coalescent trees, more accurate repeat number estimation is expected for STR regions longer than the length of sequence reads. For the estimation of repeat numbers, a new belief propagation algorithm is proposed to search repeat numbers maximizing the model likelihood, while handling the coalescent trees as hidden variables. The effectiveness of our approach was verified from the comparison with lobSTR, RepeatSeq, and STRViper on simulation datasets and real exome data for 33 JPT individuals in the 1000 Genomes Project.

Bayesian learning of risk variants and functional enrichments in pleiotropic traits. *Y. Li.* MIT, Cambridge, MA.

Genome wide association studies have provided valuable information to decipher the underlying causal variants across many common complex human diseases. However, we are often underpowered due to sample size, rare variants, linkage disequilibrium, etc. One promising direction is to integrate facets of functional genomic data with GWAS summary statistics across several related dieases to (1) re-prioritize GWAS hits; (2) detect functional enrichment of risk variants; (3) identify pleiotropic causal variants in multiple related disorders. In this regard, we present a novel Bayesian framework to jointly learn the underlying disease-associated signals across multiple disorders. Our model demonstrates promising performance on both simulation and applications to real GWAS datasets.

1619T

Improving Specificity in Ion Proton Data. *D. S. Lieber[1], N. Chennagiri[1], E. White[1], D. Brinza[2], J. Veitch[2], T. Yu[1], J. F. Thompson[1].* 1) Claritas Genomics, Cambridge, MA; 2) Thermo Fisher Scientific, San Francisco, CA.

The Ion Proton instrument by Life Technologies is a chip-based sequencing technology that can produce whole-exome scale next generation sequencing data within hours. A critical part in development of a sequencing platform involves improving specificity via data filtering and thus we have worked to improve Ion Proton variant calls using a dual strategy. We first created and applied a strand-specific error (SSE) filter, whereby variants with strand bias across multiple samples were removed. We additionally created a filter using data derived from over 8,000 exomes sequenced at Claritas Genomics and compared the allele frequencies to the ExAc database. Any variant with high allele frequency in the Claritas database but low allele frequency in ExAc was deemed to be a likely false positive. Using NA12878 NIST data to benchmark performance, these methods allowed us to reduce the number of false positive SNPs by 3. 8-fold and indels by 5. 6-fold, with a 0. 1% loss in sensitivity for both SNPs and indels. These results demonstrate that Ion Proton variant call accuracy can be significantly improved through downstream bioinformatics processing.

1620F

Low-cost ancestry inference using targeted sequencing. *B. Liu[1], S. Shringarpure[1], C. Gignoux[1], R. Zhang[2], K. S. Smith[1], C. D. Bustamante[1], S. B. Montgomery[1], D. Vollrath[1].* 1) Pathology, Stanford University, Palo Alto, CA; 2) Sun Yat-Sen University, Guangzhou, P. R. China.

To control for population structure in genetic studies, one can preselect specific individuals based on self-reported ancestry. However, such information may not be available at the time of study, or may be inaccurate in cases where subjects are from admixed populations. Under such circumstances, it is desirable to genotype study participants for the purpose of ancestry inference. Current platforms for ancestry determination mostly use array technology. Such technology is cost-efficient on a production scale, where thousands of samples need to be genotyped. However, microarray platforms become costly on a laboratory-scale, where less than 100 individuals need to be genotyped for a more targeted set of ancestry informative markers. For example, Illumina's lowest-cost microarray platform, HumanCore-24, charges $88 – $98 per sample for the chip alone. If the project requires more variants than packaged on the chip, custom markers can be added at a minimum of 1,152 samples and 1,000 markers at an additional cost. This is often greater than required when fewer than 100 individuals need ancestry inferred. We have developed a targeted sequencing pipeline to determine ancestry proportion using ancestry informative markers (AIMs). Our approach consists of the following steps. We first ascertain the ancestral common variants from the 1000 Genomes Project Phase 3 catalog. We iteratively add markers to each population of interest to ensure a set of AIMs with a balanced cumulative locus specific branch length (LSBL) for each population. We designed primers pools for the AIMS sites iteratively using yamPCR. Targeted amplifications are performed on the Fluidigm Access Array platform. Amplicons are then barcoded by sample and sequenced to a depth of 100-1000 reads per site. We infer ancestry proportions using the likelihood frameworkof ADMIXTURE. As a proof of principle, we used this approach to select 123 SNPs that explain more than 99% of ancestry proportions between African and European populations. We performed targeted amplification on 12 admixed African American samples genotyped by the 1000 genomes consortium. The true ancestry proportions are recapitulated at a high proportion using the 123 AIMs sites alone (R2 = 0. 99). Compared to commercially available microarray platforms, this pipeline can be completed under comparable time scale, is several-fold cheaper ($17 - $55, depending on the sample size), and offers competitive accuracy in ancestry inference.

1621W

Improved Algorithm for Amplicon Sequencing Assay Designs. *G. Liu, M. Manivannan, C. Lou, A. Atkins, K. Rhodes, A. Broomer, F. Hyland, M. Andersen.* Thermo Fisher Scientific, South San Francisco, CA.

Ion AmpliSeq™ sequencing is one of the most promising applications of the Ion Torrent NGS platform. It involves multiplex PCR for target enrichment. Thermo Fisher offers online Ion AmpliSeq Designer to customers to assist assay designs. While more and more people are adopting Ion AmpliSeq technologies, challenges for assay designs started to emerge. Here we present bioinformatics approaches to improve the following areas of assay design: 1) assay specificity; 2) primer quality control; 3) SNP under primer; and 4) flexibility to adapt to different applications of Ion AmpliSeq sequencing including variant calling, copy number variation detection, and metagenomics. Design algorithms are developed to ensure high coverage with controlled risk of amplification efficiency, off-target reads and SNP effects. With the optimized design algorithm, numerous community and customer panels have been created, including the Ion AmpliSeq Exome Panel, TP53 Panel, and CFTR Panel. Design details of those panels are also presented. *For Research Use Only. Not for use in diagnostic procedures.* .

1622T

Normalization for correcting systematic variation in microarray genotyping. *J. Liu, B. Eynon, J. Brodsky, J. Gollub, T. Webster.* Affymetrix, Inc. , 3420 Central Expressway, Santa Clara, CA 95051.

Genotyping on array platforms has very high accuracy, exceeding 99. 5% across a large number of markers and samples. Occasional, systematic, artifactual variation in genotypes of a small set of markers can arise from non-genetic sources, including differences in sample collection and handling; laboratory, instrumentation, and reagents used in the genotyping assay; time period of processing; or other environmental influences. This can result in biased allele measurements and lead to incorrect genotype calling. Advanced normalization techniques to mitigate these systematic variations can significantly improve the quality of results.

We have developed a normalization approach to remove systematic effects arising from identified sources from genotyping data. Log-linear regression is used to quantify and subtract identified effects from the measured intensities for each allele. A critical assumption of this approach is that the identifiable effect being mitigated is not confounded with genetically relevant differences. For example, if a systematic effect is introduced by one or more collection centers, it is critical that genetically relevant factors such as population of origin and case-control status be randomized across centers so that meaningful information is not removed along with the irrelevant bias.

To evaluate our normalization approach, we examined a set of approximately 1,100 samples genotyped using Axiom® Genotyping Solution. Samples were arranged on Axiom® array plates: (1) with population of origin strongly confounded with the array plate, and (2) with samples randomized across the array plates, with no confounding. Genotyping was performed with no adjustment of signals and with our advanced normalization using plate of origin as a possible source of bias. Results from the experiment showed that normalization improved concordance to 1000 Genomes Project genotypes for a small set of probesets with performance below standard quality metrics in the non-normalized data. 1. 2% of probe sets were filtered out using Axiom® SNP quality control methods (SNPolisher) from Affymetrix. Normalization improved performance for 30% of the probesets below QC thresholds, and their concordance increased from 92. 4% to 98. 4%. However, when the randomization assumption was violated, this approach was not successful. We conclude that normalization to remove systematic biases can be a useful tool when coupled with appropriate experimental design.

1623F

APIGenome: A public library for big data genomic analysis tools. *A. Liu, H. M. Kang.* Department of Biostatistics, University of Michigan, Ann Arbor, Ann Arbor, MI.

Querying over large-scale genomic data requires many different computational tools for each particular questions of interest. In many cases, in-house software tools that were written to answer to a particular type of task can be recycled for answering different types of questions by others. Simple examples tasks include extracting particular subset of samples or markers from a VCF file, producing basic summary statistics from a VCF file, comparing genotypes between VCF files, plotting allele frequency spectrum from a VCF file. Here we present APIGenome, a public library of software tools for analyzing large-scale genomic data. APIGenome is a collection of reusable genomic analysis software tools hosted as a github repository and open to contribution from public. APIGenome provides generic interfaces that allow automated documentation of software (wGetOptions) and seamless parallelization or a large number of tasks (run-make). These features substantially reduce the burden of software maintenance and facilitate further extensions through collaborative contribution from the community with minimal effort. As of June 2015, APIGenome includes a rapid VCF analysis tool written in C++ (vcfast), genotype comparison and visualization tool between VCF and/or PLINK-formated files (bed-diff), visualization tools of allele frequency spectrum (draw-afs), likelihood-based variant filtering tool from VCFs of family-based samples or duplicate samples (MiFt), various utilities for VCF summarization or manipulation (vcf-summary, vcf-add-rsid, vcf-lookup-rsid, vcf-resolve-chrX-hets, vcf-issac-summary), and software summarizing QC metrics from a large-scale sequencing study (now-seq-scan). We expect that APIGenome will continually grow as a library of practical utilities for big data genomic studies.

1624W

WGSA: an annotation pipeline for human genome sequencing studies. *X. Liu[1,2], S. White[3], B. Peng[4], A. D. Johnson[5,6], J. A. Brody[7], A. H. Li[1], A. Carroll[8], Z. Huang[3], N. Rustagi[3], P. Wei[1,9], R. Gibbs[3], F. Yu[3], R. J. Klein[10], E. Boerwinkle[1,2,3].* 1) Human Genetics Center, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 2) Department of Epidemiology, Human Genetics and Environmental Sciences, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 4) Department of Bioinformatics and Computational Biology, University of Texas MD Anderson Cancer Center, Houston, TX, USA; 5) NHLBI Framingham Heart Study, Bethesda, MD, USA; 6) Population Sciences Branch, NHLBI Division of Intramural Research, Bethesda, MD, USA; 7) Cardiovascular Health Research Unit, Department of Medicine, University of Washington, Seattle, WA, USA; 8) DNAnexus, Mountain View, CA, USA; 9) Department of Biostatistics, School of Public Health, University of Texas Health Science Center at Houston, Houston, TX, USA; 10) Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, Icahn Institute for Genomics and Multiscale Biology, New York, NY, USA.

Large-scale sequencing technologies have made unprecedented progress during the recent years. We are witnessing an exciting era when genetic variants—including single nucleotide variants (SNVs) and insertion-deletion variants (indels)—in both healthy human subjects and those with Mendelian or complex diseases can be comprehensively identified by re-sequencing studies. Unfortunately, there is a large gap in the ability to ascertain enormous amounts of variants and the ability to understand their functionality. This gap will grow even wider as we transition from whole exome capture sequencing to whole genome sequencing (WGS). There are currently few tools available to integrate coding and non-coding functional annotation resources and provide a convenient and efficient pipeline for annotating millions of variants discovered in a WGS study. As a first step to narrow this gap, we developed WGSA, an annotation pipeline for human genome sequencing studies, to facilitate the functional annotation step of WGS. Currently WGSA supports the annotation of SNVs and indels locally without remote database requests, so it can be scaled up for large studies. Compared to existing annotation tools, our study has the following unique aspects:1. We integrated annotations from three popular annotation tools (ANNOVAR, SnpEff and VEP) versus two popular gene model databases (Ensembl and RefSeq). A recent study has shown that the consequence prediction of a variant often varies depending on the underlying gene model and the annotation tool used. Therefore, it is suggested to obtain annotations from multiple tools across multiple databases for a more complete interpretation of the variants. Here we provide a one-stop resource to achieve that goal. 2. To further speed up the process, we precomputed the annotations for all potential human SNVs (a total of 8,584,031,106) based on human reference hg19 non-N bases and use it as a local database. 3. We integrated many annotation resources for both coding and non-coding variants, including functional prediction scores (CADD, FunSeq, etc), population allele frequencies (ExAC, UK10K, etc), conservation scores, mappability, and annotations from epigenomic projects (ENCODE, Roadmap, etc). 4. To provide convenience to a broader community, we have built an Amazon Machine Image for running WGSA on the cloud from Amazon Web Services, in addition to a downloadable version. More information can be found at https://sites. google. com/site/jpopgen/wgsa.

Slippage-Associated Repeat Identification and Analysis (SARIA) *in silico* at Sites of Chromosomal Structural Change. *S. Ma[1], N. Pannunzio[2], K. Wang[3], M. R. Lieber[4].* 1) Cancer Biology and Genomics Program, Keck School of Medicine, University of Southern California, Los Angeles, CA; 2) Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA; 3) Zilkha Neurogenetic Institute, Biostatistics Division, Keck School of Medicine, University of Southern California, Los Angeles, CA; 4) Norris Comprehensive Cancer Center, University of Southern California, Los Angeles, CA. lieber@usc. edu.

DNA structural aberrations, such as translocations, insertions and deletions, often have a non-random distribution in the human genome, but are predisposed to occur in certain regions. Despite this, the relation between structural abnormalities and their surrounding sequences has not yet been fully studied. One major cause of these structural abnormalities is transient DNA slippage, which usually occurs during replication or transcription, when the DNA duplex melts and re-anneals. One common cause of DNA slippage is mis-alignment at short, closely spaced DNA repeats (direct or inverted, less than 15bps in length, distance between repeats less than 15bps) due to passage of a polymerase. To precisely illustrate the distribution of sequences prone to DNA slippage throughout the human genome, and to determine the differences in DNA repeat locations between healthy individuals and patients with various diseases, we have developed a python program: Slippage-Associated Repeats Identification and Analysis (SARIA). Because of the nature of DNA slippage, our program focuses on searching the surrounding sequences for repeats. Our program includes convenient user defined parameters, such as minimum/maximum distances between repeats, shortest/longest repeat length, and percentage of mismatches allowed. It provides follow-up analysis support, such as G/C content calculation, labeling of nearby histone modification sites, and statistical comparisons between different inputs. Together with its visualization functions, SARIA will provide users with a straight forward output displaying the repeat sequences and their genomic locations. Currently, there is no existing software serving to extract such information for neighboring repeat pairs in a large genome range. Using SARIA, one can easily locate potential DNA slippage sites in genome regions of interest, and examine whether or not slippage is a possible cause of genome structural changes. This program seeks to provide insights at the DNA level in diseases, such as cancer, which involve DNA abnormalities.

1626F

A pairwise genomic distance measure to evaluate the effect of donor/recipient genomic proximity on unrelated stem cell transplantation. *A. Madbouly, V. Paunic, M. Albrecht, M. Maiers.* Bioinformatic Research, National Marrow Donor Program, Minneapolis, MN.

Survival after hematopoietic cell transplantation (HCT) is dependent on donor/recipient (D/R) HLA matching. However, other factors such as D/R non MHC admixture can affect outcomes. To investigate these effects, we developed a robust pairwise D/R genomic distance that captures signal variability while minimizing signal-to-noise ratio. The study was designed in two phases. We initially genotyped 300 D/R pairs for 500 autosomal ancestry SNPs using SequenomiPLEX assay. In the 2nd phase 995 D/R pairs were genotyped on the HumanOmniExpress BeadChip array, which contained 307 of the 500 pilot SNPs. The remaining 193 SNPs were imputed to the 1000 Genomes reference panel using IMPUTE2. After running basic sample QC (SNP and sample call rate >98%, MAF > 1%), gender concordance was run using X-chromosome homozygosity. Twelve samples were found discordant with reported gender and were further evaluated for sample mix-up. All gender discordant samples were disregarded from further analysis. Pairwise D/R Euclidean distance was evaluated on PCA eigen vectors by varying the number of PCs in each vector and comparing correlation with distance from raw genotypes (ʃ). Selected distance vector size (N=88 PCs) was chosen such that the first derivative of the correlation ʃ is minimized, thus minimizing signal-to-noise ratio. Average PCA distance was 11. 67 (range [1. 83, 19. 5]). Average distance was higher for D/R pairs with mismatched versus matched reported race (N-mismatched=160, mean = 12. 2, [8. 09, 19. 2]), (N-matched= 1075, mean = 11. 6, range [1. 83, 19. 4]). Minimizing signal-to-noise ratio in the developed distance measure can potentially help reduce the effect of confounding factors on subsequent outcomes analyses. A multivariate analysis is currently being conducted to evaluate the association of D/R genomic distance and D/R admixtures with multiple HCT outcomes.

SPRITE: A Fast Parallel SNP Detection Pipeline. *K. Madduri[1], V. Rengasamy[1], P. Medvedev[1,2].* 1) Computer Science and Engineering, The Pennsylvania State University, University Park, PA; 2) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA.

Variant calling analysis of whole genome sequencing data is a computationally-intensive process, often taking several hours to even multiple days. We develop SPRITE, an open-source toolkit for detecting Single Nucleotide Polymorphisms (SNPs). By combining fast new algorithms and parallel computing technologies, SPRITE significantly accelerates the computational tasks of alignment, intermediate file processing, and SNP detection. For a benchmark human genome with 30X coverage, SPRITE takes just 30 minutes (from FASTQ data ingestion to VCF file creation) on a compute cluster with 16 servers. We also evaluate SPRITE on several Illumina Platinum Genome data sets. PARSNIP, the SNP detection tool in SPRITE, is orders-of-magnitude faster than the SNAP callers in GATK, samtools, and Freebayes. In our preliminary analysis, we find that that the quality of results obtained (PARSNIP precision and recall using high-confidence variant calls as ground truth) is comparable to state-of-the-art SNP-calling software. A prototype implementation of SPRITE is available at sprite-psu. sourceforge. net.

1628T

Alignment, phasing and structural variant detection with linked reads. *P. Marks, M. Schnall-Levin, S. Kyriazopoulou-Panagiotopoulou, H. Heaton, D. Stafford, G. X. Y. Zheng, S. Saxonov.* 10X Genomics, Pleasanton, CA.

We have developed algorithms for the GemCode platform from 10X Genomics to recover long-range information from short-read sequencers. Our approach exploits the throughput and accuracy of short-read sequencing while enabling haplotype phasing and vastly improved structural variant detection and short-readalignment. In the GemCode system, long fragments from 1ng of DNA are randomly partitioned into hundreds of thousands of individually-barcoded microfluidic droplets (~3Mbp/droplet) from which libraries are made that are compatible with standard exome capture. Many linked reads cover each input fragment, providing a powerful new data for novel algorithms that enable phasing and structural variant detection from WGS and WES samples. Our barcode-aware alignment algorithm exploits prior knowledge that the long molecules within one partition cover a very small fraction of the genome (0. 1%). A group of reads mapping to distant duplicated regions have a 99. 9% prior probability of having originated from a single copy of the locus. Unique alignments from flanking regions and single unique nucleotides within the copies combine to inform the correct mapping location and mapping quality score for each group of linked reads. Our phasing algorithm uses a maximum likelihood approach to optimize the conditional probability of read and barcode support for each allele given a phasing configuration. The algorithm first finds near-optimal local haplotype configurations using a beam-search approach to phase blocks of ~50 variants. It then joins neighboring blocks together, and makes local corrections until convergence. For SV detection, our algorithm first searches for all pairs of genomic loci with significant barcode intersection, encoding this search as an efficient sparse matrix-multiplication. Candidates from this first stage are then filtered utilizing a probabilistic model that incorporates read-pair, split-read, and barcode data. We tested our phasing algorithm on data from the CEPH cell line NA12878 and the GiaB Ashkenazi trio. For WGS, we achieve mega-base N50 phase blocks, >95% of SNPs phased and long switch error rates <0. 05%, without relying on statistical phasing. For WES, we phased 95% genes <100Kb into single phase blocks. We tested our SV-calling on NA12878 and NA20847, calling multiple large-scale structural variants and phasing them with respect to adjacent phase blocks, showing consistency of phasing with inheritance patterns in the nuclear trio.

Geisinger GenomeFIRST™ and Targeted Family History Collection. *S. A. Martin, M. A. Giovanni, A. H. Buchanan, M. L. Barr, J. B. Leader, C. J. Seiler, J. R. Hill, M. F. Murray.* Geisinger, Danville, PA.

BACKGROUND:The Geisinger Health System (GHS) MyCodeTM Biorepository-Regeneron Genetics Center collaboration (DiscovEHR) is assembling a cohort of 250,000 participants who will undergo whole exome sequencing (WES). Through the GenomeFIRST™ return-of-results program, participants found to have a pathogenic or likely pathogenic variant in a gene associated with one of 27 medically actionable conditions (inclusive of the ACMG secondary findings list) will have the result CLIA-confirmed and clinically returned. This program includes a web-based, patient-entered family history tool with EHR compatibility, the GenomeFIRST™ Family History Tool. METHODS:The GenomeFIRST™ Family History Tool was developed utilizing response-based logic to collect only targeted family history information relevant to the returned result. After results are reviewed with participants, they are directed to a secure URL where they enter a unique identification number and are presented with a condition-specific family history survey. Through brief prompts and questions, the survey collects family structure information (including first and second degree relatives) and condition-specific family health information for each relative. The patient-entered data is used to generate a detailed report to enable clinical decision support. RESULTS:The family history tool was beta tested by 35 individuals who responded for all first and second degree relatives. Testers were surveyed regarding usability and total time for completion. The average completion time was: 8 minutes (range 4. 5 to 14). A total of over 42,000 patients have undergone WES to-date. It is anticipated that at least 840 patients (2%) will receive a report of a pathogenic/likley pathogenic variant. The first participants will receive results in July 2015. The tool will be used by these participants and their relatives who receive cascade testing for familial mutations (> 1,000 patients). CONCLUSIONS:The use of sequencing to screen populations for clinically actionable genomic findings will lead to the need for easy to use tools for patient-reported data entry, provider decision support, and interface with EHRs. The “GenomeFIRST™ Family History Tool” will be used to satisfy these needs. The utility of this approach for identifying both at-risk family members and affected family members is under investigation. Detailed results on the first 50 cases will be presented.

1630W

Massively Parallel Demultiplexing of Raw Illumina Sequencing Data. *B. R. Myers[1], S. M. L. Griffith[1], K. N. Hetrick[1], B. D. Craig[1], D. Mohr[1], K. Roberts[1], M. Z. Mawhinney[1], A. Robinson[1], D. R. Leary[2], J. D. Newcomer[3], L. Watkins, Jr. [1], K. F. Doheny[1].* 1) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 2) The New York Genome Center, New York, NY; 3) The Johns Hopkins Applied Physics Lab, Laurel, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. Before Illumina sequencing data can be analyzed, raw base call files (BCL) produced by the various Illumina sequencing technologies (HiSeq, MiSeq, etc.) are demultiplexed and converted into FASTQ files. While the demultiplexing tools provided by Illumina are typically used for this conversion process, the software development group at CIDR has designed and implemented a distributed BCL demultiplexing tool. Written in Java, the CIDR BCL conversion tool is integrated with CIDRSeqSuite, a software application designed to implement and run sequencing analysis pipelines in a distributed fashion across a computational cluster. Because of this integration, the BCL conversion tool takes advantage of the high degree of parallelism made available by the CIDRSeqSuite toolset. The data associated with each of the tiles of an Illumina flowcell are not directly related to one another, meaning that each tile can be processed independently. Because the set of tile-conversion tasks is embarrassingly parallel, the BCL conversion and demultiplexing process scales well with available computational resources. Previously, FASTQ files were generated in two general steps. Illumina's Offline Base Caller (OLB) was used to generate QSEQ files, and CIDRSeqSuite demultiplexed and converted them into the FASTQ format. Whereas the combined aforementioned methods could take many hours, the current approach takes anywhere from five to 30 minutes, depending upon data size and the number of concurrent tasks. This increase in speed is particularly germane for high-throughput runs that are available on the current generation of HiSeq sequencers. The tool works for single- and paired-end runs; and supports both currently used location file formats (. clocs and . locs). In addition to the benefits mentioned above, the CIDR BCL conversion tool also writes detailed reports on the sample index distribution discovered while demultiplexing. This allows users to quickly determine incorrect or underrepresented indices present in a given run. The tool is also capable of removing tiles that have corrupt or truncated associated BCL files. Current work includes enabling dual-index demultiplexing.

CANNOTATE: A Genomic Sequencing and Annotation Database. *J. D. Newcomer[1], S. M. L. Griffith[2], E. W. Pugh[2], D. R. Leary[3], R. T. Hider, Jr. [1], P. Zhang[2], D. Mohr[2], L. Watkins, Jr. [2], C. Bradburne[1], K. F. Doheny[2].* 1) Applied Physics Lab (APL), The Johns Hopkins University Applied Physics Laboratory, Laurel, MD; 2) Center For Inherited Disease Research (CIDR), The Johns Hopkins University School Of Medicine, Baltimore, MD; 3) The New York Genome Center, 101 Avenue of the Americas, New York, NY 10013.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. The Johns Hopkins University Applied Physics Lab (APL) supports independent research and development programs that pioneer and explore emerging technologies and concepts to address future national priorities. CIDR and APL staff have collaborated to produce CANNOTATE, a software tool designed to store and analyze large-scale genomic data. CANNOTATE was developed because CIDR staff encountered the following two problems:1. Genomics data is typically stored in flat VCF files, which leads to slow data access and analysis2. Some current genomics annotation tools are extremely resource (RAM) and time intensive when running many samples over large data sets. CANNOTATE is designed to solve these problems by organizing variant (from VCF) and annotation data in a NoSQL database using Accumulo, a NoSQL technology built on top of the Hadoop File System (HDFS). Because Accumulo is based on HDFS, the data are spread across a distributed computing cluster (Hadoop HDFS), which leads to faster data access and storage. This software stack organizes, compresses, and indexes the variant and annotation data for fast query and retrieval. CANNOTATE also includes software tools that perform fast and efficient sample annotation. CANNOTATE is a work in progress; our prototype has yielded very promising results. Data is ingested two to three orders of magnitude faster than a previous RDBMS implementation allowed. Annotations complete 26 times faster than comparable tools: a 51-sample annotation went from 4. 5 hours down to 10 minutes. Current work includes a GUI toolset and additional analysis capabilities. Eventually, CANNOTATE will be released to the genomics community as an open-source tool.

1632F

Integrated Genome Mapping in Nanochannel Arrays and Sequencing for Better Human Genome Assembly and Structural Variation Detection. *A. W. C. Pang, A. Hastie, P. Sheth, T. Anantharaman, Z. Džakula, H. Cao.* BioNano Genomics, Inc. , San Diego , CA.

De novo genome assemblies using purely short sequence reads are generally fragmented due to complexities such as repeats found in most genomes. These characteristics can hinder short-read assemblies and alignments, and that can limit our ability to study genomes. The BioNano Genomics Irys® System linearizes long DNA molecules, thus yielding single-molecules containing long-range information. These hundreds of kilobases molecules can capture structural information that may be missed by other sequencing platforms. The assembled genome maps from these molecules can scaffold sequencing assemblies to validate the accuracy of the sequences, and to anchor the adjacent sequences into the proper order and orientation. The long-range hybrid scaffolds are able to identify novel chromosomal rearrangements undetectable by short-read alignment or reference-guided assembly approaches. We present a comprehensive analysis of a human genome by combining single molecule genome mapping with one of the most annotated sequence assemblies, the HuRef (Human Reference Genome – J. Craig Venter Institute) assembly. Overall, we found that assemblies from the sequencing and genome mapping technologies correspond well, and the resulting hybrid scaffolds are highly contiguous, with a N50 exceeding 35 Mb, a value typically unachievable by short-read sequencing technologies alone. In addition, we compared the structural variation with calls previously detected in the HuRef assembly, and found multiple novel variants spanning over hundreds of kilobases in size. Some of these variants reside in areas where the sequence assembly was poorly covered or was highly fragmented; yet these variants encompass numerous genes, and can be of functional importance. Finally, we identified genome maps that span over the remaining reference gaps, and maps that resolve and measure long tandem repeats.

An accurate and sensitive approach to detecting source of variance in DNA methylation Beta values. *Y. Park[1,2], L. B. Chibnik[2,3,4,5], M. Kellis[1,2], P. L. De Jager[2,3,4].* 1) Computer Science and Artificial Intelligence Laboratory, MIT, Cambridge, Massachusetts; 2) Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts; 3) Program in Translational NeuroPsychiatric Genomics, Institute for the Neurosciences, Departments of Neurology and Psychiatry, Brigham and Women's Hospital, Boston, Massachusetts; 4) Department of Neurology, Harvard Medical School, Boston, Massachusetts; 5) Department of Epidemiology, Harvard T. H. Chan School of Public Health, Boston, Massachusetts.

From DNA methylation we keep track of cumulative epigenetic changes in cells, and we can utilize DNA methylation as a good indicator of diagnosis and prognosis. In case-control studies, differential DNA methylation levels can occur due to abnormal acceleration of enrichment or depletion. However, methylation is result of disease status and other factors such as aging and gender. Unless we factor out unwanted effects from DNA methylation, downstream analysis is affected by spurious factors will dilute valuable information of subtle, yet statistically significant, disease associations. This is true of the Beta values provided by the Illumina Humanmethylation450 beadset. Nonetheless common practice of modeling heavily rely on a simple linear regression, which assumes Gaussian noise distribution. We propose a sparse regression model that builds on the Beta regression. We extend the original regression model with spike-slab prior (Mitchell and Beauchamp, 1988), and computed posterior inclusion probability of known and latent variables. The spike-slab prior has been adopted to variable selection problems and showed success in modeling Gaussian variables (e. g. , Carbonetto and Stephens, 2013). However the Beta probability distribution is non-conjugate to the spike-slab prior, we performed hybrid algorithm using elliptical slice sampling (Murray et al. , 2010) and expectation propagation (Hernandez-Lobato et al. 2014). We regressed DNA methylation separately in the Brain and CD4+ cells on Alzheimer's Disease (AD) phenotypes (beta amyloid and tau tangles), cognitive decline score, and other confounding factors such as age, gender, and experimental batches. First we evaluated the utility of cognitive decline score as a non-invasive proxy to AD pathology. We found strong agreement between the cognitive score association and AD pathology. We then tested a clinical value of CD4+ methylation searching for a convergence point of the Brain and CD4+ cells. We confirmed convergence points at pathway level. Examples includes WNT signaling, notch signaling, gap juction, hypoxia, and SMAD2 pathways. Many of them are supported by current knowledge of metabolism and neurodegenerative disease mechanism. Moreover we extended our regression method to hierarchical models that take into account genetic bias and downstream gene expression regulation. Finally we evaluated statistical power of our methods in extensive simulations. We will release source codes in a public repository.

Discovering Combinatorial Patterns of histon modification regulating gene expression. *S. Park.* Department of Bioinformatics and Life SCience, Soongsil University, Seoul, South Korea.

To dissect histone code hypothesis, it is challenged that computational methods can be capable to discover de novo combinatorial patterns of chromatin modifications across cell types. We report a new computational approach based on association rule mining for de novo combinatorial pattern discovery of chromatin modifications. We identify the patterns correlated to gene expressions and enriched in functional categories. The method, an unsupervised approach to discover combinatorial chromatin modification patterns, can identify globally occurring chromatin modifications to locally rare modifications. It has advantages over existing methods since the patterns as rules are a quantitative description of properties and their interpretation is straightforward and simple to biologists.

GenomeWhiff and DigitalKindred: Ultra-Fast Similarity Search, Clustering and Classification of Very Large Number of NGS Samples Using Bitwise Operations. *J. Patel, A. Abhyankar.* New York Genome Center, New York, NY.

GenomeWhiff is a marker-based super-fast sample concordance and similarity search. DigitalKindred extends the ideas of bitwise representation and fast similarity search to biological applications like GWAS/case-control, clustering/classification of samples and single cell genomics. **GenomeWhiff**GenomeWhiff was developed as the next step of concordance check, wherein a sample is cheaply genotyped using a chip to be compared with the sequencing data for that sample to check for sample swaps and contamination. GenomeWhiff maintains a compact index of all the previously processed samples and checks the new sample against the index efficiently. A sample can be checked against 26,000 samples in 200 milliseconds. This is a similarity search that exposes inherent relationships like parent-child and siblings as well as indicates sample contamination. GenomeWhiff uses a set of LD-pruned, biallelic markers that have high minor allele frequency. Each marker is represented as a pair of bits encoding 2 alleles. Specific combination of allele bit values creates a sample signature. Using series of bitwise operations, a ranked list of samples similar to the query sample is created. Each sample signature is accompanied by a bitmask that indicates valid markers for the sample. The bitmask also allows partial searches involving a subset of total marker set. In case of contamination, a candidate list for the contaminating sample is created by looking at discordant calls and by searching for samples that would explain the allele change at the discordant calls. **DigitalKindred**For biological applications, the above ideas are generalized by separating the encoding scheme from the fast bitwise similarity search mechanism. Each application has its own encoder and decoder that describe how the data is represented as bitsets. The markers need not be positions on the genome. For a DNA sample set, the set of all the variants seen in the sample set is considered and a sample signature encodes whether each of those variants is present in the samples. For an RNA sample set, individual exonic expression levels are encoded after binning. Irrespective of encoding, systematic and exhaustive enumeration over marker combinations reveals the combinations that would cluster or classify the samples in line with observed phenotypes. Due to compact and efficient bitwise representation, this approach can scale to millions of samples and millions of markers.

1636W

Software for the visualisation of genetic variation and its implication on protein sequences and 3D structures. *A. Prlic[1], R. Bhattacharya[2], S. K. Burley[3,1], H. Tilgner[4], P. W. Rose[1].* 1) RCSB Protein Data Bank, San Diego Supercomputer Center, University of California San Diego, San Diego, CA; 2) Bioinformatics and Medical Informatics, San Diego State University, San Diego, CA; 3) RCSB Protein Data Bank, Center for Integrative Proteomics Research and Department of Chemistry and Chemical Biology, Rutgers, The State University of New Jersey, New Brunswick, NJ; 4) Stanford University, Stanford, CA.

Statement of purpose: Knowledge of an atomic-level resolution structure of a protein, provides deeper insight into the molecular mechanisms that underpin the function of a gene/protein, as well as their role in disease. To enable a deeper analysis of the possible changes related to genetic variation, we have developed novel tools that facilitate mapping of any genetic location onto corresponding protein sequence isoforms and 3D protein structure available through the RCSB Protein Data Bank. Our tools permit annotation of large sets of genetic variation data by correlating genomic location and sequence variation data with over 60 external resources and protein 3D structural data housed within the data-warehouse that supports the RCSB PDB website. We are apply these tools in several collaborations, wherein we annotate genetic variation data obtained through Next-generation sequencing. We have also developed novel visualisation tools that provide a graphical depiction of the impact of genetic variation on protein sequence and 3D structure. **Methods used**:We developed a mapping for every nucleotide in a known human gene (as available from the Human Gene Nomenclature Committee) at a specific position in the reference genome to mRNA and codon position together with the corresponding amino acid sequence position and atomic coordinates. A mapping pipeline is available for manual analysis of single genomic positions via a user interface. It can also be scripted for batch-analysis of large number of genetic locations (e. g. ,for SNP analysis). It forms the core of new user interfaces at the RCSB PDB web site, including Gene View (e. g. http://www. rcsb. org/pdb/gene/BRCA1) and Protein Feature View (e. g http://www. rcsb. org/pdb/protein/P38398). **Summary of Results:**Our database contains annotations for about 19,000 human genes. Using our analysis tools, at http://www. rcsb. org/pdb/chromosome. do, any genomic location can be manually mapped to UniProt and the PDB archive of 3D structures (if a mapping is possible). At present, ~5100 distinct human genes can be mapped onto ~7900 PDB entries. The same pipeline is also being used to analyze the impact of experimentally verified (synthetic long-read mRNA sequencing) alternative pre-mRNA splicing events on 3D protein structures, where we can associate alternatively spliced exons with protein features.

1637T

Improved Transcription Factor Binding Site Prediction using DNase-seq Footprinting in a Supervised Discriminatory Machine Learning Framework. *B. C. Quach[1,3], T. S. Furey[1,2].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Curriculum in Bioinformatics and Computational Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Transcription factors (TFs) bind to sequence motifs and regulate gene expression through interactions with other components of the transcriptional machinery. Identifying TF binding sites (TFBSs) remains a long-standing challenge due to TFs tolerating motif degeneracy, and only a small fraction of motif sites across the genome exhibit binding activity in a given cell-type. DNase-seq assays accessible chromatin corresponding to active regulatory regions, represented as reads enriched for nucleosome-depleted open chromatin. TFs bind at smaller sites within the broader open chromatin and protect the TF-bound DNA from DNaseI digestion. This creates a local depletion of reads within open chromatin known as footprints, which can be utilized to locate active TFBSs. Existing footprint detection methods differentiate between TF bound and unbound sites using only a single generative model for each binding state. With DNaseI digestion data from ENCODE DNase-seq experiments, we show that this assumption fails to fully capture footprint signal heterogeneity. To address this weakness, we developed a support vector machine (SVM) classification framework called DeFCoM (Detecting Footprints Containing Motifs) to better model DNase-seq footprint diversity. DeFCoM starts with a training set of ChIP-seq defined bound and unbound sites that contain a motif for a factor of interest. DNaseI cut patterns for these sites are clustered within both the bound and unbound groups, where clusters denote subclasses or profile patterns. DeFCoM models each of these diverse digestion profiles based on features of the digestion pattern, then uses these feature vectors to train an SVM to distinguish profile patterns characteristic of active and inactive TFBSs. To assess the performance of DeFCoM, we compared it to 5 existing footprinting methods. The comparative analysis included 18 TFs and DNase-seq data from 6 ENCODE cell-lines. At low false positive rates (<0. 05), we find DeFCoM is consistently better or at least comparable in accuracy toexisting methods across these diverse factors, demonstrating its ability to correctly identify true binding sites. Our results suggest that modeling DNaseI cut profiles using DeFCoM enhances active TFBSs prediction accuracy relative to current footprint detection methods.

1638F

Authorial: An author list management system for scientific papers. *N. W. Rayner[1,2,3], N. R. Robertson[1,2], M. I. McCarthy[1,2,4].* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, Oxford, United Kingdom; 3) Wellcome Sanger Institute, Hinxton, Cambridge, United Kingdom; 4) Oxford NIHR Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

The continued decrease in the cost of genotyping has led to an increase in the size and number of data sets genotyped. This abundance of cohorts with, usually, multiple phenotypes has led to a proliferation of data sharing via disease specific consortia. These large collaborative efforts have resulted in a greatly increased number of authors on publications and managing the long lists of authors, author contributions and institutions by hand is error prone and extremely time consuming. To address this issue we have developed a web application, Authorial, designed to collect authorship details for a publication and create an ordered, annotated author list in Microsoft Word format. Authorial is a server-side application written in Java and runs in all major internet browsers including Firefox, Chrome, Safari, Internet Explorer and Opera. The system operates in a hierarchical manner and there are a number of roles defined in the application, these are; publication organiser, author group leader and author. The publication organiser assumes overall responsibility for the publication and defines a series of author groupings and an author group leader for each. The author group leaders are emailed directly by the application and are asked to confirm their own details and to populate their assigned author groups with participating authors. Once the membership of all author groups has been completed, individual authors are directly emailed a unique access link URL which allows them to check their details and the details of their affiliated institutions. To avoid issues with multiple institutional spellings the system caches institutions entered to date so that these can be selected via autocomplete and reused by subsequent authors. Within Authorial there are various reports to allow the organiser to review and sift out duplications and inconsistences in the collected data. Authorial tracks the progress of each author so the organiser is able to re-email and chase up non-responders. Once the information is complete a Word Document is created containing the ordered author list. Should the author order change or an author or institution be added or removed, unlike traditional methods, it is quick to create the new Word format author list. To date the application has been used successfully by a number of different publication leaders representing multiple consortia, such as GoT2D which consists of over 250 authors and 170 institutions.

Best practices for deploying a high throughput pipeline for variant calling in an extremely large cohort of whole genome sequenced samples. *N. Rustagi[1], Z. Huang[1], N. Veeraraghavan[1], A. Carroll[2], M. Gorentla Venkata[3], E. Boerwinkle[1,4], R. Gibbs[1], F. Yu[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) DNAnexus, Palo Alto, CA; 3) Oak Ridge National Laboratory, Oak Ridge, TN; 4) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Large cohort studies have the potential to inform gene discoveries and directly influence personalized medicine. The surge of large cohort studies aided by decreasing costs of genome sequencing are driving a need for variant calling pipelines with the ability to handle ultra-large-scale computes and a short turn around time. Even with low coverage(~6x-10x) whole genome sequencing (WGS), the amount of genomic data processing for cohorts with >5000 samples is beyond the capacity of commodity compute clusters, typical of most research environments. Joint calling on cohorts with over 200 Tb of aligned read data imposes constraints on the length of the atomic genomic compute window. Minimizing data and memory footprint, transfer latency and costs, IO bottlenecks, and file system inconsistencies also becomes challenging at this scale. In this work, we present a high throughput framework for SNP and INDEL calling, which leverages heterogeneous computing infrastructures and is easily scalable to accomplish cohorts with over 10k samples. As a proof of principle, we present results of analysis on Cohorts for Heart And Aging Research in Genomic Epidemiology(CHARGE) WGS freeze 3 dataset in which joint calling, imputation and phasing on over 5200 whole genome samples was produced under six weeks using four state of the art callers, namely SNPTools, GATK-HC, GATK-UG and GotCloud. We used Amazon AWS provided by DNAnexus, a 4000-core in-house cluster at HGSC, IBM power PC Blue Biou at Rice and Rhea at Oakridge National Labs. We had approximately 180 TB of raw aligned read data, which was split into a genomic window size of 1MB across all the BAMs for the variant calling phase. The total number of compute core hours used were 5. 2 million. The SNP and INDEL site calling was accomplished on Amazon AWS architecture, with 1000 concurrent runs on average, with an average schedule time of approximately 60hrs. To optimize transfer costs and file system stress, four callers were executed on the 1MB genomic region at one go. Approximately 75% of the imputation was accomplished on Rhea, and the rest at Blue Biou, with 64,000 and 1000 concurrent runs respectively. Average time to completion was 30 hrs and 13 hrs for each window on Rhea and Blue Biou respectively. Our data footprint never exceeded three times the data through the whole operation. We hope that our experience with this compute can serve as a roadmap for future large scale variant calling efforts. .

1640T

VarAFT: A variant annotation and filtration system for exome sequencing data. *D. Salgado[1], J. P. DESVIGNES[1], M. BARTOLI[1], V. DELAGUE[1], M. KRAHN[1,2], M. MILTGEN[1], C. BEROUD[1,2].* 1) Aix-Marseille Université, Inserm, GMGF UMR_S 910, 13385, Marseille, France; 2) APHM, Hôpital TIMONE Enfants , Laboratoire de Génétique Moléculaire, 13385, Marseille, France.

High-throughput DNA sequencing technologies provide an unprecedented opportunity to identify disease-causing mutations for Mendelian disorders. However even if primary analysis of WES raw data such as alignment, variant calling and annotationare almost standardized and usually performed by bioinformaticians, the filtration step aiming at reducing the number of variationsto a handfulof candidate disease-causing mutationsremains a challenge. To facilitate this selection process an ideal system should allow: the combination of data from multiple individuals in order to evaluate autosomal recessive, dominant, X-linked and *de novo* hypothesis; the collection of extensive annotations for each variant; and the selection of the most relevant mutations based on multiple selection criteria. Additional features such as the coverage at the gene/exon/nucleotide levels are critical for clinical applications to ensure proper gene exclusion. As such tool is not currently publically available, we designed VarAFT (**Var**iant **A**nnotation and **F**iltration **T**ool - http://varaft.eu) as a freely available systemrunning on MacOS, Windows and Linux operating systems. It has been tailored with the recommendations of researchers, geneticists and clinicians from the Department of molecular diagnosis of the La Timone Children Hospital and the INSERM UMR_S910 research unit, taking into account international recommendations from ACMG and ESHG. VarAFT offers three application modules:1) The “CoverageAnalysis tool”is particularly useful for clinical applications as it allows evaluation of the coverage and depth for any nucleotide, exon or transcript;2)The “Annotation Module” can be used to perform variant annotation from any VCF file. It is a mandatory step to further apply filtration criteria to highlight potential disease-causing mutations. VarAFT makes use of the ANNOVAR annotation system in combination to theUMD-Predictor for pathogenicity prediction of exonic SNVs and the Human Splicing Finder system to evaluate the impact of any exonic or intronic mutation on splicing signals;3)The “Analysis and Filtration module”provides various filtration options to accommodate the international recommendations such as:localization, impact on the protein, pathogenicity, quality, zygosity, and frequency. . . VarAFT is currently designed for WES analysis. It can also handle gene panels. Optimizations are ongoing for WGS analysis.

1641F

cnvScan: a CNV screening and annotation tool to improve the clinical utility of computational CNV prediction. *P. S. Samarakoon[1,2], H. S. Sorte[1,2], A. Stray-Pedersen[3,4,5], O. K. Rødningen[2], T. Rognes[6], R. Lyle[1,2].* 1) Department of Medical Genetics, University of Oslo, Oslo, Norway; 2) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 3) The National Neonatal Screening Unit, Oslo University Hospital, Oslo, Norway; 4) Center for Human Immunobiology/Section of Immunology, Allergy, and Rheumatology, Texas Children’s Hospital, Houston, TX, USA; 5) Baylor-Hopkins Center for Mendelian Genomics of the Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 6) Department of Informatics, Faculty of Mathematics and Natural Sciences, University of Oslo, Oslo, Norway.

With advances in next generation sequencing technology and analysis methods, single nucleotide variants (SNVs) and indels can be detected with high sensitivity and specificity in exome sequencing data. While recent studies have demonstrated the ability to detect disease-causing copy number variants (CNVs), exonic CNV prediction programs have shown high false positive (FP) CNV counts. The high false discovery rate is the major limiting factor for the applicability of these programs in clinical studies. Thus, we developed a tool (cnvScan) to improve the clinical utility of computational CNV prediction by reducing the false discovery rate. cnvScan consists of two stages: CNV screening and CNV annotation. The screening stage utilizes CNV quality scores reported from prediction programs and further evaluates the quality of CNV calls by using an in-house CNV database. The annotation stage is designed to annotate predicted CNVs with functionally and clinically significant information using different source datasets. In addition, known CNVs within predicted variants were annotated using publicly available CNV datasets. CNV quality scores and annotated information reported from cnvScan are then used to filter high-quality rare CNVs from computational CNV predictions. To assess the utility of our method, we tested cnvScan using 64 exomes from Primary Immunodeficiency (PID) patients. Here we demonstrate that cnvScan can be used to generate a significantly small set of high-quality rare CNVs from a relatively large set of computationally predicted CNVs (4 high-quality rare CNVs in 4 patients from 17147 CNVs predicted from ExCopyDepth). Three CNVs out of these four high-quality rare CNVs were confirmed as PID-causing CNVs. We further compared CNV predictions from five programs (ExomeCopy, ExCopyDepth, ExomeDepth, CoNIFER and XHMM) and demonstrated the ability to derive high-quality rare CNVs using cnvScan. Finally, we assessed the efficiency of cnvScan using different filtration criteria and showed the ability to reduce false discovery rate by filtering-out FP CNVs while retaining rare true positive variants. In summary, cnvScan improves the clinical utility of computational CNV prediction by reducing the false discovery rate and providing annotation.

1642W

Benchmarking Strand NGS RNA aligner against TopHat2 and other common splice aligners. *A. Sathyanarayanan, R. Gupta.* Strand Life Sciences, Bangalore, India.

Background and objective: RNA alignment involves mapping of short reads produced from next generation sequencing of cDNA obtained from RNA, to a transcript annotation or reference genome. Alignment of millions of short reads with high accuracy is one of the biggest challenges of RNA Seq analysis. It is pivotal for discovering splicing events, differential gene expression, gene fusion and RNA editing. In this study, we compared the performance of the RNA mapping algorithm implemented in Strand NGS with TopHat v2 and several other algorithms. Strand NGS RNA aligner is a split read aligner with three options: 1) Alignment against transcriptome with no novel splices detection, 2) Alignment against transcriptome with novel splices detection and 3) Alignment against transcriptome and genome with novel splices detection. **Results:** We used four samples for the study, two samples each of mouse and human. Human samples comprise of RNA-Seq libraries from K562 cell line and the mouse data comprises of RNA-seq data obtained from brain tissue from adult mice of C57BL/6NJ strain. Alignment was performed in both, Strand NGS and TopHat v2, using similar parameters. Assessment of the alignment results was done using several benchmarks such as alignment yield, mismatch detection, indel placement and splice detection. While similar results were obtained for alignment yield and mismatch frequency, splicing events were detected more effectively in Strand NGS than TopHat v2. The number of known and novel junctions was plotted for increasing supporting reads cut-off to obtain receiver operator curves (ROC). For all the datasets, the ROC curve showed that Strand NGS outperforms TopHat v2 in identifying similar number of annotated junctions for much fewer false/novel junctions. Based on metrics of alignment yield and mismatch frequency, Strand NGS results are comparable to GSNAP, GSTRUCT, MapSplice and STAR, and better than GEM, ReadsMap and PALMapper. **Conclusions:** Several algorithms have been developed to overcome the challenges posed in RNA Seq analysis. High alignment accuracy, right placement of indels and gaps, and efficient detection of splice junctions are some desired features of RNA spliced read aligner. Detailed assessment shows that Strand NGS compares well with other state-of-the-art aligners for RNA alignment and also offers comprehensive approaches to data visualization, filtering and downstream analysis such as quantification and differential analysis.

1643T

Accurate somatic mutation detection at low allelic frequency and low copy number applied to liquid biopsy samples. *M. Schwartz[1], C. Ionescu-Zanetti[1], N. Kamps-Hughes[1], R. Brobey[2], K. Rosenblatt[3], M. Dehghani[3], R. Amato[2].* 1) Research and Development, Fluxion Biosciences, South San Francisco, Ca; 2) University of Texas Health Science Center at Houston, Houston, TX; 3) Research and Development, CompanionDx, Houston, TX.

Purpose: Tumor genotyping experiments are increasingly moving from the characterization of solid primary tumor biopsies to blood samples to track dynamic mutational changes over time. These sample types require tumor DNA enrichment steps and modifications of the molecular analysis protocols be able to detect rare variants. For circulating tumor cell (CTC) samples, the processing must also accommodate low copy input as sometime only a few cells (<5) are recovered from a blood draw. Here, we present validation of a method to detect somatic mutations from a blood draw, where typical CTC enrichment above 10% of total cell numbers enables the use of standard amplicon libraries. **Methods:** Analytical samples were created by spiking tumor cell lines into whole blood from healthy donors, followed by CTC enrichment using immunomagnetic beads in a microfluidic chamber. Further reference samples were created by spiking tumor cells into known numbers of donor-derived white blood cells (WBCs). CTCs were lysed and DNA was amplified by whole genome amplification (WGA). Targeted libraries were created using different amplicon sets, then sequenced using either the PGM (ThermoFisher) or MiSeq (Illumina) instruments. Data was analyzed using a customized variant pipeline based on standard alignment tools, variant filtering, and functional interpretation. Clinical samples were processed using the same protocols. Matched clinical samples were enumerated to determine the CTC load (CK+, CD45-, nucleated cells). All data was analyzed in a blinded manner. **Results:**Multisite analytical validation data demonstrated a detection limit down to 10 cells from a blood draw with a very low false positive rate. This translates into a robust detection of variants down to 0. 5% mutant allele frequency, without the use of nonstandard NGS techniques like single molecule sequencing. Results are shown for a number of analytical validation experiments, detecting variants down to 2 mutated copies in a background of wild type cells. Exemplary clinical data is presented from 10 patient sample sets, including biological replicates and analysis replicates using different amplicon sets and sequencing technologies to validate the results. **Conclusions:** A sensitive assay for the detection of somatic variants from a blood draw using standard amplicon panels developed for somatic mutation detection from solid cancers has been validated using analytical and clinical samples.

COSMOS: accurate detection of complex somatic structural variations through asymmetric comparison between tumor and normal samples. *J. Sese[1], K. Yamagata[1], A. Yamanishi[2], C. Kokubu[2], J. Takeda[2].* 1) BRD, AIST, Tokyo, Japan; 2) Grad. School of Medicine, Osaka U. , Osaka, Japan.

An important challenge in cancer genomics is precise detection of structural variations (SVs) by high-throughput short-read sequencing, which is hampered by the high false discovery rates of existing analysis tools. Here we propose an accurate SV detection method named COSMOS, which compares the statistics of the mapped read pairs in tumor samples with isogenic normal control samples in a distinct asymmetric manner. COSMOS also prioritizes the candidate SVs using strand-specific read-depth information. Performance tests on modeled tumor genomes revealed that COSMOS outperformed existing methods in terms of F-measure. We also applied COSMOS to an experimental mouse cell-based model, in which SVs were induced by genome engineering and gamma-ray irradiation, followed by polymerase chain reaction-based confirmation. The precision of COSMOS was 84. 5 %, while the next best existing method was 70. 4%. Moreover, the sensitivity of COSMOS was the highest level, indicating that COSMOS has great potential for cancer genome analysis. COSMOS is available from http://seselab. org/cosmos/.

A tool for developing and validating supervised learning risk prediction models. *S. Shankaracharya, Y. Ye, H. Hu, X. Wu, CD. Huff.* Department of Epidemiology, University of Texas MD Anderson Cancer Center, Houston, TX.

Machine learning (ML) methods have the potential to substantially improve the accuracy of disease risk prediction, but the technical complexities of these methods have been a barrier to widespread adoption. Here we present the PREdiction by SUpervised Learning Toolkit (PRESULT), a toolkit designed to simplify the development, validation, and dissemination of supervised machine learning risk prediction models. PRESULT supports four supervised ML methods: Mixture of Experts, Support Vector Machine, Random Forest (RF), and Regression Tree. PRESULT generates receiver-operating characteristics (ROC) curves and calculates the area under the curve (AUC) for training and validation datasets, comparing each ML model with a traditional logistic regression model. PRESULT produces a compact, distributable, and machine-readable description of each training model, ensuring reproducibility and enabling external validation. The toolkit also performs k-fold cross validation and provides robust support for parameter tuning and optimization for each ML method. PRESULT calculates 5-year and 10-year absolute risk by incorporating overall incidence and mortality rates with relative risk, which we estimate by fitting a logistic regression model to the continuous prediction score for each ML method. We evaluate the performance of this toolkit in two common, complex disease datasets: a case-control study of type 2 diabetes in Pima Indians with epidemiological data and a case-control study of lung cancer in European Americans with epidemiological and GWAS data. We found that RF consistently outperformed logistic regression and other ML methods in these particular datasets, with an average 10-fold cross validation AUC of 75. 6 in lung cancer and 84. 3 in type 2 diabetes compared to 69. 2 and 72. 5, respectively, for logistic regression models. PRESULT mitigates many of the major challenges of ML risk prediction modeling, providing new opportunities for more accurate assessment of personalized disease risk.

1646T

QuicK-mer: A rapid paralog sensitive CNV detection pipeline. *F. Shen, J. Kidd.* Human Genetics, University of Michigan, Ann Arbor, MI.

Copy number variation (CNV) is an important class of variation that contributes to genome evolution and disease. CNVs that become fixed in a species give rise to segmental duplications; whereas already duplicated sequence is prone to subsequent gain and loss leading to additional copy-number variation. Multiple methods exist for defining CNV based on high-throughput sequencing data, including analysis of mapped read-depth. However, accurately assessing CNV can be computationally costly and multi-mapping based approaches may not specifically distinguish among paralogs or gene families. We describe a rapid, mapping free, paralog-specific pipeline for CNV detection from second generation sequencing datasets by counting the occurrence of predefined 30-mers. The pipeline achieves paralog specificity while maintaining an efficiency of less than 7 hours for analysis of a typical 10x mammalian genome. We have utilized the QuicK-mer pipeline to explore variation among duplicated sequences in human, chimpanzee, and mouse sequencing data. Preliminary results demonstrate concordance between CNV prediction and experimentally validated copy number across mouse strains C57BL/6J, 129S5/SvEvBrd and BALB/cJ for KRAB-ZFP genes associated with sex-specific phenotypes in the *Rsl1/2* locus. Data further reveals significant overlaps between CNV hot spots and the existing segmental duplications in human and mouse genomes.

1647F

GENALICE MAP: efficient and accurate population genomics. *B. Tolhuis, L. Baarspul, H. Karten.* GENALICE BV, Harderwijk, GLD, Netherlands.

Current DNA sequencing platforms can analyze tens of thousand individual genomes per year, enabling large scale population genetics. Indeed, several nation-wide genomics initiatives are emerging, which aim at deciphering hundreds of thousands human genomes. Detection of sequence variants is ideally performed in the context of the entire cohort, begging that thousands of samples be analyzed in parallel. This is a computational and bandwidth challenge due to the huge amount of data that needs to be processed.

Here, we present a novel population scale variant caller as an extension of our proprietary GENALICE MAP NGS secondary data analysis suite. Earlier, we showed that GENALICE MAP aligns sequence reads for a single human genome (37x coverage) in 25 minutes and subsequent variant detection requires 5 minutes. The population caller investigates mapped reads from multiple genomes in parallel while each individual genome benefits from the population context. In a benchmark test, analyzing 17 individuals from Illumina's Platinum Genomes, we observed that variant detection in population context takes 7 minutes per genome using a single compute node with a Dual Intel Xeon E5 2620 V2 CPU architecture. This is a time reduction of approximately two orders of magnitude compared to GATK's joint variant calling method run on the same data and hardware. Moreover, our population caller has a single step workflow, employed directly on aligned reads without any additional and pre- and post-processing. Finally, compared to single sample variant calling the population caller yields substantially more and accurate genotype information. For example, the number of false negative SNPs in a 'truth' set comparison is reduced with 30%.

GENALICE MAP's population caller significantly reduces computational and workflow requirements of multi-genome variant detection. It allows individual genomes to take advantage of the population context resulting in more genetic information with increased accuracy per genome. Currently, the GENALICE MAP population caller works on a single compute node and its runtimes scale linearly. In the future, it will run in parallel on multiple compute nodes, enabling the analysis of thousands of genomes using compute grids or cloud environments. Given its low computational requirements per genome, the GENALICE MAP population caller is a highly time and cost effective manner to detect sequence variants in large cohorts.

Applying compressed sensing to genome-wide analysis of qualitative traits. *S. Vattikuti[1], J. J. Lee[2], C. C. Chang[3], S. D. H. Hsu[4], C. C. Chow[1].* 1) MBS, LBM, NIDDK, NIH, BETHESDA, MD; 2) Department of Psychology, University of Minnesota, Minneapolis, MN; 3) Complete Genomics, Inc. , Mountain View, CA; 4) Research and Graduate Studies, Michigan State University, East Lansing, MI.

Genome-wide analysis is an underdetermined problem due to many fewer samples than measures. This poses a challenge for discovering genetic predictors and causal variants. Compressed sensing (CS) is the theory for selection that explains the properties of this problem for well-conditioned sensing matrices. As we have shown before for quantitative traits, the genome is such a matrix and there is a phase transition for complete selection of true associated variants [1]. For narrow-sense heritability of 0. 5 this is expected to occur around 30 times the number of trait-associated variants. Here we extend our prior work to qualitative traits and ask whether the same predictions can be made for these discrete traits. We explore factors such as case prevalence, sampling bias, and regression model (e. g. , linear, logistic). 1. Vattikuti S, Lee JJ, Chang CC, Hsu SD, Chow CC. Applying compressed sensing togenome-wide association studies. Gigascience. 2014 Jun 16;3:10. doi:10. 1186/2047-217X-3-10. eCollection 2014. PubMed PMID: 25002967; PubMed Central,PMCID: PMC4078394.

Computational Framework for Heterogeneity Assessment and Characterization in Single Cell Sequencing Data. *K. Volyanskyy[1], Y. Mao[1], T. Baslan[2], N. Dimitrova[1].* 1) Philips, Briarcliff Manor, NY; 2) Memorial Sloan Kettering Cancer Center, New York, NY.

Background: Heterogeneity is a common feature in both normal and diseased tissues. This phenomenon manifests itself in multiple modalities of genetic and epigenetic biological cell data such as gene expression, copy number variations, methylation, peptide profiling and others. For various purposes it is important to accurately identify and characterize distinct sub-populations of cells constituting heterogeneity profile of a sample. This becomes especially relevant with the adoption and rapid development of single cell sequencing technologies allowing previously unseen resolution of genomic data. In our work we developed an efficient computational framework to accurately identify heterogeneity profile from single cell sequencing data and analyze multiple modalities of genomic data. *Method*: We developed a computational framework based on optimal partition selection characterizing distinct sub-populations in a cohort of samples from single cells sequencing. The framework identifies optimal minimum variance partitions of the input in various modalities such as, RNASeq or copy number variation, or combined data set consisting of data from several modalities at once. In addition, we developed phylogeny reconstruction algorithm allowing identification of sub-populations in iterative procedure of minimum distance search. We tested our algorithm on a publicly available single cell transcriptome data set from [1] consisting of 82 single-cell transcriptomes from mouse lung epithelium obtained via microfluidic single-cell RNA sequencing. *Results*: We successfully identified distinct subpopulations in considered sets of samples. Compared to the ground truth published in [1] where transcriptomes were analyzed using unbiased genome-wide approach, we independently generated analogous partitions of the transcriptome into four main distinct sub-populations. *Summary:* Developed algorithms allow splitting heterogeneous data into a set of distinct sub-populations with guarantees of minimum within sub-population variability. The algorithm flow is contextually interpretable and the performance has been successfully tested on several data sets. The developed framework can find immediate applications in genomic studies that map out tumor heterogeneity at a deeper sequencing level. Deconvolution for Mixed Cancer Transcriptomes from Heterogeneous Tumor Samples with Immunal Infiltration. *Z. Wang[1], C. Holmes[4], W. Lu[5], X. Tang[5], I. Wistuba[5], J. Morris[3], W. Wang[2].* 1) Statistics, Rice University, Houston, TX; 2) Bioinformatics and Computational Biology, The University of Texas MD Anderson Cancer Center, Houston, TX; 3) Biostatistics, The University of Texas MD Anderson Cancer Center, Houston, TX; 4) Statistics, University of Oxford, Oxford, United Kingdom; 5) Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston, TX.

Tumor tissue samples are comprised of a mixture of cancerous and surrounding stromal cells. Understanding tumor heterogeneity is crucial to analyzing gene signatures associated with cancer prognosis and treatment decisions. Compared with the experimental approach of laser micro-dissection to isolate different tissue components, in silico dissection of mixed cell samples is faster and cheaper. A computational approach “DeMix” was previously developed to address this challenging problem when the observed signals are assumed to come from a mixture of two cell compartments, the cancerous tissue and its surrounding stroma. We have significantly extended DeMix to develop a three-component deconvolution model, DeMixT, that can account for a third component such as the immune cell compartment explicitly and is more realistic than a two-component model. Straightforward generalizations of the two-component DeMix model to the three-component setting are not computationally feasible because of the need to compute high-dimensional integrals. DeMixT therefore involves a novel two-stage filtering method yielding accurate estimates of cell purities and compartment-specific expression profiles. Simulations and real data analyses have demonstrated the good performance of our method. Compared to DeMix, DeMixT can be applied more widely and provides deeper insight in cancer biomarker studies. It allows for a further understanding of immunal infiltration in cancer and assists in the development of novel prognostic markers and therapeutic strategies.

Correcting nucleotide-specific biases in high-throughput sequencing data. *J. R. Wang[1], T. S. Furey[2].* 1) Department of Genetics, University of North Carolina, Chapel Hill, NC; 2) Departments of Genetics and Biology, Carolina Center for Genome Sciences, Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC.

High-throughput sequencing (HTS) assays use short (50-250bp) reads to determine the genome, transcriptome, and functional activity of biological samples. HTS-based methods include whole-genome sequencing (DNA-seq), transcription profiling (RNA-seq),chromatin accessibility (DNase-seq, FAIRE-seq, ATAC-seq), and transcription factor binding (ChIP-seq). These methods exhibit nucleotide-specific biases at specific read positions as a result of assay and/or HTS preparation steps. For example, DNase-seq data shows large biases at the 5' end as a result of the DNase I hexamer binding/cutting preferences. Common HTS protocol steps include sonication and adapter-mediated PCR, which may also introduce subtle biases in the final reads. We have developed a method to adjust for observed nucleotide-specific biases in HTS data, regardless of the bias source. Briefly, we first build a model of both the observed and expected nucleotide content within and surrounding each read. We then calculate read weights based on combined ratios of expected component k-mer frequencies relative to observed frequencies. We applied our method to DNA-seq, DNase-seq, FAIRE-seq, ATAC-seq, and ChIP-seq data from GM12878, K562, and LNCaP human cell lines produced at different labs, times, and under various experimental conditions. Using principal component analysis, we observed that the bias signature of these data cluster primarily by assay and lab, as expected. After bias correction, the average nucleotide frequency variance across reads is reduced from 0. 012 to 0. 0052. DNase, FAIRE, and ATAC commonly measure chromatin accessibility where transcription factors bind. Therefore, we compared correlations between these assays before and after bias correction. We used ChIP-seq data from CTCF, a widespread and abundant regulator. After bias correction, we observed an average increase in covariance from 0. 532 to 0. 544 between features predicted by these assays from the same cell line. The convergence of these corrected data implies they more accurately represent true epigenetic features. Additionally, corrected DNA-seq exhibited a shift in the ratio of alleles represented at heterozygous loci toward 1:1. The reduced level of nucleotide-specific biases at these loci can help identify true heterozygotes and differentiate these from misalignments, sequencing error, and homologous sequences.

HGSC Variant warehouse, a scalable, varianted-centered database running in hadoop. *S. J. White[1], S. Ambreth[1], T. Chiang[1], M. Dahdouli[1], A. English[1], A. Hawes[1], Z. Kahn[1], W. Salerno[1], N. Veeraraghavan[1], E. Boerwinkle[1,2], DM. Muzny[1], RA. Gibbs[1].* 1) HGSC, Baylor College of Medicine, Houston, TX; 2) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Personalized medicine is being ushered in tandem with large cohort studies, leveraging DNA sequencing technologies with higher throughput, lower cost per sample, and larger sample sizes. Consequently there are demands in terms of scale, heterogeneity of data and richness of annotation. We present a Hadoop variant data warehouse, which is flexible and scalable and provides rapid access to massive data sets. We use Hbase to store variant data in a NOSQL schema where rows represent variants and columns represent samples. This allows for rapid retrieval of data for a given variant / loci, typically with millisecond response times across thousands of samples. Sources of annotation such as DBSNP, HGMD, COSMIC are easily imported into the same schema. By holding all these data together we can move away from sequentially annotating and prioritizing variants for each sample to a paradigm of continual annotation across all samples, using allele frequencies generated on the fly. Using this technology in a CAP-CLIA environment will enable us to automatically flag unsolved cases for re-analysis as soon as new disease associations are published. In addition to variants we also encode read depth and base quality. By allowing us to distinguish between reference homozygous calls and regions with no coverage, these data provide us with a variant-caller agnostic solution to the "N+1" population level VCF (pVCF) problem. This significantly reduces compute time and simplifies the process of comparing large cohort studies consisting of heterogeneous data from different pipelines and sequencing centers. Storing coverage and quality increases the data footprint significantly; by using a novel, highly compressed, run-length encoded format we store at base level resolution, all the required data for a 30x whole genome in around 5Gb. This represents around 2% of the BAM size and includes data triplication within Hbase, making practical the persistent storage of 10's of thousands of whole genomes, such as the anticipated Illumina X-Ten production for the CHARGE cohort. Hadoop provides us with a flexible ecosystem of open-source tools, allowing us to easily integrate other sources of meta data such as LIMS, phenotypic data and electronic medical records. We will describe applications of the Variant Warehouse to more than 500 whole genomes, including variant annotation, summary statistics and QC, data footprint and pVCF generation.

1653F

NGS-SWIFT: A Cloud-Based Variant Analysis Solution Using Control-Accessed Sequencing Data. *C. Xiao, E. Yaschenko, S. Sherry.* NIH, 45 Center Drive, Bethesda, MD.

Variation analysis plays an important role in elucidating the causes of various human diseases. The drastically reduced costs of genome sequencing driven by next generation sequence technologies now make it possible to analyze genetic variations with hundreds or thousands of samples simultaneously, but currently with the cost of ever increasing local storage requirements. The tera- and peta-byte scale footprint for sequence data imposes significant technical challenges for data management and analysis, including the tasks of collection, storage, transfer, sharing, and privacy protection. Currently, each analysis group facing these analysis tasks must download all the relevant sequence data into a local file system before variation analysis is initiated. This heavy-weight transaction not only slows down the pace of the analysis, but also creates financial burdens for researchers due to the cost of hardware and time required to transfer the data over typical academic internet connections. To overcome such limitations and explore the feasibility of analyzing control-accessed sequencing data in cloud environment while maintaining data privacy and security, here we introduce a cloud-based analysis framework that facilitates variation analysis using direct access to the NCBI Sequence Read Archive through NCBI sratoolkit, which allows the users to programmatically access data housed within SRA with encryption and decryption capabilities and converts it from the SRA format to the desired format for data analysis. A customized machine image (ngs-swift) with preconfigured tools (including NCBI sratoolkit) and resources essential for variant analysis has been created for instantiating an EC2 instance or instance cluster on Amazon cloud. Performance of this framework has been evaluated using dbGaP study phs000710. v1. p1 (1000Genome Dataset in dbGaP, http://www. ncbi. nlm. nih. gov/projects/gap/cgi-bin/study. cgi?study_id=phs000710. v1. p1), and compared with that from traditional analysis pipeline, and security handling in cloud environment when dealing with control-accessed sequence data has been addressed. We demonstrate that it is cost effective to make variant calls using control-accessed SRA sequence data without first transferring the entire set of aligned sequence data into a local storage environment, thereby accelerating variation discovery using control-accessed sequencing data.

A hidden Markov random field based Bayesian method for the de-tection of long-range chromosomal interactions in Hi-C Data. *Z. Xu[1,2,3], G. Zhang[3,4], F. Jin[5], M. Chen[1,2], T. S. Furey[2], P. F. Sullivan[2,6], Z. Qin[7], M. Hu[8], Y. Li[1,2,3].* 1) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Department of Computer Science, University of North Carolina at Chapel Hill, Chapel Hill, NC; 4) Curriculum in Bioinformatics and Computational Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 5) Ludwig Institute for Cancer Research, 9500 Gilman Drive, La Jolla, CA 92093, USA; 6) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden; 7) Department of Biostatistics and Bioinformatics, Rollins School of Public Health, Emory University, 1518 Clifton Road Atlanta, GA 30322, USA; 8) Division of Biostatistics, Department of Population Health, New York University School of Medicine, 650 First Avenue, New York, NY 10016, USA.

Advances in chromosome conformation capture and next-generation sequencing technologies are enabling genome-wide investigation of dynamic chromatin interactions. For example, Hi-C experiments generate genome-wide contact frequencies between pairs of loci by sequencing DNA segments ligated from loci in close spatial proximity. One essential task in such studies is peak calling, that is, the identification of non-random interactions between loci from the two-dimensional contact frequency matrix. Successful fulfillment of this task has many important implications including identifying long-range interactions that assist in interpreting a sizable fraction of the results from genome-wide association studies (GWAS). The task – distinguishing biologically meaningful chromatin interactions from massive numbers of random interactions – poses great challenges both statistically and computationally. Model-based methods to address this challenge are still lacking. In particular, no statistical model exists that takes the underlying dependency structure into consideration. We propose a hidden Markov random field (HMRF) based Bayesian method to rigorously model interaction probabilities in the two-dimensional space based on the contact frequency matrix. By borrowing information from neighboring loci pairs, our method demonstrates superior reproducibility and statistical power in both simulations and real data.

Pathway analysis of genomic loci uisng the *seq2pathway* Bioconductor package. *X. H. Yang, B. Wang, J. M. Cunningham.* Section of Hematology/Oncology, Department of Pediatrics, the University of Chicago, Chicago, IL.

IntroductionPathway analysis improves biological interpretability of genomic features with respect to prior knowledge and has led to important biological discoveries (Khatri, et al. , 2012). However, non-coding regulatory loci pose a critical challenge, as nearly 99% of the nucleotides in the human genome do not code for proteins but instead are enriched for critical functional genetic regulators (Kellis, et al. , 2014). The first sequence-derived pathway analysis method is GREAT (the Genomic Regions Enrichment of Annotations Tool) (McLean, et al. , 2011). GREAT quantifies a pathway score by determining if the total number of loci within the regulatory domain of genes in a gene-set is greater than expected. The ChIP-Enrich method then empirically adjusts the length of the gene body and its surrounding non-coding sequence (Welch, et al. , 2014). However, both methods treat all loci equally, despite the fact that a threshold for significance is always experimentally context-dependent and arbitrary. We propose a new sequence-derived pathway analysis approach named “seq2pathway”, considering quantitative sequencing measurements (Wang, et al. , 2015). Seq2pathway provides the community a Bioconductor package that **1)** quantifies the functional impact of both coding genes and non-coding loci (Yang, et al. , 2015), **2)**generalizes four pathway analysis methods, including FAIME (Yang, et al. , 2012), to variable next-generation sequencing (NGS) data, and **3)** wraps gene locus definitions for human and mouse genomes from GENCODE into R objects. **Main features**Seq2pathway is designed for knowledge discovery using a variety of NGS data (eg, ChIP-seq, RNA-seq, SNPs, etc) by taking the contribution of distal non-coding loci and their experimental significance scores into consideration. Users can apply the “seq2pathway” function jointly, or in a two-step algorithm consisting of “seq2gene” and “gene2pathway” components separately. The seq2gene step collapses significant scores per gene when a gene was mapped to multiple neighboring genomic loci, removing the bias of linkage disequilibrium for the downstream pathway analysis. The gene2pathway step condenses gene-by-sample measurements to pathway-by-sample measurements, which are gene-coverage-difference tolerable and free of pathway size preference. With a search radius of 100 kbps, seq2pathwaydefined a novel cis-regulatory element from both ChIP-seq and transcriptomic data (Hoffmann, et al. , 2014). **Availability**www. bioconductor. org/.

Development of an effective clinical interpretation solution for genomic data. *P. Yu, M. Wei, J. Li, G. Hu.* Admera Health LLC, South Plainfield, NJ.

With the rapid cost decline of high-throughput sequencing data generation, one major hurdle in making precision medicine a reality is to turn genomic data into clinical information that can be easily used in medical practice. Even though it has been pursued by many institutions and companies, a truly effective solution is still elusive, which at minimal requires: 1) a fully automated data analysis and interpretation workflow from raw data to clinically actionable report; 2) a scalable and reliable IT infrastructure; 3) a comprehensive and high-quality database; 4) a clinically validated process that meets regulatory requirements; 5) accurate, fast and cost-effective; and 6) being demonstrated in real medical practice with great satisfaction. To address this unmet need, we have developed Actionable Genomic Interpretation System (AGIS) that has all above features. Currently it contains three major modules that can be used separately or in combination: Pharmacogenomics Module for guiding personalized disease treatment; Disease Risk Module for disease risk assessment; Genetic Disease Module for diagnosing hereditary diseases. In this presentation, besides introducing the overall design and functionalities of AGIS, we will also report a real clinical application case that AGIS has successfully enabled the delivery of pharmacogenomic testing results for thousands of patients. The prototype of the AGIS system is available at: https://agis. admerahealth. com/.

Introducing Awsomics: a cloud-based bioinformatics toolbox. *Z. Zhang.* Department of Biomedical and Health Informatics, The Children’s Hospital of Philadelphia, Philadelphia, PA.

The processing and management of evergrowing genomics data is dominating the attention of bioinformatics field. However, the long-term bottleneck of using genomic data in biomedical research is the information-to-knowledge process, which is usually carried out by biomedical researchers who have been studying specific biomedical questions through their careers. Proper and efficient usage of genomic data and information are often challenging to these researchers, and we developed Awsomics toolbox to assist them through this process. The frontend of this toolbox is a series of independently run APPs that were designed to address research questions commonly arisen from genomic data sets. The APPs are supported by a backend collection of curated, high quality collection of genomic data, named Rchive. The contents of Rchive range from standard annotation databases, such as dbSNP and NCBI Gene, and curated experimental data, such as GWAS results and transcriptome data sets, that can be directly applied to integrative analysis without further processing. The backend Rchive and frontend APPs are connected through a number of data mining algorithms that integrate multiple data sets or different types of data. Two APPs have been implemented in Awsomics. GWAS Hub is a tool that searches and summarizes GWAS results from 7,000+ analyses reported by databases such as dbGaP and GWAS Catalog. Users can use it to look up their favorite SNPs, genes, and genomic regions in previous GWAS results, and link them to chemicals, diseases, and other genes through the annotation of these results. The other APP, GeEx (Gene expression Explorer), is a tool for exploring collections of transcriptome data sets. Data sets in each collection could be generated from different experiments, experimental conditions, technical platforms, or even species, but all share a common theme. For example, the ToMD (Transcriptomes of Mitochondrial Dysfunctions) collection currently includes 119 sample groups in 35 data sets, each including samples with impaired mitochondrial functions or respective control samples. All data sets were properly normalized and formatted, so users can easily utilize GeEx functions to query, compare, and visualize them together. In conclusion, Awsomics toolbox provides platform for faster access of genomic data and knowledge discovery. The number of its APPs will keep growing to cover a variety of research applications. Awsomics is available at: http://awsomics. org.

Sequence Analyzer (SeqA): a computationally efficient large-scale sequence data quality control pipeline and analysis framework. *D. Zhang, G. T. Gao, S. M. Leal.* Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX.

The ability to harvest massive genomic data through cutting-edge technologies has opened spectacular opportunities for discovering moderate effect variants in complex disease etiology via sequencing based association studies involving hundreds of thousands samples. Current analytical tools for association analysis are becoming obsolete, because of their inability to scale with "big data", which is a major impediment to successful gene-mapping practices. Here we report on Sequence Analyzer (SeqA), a new analysis platform for extremely rapid quality control and association testing of large-scale sequence data. Powered by modern distributive computing system, i. e. , Spark and Hbase, SeqA performs quality control for association studies and provide reports on various data attributes including but not limited to genotype call quality, variant/sample level missing rates evaluation, global ancestry and cryptic relatedness analysis, genetic sex check, and batch-effect analysis. Data query and processing using SeqA is drastically faster than PSEQ and VAT and can also handle much larger data sets due to the distributed database infrastructure optimized for management of large quantities human genome data which are sparse in nature. SeqA also intensively utilizes Spark's statistical libraries to perform ultra-fast rare variant association analysis via automatically paralleled computational procedures, and in addition to providing most widely used statistical methods for common and rare variant association testing, an Application Program Interface (API) is available for incorporation of user-specific analyses in the SeqA platform. Although SeqA is capable of handling up to a million whole genome sequences on a moderate local cluster environment, it can also be deployed to commercially available cloud computing platforms such as Amazon EC2. To our knowledge, SeqA is the first tool to implement the current best practice of sequence based association analysis workflow in a scalable and simple fashion readily available for use in modern genetic epidemiological research projects, maximizing the potential to uncovering novel variants in massive amount of data formidable to traditional analysis toolkits.

Speciman: A new low-frequency variant caller with significantly increased specificity. *J. Zhang[1,2], H. Hikbakht[1,2], J. Majewski[1,2].* 1) McGill University, Montreal, Quebec, Canada; 2) Genome Quebec Innovation Centre.

Introduction The identification of point, tumor-only mutation remains challenging, mainly because the ratio of DNA harboring the mutation in the sample is often low. However, precisely identifying low frequency variants (LVFs) in tumor samples is crucial to understand cancer heterogeneity, tumor evolution and treatment response. Many variant callers have been developed to increase the sensitivity of detecting LVFs, but lead to a large number of false positives. Accurately estimating site-specific error rates can significantly increase specificity. Here, we introduce a new tool that calling variants from exome sequencing using information from large set of tumor or normal samples. **Methods**To distinguish true LVFs from errors, we prepared a control cohort using 500 blood samples and for each sites we first filtered reads based on base quality and mapping quality. We also filtered reads if the same read name or read position were seen in the same sample. We then counted the reference and altered reads for all samples. For variant calling from only one pair of tumor and matched normal, we calculated error rates across all sites with potential variants based on the read count of control samples with mutant allele ratio less than 10%. We then performed binomial tests followed by FDR corrections in both tumor and matched normal. For variant calling from multiple tumor samples, we calculated the mutant allele ratio in each tumors and controls, and identified LVFs using *k*-means clustering. **Results and Conclusions** To evaluate the sensitivity of our algorithm, we merged one tumor sample benchmarked by Sanger validation with matched blood sample to lower the mutant allele ratio. To evaluate the specificity, we used one sample underwent exome sequencing twice, and therefore any variants should be false positives. Compared to MuTect, our method showed similar sensitivity, but significantly increased specificity. Moreover, we performed somatic variant calling in exome sequencing studies of five spatially distinct biopsies from a primary glioblastoma multiforme (pGBM) tumor and the matched blood sample, followed by targeted re-sequencing validation. We found low-frequency mutation in PIK3CA contributed to tumor profession, and provided the potential applications of our approach to similar studies.

Zodiac: A Comprehensive Information System of GeneticInteractions in Cancer Based on Statistical Models of TCGA Data. *Y. Ji[1,2], R. Mitra[6], Y. Xu[7], S. Yang[1], L. L. Pesce[3], P. Mueller[4], W. Guo[5], I. Foster[3], S. Sengupta[1], K. W. White[8,9,10], Y. Zhu[1].* 1) Program of Computational Genomics & Medicine, NorthShore University HealthSystem, Evanston, IL; 2) Department of Public Health Sciences, The University of Chicago, Chicago, IL; 3) Computation Institute, The University of Chicago, Chicago, IL; 4) Department of Mathematics, University of Texas at Austin; 5) School of Public Health, Fudan University, Shanghai, China; 6) Department of Bioinformatics & Biostatistics, University of Louisville, Louisville, KY; 7) Department of Applied Math and Statistics, Johns Hopkins University, Baltimore, MD; 8) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL; 9) Department of Human Genetics, The University of Chicago, Chicago, IL; 10) Department of Ecology & Evolution, The University of Chicago, Chicago, IL.

Genetic interactions play a critical role in cancer development. Existing knowledge about cancer genetic interactions is incomplete, especially lacking evidences derived from large-scale cancer genomics data. The Cancer Genome Atlas (TCGA) produces multi-layer measurements across genomics features of thousands of tumors. We introduce Zodiac, a computational resource to integrate existing knowledge about cancer genetic interactions with new information contained in TCGA data. It is an evolution of existing knowledge by treating known genetic interactions and pathwaysas a prior graph, integrating it with a likelihood model derived by Bayesian graphical model based on TCGA data, and producing a posterior graph as updated and data-enhanced knowledgebase. In short, Zodiac realizes "*Prior interaction map + TCGA data –Posterior interaction map.* "**Zodiac provides molecular interactions for about 200 million pairs of genes.** All the results are generated from a big-data analysis and organized into a comprehensive database allowing customized online search. In addition, Zodiac provides data processing and analysis tools that allow users to customize the prior networks and update the genetic pathways of their interest. Zodiac recapitulates and extends existing knowledge of molecular interactions in cancer. It can be used to explore novel gene-gene interactions, transcriptional regulation, and other types of molecular interplays in cancer. Zodiac has independently confirmed recent case studies reported in cancer literature, such as novel gene-gene interactions related to BRCA1/2 and TP53. In addition, potentially novel discoveries are being reported in our online website**www. compgenome. org/ZODIAC**. Some discoveries appear to be useful for drug discovery in oncology. We will report some results in this presentation.

Genomic analysis of multiple data types in cancer patient cohorts in GenePool platform allows fast and efficient multi-dimensional view of biological mechanisms. *A. Vladimirova, R. D. Goold, S. Sanga, T. Klingler.* Station X , Inc. , San Francisco, CA.

The ability to analyze genomic data generated by using different and complementary technologies allows us the opportunity to generate multi-dimensional views of the biological mechanisms involved in disease, and to formulate integrative hypotheses based on all-encompassing results from orthogonal molecular tests that reveal the full spectrum of molecular alterations observed in the patient samples. GenePool™, a commercial software application for biomarker discovery and validation in large patient cohorts (Station X, San Francisco, CA), is a cloud-based genomics platform for analysis, management, visualization and sharing of genomics data and results, where we have integrated, curated and organized TGGA multi-dimensional reference data from 33 cancer patient cohorts spanning copy number, methylation, protein arrays, miRNA, RNA-seq and exome information, and including primary tumor, blood, and in many cases, metastasis and adjacent normal tissue samples per patient. We used this multi-dimensional TCGA data in GenePool platform to integrate diverse data types, and probe entire cohorts of hundreds of patients to uncover biological mechanisms that span multiple data types. We demonstrate examples where GenePool was able to quickly and efficiently integrate a variety of genomic data, analyze and visualize it in the cloud to explore entire patient cohorts and generate testable hypotheses in real time. We present results of integrative analysis of multiple molecular assays in a patient cancer cohort. In GenePool platform reference data can be further combined and extended with proprietary data sets to illuminate new mechanisms or validate existing hypotheses to further our understanding of the disease and highlight approaches for tumor treatment.

1662F

Decoding the code of chromosomal translocation: a computational approach. *R. M. Rawal.* Cancer Biology, The Gujarat Cancer & Research Institute, Ahmedabad, Gujarat, India.

Recurrent chromosomal rearrangements including deletion, duplication and non-random chromosomal translocations are hallmark characteristics of leukemogenesis however molecular mechanisms underlying these rearrangements are still not completely understood. The fundamental question is, why and how chromosomes break and reunite so precisely in the genome. Meticulous understanding of mechanism leading to chromosomal rearrangement can be achieved by characterizing breakpoints. To address this hypothesis, a novel multiparametric computational approach for characterization of most frequent leukemic translocations within and around breakpoint region was performed. Breakpoint islands were also analyzed for other complex genomic architecture and physical properties. Our study distinctly emphasizes on the probable role of SDs, quadruplex and various genomic features in breakage and reunion of chromosomes leading to translocation. Various physico-chemical parameters were also taken into consideration for characterization of chromosomal breakpoint island. To best of our knowledge, this is an unique approach to decipher the basis of chromosomal translocation in leukemias.

1663W

Design and Implementation of an Cloud-Based Graphical Interface for Variant Exploration and Classification. *X. Xu, J. Cohen, D. Caplan, D. Gross.* SolveBio, New York, NY.

High throughput sequencing has transformed the field of genetic diagnostics. Current practices for curation and clinical significance classification of sequenced genetic variants stem from Sanger-based sequencing of single genes or less and cannot handle the avalanche of variants identified from next-generation sequencing technologies. Geneticists currently take a median of 54 minutes per genetic variant to classify the variant's clinical significance (Dewey, 2014). The purpose of this project is to build a cloud-based graphical interface, designed specifically for the clinical geneticist or other variant curation expert, to improve speed and accuracy in clinical decision-making regarding sequenced genetic variants.

Variant analysis requires accurate and up-to-date genetic reference annotation data. We have built a Data Library, that, as of June 2015, has indexed 25 publicly available reference data sources with 154 individual datasets, ~1. 2 billion independent records, and ~28 billion data points. All of these data has been integrated into one platform, versioned, and made programmatically accessible via an Application Programming Interface (API). With this underlying data infrastructure, we have built the Variant Explorer (VE): a cloud-based graphical interface that displays variant-specific data. The VE consists of modular components: variant identification, genomic visualization/localization, clinical evidence from publicly available sources, and variant effect/consequence prediction. Each displayed variant is the result of querying and combining a dozen disparate reference datasets.

We have also designed a cloud-based graphical interface for variant curation and classification built on top of the Variant Explorer. This interface guides an expert curator through a series of steps that systematically and computationally codify each evidence criteria in the American College of Medical Genetics and Genomics (ACMG) and Association for Molecular Pathology (AMP) standards and guidelines for the interpretation of sequence variants (Richards, 2015).

NGS-based tests has the potential to dramatically improve molecular diagnostics and understanding of the genetic etiology of diseases. Geneticist-guided variant classification will ameliorate the analysis bottleneck in the variant curation and classification step.

Run Smarter, Not Harder: Scalable Joint Variant Discovery with GATK. *S. Chandran[1], G. Van der Auwera[1], R. Poplin[1], V. Ruano-Rubio[1], M. DePristo[1], T. Fennell[1], M. Carneiro[1], D. Kling[1], L. Gauthier[1], A. Levy-Moonshine[1], D. Roazen[1], B. Haas[1], K. Shakir[1], J. Thibault[1], D. Benjamin[1], C. Whelan[1], S. Ashrafzadeh[2], M. Lek[2], S. Gabriel[1], D. Altshuler[1], M. Daly[1,2], D. MacArthur[1,2], E. Banks[1].* 1) Data Sciences and Data Engineering, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA 02114, USA, Broad Institute of Harvard and Massachusetts Institute of Technology, Cambridge, Massachusetts, and Department of Medicine, Harvard Medical School, Boston, Ma.

Studying a single individual's genome or exome in isolation is almost never useful: practically every genomic study design involves comparing one or several individuals to another group of individuals. However, traditional multisample analysis methods in which all samples are processed simultaneously through variant calling and genotyping scale very poorly. This is especially the case of the newer assembly-based methods, which yield superior indel calls but impose a heavy computational cost. In addition, adding any new samples to existing analyses entails re-running compute-intensive algorithms on the entire cohort, which is costly and slow -- the so-called "N+1 problem".

Here we present a scalable approach that overcomes these obstacles without sacrificing accuracy. Firstwe determine genotype likelihoods individually per-sample for all possible alleles using the assembly-based HaplotypeCaller. Thenwe perform joint genotyping across all samples within a project withGenotypeGVCFs. This yields the same great accuracy as traditional multisample calling and the superior indels calls of an assembly-based method, while scaling efficiently to ridiculously large cohort sizes. It also solves the N+1 problem since samples can be added incrementally; only the joint genotyping step needs to be re-run, which is computationally trivial. On top of that, the Reference Confidence Model (RCM) implemented within HaplotypeCaller produces a fully squared-off matrix of genotypes across all samples at every genomic position being investigated.

The HaplotypeCaller + GenotypeGVCFs workflow is the most scalable and incremental workflow to yield highly accurate variant calls, with abundant applications for population genetics and clinical studies.

Risk Allele Distribution Visualizer (RADViz-QT): A novel computational tool to estimate continent-specific differences in Cumulative Genetic Risk (CGR) for quantitative traits and diseases. *A. Choudhury[1], M. Ramsay[1,2].* 1) SBIMB, University of the Witwatersrand, Johannesburg, Gauteng, South Africa; 2) Division of Human Genetics, National Health Laboratory Service and School of Pathology, Faculty of Health Sciences, University of the Witwatersrand, Johannesburg, South Africa.

Background : Population genetic variation is shaped by history (population size, migration, bottlenecks and admixture), environment (selection) and chance (new mutations and genetic drift). These forces also influence genetic susceptibility to diseases and may lead to population-level differences in predisposition. Previous studies based on cumulative frequency distribution comparison of risk alleles of SNP sets identified in genome wide association studies (GWAS) have shown the genetic risk for some diseases to vary significantly across continents. These studies have not addressed quantitative traits (QTs) nor have they investigated intra-continental differences in risk allele distributions. We examine the spread of risk alleles from ~90 QT GWA studies, across and within continents. **Methods:** The risk-associated alleles for SNP sets identified in GWA studies were retrieved from the GWAS catalog and examined using the 1000 Genomes Project (1KGP) population genetic data. A simple additive model was used to integrate the risk status for all the SNPs identified in a GWA study into a cumulative genetic risk (CGR) statistic. The CGR distributions were compared across populations and continents. **Results:** Risk allele sets from about 10% of the QT studies (including eGFR levels related to chronic kidney disease (CKD), bone mineral density (BMD), and menopause) exhibit significant high differentiation between one or more pairs of continental populations. SNPs sets associated to 15% of the QTs (including breast size, waist to hip ratio and systolic blood pressure) were found to show high intra-continental CGR differentiation. Both inter and intra-continental CGR differentiations were observed for risk alleles from some of the QTs. Moreover, alignment between the geographical distribution of CGR and the associated phenotypes was observed for SNP sets related to QTs like CKD and BMD. **Conclusions**: The levels of inter and intra-continental differentiation of genetic risk for complex traits and diseases can be used to formulate hypotheses on geographical variation in traits and diseases, and to inform country-specific public health intervention policies. As GWAS data accumulates for more populations, this approach will become both more accurate and useful. A tool- Risk Allele Distribution Visualizer (RADViz-QT) has been developed to assess and compare CGR scores between continents and populations (www. bioinf. wits. ac. za/software/radvizqt).

Characterizing transcriptional heterogeneity through pathway and gene set overdispersion analysis. *J. Fan[1], N. Salathia[2], R. Liu[3], G. Kaeser[4], Y. Yung[4], J. Herman[1], F. Kaper[2], J. B. Fan[3], K. Zhang[3], J. Chun[4], P. V. Kharchenko[1].* 1) Center for Biomedical Informatics, Harvard University, Boston, MA; 2) Illumina Inc. , San Diego, CA; 3) Department of Bioengineering, University of California, San Diego, CA; 4) Department of Molecular and Cellular Neuroscience, Dorris Neuroscience Center, The Scripps Research Institute, La Jolla, CA.

Single cell RNA-sequencing provides the means to dissect the transcriptional composition of complex tissues and organs, including the mammalian brain. The transcriptional state of each cell, however, reflects a variety of biological factors, including persistent cell-type specific regulatory configurations, transient processes such as cell cycle, local metabolic demands, and extracellular signals. All such aspects of transcriptional heterogeneity may be of potential interest, but detecting and resolving them from inherently noisy single-cell data presents analytical challenges. We developed PAGODA to recover multiple, potentially overlapping, aspects of transcriptional heterogeneity by identifying known pathways and novel gene sets that exhibit a significant excess of coordinated variability among the measured cells. We demonstrate that our method effectively recovers known cellular subtypes and their corresponding functional characteristics in a variety of single-cell samples. Furthermore, we apply PAGODA to characterize the transcriptional diversity of neuronal progenitor cells in the developing mouse brain.

BDQC: a general-purpose analytics validation tool for Big Data Discovery Science. *G. Glusman[1], R. Kramer[1], E. W. Deutsch[1], I. Foster[2], C. Kesselman[3], R. Madduri[2], K. Chard[2], B. D. Heavner[1], I. D. Dinov[4], J. Ames[5], J. Van Horn[5], N. D. Price[1], L. Hood[1], A. W. Toga[5].* 1) Institute for Systems Biology, Seattle, WA; 2) Computation Institute, University of Chicago and Argonne National Laboratory, Chicago, IL; 3) Information Sciences Institute, University of Southern California, Los Angeles, CA; 4) Statistics Online Computational Resource (SOCR), UMSN, University of Michigan, Ann Arbor, MI; 5) Laboratory of Neuro Imaging, USC Stevens Neuroimaging and Informatics Institute, University of Southern California, Los Angeles, CA.

Biomedical data acquisition is generating exponentially more data: thousands of whole-genome sequences (WGS) are now available; brain data is doubling every two years. Analyses of Big Data, genomic or otherwise, presents qualitatively new challenges as well as opportunities. Among the challenges is a proliferation in ways analyses can fail, due largely to the increasing length and complexity of processing pipelines. Anomalies in input data, runtime resource exhaustion or unavailability of nodes in a distributed computation can all cause pipeline hiccups that are not necessarily obvious in the output. Flaws that can taint results may persist undetected in complex pipelines, a danger amplified by the fact that research is often concurrent with the development of the software on which it depends. On the positive side, the huge sample sizes increase statistical power, which in turn can motivate entirely new analyses. We have developed a framework for Big Data Quality Control (BDQC): an extensible set of analyses, heuristic and statistical, that identify deviations in data without regard to its meaning (domain-blind analyses). BDQC takes advantage of large sample sizes to classify the samples, estimate distributions and identify outliers. Such outliers may be symptoms of technology failure (e. g. , truncated output of one step of a pipeline for a single genome) or may reveal unsuspected “signal” in the data (e. g. , evidence of aneuploidy in a genome). We have applied the framework to validate our WGS analysis pipelines. BDQC successfully identified data outliers representing genome analyses missing a whole chromosome or part thereof, hidden among thousands of intermediary output files. These failures could then be resolved by reanalyzing the affected samples. BDQC both identified hidden flaws (in some cases, in software deemed “too simple to fail”) as well as yielded unlooked-for insights into the data itself. BDQC is meant to complement quality software development practices. There are multiple benefits from application of BDQC at all pipeline stages. By controlling input, it can help avoid expensive computations on flawed data. Analysis of intermediary and final results facilitates recovery from aberrant termination of processes. All these computationally inexpensive verifications reduce cryptic analytical artifacts that could seriously preclude clinical-grade genome interpretation. This Big Data for Discovery Science work is supported by NIH 1U54EB020406.

A novel approach to genome-wide association analysis: *S*NP *P*airs *I*n *N*eighboring *D*istance and *L*inkage *E*quilibrium (SPINDLE). *A. P. Khawaja[1], L. R. Pasquale[2,3], J. H. Kang[3], J. N. Cooke-Bailey[4], M. A. Hauser[5,6], J. L. Haines[4], J. L. Wiggs[2], NEIGHBORHOOD Consortium.* 1) NIHR Biomedical Research Centre, Moorfields Eye Hospital NHS Foundation Trust and UCL Institute of Ophthalmology, London, UK; 2) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 3) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 4) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 5) Department of Ophthalmology Duke University Medical Center, Durham, NC; 6) Department of Medicine, Duke University Medical Center, Durham, NC.

Standard analysis of genome-wide association studies (GWAS) is limited by examining SNPs one at a time and ignoring potentially important nearby SNPs. Gene-based approaches are limited by the fact that all SNPs in a region are considered in aggregate, even though only a small proportion of independent SNPs within a gene may be relevant for disease. SPINDLE (**S**NP **P**airs **i**n **N**eighboring **D**istance and **L**inkage **E**quilibrium) is a new approach that only examines **pairs** of independent SNPs, thereby avoiding association signals being lost due to inclusion of nearby SNPs that are disease irrelevant. SPINDLE uses summary GWAS results as input and uses HapMap data to identify pairs of SNPs that are neighboring (<20Kb) and in linkage equilibrium (r2<0. 2). A combined *P*-value (com*P*) for each SNP pair is calculated using Fisher's method, and a Bonferroni corrected genome-wide significance threshold is calculated based on the number of SNP pairs SPINDLE identified. To test SPINDLE, we used data from the GLAUGEN and NEIGHBOR consortia (3430 cases, 3108 controls) which examined associations with primary open-angle glaucoma (POAG [MIM 603383]). We deleted genome-wide significant SNPs from the standard GWAS results and tested whether SPINDLE would identify significant SNP pairs in the same regions despite no individually significant SNPs. We further analysed normal tension glaucoma (NTG) and high tension glaucoma (HTG) subgroups, as these have been shown to have distinct genetic associations. SPINDLE identified the originally significant loci for POAG (in *CDKN2A* [com*P* = 3. 7x10-11] and near *PPM1A* [com*P* = 2. 5 x 10-8]) and NTG (in *CDKN2A* [com*P* = 1. 2x10-9]), despite individually significant SNPs not being present in the input files. Additionally, SPINDLE identified new loci that were not significant in the standard GWAS; in *GAS7* for POAG [com*P* = 1. 4x10-8], *SLC27A1* for NTG [com*P* = 3. 7x10-9], and in *AFAP1* for HTG [com*P* = 2. 0x10-8]. *GAS7* and *AFAP1* have previously been associated with POAG in independent studies. We sought replication of the *SLC27A1* locus in the Women's Genome Health Study (158 cases, 22508 controls); one SNP in the pair was nominally associated with POAG with the same direction of association (rs11672333, *P*=0. 016). In summary, SPINDLE is a new method for analysing GWAS data that has advantages over current gene-based approaches. Testing SPINDLE in a large GWAS supported its validity and identified a new locus associated with NTG in *SLC27A1*.

Genvisis: Visualization and batch correction of copy number variation at the population level leads to higher accuracy and the ability to analyze data on sex chromosomes. *J. Lane, B. Cole, Z. Xu, N. Pankratz.* University of Minnesota, Minneapolis, MN 55455.

Genvisis is an open-source, platform-independent Java software package that we designed to efficiently store, normalize, analyze and visualize genetic data. The underlying databases are fully scalable to hundreds of thousands of samples with genome-wide data that would comprise terabytes of data even when using our unique compression algorithms. Even so, we structure the data so that any individual or any marker can be loaded into memory in milliseconds for visualization or analysis. This has therefore become a platform for the efficient review of sample quality, locus quality, sex aneuploidy, chromosomal arm mosaicism, DNA contamination, batch effect correction, population stratification, joint calling, and more. It is also the foundation for the processing and analysis of copy number variants (CNVs), including data from the X and Y chromosomes. We have also developed novel methodology to improve blind duplicate concordance from 68% using standard methodology to as high as 91% for heterozygous copy number changes and 99% for homozygous deletions. This is accomplished by performing a principal component analysis (PCA) of the normalized intensity data at the allelic level (as opposed to at the marker level) in order to detect and correct for batch effects and DNA quality. Originally designed for Affymetrix and Illumina array data, the software has recently been extended to take advantage of next generation sequencing data either in processed (. VCF files) or raw alignments (. BAM files). One of the unique aspects of our visualization tools is the ability to interactively and dynamically link data points from one plot to another. For example, the genome browser can be used to visualize all of the CNVs on a particular arm of a chromosome, color-coding them by study, copy number, and calling algorithm. Clicking on a particular CNV will open up the raw intensity data for that individual for that region. Clicking on that intensity data for a particular marker will then open up a plot of intensity data for all individuals for that marker. The marker can then be manually re-clustered, which automatically re-computes the Log R ratio intensities, which can be fed back through the calling algorithms and updated for all samples. The uniform application of this software to multiple studies will allow for the meta-analysis of many traits and should identify new targets for functional research and future therapies. Manual and tutorials are available at http://genvisis. org.

KeBABS: an R/Bioconductor package for kernel-based analysis of biological sequences. *J. Palme, S. Hochreiter, U. Bodenhofer.* Institute of Bioinformatics, Johannes Kepler University, Linz, Austria.

The computational analysis of biological sequences is a fundamental task. On the one hand, sequence analysis methods have supplied highly valuable insights into how patterns/motifs in amino acid sequences govern protein structure. On the other hand, a large proportion of our current knowledge about how DNA sequence patterns control transcription factor binding, nucleosome positioning and remodeling, alternative splicing, etc. , is the result of computational sequence analysis. In genetics, discriminative sequence analysis is becoming increasingly important to predict potential effects of single-nucleotide variations in the context of surrounding sequences.

In the last two decades, kernel methods have been established as an important class of sequence analysis methods. For the classification of sequences, in particular, support vector machines (SVMs) have emerged as a sort of best practice. To apply SVMs for sequence analysis, it is necessary to either use a vectorial representation of the sequence data or to use kernels, that is, positive semi-definite similarity measures for sequences. The use of sequence kernels, however, is not limited to sequence classification. For example, they can also be used for regression tasks and similarity-based clustering.

This contribution is devoted to introducing KeBABS, a powerful, flexible, and easy-to-use framework for kernel-based analysis of biological sequences based on the widely used scientific computing platform R. KeBABS is publicly and freely available via the Bioconductor project (for more information, see http://www. bioinf. jku. at/software/kebabs). It includes efficient implementations of the most important sequence kernels, also including variants that allow for taking sequence annotations and positional information into account. KeBABS seamlessly integrates three common support vector machine (SVM) implementations with a unified interface. It allows for hyperparameter selection by cross validation, nested cross validation, and also features grouped cross validation. The biological interpretation of SVM models is supported by (1) the computation of weights of sequence patterns and (2) prediction profiles that highlight the contributions of individual sequence positions or sections. The features of the package will be described in detail along with illustrative biological examples.

HPMV: Human Protein Mutation Viewer. *W. A. Sherman[1], D. B. Kuchibhatla[1], V. Limviphuvadh[1], S. Maurer-Stroh[1,2], F. Eisenhaber[1,3,4], B. Eisenhaber[1].* 1) A*STAR Bioinformatics Institute (BII), Singapore, Singapore; 2) School of Biological Sciences (SBS), Nanyang Technological University (NTU), Singapore, Singapore; 3) Department of Biological Sciences (DBS), National University of Singapore (NUS), Singapore, Singapore; 4) School of Computer Engineering (SCE), Nanyang Technological University (NTU), Singapore, Singapore.

Next-generation sequencing advances are rapidly increasing thefraction of genetic disorders for which causative variants can beidentified. Our Human Protein Mutation Viewer (HPMV) can helpidentify causative variants in genetic disorders that are caused by asingle small change in a protein sequence (e. g. a non-synonymous pointmutation). HPMV fills a niche between initial variant filtering anddetailed analysis of individual mutations. It allows a researcher toquickly assess dozens of potential causative variants by presenting aninteractive cartoon that shows where each mutation of interest fallsalong the corresponding protein sequence - in relation to proteinfeatures that can help interpret the mutation. These protein featuresinclude post-translational modification sites, targeting signals,transmembrane helices, charge clusters, known conserved (Pfam)domains, and relevant 3D (PDB) structures, among others. As input, HPMV accepts protein mutations - as UniProt accessions withmutations (e. g. HGVS nomenclature), genome coordinates, or FASTAsequences. The main output of HPMV is its interactivecartoon. Clicking a sequence feature in the cartoon expands a treeview of additional information including multiple sequence alignmentsof conserved domains and a simple 3D viewer mapping the mutation torelevant PDB structures. A multiple sequence alignment of similarsequences from other organisms is provided directly below the cartoonand the cartoon itself includes a band showing the conservation ateach sequence position. In cases where a mutation is likely to havea straightforward interpretation (e. g. a point mutation in a wellunderstood targeting signal), this interpretation is suggested. The interactive cartoon is implemented as a web page using standardHTML, CSS, and JavaScript. It is also available as a standalone viewerimplemented in Java that can be downloaded in jar format, withembedded data, to be saved and viewed later with only a standard javaruntime environment. The HPMV website is: http://hpmv. bii. a-star. edu. sg/.

The ENCODE Analysis Pipelines: Tools for Repeatable, Standards-Based Analysis and Quality Control of Chromatin, Expression, and Methylation Experiments. *J. S. Strattan, T. Dreszer, B. C. Hitz, E. L. Hong, J. M. Cherry, ENCODE Data Analysis Center, ENCODE Data Coordinating Center.* Stanford University School of Medicine, Department of Genetics, Stanford, CA.

From Ammon's horn to zone of skin, members of the ENCODE Consortium have measured RNA quantity, RNA-protein interactions, DNA-protein interactions, DNA methylation, replication timing, chromatin structure, and histone modifications in over 4,000 experiments on more than 400 cell or tissue types. The ENCODE Data Analysis Center (DAC) have specified uniform processing pipelines for four ENCODE datatypes: ChIP-seq, RNA-seq, DNase-seq, and whole-genome bisulfite sequencing. The ENCODE Data Coordinating Center (DCC) have implemented these pipelines and deployed them to a cloud-based platform. Importantly, the pipelines can be run on the cloud via a web interface with no technical prerequisites other than input data. In this way researchers can perform the same analyses as ENCODE on their own data and repeat ENCODE analyses on ENCODE data. For ENCODE, the results of these analyses and metadata describing them are distributed through the ENCODE Portal, and illustrate general methods of accessing and interpreting ENCODE data. The ENCODE Portal is https://www. encodeproject. org/. The DCC codebase is freely available at https://github. com/ENCODE-DCC/.

1673T

PhASTESt, a user friendly tool for power calculations in pharmacogenomic studies with "time to event" outcomes. *H. Syed, A. Jorgensen, A. P. Morris.* Biostatistics, University of Liverpool, Liverpool, United Kingdom.

With the increased scale of genome-wide pharmacogenomic association studies, and the complexity of clinical outcomes they consider, there is a need for software to perform power calculations over a range of trial designs. There are already genetic power calculators available for binary phenotypes and quantitative traits, but the key outcome of interest in pharmacogenomics studies is often "time to event" (survival) data, which cannot adequately be modelled by existing software. To address this issue, we have developed the user friendly software tool PhASTESt (Pharmacogenomic Time to Event Association Study) to perform power calculations and generate sample pharmacogenomic data with time to event outcomes over a range of study designs. PhASTESt was built using C#, utilising pre designed methods packages Math. NET and Accord. NET for the generation of pharmacogenomic data and statistical analyses, respectively. PhASTESt is able to calculate the power to detect association of a SNP with a time to event outcome (at a pre-specified significance threshold) over a range of trial design scenarios. The software requires specification of genetic parameters, such as the magnitude of the SNP effect on the outcome and the effect allele frequency. The varied collection of design scenarios includes adding a recruitment period, multiple treatments with differential effects on outcome, SNP-treatment interactions, and/or different censoring options (for example, withdrawal due to adverse treatment event). Time to event and censoring data are then simulated on the basis of this model by making use of a Weibull distribution, so as to allow for the possibility of a deviation from a proportional hazards assumption. The data are then analysed by means of a Cox proportional hazards model. To allow for flexibility of analysis using methods not supported by the power calculator, individual simulated data sets can also be output from the software. In conclusion, this application offers a much needed user-friendly and flexible software tool for power calculations for time to event outcomes in pharmacogenomic association study designs.

1674F

Homozygous and hemizygous deletion CNV detection from exome sequence in a Mendelian disease cohort. *T. Gambin[1,2], Z. C. Akdemir[1], C. Shaw[1], S. Jhangiani[1,3], P. M. Boone[1], M. K. Eldomery[1], D. Muzny[1,3], E. Boerwinkle[3,4], R. A. Gibbs[1,3], A. L. Beaudet[1,3], J. R. Lupski[1,3,5,6], The Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Institute of Computer Science, Warsaw University of Technology, Warsaw, Mazowieckie, Poland; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston, TX.

We developed an informatics algorithm, HMZDelFinder, to discover rare, small (potentially single exon) homozygous and hemizygous deletions with a high sensitivity (84%) and specificity (53. 3%). HMZDelFinder is a joint CNV calling algorithm that uses read count information at each exon (RPKM) provided by BAM files together with independent B-allele frequency information calculated from VCFs. The identified homozygous and hemizygous intragenic deletions may play a role in the complete loss-of-function of the indicated gene in that personal genome. Our algorithm detected 13,868 deletions in total, consisting of homozygous (9,482) or hemizygous (4,386) deletion CNV calls from whole exome sequencing (WES) data for 4,124 samples in the Baylor-Hopkins Center for Mendelian Genomics (BHCMG) cohort. From 4,124 samples, 3,033 samples were found to have at least 1 homozygous or hemizygous deletion with the median number of 3 calls per personal genome. Interestingly, 97% of these deletions (13,449 out of 13,868) encompass merely a single exon. Investigation of homozygous and hemizygous deletions in the BHCMG cohort revealed 74 deletions of known disease genes in patients with phenotypes matching known OMIM (http://www. omim. org/) diseases associated with these genes. A subset of these known disease gene deletions was subjected to array comparative genomic hybridization (aCGH) and breakpoint junction specific PCR for orthogonal technology experimental verification of the bioinformatically identified CNV. The presence and zygosity of 17/17 known disease gene deletions were confirmed by at least one orthogonal experimental validation. Only 5 out of those 17 deletions (0 out of 6 single exon deletions) were detected by other state-of-the-art CNV calling methods (CoNIFER, CoNVeX, exonDel). Utilization of WESdata as a single comprehensive assay for both the detection of point mutations, InDels and CNVs is urgently needed. HMZDelFinder outperforms currently available CNV calling methods in terms of detection of small homozygous and hemizygous deletions. We demonstrated that this algorithm has a potential to increase the molecular diagnostic 'solution rate' and facilitate the process of novel disease genes discovery.

1675W

Detection, validation and visualization of copy number variations in targeted panels without matched normal samples using next generation sequencing data. *R. Gupta, A. Sathyanarayanan, M. Nagarajan, S. Katragadda, V. Veeramachaneni.* Strand Life Sciences, Bangalore, Karnataka, India.

Background and Objectives: Copy number variations (CNVs) are a specific form of structural variations (SVs) that are defined as large-scale amplifications or deletions (typically of size more than 1kb). Several algorithms are developed in the past to detect CNVs in whole-genome sequencing data, however recently detecting CNVs from targeted panel data is gaining attention of researchers and clinicians. Further to reduce the cost, data from matched normal samples is often not available. Therefore, the objective of this study is three-fold: 1) to accurately detect CNVs in targeted sequencing data without matched normal samples; 2) to independently validate the detected CNVs using supporting read % of the heterozygous SNPs in the CNV region; and 3) to visualize CNVs with estimated copy number values and confidence scores such that patterns either within or across multiple samples can be elucidated. **Methods:** Detection of CNVs in targeted sequencing data is challenging due to several technical and biological issues including noise in the data, alignment artifacts, absence of a reference from matched normal sample, tumor aneuploidy, normal/stromal cell contamination, heterogeneity in tumor cells etc. We have implemented a robust approach in Strand NGS software to detect, validate and visualize CNVs while addressing most of the above concerns. To alleviate the need for a matched normal sample, a coverage profile is first generated which stores mean and standard deviation of coverage across a group of samples for each target region. The group of samples can be a carefully selected pool of normal samples, which can be used as a reference to detect CNVs in other samples. Robust ways have been developed to ignore outlier values and corresponding target regions or samples from coverage profiles. **Results:** We demonstrated the applicability of the proposed approach using data from several clinical research samples available at Strand Life Sciences. We were able to detect CNVs in samples and narrow them down to few high confidence CNV calls using a z-score cut-off of 3. Z-score is computed for each target region by comparing sample mean to the profile mean coverage. In addition, these CNV calls are validated by measuring the deviation of supporting reads % from 50% of the heterogyzous SNPs called in the CNV regions. Copy number values and z-scores are also visualized across single sample as well as across multiple samples to quickly identify significant patterns.

1676T

CNValloc : a Bayesian approach for identifying copy unit alleles of CNVs from population-scale high-throughput sequencing data. *T. Mimori, N. Naoki, K. Kojima, Y. Sato, Y. Yosuke, Y. Yamaguchi-Kabata, M. Nagasaki.* Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan.

Recent development of high-throughput sequencing (HTS) technologies enable number of studies to reveal genetic variation among individuals, such asSNPs and short indels at nucleotide resolution. However, prediction of exact sequences of CNV is still challenging due to limited read length of HTS data, and CNV analysis has been mainly confined in predicting its existing regions and total copy numbers. We propose an approach that is named CNValloc to identify allele sequences at CNV locus from population-scale HTS data. CNValloc infers the copy unit alleles existing in population and their copy numbers for each individual simultaneously. The approach employs variational Bayesian inference for a graphical model inspired by latent Dirichlet allocation, which is a well known topic model in natural language processing field. We conducted simulation and real data studies to evaluate utility of CNValloc. In the simulation studies, degree of concordance between inferred and true alleles were evaluated for dataset with lower, middle, and higher copy number populations. We devised precision- and recall-like metrics for the evaluation and confirmed that the metrics were ≥ 0.9 for data with mean coverage $\geq 10\times$ per copy unit, which is a typical depth of coverage of HTS data. In real data study, we applied CNValloc to 1123 samples at highly variable salivary amylase gene locus and a pseudogene locus, and confirmed consistency of the estimated alleles within samples belonging to a trio of CEPH/Utah pedigree 1463 with 11 offspring. We also demonstrate that possible diplotypes of amylase alleles in the trio could be reconstructed from our results.

BAM Consensus: Copy Number Data Analysis for Targeted Panel NGS. *A. O'Hara, Z. Che, A. Venier, J. Fierro, S. Verma, S. Shams.* BioDiscovery Inc. , Hawthorne, CA.

Introduction: Targeted panel Next-Generation Sequencing (NGS) provides cost-effective single base pair resolution, with results focused on targeted genes and regions that have a clear diagnosis, are actionable with prescription drugs or compounds in clinical trials, or have known impacts on prognosis or outcome. Until recently, DNA microarray technology has been the gold standard for detection and analysis of copy number events. However, many labs with this technology must simultaneously test each sample on targeted NGS to detect sequence mutations and on DNA microarray to obtain the coordinating copy number information, which requires extra cost, labor, and time. Thus, using targeted panel NGS results for both copy number and sequence mutations is extremely valuable on many levels. **Methods**: We have developed a method called BAM Consensus which only requires the loading of BAM files from affected samples and targeted panel design files to generate copy number results. Germline normal reference samples are not required for analysis. In combination with the VCF files that contain the sequence mutations, an integrated analysis of both events can be easily carried out. **Results**: BAM consensus was applied to targeted sequencing panels in constitutional sample sets. Differences in overall read-depth resulted in variable sample quality across the cohorts, however most sample quality was adequate for copy number estimation and a quality threshold was assessed. Results indicate that relative copy number can be estimated for targeted regions comparable to the results achieved with microarray for the same targeted regions. Additionally, some larger arm length changes can also be estimated in genomic areas with wider targeted coverage. Integration with VCF files identified several samples with co-occurring copy number and sequence variant changes in targeted regions of interest. **Conclusions**: Targeted panel NGS is useful in constitutional samples as it provides a second tier of analysis for genes of interest, especially when no clear sequence mutation is detected. We have tested BAM Consensus in a variety of constitutional sample cohorts and it proves a very easy and straightforward way for targeted panel analysis.

A Multiple Feature Approach for Robust and Accurate Structural Variation Discovery for Whole Genome Sequencing Data of Varied Designs. *L. C. Xia[1,2,3], H. P. Ji[1,2], N. R. Zhang[3].* 1) Division of Oncology, Department of Medicine, Stanford University School of Medicine, Stanford, CA; 2) Stanford Genome Technology Center, Stanford University, Palo Alto, CA; 3) Department of Statistics, The Wharton School, University of Pennsylvania, Philadelphia, PA.

We present SWAN, a statistical framework with open source software package for detection of genomic structural variants in next-generation sequencing (NGS) data. SWAN accommodates mixed library sequencing designs and adjusts for variation in fragment length distribution across multiple libraries. SWAN is shown to have improved sensitivity for small deletions, for insertions of all ranges, and for variants that may be present at low proportions in the sample. The scan statistics used by SWAN collectively quantify evidence available from read-pair, read-depth and hang-read through statistical likelihoods based on Poisson field models. At the core of SWAN is a novel marked Poisson Process model for paired-end sequencing, giving rise to likelihood ratio scan statistics that collectively quantify evidence from read-pair, hang-reads, and coverage. SWAN also remaps soft-clipped reads, thus allowing base-pair resolution for breakpoint junctions whenever possible. Using a spike-in dataset, we compared SWAN against mainstream structural variant callers in recovering simulated homozygous and heterogeneous variants of various sizes and types. SWAN maintained high accuracy, high precision and low false positives across a broad spectrum of SV sizes and purities. In addition, we benchmarked SWAN calls on NA12878 using long-read sequence data, PCR validation, and new targeted sequencing data. SWAN also performed the best among existing callers, attaining 30% higher sensitivity in detecting validated deletions than the runner-up caller at 50x coverage. At 5x coverage, SWAN was able to recover 40% of the validated deletions while the runner-up recovered 20% at the same false discover rate. SWAN is quite efficient in memory utilization and speed, and can be used for large-scale genome-wide structural variant genotyping and discovery based on NGS data. As a demonstration, we analyzed the whole genome sequencing dataset of a sample sequenced under 3 different library designs, and illustrate how the effective aggregation across libraries improves the sensitivity of calls. SWAN is freely available for academic use at http://bitbucket. org/charade/swan.

molQTL, An integrated NCBI resource for molecular QTL results. *N. Sharopova, A. Borkar, A. A. Schaffer, S. Sherry, M. Feolo.* NCBI/NLM/NIH, Bethesda, MD.

Molecular QTL (Quantitative Trait Loci) data are results of the analysis of association between genotypes and quantitative molecular phenotypes often generated by high throughput analysis pipelines processing data from technologies such as genotyping/expression/methylation arrays as well as DNA and RNA sequencing. The increasing volume and complex nature of molecular QTL data has motivated our development of a data archive and a web-based browsing tool that integrates genotype-phenotype association analysis data with a multitude of meta-information about genotypes, phenotypes, and analysis to facilitate data sharing, mining and interpretation. Here, we present a newly developed NCBI resource, molQTL, which archives and distributes molecular QTL data integrated with a variety of NCBI resources including dbSNP, BioSystems, Gene, Clinvar, dbGap, and GEO. Currently, molQTL database contains data from several published or submitted molecular QTL datasets with more than 17 million eQTL, methQTL, and mirQTL associations between 7,022,835 SNP and indel genomic markers and 38,195 molecular phenotypes derived using mRNA expression, methylation level, and microRNA expression assays. The integration of molQTL data is achieved by re-annotation of the datasets using the same versions/builds of annotation resources (SNP, GEO, Gene, BioSystems, Clinvar, dbGap, and MirBase). Annotation-based data integration allows investigators to conduct cross-dataset and cross-resource searching, for example, mining through 9,570,794 molQTLs using 2,840 Biosystems' pathways/terms. Investigators can publically access the data archived at molQTL using molecular QTL Browser, which currently has two views (i) by 'Study' - https://preview. ncbi. nlm. nih. gov/gap/eqtl/studies/ and (ii) by 'Bioprocess/Molecular Function', and via FTP. The browser allows investigators to search and filter the data using genome location, parameters of association analysis, and functional annotations (GWAS/Clinvar phenotypic traits, genes, biological pathways). By integrating data from a variety of molecular QTL datasets, molQTL promotes data sharing and data validation which is important for datasets generated using high-throughput lab and analysis methods. The presentation will summarize the resource data content and annotation pipelines.

Random Walk on Ontology for Rare Disorder Diagnosis. *C. Wu[1], M. A. Deardorff[2,3], M. Sarmady[1].* 1) Division of Genomic Diagnostics, Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, The University of Pennsylvania Perelman School of Medicine, Philadelphia, PA; 3) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA.

Recognition of a rare diagnosis to best explain a patient's clinical features has always been a challenging task. Computational methods have been designed to assist this process involving searching of structured and unstructured electronic databases. Specifically, the development of the Human Phenotype Ontology (HPO) to relate diseases, phenotypes and genes has provided an invaluable dataset from which to develop algorithms to assist in diagnosis. Despite of these efforts, clinical diagnosis remains formidable when an enormous number of clinical features with varying levels of specificity are shared among numerous rare disorders. In this work, we present a network-based approach using a stochastic process to simulate a random walker on the HPO to rank candidate diseases. Given a set of precise standardized HPO terms describing patient phenotypes, our method traverses the ontological tree of HPO to retrieve all of the direct and indirect children terms of each individual phenotype respectively and thereby builds a sub-network of all these terms. Following this, a PageRank *with priors* model is implemented on the formed sub-tree to prioritize the nodes and assign a score to each individual term. Finally, candidate diseases are ranked accordingly by summing the scores of the phenotypes they are associated with. Since it is difficult to evaluate a diagnostic method by using real patient data, simulations were performed to validate our method. A collection of 32 monogenic Mendelian diseases from OMIM was used to generate synthetic patient profiles. 100 simulated patients were generated for each disorder taking into account the disease's penetrance information, and the target disease was being ranked against all annotated disorders from OMIM. Additionally, since the method relies on human input, we modeled human factors by introducing noise (i. e. irrelevant phenotypes) and imprecision (i. e. parent terms of precise phenotypes) as well. The target diseases were ranked on top in 95% of the optimal cases with an area under curve (AUC) over 0. 99. Meanwhile, our method demonstrated robustness with similar performance in noise and imprecision scenarios with AUCs of 0. 99 and 0. 96 respectively. In summary, our computational method shows great promise to improve clinical diagnosis by implementing a random walk model on HPO. We expect a statistical model such as Monte Carlo sampling will further enhance the method by adjusting scores of the original rankings.

1681W

Virtual progeny analytics providesa multidimensional view of phenotype expectationsfor couples prior to conception. *A. J. Silver, M. J. Silver, J. L. Larson, N. Delaney, R. Lim, L. M. Silver.* Genetics, GenePeeks, New York, NY.

Purpose

Genetic test results are typically limited to two possible outcomes: positive or negative. This binary choice may work well in clinical diagnostics, but reveals itself to be a rigid and uncompromising framework in reproductive risk assessment. Variants differ in their effect on gene function and expression, and certain manifestations can result in an altered phenotype in some allelic combinations but not others. By treating variant pathogenicity as an all-or-none phenomenon, the impact of allelic heterogeneity on disease severity, penetrance and expressivity is lost. To capture this biological reality, we developed a generalizable methodology for predicting the likelihood of heritable traits in a couple's potential offspring.

Methods

Virtual Progeny Analytics (VPA) simulates genetic recombination to produce "virtual gamete" sequences that are combined pairwise to create a pool of novel diploid genomes - "virtual progeny" (VP). A neural network-inspired Variant-specific Gene Dysfunction (VGD) score, combining all informative quantitative and qualitative metrics of variant impact on protein function, was computed for each variant in the haploid contribution to the VP. Important nodes include large population-based allele and genotype frequencies and measures of "clinical visibility. " By interpreting the VP at the level of a particular gene and genotype, rather than at the level of individual variants, we calibrate specific gene dysfunction to a gene's acceptance of general variation. We then sum together the functionality of the two gene copies to determine if the total gene product is sufficient to avoid a disease state.

Discussion

The distribution across the entire VP pool provides an estimate of the multidimensional probability space of progeny phenotype expectations for any two people defined solely by their genome sequences. VPA can operate easily on clinically identified genotype-phenotype correlations and is applicable to any combination of simple and complex genetic traits.

Conclusion

By focusing on gene dysfunction in the context of potential offspring genomes, the unrealistic imperative of a simplistic binary classification system is eliminated. The impact of this alternative perspective on reproductive risk rises as VGD scores retreat from the two extremes. Together, a large pool of virtual progeny provides an opportunity, preconception, for two prospective parents to obtain a nuanced view of their joint reproductive disease risk.

Geneious R9: CRISPR design tool. *C. Olsen[1], H. Shearman[2], K. Qadri[1], R. Moir[2], M. Kearse[2], S. Markowitz[2], J. Kuhn[2], S. Dunn[2], T. Paulin[2], A. Cooper[2].* 1) Biomatters Inc. , San Francisco, CA; 2) Biomatters Ltd. , Auckland, New Zealand.

The CRISPR/Cas9 system, a pioneering genome-editing technique, allows for the manipulation of genes and enables researchers to examine the consequence of sequence modifications in a precise and repeatable manner. The CRISPR tool in Geneious R9 will identify potential CRISPR target sites, including paired nickase sites, in a selected sequence and assess the target sites based on off-target interactions. Identified CRISPR sites are annotated on the target sequence using innovative heatmap-style annotations.

Each CRISPR site in the selected sequence is scored according to how many off-target sites it potentially will bind to and how similar the off-target sites are to the original sequence. Scores are calculated according to the method developed by the Zhang lab at the Massachusetts Institute of Technology1. CRISPR sites are displayed as an annotation track on your original sequence and the annotations are colored according to the corresponding score to enable you to see the best sites at a glance.

CRISPR sites need to be targeted to the gene of interest and not cut elsewhere in the genome; however, many other design tools provide a small number of choices for the target genomes. In Geneious, the researcher creates their own off-target database by simply creating a folder within Geneious and placing sequences within this folder. Any sequence may be placed inside this folder, including reference genome sequences downloaded from external databases and/or proprietary sequences created in-house. This allows researchers to use genomes from their organism of interest or from closely related organisms. The researcher then specifies the folder in the CRISPR options.

As this tool is contained within Geneious, researchers can leverage all of the other functionality in Geneious, including creating and sharing workflows for CRISPR design standard operating procedures. This poster aims to demonstrate the functionality of the CRISPR tool, including the benefits of providing the researcher the control to create their own off-target database.

Apollo: A Production Tested, Vertically Integrated, Operations Enhanced, Science Aware Framework for Launching Large Cohorts of Genomics Pipelines. *R. Z. Castellanos[1], Y. Wang[1], Z. Giles[2], H. Shah[1], E. Schadt[1].* 1) Department of Genetics and Genomic Sciences, Icahn, Mount Sinai School of Medicine, New York, NY; 2) Scientific Computing, Icahn School of Medicine at Mount Sinai, New York, NY.

Apollo is a Platform As A Service (PAAS) that handles dependency resolution, workflow management, visualization, reproducibility, error reporting, error resolution and command-line integration while addressing the plumbing associated with heterogeneous genomic analyses workflows run in a High Performance Computing (HPC) environment.

Apollo integrates the running, tracking, managing and metadata of the Illumina Demultiplexing, GATK Whole Exome or Whole Genome or custom captures, RNA-Seq, and ChIP-Seqχ pipelines into a single framework. Apollo also integrates with SMRT Portal to help manage PacBio data flows. All pipelines are tracked in an online interface which can be configured to send notifications to clients if Service Level Agreements (SLAs) are violated.

Clients can take advantage of Apollo's Standard Development Kit (SDK) to add their own pipelines. This allows investigators to spend less time worrying about operational details and environmental overhead and more time on their actual research. A Service Desk provides a web based entry point for clients to submit data processing requests. "Recipes" provide a concise JSON specification for configuring analyses on cohorts of samples. Strict versioning and provenance facilitate experimental reproducibility. In addition to command line and online access, many of Apollo's services can be accessed via RESTful APIs.

Apollo's backend is tightly integrated with the JIRA project management suite. Each run has it's own JIRA issue. If a given task - human or machine - is not completed *correctly* a JIRA issue is automatically assigned to the appropriate party. Apollo and its many services are self-aware.

System-wide issues as well as local exceptions raise automatic alerts that notify engineers. These service alerts are tracked on Apollo's Services Page and on JIRA.

Apollo's software lifecycle employs industry standard best practices including strict versioning, source control via git, and continuous integration. Nightly regression tests are performed on all pipelines. Changes to the codebase are not permitted until all unit tests have passed.

The result is more correct results, faster turnaround, fewer man-hours, and better science. As of June 11, 2015 the framework has 1. 2 petabytes under management and has been used to process 26,618 samples.

A virtuous cycle of large cohort research, personal genome analysis, and clinical deployment. *N. Veeraraghavan[1], A. English[1], S. White[1], T. Chiang[1], Z. Khan[1], A. Hawes[1], S. Ambreth[1], J. Farek[1], A. Carroll[2], S. Ma[2], W. Salerno[1], K. Andrews[1], D. Muzny[1], E. Boerwinkle[1,3], R. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) DNAnexus, Mountain View, CA, USA; 3) Human Genetic Center, University of Texas Health Science Center, Houston, TX 77030, USA.

Large common disease studies such as the Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium and Mendelian disease gene discovery and diagnostic efforts like the Baylor College of Medicine's Whole Genome Laboratory (BCM-WGL) and Center for Mendelian Genetics (CMG) are transitioning from targeted or whole-exome sequencing to whole-genome sequencing. Whole genome sequence data is very large in size and complex because of a paucity of non-genic annotation. We have developed, deployed and validated an integrated data processing and analysis pipeline, Mercury, for whole genome sequence data. The features of the pipeline include:(a) incorporating multiple protocols for whole exome and genome sequencing with particular optimization for the Illumina X Ten (b) expanding annotation capabilities to include regulatory information from Encode, GTEx, promoter and enhancer sites from FANTOM5 and deleteriousness scores from CADD, RegulomeDB, and Funseq2; (c) tackling discovery of structural variants (SV) under the Parliament framework, a multi-source consensus SV discovery and evaluation tool that automates assembly-based force calling and can incorporate long-read data via PBSuite; (d) developing a NoSQL-based data warehouse to integrate annotation, phenotype, and variant information, with capabilities to provide up-to-date annotations and an "N+1" pVCF solution for large cohorts studies; (e) porting analysis tools and protocols to the DNAnexus cloud platform, with emphasis on security, accessibility, trackability, data integrity, validation and reproducibility, towards compliance under CAP/CLIA guidelines. Efforts have been invested in developing a high-quality personal genome, HS-1011, for calibrating new features as they arise. This reference genome has been characterized across multiple sequencing platforms, including aCGH, Illumina, Pacific Biosciences, Hi-C, and BioNano Irys. These data have been subject to deep variant calling, trio analysis, whole genome assembly, long-read structural variant analysis, and Mendelian prioritization, generating high-quality variants against which novel tools, methods and protocols can be automatically and objectively evaluated, and then transplanted into a diagnostic environment. Our model of development, validation, and deployment delivers comprehensive genomic data to signout teams in a scalable and secure manner, and provides a mechanism for clinical findings to re-inform research protocols.

1685T

Multiple Testing Correction in Linear Mixed Models. *J. W Joo[1], F. Hormozdiari[2], B. Han[3,4], E. Eskin[5].* 1) Bioinformatics IDP, UCLA, Los Angeles, CA; 2) Computer Science Department,, UCLA, Los Angeles, CA; 3) Asan Institute for Life Sciences, Asan Medical Center, Seoul 138-736, Republic of Korea; 4) Department of Medicine, University of Ulsan College of Medicine, Seoul 138-736, Republic of Korea; 5) Department of Human Genetics, University of California, Los Angeles, CA, USA.

Multiple hypothesis testing is a major issue in genome-wide association studies (GWAS) that often analyze millions of markers. The permutation test is considered as the gold standard in multiple testing correction, which accurately takes into account the correlation structure of the genome. Recently, linear mixed model (LMM) has become the standard practice in GWAS, effectively addressing two important issues in GWAS: population structure and low power. However, the current approaches for multiple testing, such as the permutation test as well as many alternative approaches that aim to increase efficiency ofpermutation test, are not applicable to LMM. This is because all these approaches are based on the assumption that uniformly permuting phenotypes will generate the null distribution,which is not the case in LMM. By simulations, we show that permutation leads to inaccurate multiple testing correction when heritability is non-zero. In this paper, we first set up the gold standard approach for multiple testing correction for LMM, called parametric bootstrapping,which is the equivalent of the permutation test for LMM. This approach is accurate, but is computationally expensive because of the large number of resampling. We then propose an efficient and accurate multiple testing correction method for LMM, MultiTrans. The key idea behind MultiTrans is to take advantage that the null LMM statistics asymptotically follow a multivariate normal distribution,whose covariance matrix is obtained by transforming the genotype data based on the kinship matrix. Utilizing this approach, we were able to estimate per-marker thresholds as accurately as the gold standard approach in real and simulated datasets, while reducingrequired time from monthes to hours. We applied our approach to mouse, yeast, and human datasets to demonstrate the accuracy and efficiency of our approach.

Fast genome-wide assessment of the likelihood for variants being causal using only summary statistics. *D. Lee, T. Bigdeli, B. Riley, A. Fanous, S. Bacanu.* Department of Psychiatry, Virginia Institute for Psychiatric and Behavioral Genetics, Virginia Commonwealth University, Richmond, Virginia, USA.

Genome-wide association studies (GWAS) have successfully identified thousands of genomic loci associated with human traits/diseases. However, these GWAS-detected loci typically possess hundreds of significant single nucleotide polymorphism (SNP) signals in strong linkage disequilibrium (LD). This makes it challenging to separate the true causal variants from significant but non-causal "LD buddies". Recently, two fine mapping methods (CAVIAR and CAVIARBF), which use summary statistics as input, were shown to outperform previous tools. These methods, while useful, have the limitations of: i) high computational burden due to the greedy-algorithm-based SNP selection procedure, ii), in their current form, the possibility of introducing false positive results when applied to multi-ethnic cohorts and iii) potential power loss due to the assumption of all causal variants being genotyped. To overcome these limitations, we propose a quasi-causality test (QCAT) for assessing the likelihood of measured/unmeasured genetic variants being causal. It uses as input only summary association statistics of measured markers and LD structures obtained from large reference population, e. g. 1000 Genomes data. QCAT is based on a simple but accurate regression test of (suitably transformed) association statistics for measured SNPs on (transformed) genotype correlations between the SNPs and a putative causal SNP. Unlike existing methods, QCAT allows i) fast and computationally efficient testing for causality of all SNPs in a particular genomic region or across the whole genome, ii) direct application to mixed ethnicity cohorts while controlling false positives and iii) capability of testing for causality SNPs not measured in the study but measured in the reference population. Using simulated null data sets with different ethnic composition, we demonstrate that, unlike the two greedy-algorithm-based methods, the proposed method controls the false positive rates for multi-ethnic cohorts. We also use alternative data sets simulated under different causality scenarios to show that QCAT provides comparable performance to the two methods for a much smaller computational burden. For more empirical assessment, we apply QCAT to summary data from the Psychiatric Genomic Consortium Schizophrenia Phase 2 and the Tobacco and Genetics Consortium for smoking quantity and present some interesting findings obtained from the results.

ZGP: a novel method for detecting candidate genes and pathways by integrating genome-wide association studies with pathway analysis. *H. Zhao[1,2], Y. Yang[3].* 1) Institute of Health and Biomedical Innovation, Queensland University of Technology, Queensland, Australia; 2) Queensland Institute of Medical Research, Brisbane, Queensland, Australia; 3) Institute for Glycomics, Griffith University.

ZGP: a novel method for detecting candidate genes and pathways by integrating genome-wide association studies with pathway analysisBackground The successes of GWA studies have provided the opportunities for detecting genetic signals beyond single markers through exploring combined effects of markers on complex diseases and traits. Recently, introduction of integrating the GWA tests with pre-knowledge on genes, such as pathways, have shown promising results to identify candidate genes associated with complex diseases. **Methods**Here we presented a new method, ZGP, to identify candidate genes for complex diseases according to gene-level GWAS results and pathway analysis results. ZGP exhaustingly searches the pathways enriched with genes having low P-values, and then detects the candidate genes. ZGP only requires GWAS summary statistics as input. **Results**We first tested the reliability of ZGP in assessing pathways by type I error rate, and compared ZGP with other available pathway analysis methods. The results show that the type I error rates of ZGP are lower than other methods across different databases. ZGP were compared with GSA-SNP and dmGWAS in detecting candidate genes when applying them to schizophrenia (SCZ) and Height GWAS databases by employing the reported genes as positive dataset. ZGP was demonstrated as an effective approach in detecting candidate genes through comparing the ROC curves with other pathway analysis approaches. **Conclusion**This study demonstrated ZGP as a pathway analysis approach with low type I error rate. This study indicated that ZGP has increased the potential for detecting candidate genes.

OpenCB: a scalable and high-performance platform for big data analysis and visualization in genomics. *J. Coll[2], CY. Gonzalez[3], J. Tarraga[4], M. Haimel[7], FJ. Lopez[3], JM. Mut[3], A. Rueda[2], R. Sultana[2], F. Salavert[4,5], M. Bleda[7], L. Garcia-Alonso[3], J. Dopazo[4,5,6], S. Grät[7,8], J. Paschall[3], P. Calleja[1], A. Rendon[2], I. Medina[1].* 1) High Performance Computing Service, University of Cambridge, Cambridge, United Kingdom; 2) Genomics England, Queen Mary University of London, London, United Kingdom; 3) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Trust Genome Campus, Cambridge, United Kingdom; 4) Computational Genomics Department, Centro de Investigación Príncipe Felipe (CIPF), Valencia, Spain; 5) Bioinformatics of Rare Diseases (BIER), CIBER de Enfermedades Raras (CIBERER), Valencia, Spain; 6) Functional Genomics Node, (INB) at CIPF, Valencia, Spain; 7) Department of Medicine, University of Cambridge, Cambridge, United Kingdom; 8) Department of Haematology, University of Cambridge, Cambridge, United Kingdom.

Current technologies in Genomics are producing data at an unprecedented scale, with projects producing tens of terabytes per day. Existing bioinformatics solutions have not been designed to work at this scale, hindering the ability to store, analyze, or visualize data. OpenCB is an open-source, collaborative platform that hosts different projects designed to provide a scalable and high-performance solution for storing, processing, analyzing, sharing and visualizing big data in genomics. To achieve this, OpenCB uses modern computing technologies such as Hadoop and Spark for data processing and analysis; NoSQL databases (MongoDB, HBase) for data indexing; or HTML5 for data visualization. The knowledge-base database for all OpenCB projects is CellBase, a NoSQL database that integrates the most relevant biological information about genomic features and proteins, gene expression, regulation, functional annotation, genomic variation and systems biology information. Content relies on repositories such as ENSEMBL, Uniprot, and ClinVar, also supporting local knowledge. CellBase has variant annotation capabilities compatible with Ensembl VEP. All data is available through a command line or by a RESTful web service. Cellbase can annotate thousands of variants per second using a remote server. OpenCGA provides a scalable and high-performance solution for big data analysis. OpenCGA implements different components: 1) a *storage engine* framework to store and index alignments and genomic variants into different NoSQL such as MongoDB or Hadoop HBase; 2) a Metadata Catalog which keeps track of users, projects, files, samples, jobs and cohorts, also providing authentication and authorization capabilities; 3) an analysis engine to execute genomic analysis in a traditional HPC cluster or in Hadoop. OpenCGA implements a command line and RESTful web services to manage and query all data. Genome Maps provides a high-performance HTML5 SVG-based genome browser to interactively display data held by CellBase and OpenCGA. Users can also extend Genome Maps to display their own data and formats. OpenCB projects are compliant with the new GA4GH data models. OpenCB is used by projects such as ICGC, NIHR Bioresource-Rare Diseases (BRIDGE), EMBL-EBI EVA and Genomics England. OpenCB is actively developed by researchers and data analysts at University of Cambridge, CIPF, BRIDGE, EMBL-EBI and Genomics England. Source code is open and it is freely available at https://github. com/opencb. .

Global expression patterns and key regulators in epithelial to mesenchymal transition. *P. Parsana[1], S. Amend[2], K. Pienta[2], A. Battle[1].* 1) Department of Computer Science, Johns Hopkins University, Baltimore, MD; 2) Department of Urology, The James Buchanan Brady Urological Institute, Johns Hopkins University, Baltimore, MD, USA.

Epithelial to mesenchymal transition (EMT) is the process where epithelial cells transdifferentiate to mesenchymal cells with increased motility. EMT is integral in developmental biology, wound healing and stem cell behavior. However, in cancer it leads to acquisition of migratory and invasive properties. While accounting for batch effects and noise inherent in gene expression data, we integrated multiple EMT studies from diverse tissue types and used probabilistic graphical models (PGM) to identify the key regulatory mechanisms and interactions that are altered during EMT. We used data from 15 published gene expression microarray studies obtained from Gene Expression Omnibus, representing cell lines from 6 different tissues across 95 samples with different modes of induction of EMT. Applying normalization methods to account for technical variability between datasets, we performed differential expression analysis to identify the individual genes and pathways that vary significantly between epithelial and mesenchymal states. Among the differentially expressed genes were CDH1, ZEB1, FXYD3, AP1M2 and numerous others, known epithelial or mesenchymal marker genes. Enrichment results show increased representation of pathways implicated in wound healing, blood coagulation and cell-cell signalling. We compared the cross-tissue patterns with differential expression results from data restricted to particular tissues in order to identify both shared and tissue-specific genes. Further, we integrated additional sources of data using probabilistic graphical models to predict which of the differentially expressed genes are most likely to play key regulatory roles, with causal influencinge on other genes. Here, we incorporated large expression quantitative trait (eQTL) studies including the Depression Gene and Networks study of 922 individuals, identifying gene pairs where a cis-eQTL in one gene is also significantly associated with the other, distant gene (a trans-eQTL), strongly suggesting a causal, directed relationship between the two genes. From these results, we identified genes such as MRC2 affect the expression of multiple other genes differentially expressed in EMT. We are now extending this to incorporate epigenetic data, further refining our network model. Together, our approach will help build an integrative model that will account for genetic, transcriptomic and epigenetic interactions to identify causal genes and regulatory interactions in EMT.

1690W

***In silico* validation of allelic imbalance by assessments of SNP arrays, whole-exome sequencing and haplotype matching.** *S. Sivakumar[1,2], F. A. San Lucas[3], P. Scheet[2,1].* 1) Biostatistics, Bioinformatics and Systems Biology Program, UT Graduate School of Biomedical Sciences, Houston, TX; 2) Department of Epidemiology, UT MD Anderson Cancer Center, Houston, TX; 3) Department of Translational Molecular Pathology, UT MD Anderson Cancer Center, Houston, TX.

Copy number alterations (CNAs) play a critical role in the initiation and progression of cancer and are typically detected by array-based technologies. Stromal contamination or tumor heterogeneity confound detection of these events, rendering it desirable to observe these from a complementary technology. Although whole-exome sequencing (WES) is conducted mainly to detect single-nucleotide variants, it provides an opportunity for validating CNAs. Since subtle forms of allelic imbalance due to CNAs are particularly difficult to resolve with WES, we have implemented a sensitive, haplotype-based algorithm (hapLOHseq) for its detection. Here, we present a procedure for validating CNAs by assessing (1) the positional overlap of the calls, and (2) the directional concordance of the alleles at heterozygous markers (ie. whether a haplotype shows putative loss or gain). This procedure is straightforward when the markers overlap, eg. between whole-genome NGS and SNP array based techniques; we compute the haplotype consistency between the reference allele frequency (RAF) and the "B allele" frequency (BAF) of each overlapping marker. However, the utility of this direct approach is limited by the set of overlapping markers, which may be small (or empty) in the case of WES and SNP arrays, especially if the CNA covers a modest number of captured exomes. We address this limitation by implementing a linkage disequilibrium (LD) based technique to first generate a haplotype map from all the heterozygous sites in the 1000 Genomes Project, followed by a greedy approach of 1:1 mapping to identify maximal surrogate marker pairs between the platforms. Although the surrogate markers are not in complete LD, they dramatically improve marker availability for cross-platform comparisons. As a proof of concept, we tested our method on a pancreatic adenocarcinoma patient in the The Cancer Genome Atlas (TCGA) showing well distributed putative AI events across the Affymetrix 6. 0 SNP array and WES platforms. We obtained 1452 overlapping CNA markers, 81. 6% of which showed directional (haplotype) concordance. We additionally identified a total of 6197 surrogate pairs (cf. 1452), 76. 8% of which showed directional concordance, not far from the trend observed from the overlapping markers. These encouraging results support an intuitive, novel framework of *in silico* statistical validation for within-sample between-platform variation.

1691T

Identification of possible pleiotropic genetic variants using ClinVar and hospital discharge data. *A. Donahue, J. Weissert, P. Tonellato.* University of Wisconsin Milwaukee, Milwaukee, WI.

This work describes a novel method linking publically available genomic data with hospital discharge data to uncover pathological pleiotropic variants. When a variant arises in a pleiotropic gene, distinct diseases with different symptoms and clinical therapies can co-occur in a patient, obscuring the diseases' shared genetic origin. Identifying pathological pleiotropic genetic variation has significant clinical implications for directing research towards targeted therapy and impacting clinical guidelines for screening and monitoring. In contrast to other techniques for pleiotropic discovery that require extensive study design and resources, we hypothesized that pathological pleiotropic genetic variants can be identified using existing genomic and phenotypic information in the National Center of Bioinformation Technology (NCBI) database ClinVar. We mined the ClinVar database for specific diseases, colorectal cancer and asthma, both of which have at least one known genetic component and are the source of significant morbidity and mortality in the US population. We found 1,120 variants linked to colorectal cancer risk; 53 variants remained after excluding those provided by a single submitter and those linked only to colorectal cancer. We identified specific variants linking colorectal cancer to other diseases with already established relationships such as Lynch Syndrome and breast cancer. We also uncovered a novel relationship between colorectal cancer and age-related macular degeneration (ARMD), linked by independent studies of the variant *rs4986790* of the *TLR4* gene. Similarly, we found 24 variants linked to asthma, and 1 variant, *rs1042713* of the *ADRB2* gene, was independently associated with both asthma and metabolic syndrome. These results support our hypothesis that ClinVar can yield valuable information on possible pathological pleiotropic variants. Further, we matched ICD-9 codes with diseases found to be associated in ClinVar. We then proceeded to test for epidemiological relationships between the associated ICD-9 codes by mining nationwide hospital discharge data. Preliminary results confirm an increase in relative risk for diseases genetically linked in ClinVar across a broad population and suggests a method for validating the pleiotropic relationships found in ClinVar. Further work is being implemented to systematically search ClinVar for pleiotropic variants and cross-validate them with ICD-9 codes in hospital discharge data.

GRIPT: A novel method to identify disease causing genes in a cohort of patients using next generation sequencing data. *L. Zhao[1], X. Wang[2], Z. Ge[3,4], Y. Chen[5], F. Wang[5], R. Chen[1,3,4].* 1) Structural and Computational Biology and Molecular Biophysics Program, Baylor College of Medicine, Houston, TX; 2) Medical Genetics Laboratories, Baylor College of Medicine; 3) Department of Molecular and Human Genetics, Baylor College of Medicine; 4) Human Genome Sequencing Center, Baylor College of Medicine; 5) Department of Computer Science, Fudan University, Shanghai, China.

It has been extensively reported that disease-causing genes can be successfully identified in large families. However, finding genetic causes underlying sporadic cases is still challenging. With the rapid development in the next generation sequencing (NGS) technology, many large disease consortiums have been established. Therefore an algorithm to systematically prioritize and identify disease-genes from large numbers of sporadic cases is highly demanding. In this study, we developed a novel method called**GRIPT** (GeneRanking,Identification andPredictionTool) to evaluate the load of pathogenic mutations in each gene and also test the mutation load differences of each gene between cases and controls with NGS data, from which causative genes are prioritized. To evaluate the performance of our method, simulation was applied and our methods showed both high sensitivity and specificity comparing to other methods. Moreover, we applied our method on a cohort of patients with retinal degenerative disease with control individuals whose phenotypes are retinal unrelated. Both the patients and the control samples were genotyped by whole-exome sequencing (WES), and mutations were called and annotated in each individual using in-house bioinformatics pipeline. A list of genes ranked by p-value was provided. Known retinal disease genes have high ranks in this list and several novel candidate genes were also identified by this method for future research. Overall, our method can effectively and robustly prioritize and identify disease causing genes for sporadic cases using case-control NGS data.

SNP-Chip Sibling Ranker: Using SNPChip Data to Inform Next Gen Sequencing Choices. *B. N. Pusey, W. A. Gahl, D. R. Adams.* Undiagnosed Diseases Program, National Human Genome Research Institute, Bethesda, MD.

In 2008, the National Institutes of Health (NIH) began the NIH Undiagnosed Diseases Program (UDP), whose purpose is to find diagnoses and conduct research for study participants who remain undiagnosed despite an extensive medical workup. Clinical exome sequencing has rapidly become incorporated into the standard clinical armamentarium for evaluation complex patients. In an effort to address the needs of patients who remain undiagnosed, even after exome sequencing has been performed, the UDP continually seeks out new techniques to maximize diagnostic return. One staple strategy is to increase the number of family members included in the analysis. Adding additional, informative family members allows segregation filtering to remove a greater number of segregation-inconsistent variants. Sequencing the parents of a proband is particularly effective for the analysis of apparent de novo variants. Recessive variants can be filtered with the addition of affected and unaffected siblings. In practice, a balance must be struck between the cost of collecting, sequencing and analyzing family DNA samples compared with the final benefit to the exome analysis. Rational decision-making around these issues should include a quantitative assessment of the potential benefits of adding the additional family members. SNP chip genotyping offers one approach to estimating the benefit of sequencing additional family members. The SNP chip data can be used to map recombination events the occurred during recombination and segregation of chromosome into the prospective sibling. We present a framework for using this type of recombination mapping to estimate the potential benefit of any given sibling to a complete exome analysis. Our technique has the potential to avoid the addition of low-contribution siblings to an exome or genome sequencing project while maintaining maximum Mendelian filtration potential. This research is supported by the Intramural Research Program and Common Fund of the National Institutes of Health.

miRge – A rational, ultrafast, multiplexed method of processing small RNA-seq data for microRNAs. *A. S. Baras[1], C. J. Mitchell[2], T. C. Cornish[1], A. Pandey[1,2], M. K. Halushka[1].* 1) Pathology, Johns Hopkins University SOM, Baltimore, MD; 2) Institute of Genetic Medicine, Johns Hopkins University SOM, Baltimore, MD.

Small RNA RNA-seq for microRNAs (miRNAs) is a rapidly developing field in which there are still opportunities to create faster, better bioinformatics tools to parse these large datasets. We built miRge, to be the first rational, ultrafast, small RNA-seq solution to process samples in a highly multiplexed fashion. It utilizes a unique hierarchical multistep processing of small RNA-seq data. From a table of unique sequences and counts, a sequential alignment is made against customized mature miRNA, hairpin miRNA, noncoding RNA and mRNA sequence libraries. Customizations are performed to include SNPs and reduce alignment error. Output is given for miRNAs as raw reads and reads per million (RPM) in addition to isomiR data and reads for all other RNA species (tRNA, rRNA, snoRNA, mRNA). In head-to-head comparisons for single sample analyses with miRExpress 2. 0, sRNAbench, omiRAs and miRDeep2, miRge was 3 to 28-fold faster and always aligned more miRNA reads per sample. In a single multiplex experiment, we fully annotated all RNA species in 100 separate samples in 52 minutes. miRge accepts both fastq and fastq. gz files, can remove any adapter type, and can be used with any species. These features make miRge an ideal tool for high and low-throughput users alike. It is a significant improvement in processing speed and quality of alignment to known miRNAs. miRge is freely available at http://atlas. pathology. jhu. edu/baras/miRge. html.

Nonparametric tests for differential expression in paired tumor-normal microRNA data with imputation-induced dependence. *A. A Suyundikov[1,2], J. R. Stevens[2], C. Corcoran[2], J. Herrick[3], R. K. Wolff[3], M. L. Slattery[3].* 1) BioStat Solutions, Inc. , 5280 Corporate Drive, Suite C200; Frederick, MD 21703; 2) Department of Mathematics and Statistics, Utah State University, 3900 Old Main Hill, 84322-3900, Logan, UT; 3) Division of Epidemiology, Department of Internal Medicine, University of Utah School of Medicine, 383 Colorow Road, Salt Lake City, UT 84108, U. S. A.

Background: Imputed microRNA (miRNA) data are often correlated and may have imputation-induced dependence among subjects. The imputed miRNA expressions may also be non-normally distributed. In this respect, differential expression tests that do not assume a specific distribution but account for the dependence structure of the data are preferable. Currently applied nonparametric methods either do not consider the correlation structure of data or are not computationally feasible for high-dimensional miRNA data with imputation-induced dependence. *Methods:* To identify differentially expressed miRNAs in paired tumor-normal colorectal cancer data with imputation-induced dependence, we proposed three nonparametric methods: the computationally efficient nonparametric permutation t-test accounting for dependence (Permutation dependent), the signed-rank test accounting for dependence (SRT dependent), and the Wilcoxon signed-rank test after whitening transformation of data (Whitening). *Results:* The performances of these proposed methods over other nonparametric methods were evaluated using simulated and real data sets. The differential expression tests show that the Permutation dependent and the SRT dependent methods have moderate power and generally control the False Discovery Rate (FDR), while Whitening has better power but fails to control the FDR. The Permutation independent and the SRT independent methods, which ignore the dependence structure of data, showed higher power than the other nonparametric methods, but do not maintain control of the FDR. *Conclusion:* When miRNA data are not distributed normally and have imputation-induced dependence among subjects, nonparametric methods accounting for dependence should be used over conventional nonparametric methods that ignore the imputation-induced dependence.

SPARS - Sequencing-based pipeline for annotating novel small non-coding RNAs. *P. P. Kuksa[1,2], Y. Y. Leung[1,2], A. Amlie-Wolf[3], B. D. Gregory[3,4], L. -S. Wang[1,2,3].* 1) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Penn Institute for Biomedical Informatics, University of Pennsylvania Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Genomics and Computational Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Biology, University of Pennsylvania, Philadelphia, PA.

The human genome contains thousands of small non-coding RNAs (sncRNAs, <200nts), but most studies have focused on miRNAs or classes involved in splicing. Many new sncRNA classes have recently been uncovered, and they perform versatile roles across different cell states and types. Inferring their regulatory roles remains challenging due to a lack of comprehensive annotation and understanding of sncRNA transcription. To facilitate the simultaneous characterization and functional annotation of multiple types of sncRNAs, we integrate naming and sequence information from various independent annotation sources: miRBase v19 for miRNAs, UCSC for ribosomal RNAs, small cytoplasmic, nuclear and nucleolar RNAs, tRNA-scan for tRNAs and NCBI for piwi-RNAs. We also included tRNA fragments, the flanking 50bp of tRNAs. As sncRNAs are processed specifically, reflected by their stereotypical lengths, we combined different biologically meaningful features with a novel discovery-oriented smRNA-seq data processing pipeline. This allows us to quantify known and predict novel sncRNAs in human across many tissues and cell types. To systematically process smRNA-seq data generated by Illumina, we first performed sample level quality control after trimming the correct adapter. As a size selection step was performed during library preparation, we next examined the distribution of the read lengths, as this reflects whether the gel was cut correctly and allows our pipeline to capture sncRNAs of different lengths. After this, we performed local read alignment using STAR and allowed for an unlimited number of multi-mapping sites, enabling us to capture sncRNAs with high sequence similarity. Incorporating multi-reads increased the sensitivity of detecting different sncRNAs: compared with uniquely-mapped data, we are able to quantify 1. 5-2 times more human sncRNAs in eight different classes using smRNA-seq data obtained from 42 tissues across 30 different resources. Next, we computed confidence levels to identify novel sncRNA annotations based on the patterns of mapped reads and the specificity of 5' and 3' sncRNA processing. Using this novel annotation approach, we are able to recapitulate the majority of known microRNAs (76%) and small nucleolar RNAs (87%) and discover over 2,900 novel, previously unannotated mature small RNA products within promoter (187), exonic (599), intronic (1,091) and intergenic (621) regions. This flexible pipeline can be used for smRNA-seq data in any organisms.

1697T

Contrasting Association Results between Existing PheWAS Phenotype Definition Methods and Five Validated Electronic Phenotypes. *J. B. Leader[1], S. A. Pendergrass[2], A. Verma[5], D. J. Carey[3], D. N. Hartzel[1], D. H. Ledbetter[4], M. D. Ritchie[2,5], H. L. Kirchner[1].* 1) Center for Health Research, Geisinger Health System, Danville, PA; 2) Biomedical and Translational Informatics, Geisinger Health System, Danville, PA; 3) Weis Center for Research, Geisinger Health System, Danville, PA; 4) Geisinger Health System, Danville, PA; 5) Center for Systems Genomics, The Pennsylvania State University, University Park, PA.

Phenome-wide association studies (PheWAS) generally use various counts of International Classification of Diseases, Ninth Revision (ICD9) codes to identify case/control status for diseases that are used as comprehensive phenotypic variables. Defining high quality algorithms for phenotype extraction (gold standard) is a laborious task, thus is not a viable solution for PheWAS. However, differences between using gold standard phenotypes and various counts of ICD9 codes for defining phenotypes have not been thoroughly examined. The most common methods of defining case/control status using ICD9 codes include grouping the codes by three digits (e. g. 250. 02 rolls up to 250), five digits (e. g. 250. 02 stays 250. 02), and "PheWAS Codes" (e. g. 250. 02 grouped to 250. 2). Using data from the Geisinger Health System electronic health record (EHR) and MyCodeTM Biorepository, we identified ICD9 code based case/control status using these methods and compared the resultant cases and controls to the results of gold standard EHR phenotypes for type 2 diabetes (T2DM), acute coronary syndrome (ACS), non-obstructive coronary artery disease (CAD), obstructive CAD, and obesity. Finally, using ~5,000,000 genetic variants with minor allele frequency > 0. 01, we performed a genome wide association (GWAS) for each gold standard phenotype and contrasted highly significant results to those from PheWAS using various ICD9 code based case/control definitions. Comparing these methods of defining phenotypes has shown thus far that for certain diseases using ICD9 count based methods agrees with gold standard algorithms while other phenotypes cannot use codes alone and require additional data from the EHR. For example, good agreement was observed for T2DM, whereas ACS exhibited poor agreement due to the lack of specificity of PheWAS codes. Our future directions include comparing the positive and negative predictive value of the various ICD9 code based methods, potentially identifying additional methods that can broadly improve phenotype definitions. We will also compare additional gold standard phenotypes that can be deployed using EHR data to solely ICD9 based approaches to further identify disease areas that have a high degree of agreement between various approaches. As ICD9 codes will soon migrate to ICD10 codes, establishing improved principles and use of ICD or other ontological code systems (i. e. SNOMED) will be of critical importance for use in PheWAS for discovery now and in the future.

Text-mined phenotype annotation and vector-based similarity improve automated classification of Mendelian phenotypes. *J. R. Saklatvala, M. A. Simpson.* King's College London School of Medicine, London, United Kingdom.

The discovery of novel causative mutations in monogenic diseases typically requires analysis of variant profiles of multiple individuals with the same disorder. The falling cost and increased abundance of genomic data creates a bottleneck to efficiently identify patients with similar phenotypes. Systematic methods have recently been developed to calculate similarity between phenotypes – these involve the annotation of phenotypes with terms from clinical ontologies (such as HPO/SNOMED CT) and using ontology structure to infer similarity between phenotypes. Such phenotypic similarity is dependent on the process of annotating vast numbers of phenotypes in addition to the clinical ontologies being well defined and structured, which may not hold true throughout all areas in an ontology. It also requires an in-depth knowledge of the particular ontology used by the similarity measure program. Here we investigate annotation of free-text phenotypic descriptions using text mining, with a view to making phenotype annotation more efficient and automated. We calculate similarity between annotated phenotypes using vector space models, a flexible method that is well suited to text-mined annotations. We evaluate the performance of this approach through annotation and calculation of the similarity between OMIM and Orphanet phenotypes. Similarity methods were assessed based on their ability to group known similar phenotypes closely, using OMIM phenotypic series as the set of known similar phenotypes. Vector-based similarity greatly improved the identification of similar phenotypes when annotated through a text mining approach and provided equivalent performance when applied to manual annotations. Our study demonstrates that a combination of text mining and vector-based similarity is an effective combination to group related phenotypes within this dataset.

A Coalescent-Based Shotgun Sequence Simulator for Evolving Microbial and Tumour Cell Populations. *K. Liao[1], W. Hsieh[1], W. Hon[2], C. Tang[1,3].* 1) Department of Computer Science, National Tsing-Hua University, Hsinchu City, Taiwan; 2) Institute of Statistics, National Tsing-Hua University, Hsinchu City, Taiwan; 3) Department of Computer Science and Information Engineering, Province University, Taichung City Taiwan.

High-throughput sequencing technology has revolutionized the study of metagenomics and cancer evolution. For relatively simple environment, microbial community is dominated by a few species with sufficiently high coverage. By analyzing alignment of reads from these species, SNPs can be discovered and evolutionary history of the populations in the species can be reconstructed. Similar situation also arise in the study of cancer evolution in which the sets of reads represent random sample of individual DNA molecules from tumour tissues. Subclonal structure and relationship between subclones can be revealed by analyzing somatic mutations. The ever-increasing read length will allow more detailed analysis about evolutionary history of microbial or tumour cell population. A simulator of shotgun sequence from such populations will be helpful in the development or evaluation of analysis algorithms. In this study, we described an efficient algorithm, MetaSMC, which simulates reads from evolving microbial or tumour cell population. Based on coalescent theory, our simulator supports all evolutionary scenarios supported by other coalescent simulators. Our simulator also supports wide range of substitution models including Jukes-Cantor Model, HKY85 and Generalised Time-Reversible (GTR) model. Our simulator supports mutator phenotypes by allowing different mutation rate and subsitution model in different subpopulations. By ignoring unnecessary chromosomal segments, our algorithm is far faster than existing coalescent simulators including Hudson's ms and MaCS. The accuracy of our algorithm is evaluated by time to the most recent common ancestor (TMRCA) and likelihood curve derived from Monte-Carlo integration over large number of possible genealogies. By comparing our algorithm with Hudson's ms, we demonstrated that our algorithm is a good approximation to Standard Coalescent model. We also proved that the process behind our algorithm is Sequentially Markov Coalescent with incomplete sample.

Accurately inferring imbalanced allele expression using logistic regression models. *K. C. Olney[1], L. Skotte[2], R. Nielsen[3], M. A Wilson Sayres[1,4].* 1) School of Life Sciences, Arizona State University, Tempe, AZ; 2) Bioinformatics Center, Department of Biology, University of Copenhagen, Copenhagen; 3) Departments of Statistics and Integrative Biology, University of California, Berkeley, Berkeley, CA; 4) Center of Evolution and Medicine, The Biodesign Institute, Arizona State University, Tempe, AZ.

Biased allele expression, refers to the imbalanced expression of the two alleles in a diploid genome. Unequal transcription of alleles may occur due to cis-regulatory element variation or allele-specific epigenetic modifications. Allelic imbalance is associated in human diseases such as metabolic disorders and in ovary and breast cancers. However, allelic imbalance may be incorrectly inferred due to technical variation inherent in RNA-Seq data, including read depth, reference mapping bias, and the overdispersion of reads. To correct for technical variation we develop a logistic regression model with a mixed effects approach to combine information regarding biased allele expression from many individuals in a population, and across multiple genes. Simulations show that our method does not suffer from an excess of false-positives when inferring biased allele expression while standard ASE methods (a SNP-wise binomial test and a binomial- based logistic regression) test showed an excess of inflated p-values in the quantile-quantile plots. Further, we conducted additional simulations to predict the power of the method to detect the possible range of biased allele expression under assumptions of variable numbers of SNPs per gene and under variable depth of coverage. We then applied this method to inferring biased allele expression across the genome in 89 lymphoblastoid cell lines samples from a Central European Utah population, and are able to more accurately detect modest degrees of allelic imbalance.

1701F

Online human population genetics simulator: a tool for genetics/genomics education and research. *J. R. Shaffer[1], J. Rogan[2].* 1) Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Computer Science, University of Pittsburgh, Pittsburgh, PA.

The technology-driven advancement of ‘omics sciences and the lure of personalized medicine have generated increased interest in genetics and genomics from diverse health science professionals and society at large. Moreover, given its growing relevance to public health, policy, and medicine, there is an urgent need for greater “genomics literacy” of professionals across disciplines. Because many of the foundational concepts of ‘omics sciences are rooted in population genetics, which has historically remained a highly mathematical discipline, efforts to make these concepts accessible are needed. Toward this end we have developed an online population genetics simulator that enables users to manipulate and experience firsthand the effects of evolutionary forces and phenomena. The online simulator (popgensimulator. pitt. edu) focuses on the phenomena impacting human evolution and was designed as a tool to facilitate genetics education and research. The simulator can model various evolutionary forces (e. g. , mutation, selection, drift, migration, population bottleneck) and mating systems (assortative mating, inbreeding) individually or simultaneously. Graphical output depicts allele (or genotype) frequency changes across successive generations in finite or theoretically-infinite populations. Multiple simulations under the same or different parameters can be plotted together for comparison. Simulations can be run in batches with aggregate summary statistics (e. g. , average time to allele fixation) reported. Due to the extensive scope of the simulator, the user interface was designed to facilitate quick and clear input of desired simulation parameters without overloading new users. Input and output is intuitive. Interactive graphs of simulation results are automatically generated, which allow users to zoom in/out, pan left/right, trace individual simulation results, and save as various image file formats. Graphs can be toggled between two color and contrast themes that are optimized for screen viewing, and projecting/printing, respectively. Numerical simulation results can be outputted. URL links can be generated to pre-populate simulation parameters for fool-proof dissemination. The user interface has been optimized for both computers and mobile devices. Though extremely sophisticated, the user-friendly implementation allows the novice user to quickly master the simulator for exploring and experimenting with the forces and phenomena shaping the human genome.

1702W

Benchmarking of splice isoform quantification methods for RNA sequence data. *F. Aguet[1], D. S. DeLuca[1], T. Sullivan[1], G. Getz[1,2], K. Ardlie[1], The Genotype-Tissue Expression (GTEx) Project Consortium.* 1) Broad Institute, Cambridge, MA; 2) Department of Pathology, Massachusetts General Hospital, Boston, MA.

A majority of human genes, including ~80% of protein coding genes, undergo alternative splicing to produce distinct transcripts. How this process is regulated at a transcriptome-wide scale, and how genetic variants affect the expression of specific splice isoforms remains poorly understood due to challenges in accurately quantifying expression at the level of individual isoforms. Due to the short average length (~200-300bp) of sequenced fragments in a typical RNA-seq experiment, reads corresponding to a specific gene may align equally well to multiple of its isoforms, requiring a probabilistic approach to assign reads to their isoform of origin. Moreover, while RNA-seq can in principle capture the full range of expressed transcripts in a sample by proxy of sequenced fragment counts, several factors limit its accuracy in practice if left uncorrected. These factors include 5' or 3' biases (i. e. , due to a combination of RNA degradation and polyA selection during library preparation) and sequence-specific biases (i. e. , non-random sequence content) at the sites of fragment start/end positions and over the full fragment. Importantly, the accuracy of isoform assignment and bias correction depends on coverage, and consequently, on the read depth of the experiment. Several approaches for the deconvolution of isoform abundances from RNA-seq reads have been proposed (e. g. , Cufflinks, Flux Capacitor, eXpress, RSEM, Salmon, Kallisto), with bias correction models of varying complexity. Comparisons between different methods often produce diverging results, and objective evaluations are hindered by the absence of ground truth data. RNA-seq data from over 40 human tissues generated by the GTEx Project Consortium provide a unique opportunity to assess alternative splicing across the human transcriptome and to identify quantitative trait loci that modulate alternative splicing. To this end, high confidence in the estimates of transcript isoform abundance is critical. We present a rigorous framework for the evaluation of isoform quantification methods, based on simulations (which reproduce biases observed in GTEx data), replicate experiments, partial ground truth derived from a subset of long read (2x250bp) data from GTEx, and measures of isoform complexity, and apply this framework to assess the strengths and weaknesses of the aforementioned methods. We expect these results to serve as a resource for future improvements to isoform deconvolution methods for RNA-seq.

1703T

Accurate quantification of allele-specific expression from single cell RNA-Seq data. *K. Choi, N. Raghupathy, S. Munger, M. Vincent, G. Beane, A. Simons, G. Churchill.* Gary Churchill's lab, The Jackson Laboratory, Bar Harbor, ME.

In diploid cells, alleles can be genetically and even functionally different from each other, and their individual expression can vary significantly depending on genetic and cellular conditions. With the emergence of high-throughput sequencing (HTS) technologies, we can now resolve how alleles are preferentially expressed during a biological process of interest; indeed, recent HTS studies have shown imbalances in allelic expression to be common. This information not only reveals which allele is responsible for a phenotype, but enables us to decode how gene expression is regulated. This insight is fundamental for understanding the genetic architecture underlying normal phenotypic diversity and disease. The application of single-cell HTS methods to the study of allelic imbalance adds valuable information about the dynamics of allele expression. As each cell is unique in terms of its state and/or environment, individual cells may exhibit distinct allelic imbalances that are obscured at the level of the tissue. HTS technologies produce millions of short DNA or mRNA sequence reads, however it is often difficult to pinpoint the alleles from which they originate due to the complex, repetitive structure of genomes and noise in the reads themselves. Naïve approaches that discard obscure reads lack the power to accurately estimate allelic expression. A compounding challenge in single-cell genomics data is the increased variation stemming from transcriptional bursting and dropouts. Capturing and sorting out this variability is key to understanding the genetic regulation and dynamics of transcription. We developed an empirical Bayes model to unravel the true cellular heterogeneity from a seemingly homogeneous cell population and refine our understanding of the regulatory mechanisms underpinning cell function. We minimized data ambiguity and information loss by integrating individual-specific genetic information, e. g. , phased SNPs and indels. The new model also borrows information across a population of individual cells and model the transcriptional states of alleles. By referring to how other individual cells transcribe alleles, the method will enable us to accurately estimate allelic expression imbalance, identify subpopulations, and, thus, provide increased sensitivity to accurately estimate alleles with smaller sampling depths, as it combines information across all alleles in a population.

1704F

***derfinder*: Software for annotation-agnostic RNA-seq differential expression analysis.** *L. Collado-Torres[1,2,3], A. Frazee[1,3], M. Love[4], R. Irizarry[4], A. Jaffe[1,2,3,5], J. Leek[1,3,4].* 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA; 2) Lieber Institute for Brain Development, Johns Hopkins Medical Campus, Baltimore, MD, USA; 3) Center for Computational Biology, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD, USA; 4) Department of Biostatistics, Dana-Farber Cancer Institute and Harvard School of Public Health, Boston, MA, USA; 5) Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA.

BackgroundDifferential expression analysis of RNA sequencing (RNA-seq) data typically relies on reconstructing transcripts or counting reads that overlap known features: genes, exons. We previously introduced an intermediate statistical approach called differentially expressed region (DER) finder that seeks to identify contiguous regions of the genome showing differential expression signal at single base resolution that does not rely on existing annotation or potentially inaccurate transcript discovery. ResultsHere we describe a complete suite of software built around the DER approach to RNA-seq analysis. We introduce the *derfinder* package that allows for: (1) a new, computationally efficient approach for base resolution annotation-agnostic analysis called expressed-region analysis, (2) genome-scale analyses in a large number of samples, (3) flexible statistical modeling, including multi-group and time course analyses, and (4) data visualization at base resolution in R. Our suite permits a comprehensive analysis of RNA-seq data at base resolution, from preprocessing, to modeling, to annotation and visualization. We perform a complete comparison to feature counts based methods and demonstrate that base-resolution analysis sacrifices a small amount of power to enable discovery. Finally we apply this approach to public RNA-seq data from the developing human brain and identify differentially expressed regions associated with human brain development. ConclusionsAnnotation-agnostic expressed-region RNA-sequencing analysis provides an alternative to feature-level analysis that allows discovery of differentially expressed regions outside known features. *derfinder* is software designed to identify, visualize, and interpret differentially expressed regions. The package is available from *Bioconductor* at www. bioconductor. org/packages/derfinderPre-printhttp://biorxiv. org/content/early/2015/02/19/015370.

1705W

SplineAdjust: Correcting length bias in differential expressionanalysis of RNA-Seq data. *L. Wang[1], X. Chen[1], C. Armoskus[2], J. Kim[2], J. Li[3], K. Wang[2].* 1) Department of Public Health Sciences, University of Miami Miller School of Medicine, Miami, FL; 2) Zilkha Neurogenetic Institute, Department of Psychiatry and Department of Preventive Medicine, University of Southern California, Los Angeles, CA 90089, USA; 3) Affymetrix Inc. , 3420 Central Expressway, Santa Clara, CA 95051, USA.

RNA-Seq has become a standard methodology for quantifying gene expression levels and detecting differentially expressed (DE) genes. However, technical artifacts may introduce biases into RNA-Seq. Recent studies have shown that DE analysis of RNA-Seq is often prone to gene length bias, that is, longer genes are more likely to be declared significant than shorter genes. When popular software tools such as CuffDiff, DESeq and edgeR are used to calculate DE p-values, substantial length bias often exist, even after normalizing counts by lengths. We proposed a novel statistical approach “SplineAdjust” that takes p-values from any DE analysis tool to generate adjusted p-values for unbiased assessment of DE. SplineAdjust models gene lengths nonlinearly using a penalized spline regression model, can accommodate a variety of study designs in addition to case-control studies, and is also useful for adjusting p-values of isoforms or exons. Using both simulated and real RNA-Seq datasets, we showed that SplineAdjust reduced bias more effectively than previously proposed methods, and the adjusted p-values had improved power and well-controlled type I error rate. With the ever-increasing application of RNA-Seq in gene expression studies, the proposed method will help improve our ability to detect genuinely DE genes in RNA-Seq studies.

1706T

Reveel2: an efficient and accurate method for large-scale population genotyping from low-coverage sequencing data. *L. Huang, S. Batzoglou.* Computer Science Department, Stanford University, Stanford, CA.

Identification of genomic variation in human DNA sequences is a key first step in associating alleles with human traits and diseases. Population low-coverage whole-genome sequencing is rapidly emerging as a prominent approach for discovering genomic variation and genotyping a cohort, because of its cost efficiency and its ability of whole-genome discovery. However, due to the sparseness and shortage of data in each individual, genotyping a cohort from low-coverage sequencing data is much more challenging than genotyping from full-coverage sequencing data. The problem becomes even more severe when attempting to genotype rare alleles at which the allele frequencies do not exceed sequencing error rates. A few existing computational methods can be applied to population genotyping. Despite their considerable success, existing methods are not ideally suited for application to large cohorts (1,000 – 1,000,000 individuals) because of their potentially massive computation time. Reveel, which is our first generation of population genotyper, has been demonstrated to be an effective method; compared to other state-of-the-arts, this method provides considerable improvement in the genotype calling of rare variants. Even though, Reveel could not fully capture the complex linkage disequilibrium (LD) patterns among high allele frequency sites. Thus, genotype phasing is used as complementary method to the genotype-calling algorithm. The phasing step reduced the efficiency of the overall algorithm by ~3x. To enable efficient and accurate population genotyping, we present Reveel2, a novel method for genotyping large cohorts that have been sequenced at low coverage. Based on a novel technique for leveraging the complex LD patterns in cohorts, Reveel2 incorporates significant enhancements to Reveel. The phasing step is not necessary in Reveel2, although we keep this option for the users place more importance on accuracy than efficiency. We evaluated Reveel2 on the empirical data from the 1000 Genomes Project, using the Complete Genomics data as a benchmark, and on extensive simulations using real data. We showed that Reveel2 outperforms its previous version Reveel and other state-of-the-art methods. Reveel2 achieved genotyping accuracy at 99. 7733% on a dataset with 100 samples; genotyping accuracy at 99. 9221% on 500 samples; genotyping accuracy at 99. 9504% on 1000 samples.

SplicER: A novel analytic scheme for the analysis of Splicing Efficiency in RNA-seq data. *L. Simon, T. Hsu, A. Renwick, N. Neill, T. Westbrook, C. A. Shaw.* Baylor College of Medicine, Houston, TX.

The advent of RNA-seq technology has created the opportunity to study transcriptomics at an unprecedented level. The nature of this technology allows researchers to study transcriptional mechanisms beyond gene expression. Global splicing efficiency is a crucial transcriptional mechanism. We define splicing efficiency as the ratio of the numbers of correctly and incorrectly spliced reads. Spliced alignments of RNA-seq data allow direct observation of splicing efficiency at exon boundaries. To better understand splicing efficiency, we have developed anew computational Python package to analyze this process (SplicER). Tovalidate the performance of the package, we used data from the Gene Expression Omnibus on known splicingmutants, and we were able to recapitulateknown differences. To extendtheanalyses with our package, we applied it to data from the Geuvadis project. Weobserved that there is great inter-individual variation insplicing efficiency that correlates with the expression of spliceosomal machinery.

Pleiotropic Variability Score: Quantifying Phenomic Associations of Genetic Variants. *M. A. Badgeley[1,2], K. Shameer[1,2], B. Kidd[1,2], B. Glicksberg[1], D. Ruderfer[3], M. S. Tomlinson[1,2], P. Wang[1], R. Chen[1], J. T. Dudley[1,2,4].* 1) Department of Genetics and Genomics, Icahn Insititute of Genomics and Multiscale Biology, Mount Sinai Health System, New York City, NY; 2) Harris Center for Precision Wellness, Mount Sinai Health System, New York City, NY; 3) Division of Psychiatric Genomics, Icahn Insititute of Genomics and Multiscale Biology, New York, NY; 4) Population Health Science and Policy, Mount Sinai Health System, New York, NY 10029, NY.

Genomic variant interpretation and assessment scores like GERP, PhyloP, SIFT, PolyPhen provides variant impact using evolutionary conservation and biophysical properties but do not account for variability induced by phenotypes. To incorporate phenomic variability into variant interpretation, we developed a method called “Pleiotropic Variability Sore”. Briefly, we mapped the phenotype information to two different phenotype ontologies (Human Phenotype Ontology and Disease Ontology) and estimated the pleiotropic similarities by combining the ontologies and semantic similarity measurements. We tested 226 unique semantic similarity assessment combinations and integrated products of six different semantic similarity metrics to obtain rankings of phenomic similarity associated with individual SNPs to define the final score. We have computed PVS for 10, 021 SNPs using 315 phenotypes mapped using GWAS catalog and PheWAS studies curated from the literature (PVSBMA=0. 777±0. 002; PVSAVERAGE=0. 525±0. 003). We used the pleiotropic SNPs defined by PVS and generated “pleiotropic hubs” using a set of genes in linkage disequilibrium with a SNP (r2<=0. 6) using SCANDB. A total of 10, 246 genes were annotated to pleiotropic hubs. PVS provide a single estimate to quantify the phenomic diversity of a given SNP. For example: 1) rs1939469 is an intronic SNP in *C11orf30* and associated with Alzheimer’s disease and vascular dementia; PVS=1 indicating low pleiotropy and the pleiotropic hub consists of *PRKRIR*, *C11orf30* and *LOC387790* 2) rs10751454 is an intronic SNP in *FAM41C* and pleiotropic hub consist of *RUNX3*, *LOC100128356*, *LOC100128356* and associated with cardiovascular system disease and cancer This variant was scored with 0. 317 indicating high pleiotropy. We examined various network properties of genes in pleiotropic hubs and found they hubs are encoded with genes mediating diverse set of drug targets, pathways and biological functions. Targeting pleiotropic hubs in the setting of complex disease could lead to better therapeutic efficacy in treating complex disease. We envisage that PVS will be a new genome interpretation metric to assess genetic variation to find SNPs with highly pleiotropic nature, and to study phenomic correlations and variants with lower PVS for explorative studies to understand specific roles of SNPs and pleiotropic hubs in mediating novel phenotypes.

1709T

A generalized non-parametric genotype caller using an EM-like Algorithm. *T. Benaglia[1], B. Carvalho[1,2], I. Lopes-Cendes[1,2].* 1) State University of Campinas, Campinas/SP Brazil; 2) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas/SP - Brazil.

Current biomedical researches make constant use of high-throughput technologies for genotyping. Microarrays and, more currently, sequencing experiments provide information at millions of variant sites, which are later investigated for association with a phenotype of interest. Prior to this association assessment, genotyping algorithms quantify the allele-specific abundance and classify subjects into genotype clusters. The series of statistical procedures involved in the aforementioned quantification and classification steps is complex and includes strong hypotheses on the distribution of the data. Models for microarray data assume that intensity signals follow an Exponential distribution combined with Gaussian error, while count data from sequencing are seen as results of a Negative-Binomial processes. We propose an alternative genotype caller that does not rely on assumptions regarding the distribution of the data. Our method uses a non-parametric approach combined with an adapted Expectation-Maximization (EM-like) algorithm to determine the membership likelihoods of each subject at every *loci*. Following this strategy, we use the maximum posterior probability to accurately perform genotype calling.

1710F

AIPS: Ancestry Inference of Subpopulations using Scores from Principal Component Analysis in Genome-Wide Association Studies. *J. Byun[1], Y. Han[1], M. F. Seldin[2], C. I. Amos[1].* 1) Biomedical Data Science, Dartmouth College, Hanover, NH; 2) Rowe Program in Genetics, U. C. Davis, Davis, CA.

Genome-wide association studies (GWAS) in high-density single-nucleotide polymorphism (SNP) genotyping data have identified thousands of common variants associated to complex disease risks and traits. An accurate inference of genetic ancestry is extremely critical in many biomedical research areas, because the difference in genetic population structure between cases and controls can lead to false-positive results. A challenge in the larger genetic data to understand the data structure is whether the individuals are from a homogeneous population or any heterogeneous subpopulation. The Principal Component Analysis (PCA) is the most common approach in the population and admixture structures of genetic data. The R-package AIPS allows us to calculate the SNP weights and scores from PCA, predict the scores from SNP weights computed on the same pre-defined AIMs, and provide the ancestry definitions using pre-defined ancestry clustering information. To estimate ancestry definitions, we applied the Inverse Distance Weighted (IDW) interpolation method from spatial analysis. IDW interpolation assumes that points that are close to one another are more likely alike than those that are farther apart. To infer an ancestry proportion for an unknown sample, IDW can compute the distance metrics from each centroid of the known population. Those estimated values closest to the centroid of known population will have more local influence that diminishes with distance and be weighted greater than those farther away. To demonstrate, we used 4,376 samples with 22 pre-defined European substructures and 2,830 unknown ancestry samples on 25,732 ancestry informative markers. It takes about 15 minutes to calculate scores with the merged 7,206 samples or to predict unknown ancestry definitions after calculating SNP weights in 4,376 known ancestry samples. Also, it takes less than 10 minutes to calculate the distance metrics of substructures for ancestry inferences. The R-package AIPS will be publicly available.

1711W

Processing microarray data using alternative annotations through the Bioconductor oligo package. *B. Carvalho[1,2], I. Lopes-Cendes[1,2].* 1) State University of Campinas, Campinas/SP - Brazil; 2) Brazilian Institute of Neuroscience and Neurotechnology (BRAINN), Campinas/SP - Brazil.

The Bioconductor *oligo* package is a well-established microarray preprocessing software. Currently, it is in the Top 5% most downloaded Bioconductor packages rank, being downloaded 20,000 times in the period of July 2014 – June 2015. The package uses annotation files provided by manufacturers to estimate statistics, like expression abundance, that are required for downstream analyses. These annotation resources often require further curation to reflect the acquired knowledge in the recent past. Common examples of such tasks are removing probes known to deliver poor performance and subsetting preprocessing to genes uniquely mapped by the available sets of probes. We implemented an infrastructure that allows researchers to use alternative annotation resources under the *oligo* framework. Researchers can use our approach to incorporate curated annotations (BrainArray remapped designs, for example) to obtain improved preprocessing results. Our novel approach requires simplified input in the form of tables, and unlocks full access to the Bioconductor environment even for complex array designs, like Gene ST chips.

1712T

Gaussian processes for medical time-series extrapolation and event prediction. *L. Cheng[1], G. Darnell[2], K. Li[3], M. Draugelis[4], B. Engelhardt[3,5].* 1) Department of Electrical Engineering, Princeton University, Princeton, NJ, USA; 2) Lewis-Sigler Institute, Princeton University, Princeton, NJ, USA; 3) Department of Computer Science, Princeton University, Princeton, NJ, USA; 4) Hospital of the University of Pennsylvania, Philadelphia, PA, USA; 5) Center for Statistics and Machine Learning, Princeton University, Princeton, NJ, USA.

In real-time monitoring of hospital patients, early detection of clinical events such as heart attacks or strokes are essential for successful medical interventions and improving patient outcomes. In this work, we develop a statistical framework for early prediction of sepsis that learns from clinically recorded physiological time-series data. Differences in the nature of sampling for clinical covariates make the data sparse and noisy, leading to challenges for real-time monitoring of a patient's status. For instance, vital signs are measured with fairly regular periodicity in the hospital setting, while other more informative measures, such as lab tests, are often invasive and expensive, and are less frequently and less regularly performed. In order to handle the incomplete data and improve the accuracy of sepsis prediction, we propose a statistical framework based on Gaussian processes (GPs), which defines a distribution over functions that map time to the set of clinical covariates for a single patient. Using GPs, we are able to characterize and predict the mean and variance (i. e. , uncertainty) forward in time for a single patient, given a large set of reference patients. In particular, we motivate our model using a collection of data from over 260,000 patent stays at the Hospital of the University of Pennsylvania. Since our data consist of multiple clinical covariates and is highly heterogeneous, we propose a model that shares strength across many clinical covariates with smoothness to reduce noise. In order to rapidly assess a new patient, we use our rich reference data to identify subgroups of similar patients by clustering patient demographic information, and we train one GP model for each group separately. Finally, we use Bayesian online changepoint detection, allowing online prediction of medically relevant events and updating the GP models on-the-fly as more information is gathered on each patient. Using the proposed framework, we show that the prediction error of covariate values is reduced compared with standard linear methods; furthermore, our model allow the explicit characterization of uncertainty in predictions, and the predictions may be traced back to the informative clinical covariates. In summary, the proposed GP framework enables tractable fine-grained prediction of temporal trends and disease onset in complex and heterogeneous time series medical data by exploiting observable dependencies among clinical covariates.

1713F

Realistic simulation of mutations for improving mutation assessment. *A. D. Ewing.* Mater Research Institute, University of Queensland, Woolloongabba, QLD, Australia.

Mutation detection is a fundamental step for many researchers studying human disease. The detection of differences between an individual genome and the reference genome, or between multiple human genomes is subject to false positive and false negative mutation calls. While false positives can be assessed through site-specific methods such as PCR or targeted resequencing, false negatives are more difficult to ascertain. This is a particularly important problem where somatic genomes are concerned, especially in the analysis of tumours with subclonal heterogeneity. Simulation of mutations provides a solution to the problem of accurate assessment of both false positive and false negative mutations, but the simulation needs to take into account normal human genomic variation and the error profile of the sequencing technology, which may vary substantially between individuals, applications, and sequencing platforms. To this end, I have developed BAMSurgeon, a software tool that allows the addition of mutations to pre-existing BAM files. BAMSurgeon is capable of simulating many mutation types including SNVs, INDELs, insertions, deletions, duplications, inversions, and translocations. It supports haplotype-aware spike-in, and many other customisable features to create realistic synthetic mutations in both germline and somatic contexts. BAMSurgeon has been used in a number of studies including the ICGC-TCGA DREAM-SMC Challenge, and the development of mutation calling methods. Through application in these studies and through user feedback, BAMSurgeon continues to improve in terms of usability and realism. In this presentation, I will cover the operation, use cases, and capabilities of BAMSurgeon, which can be obtained at https://github.com/adamewing/bamsurgeon.

1714W

Evolutionarily Derived Networks to Inform Disease Pathways. *B. E. Graham[1], C. Darabos[1,4], M. Huang[1], L. Muglia[3], J. H. Moore[4], S. M. Williams[1,2].* 1) Institute for Quantitative Biomedical Sciences, Dartmouth College, Hanover, NH; 2) Department of Genetics, Dartmouth College, Hanover, NH; 3) Cincinnati Children's Hospital, Cincinnati, OH; 4) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Identifying genes or pathways that associate with human phenotypes continues to be a useful means to understanding disease etiology. However, for complex diseases methods to do this are often inadequate to elucidate a majority of risk. We have previously developed human phenotype networks (HPN) as a means to identify connections between traits or diseases based on shared genetic backgrounds. This has proven useful in terms of demonstrating common processes among diverse phenotypes. In the present study, we expand HPN to include another novel method we have developed, Evolutionary Triangulation (ET), which is a statistical comparison of allele frequencies among three populations and their relationship to phenotype prevalences. ET can refine the selection of genes or pathways prior to implementing HPN. Briefly, with ET we select continental populations based on differences in disease frequencies, such that two populations have similar prevalence while a third is divergent. To build our network, we use ET to identify SNPs by triangulating for a target disease and we rely on prior association data to map the SNPs to their associated phenotypes. The resulting network is bipartite, containing two distinct sets of nodes: SNPs and traits. The ET derived HPN is obtained by projecting the bipartite graph into the disease space. For melanoma (our index disease in the present study), we selected YRI, GIH and CEU as sample populations based on disease prevalences. The ET analysis we used extracted 733 SNPs mapped to 25 phenotypes linked by 236 edges. Four of the phenotypes identified, including ALS and Hodgkin's lymphoma, follow the same distribution as melanoma in these populations. Although the index phenotype is missing from the network, we found tanning and vitamin D as traits, both of which are associated with melanoma. We also identified additionally associating traits, related to Type 2 diabetes (T2D) which also follows the same distribution. Specifically, we identified 18 related traits, including Glucose and HbA1c levels, both major markers for T2D. In conclusion, applying network analysis to ET datasets can extract subnetworks of traits related to multiple phenotypes that follow the same distributions across populations, demonstrating the utility of combining these two analytical approaches to further elucidate underlying etiological pathways of complex disease.

1715T

Rapid Generation of Illumina Infinium Genotyping Release Data. *S. M. L Griffith[1], H. Ling[1], K. N. Hetrick[1], J. Romm[1], E. W. Pugh[1], I. A. McMullen[1], D. R. Leary[2], B. R. Myers[1], M. Z. Mawhinney[1], M. E. Hurley[1], A. B. Robinson[1], L. Watkins, Jr. [1], K. F. Doheny[1].* 1) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 2) New York Genome Center, New York, NY.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. Prior to release, raw data (in the form of image files, or . idats) generated by the Illumina Infinium chemistry are put through a data analysis pipeline, generating genotypes. Specifically, the raw . idat files generated by HiScan scanners are loaded into GenomeStudio to generate quality control metrics for each project. Next, final genotypes for a project are generated by first clustering SNPs using a project's high quality samples, and then applying a technical SNP filter to get final SNP cluster definitions. Historically, using this cluster definition, the final genotypes have been generated using GenomeStudio. As projects have gotten larger over time, it can take weeks to generate these genotype files and, thus, this approach has become time-prohibitive. For example, processing a set of 19,000 samples run on the two-million-SNP MEGA Array, and analyzed with GenomeStudio would have taken more than a month using a blade server with 192 GB of RAM and 32 processor cores. To generate these data more rapidly, the software development group at CIDR has created a massively parallel data generation tool. Following reclustering and final cluster assignments for each variant, this tool generates genotyping release data by directly parsing the GTC files generated via Beeline, Illumina's standalone genotype caller. Using these data, the tool normalizes the raw intensity data and calculates several metrics, including Log R Ratio and B Allele Frequency. The per-sample data generation tasks are embarrassingly parallel, and the entire process scales with available resources. Using the same blade server, data were generated for the 19,000 MEGA array samples in fewer than 24 hours. In addition to generating individual genotyping reports on a per sample basis, this tool also generates several supplementary PLINK files containing the same genotypes as the individualized genotyping reports. These files include two PLINK Ped files (one with pedigree information and one without), a PLINK Map file, and strand translation files from top/bottom to forward/reverse or A/B formats.

1716F

Integration of Bina RAVE for genomic data analysis at the Center for Inherited Disease Research. *K. N. Hetrick, B. Myers, S. M. L. Griffith, D. Snyder, K. F. Doheny, L. Watkins.* Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. With the ever increasing volume of NGS data being generated and constantly evolving ways to analyze them; software development, bioinformatics and IT personnel, as well as local HPC resources can find themselves straining to maintain the same level of quality and efficiency with fast turn-around times and expertise. There are a bevy of commercial platforms that aim to lessen this burden with a multitude of those aimed at uploading and analyzing data in the cloud. However due to privacy concerns with sample data, cloud-based solutions are not an option for all facilities. CIDR assessed the Bina RAVE (Read Alignment, Variant Calling and Expression) module (Bina Technologies, Redwood City, CA) deployed on a single Bina Rack local analysis appliance (4 nodes, 64 cores) with optimized workflows for whole genome/exome (WGS/WES) SNV/indel calling, WGS CNV calling, tumor/normal, and RNA analyses. For our initial evaluation, we focused on comparing the results of a WGS sample sequenced on an Illumina® HiSeq™ 2000 at 38x depth analyzed on the Bina appliance using bwa mem and GATK 3 HaplotypeCaller in GVCF mode to an analysis generated outside of the appliance using the same workflow and software versions. Between the two analyses, there was a 99. 9% overlap of the unfiltered SNV calls, with 98. 3% of passing SNVs overlapping. The workflow finished in 9 hours on the Bina appliance with complete BAM and VCF outputs, and included CNV analyses that we had not otherwise implemented. This lessened the burden on our IT and software development staff (e. g did not need to reconfigure our HPC system, develop a software framework to optimize complex/distributed analyses needed to complete WGS analysis in under a day, etc). Throughout and after the evaluation period, more features were added to the appliance software. In addition, we jointly called and filtered ~800 WES samples on the appliance using the GATK 3 joint calling and Variant Quality Score Recalibration workflow in 2 hours. We are currently integrating their API to automate submission of samples for analysis on the appliance as well as automate submission of other downstream analyses on our cluster after the Bina analyses are done. We also plan to evaluate their other analysis workflows (e. g. tumor/normal).

1717W

Efficient approach to correct read alignment for pseudogene abundance estimates. *C. J. -T. Ju, Z. Zhao, W. Wang.* Computer Science, University of California, Los Angeles, Los Angeles, CA.

RNA-Sequencing has been the leading technology to quantify expression of thousands genes simultaneously. The data analysis of an RNA-Seq experiment starts from aligning short reads to the reference genome/transcriptome or reconstructed transcriptome. However, current aligners lack the sensitivity to distinguish reads that come from homologous regions of an genome. Pseudogenes arise from duplication of a set of protein coding genes, and have been considered to be degraded paralogs in the genome due to their lost of functionality. Recent studies have provided evidence to support their novel regulatory roles in biological processes. With the growing interests in quantifying the expression level of pseudogenes at different tissues or cell lines, it is critical to have a sensitive method that can correctly align ambiguous reads and accurately estimate the expression level among homologous genes. Previously in PseudoLasso, we proposed a linear regression approach to learn read alignment behaviors, and leverage this knowledge for abundance estimation and alignment correction. In this paper, we extend the work of PseudoLasso by grouping the homologous genomic regions into different communities using a community detection algorithm, followed by building linear regression models separately for each community. The results show that this approach is able to retain the same accuracy as PseudoLasso. By breaking the genome into smaller homologous communities, the running time improves drastically with an increase number of genes.

1718T

Ferret: a user-friendly Java tool to extract data from the 1000 Genomes Project. *S. Limou[1], A. Taverner[2], G. Nelson[3], C. Winkler[1].* 1) Molecular Genetic Epidemiology Section, Basic Research Laboratory, Basic Science Program, NCI-Frederick, Leidos Biomedical Research, Inc. , Frederick National Laboratory, Frederick, MD; 2) Quantitative and Computational Biology program, Princeton University, Princeton, NJ; 3) Center for Cancer Research Informatics Core, Leidos Biomedical Research, Inc. , Frederick National Laboratory, Frederick, MD.

The 1000 Genomes (1KG) Project provides a near-comprehensive resource on human genetic variation in worldwide reference populations. 1KG variants can be accessed through a browser and through the raw and annotated data that are regularly released on an ftp server. Two years ago, we developed Ferret as a Perl script to easily extract genetic variation information for a locus of interest from these large and complex data files. We now provide Ferret as a user-friendly Java tool with novel features: (1) the input can be a locus, gene(s) or SNP(s) of interest; (2) Ferret retrieves genotype data for 1KG SNPs and indels; (3) Ferret computes SNP, indel and CNV allelic frequencies for 1KG populations and (4) optionally for the Exome Sequencing Project populations. By converting the 1KG data into files that can be imported into popular pre-existing tools (*e. g.* PLINK and HaploView), Ferret hence offers a straightforward way, even for non-bioinformatics specialists, to manipulate, explore, and merge 1KG data with the user's dataset, as well as visualize linkage disequilibrium pattern, infer haplotypes, and design tagSNPs. Ferret is publicly available at: https://ccrod. cancer. gov/confluence/display/BCGC/BCGC+Software. You may contact us at ferret@nih. gov.

GAMETES 2. 0: Expanding the complex model and data simulation software to generate heterogeneous datasets, custom models, and quantitative traits. *J. H. Moore, R. U Urbanowicz, P. Andrews.* Genetics, University of Pennsylvania, Philadelphia, PA.

Increasing acknowledgement of the complexity of common diseases, particularly with regards to complex multivariate patterns of association, has led to an increased interest in the development of new analytical methodologies, algorithms, and software able to detect, model, and characterize such patterns. In order to properly develop, test, and evaluate such methodologies, a variety of representative simulated datasets for simulation studies are required. Previously we developed the GAMETES software for the rapid, deterministic generation of strict, purely epistatic single nucleotide polymorphism (SNP) models based on user defined parameters such as heritability, minor allele frequencies, prevalence, and the order of interaction (e. g. 2-way, or 3-way). GAMETES 2. 0 expands the capabilities of this software, allowing users to (1) combine multiple genetic models for the simulation of datasets with patterns of genetic heterogeneity, (2) generate custom 2 or 3-way SNP models with a report of the model's characteristics and predicted relative detection difficulty, (3) generate datasets with a quantitative trait/endpoint as opposed to a binary discrete class endpoint. Quantitative endpoints are generated from GAMETES genetic models by using the penetrance values of specific genotype combinations as a centroid for selecting a continuous trait value for each subject in the dataset. We test this new simulation software by generating simulation studies with heterogeneity and quantitative traits respectively and demonstrate that we can identify these simulated patterns using advanced machine learning approaches (i. e. QMDR and EXSTRACS), and feature selection approaches (ReliefF, SURF, SURF*, and MultiSURF).

1720W

Gene: a gene-centered information resource at NCBI. *T. Murphy, D. Maglott, K. Pruitt, the Gene Team, and the RefSeq Curation Team.* NCBI, NIH, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) Gene resource (www. ncbi. nlm. nih. gov/gene/) integrates gene-centric information for over 11 million genes from over 12 thousand taxa spanning the tree of life. Records include a diverse set of content including citations, nomenclature, genome annotation, gene products and their attributes, phenotypes, sequences, interactions, variation details, maps, expression, homologs, protein domains and crosslinks to a variety of external databases. Genome annotation and products originate from NCBI's RefSeq resource, which includes extensive manual curation for human and mouse genes and genome annotation from NCBI's Eukaryotic Genome Annotation Pipeline. Gene web pages also serve as a central hub to other NCBI resources, including browsers (Map Viewer, Variation Viewer, 1000 Genomes, Epigenomics), RefSeq genome, transcript and protein sequence records, ClinVar, dbSNP, PubMed, HomoloGene, and many others. This presentation will focus on the sources and types of content available on human gene records, including data tracks available in the Graphical viewer, support for annotation on multiple assemblies (GRCh38. p2, GRCh37. p13, and CHM1_1. 1), annotation from both NCBI and Ensembl, and crosslinks to orthologous records from hundreds of other vertebrates. Plans for ongoing development in reporting expression data and improved web presentations will be discussed. All data is available via web pages, FTP, and NCBI's e-utils programming utilities.

1721T

BioBin: A comprehensive tool for the biologically-inspired binning and association analysis of low frequency variants in sequence data. *A. Okula[1], J. Wallace[1], A. Frase[1], M. D. Ritchie[1,2].* 1) Center for Systems Genomics, Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Geisinger Health System, Danville, PA.

Advances in sequencing technology and decreases in cost have presented an opportunity for the investigation of low frequency and rare variants beyond traditional GWAS-based approaches. Rare variant analysis, however, is challenging as statistical power for detection is low. As a means of boosting power, many methodologies have been specifically developed to facilitate rare variant analysis. Many methods focus either on the creation of a relevant set of variants or on the statistical analysis of an arbitrary set of variants. In this work, we expand the framework of BioBin providing a comprehensive bioinformatics tool for the automated and biological inspired binning and association analysis of rare variants. BioBin was initially developed to perform multi-level binning of rare variants based on user-designated features such as genes, pathways, ECRs, and regulatory regions. BioBin follows a flexible, biologically informed binning strategy using an internal biorepository known as LOKI, or the Library of Knowledge Integration. LOKI combines over a dozen databases from the public domain including NCBI Entrez Gene, KEGG and Protein Families. These databases provide variant details, regional annotations and pathway interactions used to generate bins of biologically-related variants, thereby increasing the power of detection for any subsequent test. To facilitate statistical analysis, we have added an extensible testing infrastructure to BioBin and have implemented select burden and dispersion tests, allowing the user to perform regression, wilcoxon and/or SKAT on binary or quantitative phenotypes subsequent to variant binning. By integrating the tests into BioBin directly, we avoid file conversion issues for specific tools, saving analysis time and making the process more robust. BioBin is also capable of multiple phenotype analysis allowing the execution of a rare variant binned phenome-wide association study (PheWAS). Because each phenotype can be analyzed independently, BioBin uses parallel processing to increase the speed of a PheWAS binning analysis through a user-specified number of processors. To highlight the speed of analysis, we were able to perform a gene-based binning SKAT test to analyze 30 quantitative phenotypes in 8,000 individuals using whole-exome sequence data in 5 hours using less than 12GB of memory. Overall, BioBin is a powerful and versatile tool for the biological binning and analysis of low frequency variants for complex phenotypes.

1722F

Geneious R9: a bioinformatics platform for biologists. *K. Qaadri[1], C. Olsen[1], H. Shearman[2], R. Moir[2], M. Kearse[2], S. Markowitz[2], J. Kuhn[2], S. Dunn[2], T. Paulin[2], A. Cooper[2].* 1) Biomatters, Inc. , San Francisco, CA; 2) Biomatters Ltd, Auckland, New Zealand.

Biomatters' Geneious R9 is a bioinformatics software platform that allows researchers the use of industry-leading algorithms for their genomic and protein sequence analyses. R9 offers a comprehensive suite of functions, including peer-reviewed tools, that enable researchers to be more efficient with their bioinformatic workflows.

Geneious is comprised of an extensive tool suite for next-generation sequence analysis, sequence alignment, molecular cloning, chromatogram assembly, and phylogenetics. This major version release includes tools for RNA-Seq expression analysis, support for scaffolding using paired data in *de novo* assemblies, a function to identify CRISPR sites and support for Golden Gate assembly. Additional features for this software release include the 16S Biodiversity tool and Sequence Classifier plugin. The 16S Biodiversity tool identifies high-throughput 16S rRNA amplicons from environmental samples using the RDP database, and visualizes biodiversity as an interactive chart using a secure web viewer. The Sequence Classifier plugin taxonomically classifies an organic sample by how similar its DNA is to your own database of known sequences using a BLAST-like algorithm with multiple loci and trees to assist with identification. New plugins include Blast2GO (Gene Ontology enrichment), FreeBayes (haplotype-based variant calling), Augustus (gene prediction), and FLASH (read merging).

R9 enables real-time dynamic interaction with sequence data and empowers biologists to produce stunning publication quality images to increase the visibility of their research. By utilizing Geneious R9, biologists can easily streamline their sequence analysis workflows. This poster aims to demonstrate the new features and benefits of the highly integrated Geneious R9 tool-suite.

1723W

Novel Approach for Correction of Cell-Type Heterogeneity Improves Power of Epigenome-Wide Association Studies. *E. Rahmani[1], Y. Baran[1], N. Zaitlen[2], C. Eng[2], D. Hu[2], J. Galanter[2,3], S. Oh[2], E. Burchard[2,3], E. Eskin[4,5], J. Zou[6], E. Halperin[1,7,8].* 1) Blavatnik School of Computer Science, Tel-Aviv University, Tel Aviv, Israel; 2) Department of Medicine, University of California San Francisco, San Francisco, California; 3) Department of Bioengineering and Therapeutic Science, University of California San Francisco, San Francisco, California; 4) Department of Computer Science, University of California, Los Angeles, California; 5) Department of Human Genetics, University of California, Los Angeles, California; 6) Microsoft Research New England, Cambridge, Massachusetts; 7) International Computer Science Institute, Berkeley, California; 8) The Department of Molecular Microbiology and Biotechnology, Tel-Aviv University, Tel Aviv, Israel.

Recent work applying epigenome-wide association studies (EWAS) suggest an important role for DNA methylation as a mechanism involved or associated with disease. The standard statistical analyses applied in EWAS test for an association between probed CpG site with the phenotype of interest, similar to the approach taken in genome-wide association studies (GWAS). The analysis of EWAS conducted in primary tissue such as blood is complicated by the fact that tissues are complex mixtures of diverse cell types, each with their own methylation profile. When cell types are correlated with the phenotype of interest, tissue heterogeneity will lead to a large number of false discoveries in standard analyses, similar to the case of population structure in GWAS. In order to overcome this challenge, different analysis methods have been proposed to account for the cell type composition. These methods are either based on reference data in which methylation profiles have been carefully measured for sorted cells, or they implicitly model cell type composition without the use of reference profiles. In this study we show that current methods do not adequately correct for false positive rate and they are sub-optimal in terms of power. We introduce a new highly efficient reference-free method for EWAS analysis. An unsupervised approach is critical since methylation is affected by many factors (e. g. , age, sex and genetics), and a reference-based method is exposed to bias from potential differences between the reference and the study population due to poor matching of these factors. Unlike GWAS were many SNPs are potentially informative, only a small number of the CpG sites are significantly different between cell types, therefore using more sites in a factorization method such as principal components analysis (PCA) may sometimes add more noise than a signal. Motivated by this observation, our method is based on an unsupervised feature selection step followed by a sparse PCA. We show, based on both simulated and real data (the GALA II study), that estimates of the cell type composition using our method are better than both reference-based estimates and PCA. We also show that applying our method to EWAS results in better control for false positives as well as a significant power increase compared to existing methods. We further demonstrate the utility of our method on a previous Rheumatoid Arthritis EWAS, revealing a new unreported methylation site associated with the disease.

Network-assisted Method of Genome-wide DNA Methylation Association Studies in Cancers. *P. Ruan[1], J. Shen[2], R. Santella[2], S. Zhou[1], S. Wang[3].* 1) School of Computer Science, Fudan University, Shanghai, Shanghai, China; 2) Department of Environmental Health Science, Mailman School of Public Health, Columbia University, New York, NY, USA; 3) Department of Biostatistics, Mailman School of Public Health, Columbia University, New York, NY, USA.

DNA methylation plays important roles in the carcinogenesis process. Many genome-wide DNA methylation association studies have been conducted that have identified aberrantly methylated genes in cancer. Most of these studies focus on analyzing methylation one site at a time; the result may be studies are underpowered to identify cancer related genes as genes interact with each other in carcinogenesis process. Incorporating prior biologic information such as biology network has been proven to be a useful way to examine the joint effect of genes. Here, using DNA methylation data, we present a network-assisted method to search for modules that are associated with cancer by incorporating the association signals that capture differences in both means and variances between the two experimental conditions, such as between tumor and adjacent normal groups with a human protein-protein interaction network. The method searches for the modules that are enriched with genes having stronger association signals. Application to DNA methylation data of hepatocellular carcinoma (HCC) from Columbia University Medical Center (CUMC) and the Cancer Genome Atlas (TCGA) project and breast invasive carcinoma (BRCA) from TCGA demonstrate that our method finds several genes that are known to be related to cancer but are missed by methods ignoring the prior biology information or signals in DNA methylation variation.

Comparison of preprocessing methods for the Luminex xMap® technology. *A. Schillert[1], T. K. Rausch[1], H. -D. Zucht[2], A. Ziegler[1,3,4,5], P. Schulz-Knappe[2].* 1) Inst Med Biom and Statistics, Universitaet zu Luebeck, Universitaetsklinikum Schleswig-Holstein, Campus Luebeck, Germany; 2) Protagen AG, Dortmund, Germany; 3) Zentrum fuer Klinische Studien, Universitaet zu Luebeck, Luebeck, Germany; 4) Deutsches Zentrum fuer Herz-Kreislauf-Forschung, Standort Hamburg/Kiel/Luebeck, Luebeck, Germany; 5) School of Mathematics, Statistics and Computer Science, University of KwaZulu-Natal, Pietermaritzburg, South Africa.

As a multiplex alternative to ELISAs the Luminex xMap® technology allows to analyze up to 500 different analytes simultaneously. As with most high throughput technologies data preprocessing is crucial to eliminate technical variation. A sequence of transforming the data and then combining it via a normalization method is widely accepted. Multiple methods for transforming and normalizing the data have been proposed for gene expression data. However, it remains unclear which combination of transformation and normalization methods yields the best results in the context of proteomics. Through literature search we identified six transformation and seven normalization methods. To test the performance of these methods we used data from a Luminex xMap® experiment of 42 samples and 384 antigens. Intensity values equal of zero were coded as missing. During quality control we excluded antigens with missing data for more than eight samples. We performed median imputation to replace missing values. We then applied a transformation followed by a normalization method. As quality diagnostics we used three statistics for the distribution of the intensity values - tail length, skewness, and coefficient of variation. Additionally, we generated Bland-Altman, Mean-Sd, and Volcano plots. These plots were then evaluated by 15 trained raters in a blinded setting. From the statistics and the rating results we constructed a score between 0 and 12 to identify useful combinations of transformation and normalization methods. The quality controlled data contained 380 antigens. Of the 37 useful combinations of transformation and normalization methods 10 achieved a score of 11 or 12. The transformations were log2, asinh and one of two versions of boxcox followed by either loess or quantile normalization or robust spline normalization after a boxcox transformation. Data preprocessing has a large impact on the validity and power of any statistical analysis using high-throughput data. This is also true for Luminex xMap®data. Our investigations show that for Luminex data transformation is mandatory and normalizing greatly improves the data quality. Suitable combinations are available.

LAMPLINK: An additional function for PLINK to detect statistically significant genetic interactions. *A. Terada[1,2,3], K. Tsuda[1,3], J. Sese[3].* 1) Computational Biology and Medical Sciences, The University of Tokyo, Chiba, Japan; 2) Research Fellow of the Japan Society for the Promotion of Science; 3) Biotechnology Research Institute for Drug Discovery, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan.

PLINK is widely used software to analyze genome-wide association study (GWAS) data. Its major functions list single nucleotide polymorphisms (SNPs) statistically significantly associated with a target phenotype. While PLINK has uncovered thousands of disease causal SNPs, it cannot detect epistatic effect, in which each chromosomal position is not highly associated with a target trait but their combination shows statistically significant association with the trait. Detecting epistatic effect is difficult not only for PLINK but also for other GWAS analysis software because they use low sensitive multiple testing procedure. Recently, a novel multiple testing procedure, called Limitless Arity Multiple-testing procedure (LAMP) [Terada et al, PNAS, 2013], was proposed for combinatorial effects discovery. It can enumerate any SNP combinations statistically significantly associated with a target trait, whereas the family-wise error rate (FWER) theoretically controls under the equal level to the Bonferroni correction. We incorporated the LAMP with PLINK as an option of multiple testing procedures, named LAMPLINK. Our demonstration using dataset including more than 100,000 SNPs and 364 individuals showed that LAMPLINK detected combinations of three or more SNPs as causal SNPs of Alzheimer's disease, all of which were overlooked by the Bonferroni correction. LAMPLINK can contribute to solve the missing heritability problem.

1727T

Calcordance: A Genotyping Concordance Tool. *B. D. Tibbils, S. M. L. Griffith, M. Z. Mawhinney, I. A. McMullen, M. Jewell, A. B. Robinson, C. M. Ongaco, M. E. Hurley, J. M. Romm, L. Watkins, Jr. , K. F. Doheny.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality genotyping and sequencing services and statistical genetics consultation to investigators working to discover genes that contribute to disease. Concordance (in genotyping) involves determining the number of identical SNP calls between two independently generated data sets for the same individual. In this particular use case, one data set comes from a fixed set of reference information and the other is from a data set submitted by the user. Calcordance (a portmanteau of calculation and concordance) is a software application created to generate concordance information for the controls of a genotyping project as quickly as possible with a very large set of reference data. Originally, HapMap genotypes were used as reference data used for concordance at CIDR. These data are comparatively small, already divided into CSV files by sample name and only contain the necessary information: SNP name and allele zygosity. At that point, the strategy was simply to grab the file with the sample name matching that submitted by the user and go through the two data sets, line by line, performing the calculations. Once a much larger reference data set was introduced, this was no longer a reasonable solution. The larger data set, genotypes from the 1000 Genomes Project, is divided by chromosome. Each file is between 10 and 60 gigabytes and the files are in the VCF format. Retaining the same strategy of looping through each line of each file could take hours or even days with this data set, so the data needed to be restructured. To compress these data, three relationships were introduced: chromosome to sample name, sample name to SNP and SNP to allele zygosity. Allele zygosity is always one of two possibilities: homozygous or heterozygous. This data is represented as a single bit. Using a compact data structure we associated each SNP for a given sample to its allele zygosity bit. By serializing this structure to the file system for repeated use, this information could now be quickly accessed during runtime. This data structure was created for each sample and all samples for a particular chromosome were stored together. This increased our efficiency and brought our processing time from two or three days down to less than an hour for a large data set.

1728F

A web portal for rapid imputation of summary statistics in association studies. *J. N. Torres[1], H. Shi[2], B. Pasaniuc[3], G. L. Wojcik[4], C. R. Gignoux[4], C. D. Bustamante[4].* 1) Biomedical Informatics, Stanford, Stanford, CA; 2) Bioinformatics, UCLA, Los Angeles, CA; 3) Human Genetics, UCLA, Los Angeles, CA; 4) Genetics, Stanford, Stanford, CA.

An important component of genome-wide association studies (GWAS) is genotype imputation to capture untyped variation. Many popular imputation packages to impute individual-level genotypes are based on Hidden Markov models (HMM), which are often computationally demanding, especially in large GWA studies. Due to growing volume of genomic data available as well as changing privacy and logistical constraints on data, individual genotypes may not be readily available or genotype imputation not computationally feasible. As a substitute, methods that can leverage summary association statistics are becoming more popular. Here, we highlight a user-friendly imputation approach built upon the ImpG-Summary algorithm to test for associations at untyped SNPS when only summary association statistics are available. Summary association statistic imputation is performed using a multivariate Gaussian model for linkage disequilibrium in a window with an added penalty term for the statistical noise introduced by a finite sized reference panel to reduce false positives. We present a web-based service written in Python that allows for summary association imputation with easy file formatting and user-defined metrics of window size, buffer length regions, and specified ridge regression penalty to account for sampling noise, as well as choice of reference haplotypes to be used. We evaluate various reference panels for diverse populations from the 1000 Genomes Project Phase 3 data release and are using admixture deconvolution to elucidate ancestral LD patterns for improved performance in various populations. This service allows for a fast and simple-to-use utility to test associations using a method that approaches the accuracy of common HMM based approaches but in orders of magnitude less time. In practice our version of the algorithm with pre-computed LD can impute chromosome 20 on the Multi-Ethnic Genotyping Array from 17k sites 20 up to over 1. 7M sites from 1000 Genomes Phase 3 data in an average of 138 seconds. As the size and scope of genetic research increases we anticipate this being a useful screening resource for rapid follow-up and increasing the utility of publicly available data.

1729W

A new 'front' in rule-based data mining for complex, heterogeneous, and noisy association analyses. *R. J Urbanowicz, J. H Moore.* Gen, University of Pennsylvania, Philadelphia, PA.

Biological and statistical phenomena such as epistasis, genetic heterogeneity, and phenocopy can mask the relationship between genotypic, epigenetic, and environmental risk factors/markers and phenotypes of interest. It has often been suggested that such phenomena may account for a substantial portion of so called 'missing heritability' across genetic association studies of common human heritable diseases. The modern data mining toolkit for association analyses mostly includes approaches that labor under restrictive assumptions such as the number of predictive variables, the application of a specific genetic model, linearity, or homogeneity in order to function quickly, effectively, and reliably. Previously, we developed a rule-based machine learning algorithm called ExSTraCS, an Extended Supervised Tracking and Classifying System, for assumption-free classification, prediction, and knowledge discovery designed to be particularly advantageous in detecting, modeling and characterizing complex, noisy, multivariate, epistatic, and heterogeneous patterns of association. The key to this flexibility is that ExSTraCS, like other Learning Classifier System algorithms learns piece-wise effective generalizations of the problem space. In other words, human interpretable rules are evolved to individually capture subspaces of the overall pattern and collectively applied to form the predictive 'model'. One major challenge is to be able to compare and rank the 'value' of these evolved rules in a way that emphasizes both the accuracy and the correct coverage of the dataset in order to reduce overfitting and promote solution interpretability in noisy or heterogeneous problems. In the present study we introduce a Pareto-front-inspired methodology for the calculation of rule-fitness within ExSTraCS that provides a reliable, multi-objective global value metric. Specifically, as rules emerge and are evaluated, a non-dominated front of points defined by the accuracy and correct coverage of a rule is updated and applied to calculate the fitness of every existing rule as a function of the distance from the non-dominated front, and the relative area under the front. We find that this methodology significantly improves performance, interpretability, and allows for dramatic and simple rule compaction, across a spectrum of complex noisy simulation studies concurrently modeling epistatic and heterogeneous patterns with assorted heritabilities and sample sizes.

1730T

A new change-point model based method for copy number variation detection. *F. Xiao[1], X. Min[2], H. Zhang[2].* 1) University of South Carolina, Department of Epidemiology and Biostatistics, Columbia, SC; 2) Yale School of Public Health, Department of Biostatistics, New Haven, CT.

Copy number variation (CNV) is an important type of structural variation and is associated with human complex disorders, such as autism, growth retardation and HIV progression. Duplication or deletion on any of the two copies of genomic segments results in CNV of this region. To detect CNVs in human genome, several change-point based techniques have been proposed. However, these methods usually present high computational complexity, given that the data points are repeatedly used in the process of determining change-points along the same sequence. Moreover, some practical issues arise when these methods are applied to real CNV data, such as handling the heavy-tailed distribution and identifying the biologically meaningful copy number states. In this study, we propose a modified screening and ranking algorithm (modSaRa). This algorithm is suitable for high-throughput genetic data due to its low computational complexity. The aforementioned issues in CNV detection are also addressed. First, modSaRa is robust to the violations of the normal assumption. Second, a novel approach using a normal mixture model coupled with a modified BIC criterion is proposed for filtering false positives and further clustering the potential CNV segments to copy number states. We compare modSaRa with an alternative method, circular binary segmentation (CBS). In both simulated and real data studies, modSaRa outperforms CBS in detecting CNVs with higher sensitivity and specificity.

Varpipe: Whole Genome Variant Analysis in Minutes. *A. Yao[1,2], E. C. Yeh[1], J. P. Su[1], Y. D. Chiu[1], D. H. Chung[1], W. J. Lin[1], L. Tang[1], F. C. Hsiao[1], K. C. Li[1], H. T. Wu[1], T. C. Chen[1], C. K. Liu[1].* 1) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 2) National Center for Genome Medicine, Academia Sinica, Taipei, Taiwan.

Analyzing variants in a human genome from raw data with 40X depth usually takes days. Setting up optimal analytical process to shorten analysis time at different scales is decidedly non-trivial. In addition, barriers such as limited resources and lack of user-friendly system are hindering the wider use of next generation sequencing (NGS) in human genome research. To address these issues, we developed Varpipe (http://hipipe. ncgm. sinica. edu. tw/varpipe), a web-based NGS analysis pipeline, which significantly reduces computation time and offers researchers a very efficient, scalable, accessible, and friendly system for whole genome sequencing projects. Varpipe uses a common computational pipeline that includes BWA for alignment, Sambamba for sorting and duplicate marking, Freebayes for variant calling, and SAMtools for final result concatenation. To improve performance, Varpipe adopts in-memory streamline processing and buffering to reduce disk input/output, local hard disk storage to reduce network traffic, and genome splitting to achieve good parallelization. Analysis of a test genome, 40X NA12878D human data set (Garvan Institute of Medical Research, DNAnexus and AllSeq), by splitting into 100 sub-regions showed that Varpipe reproduces 99. 97% SNPs and 99. 85% indels and completes analysis within 7 h using a single 64-core server (Dell R815). We further demonstrated that Varpipe, through distributed computing and splitting the genome into 380 sub-regions, completes variant analysis of the test genome in only 56 min with nearly identical results for both SNPs (99. 95%) and indels (99. 82%) on a 10-node 640-core cluster. Furthermore, our web-based Varpipe greatly reduces learning curve by providing carefully designed user interface and pre-configured analysis flow facilitating fast adaptation for users with minimum IT or bioinformatics background. In conclusion, not only can Varpipe analyze a genome in minutes, it also can provide good scalability for researchers to carry out efficient whole genome sequencing analysis at various scales easily.

1732W

FASTQuick: Comprehensive real-time quality assessment of ultra-high-throughput sequence data. *F. Zhang[1], H. M. Kang[1,2].* 1) Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Biostatistics, University of Michigan, Ann Arbor, MI.

The rapidly accelerating throughput of sequencing technologies allows us to sequence more than18,000 genomes a year at 30x coverage, producing 1 quadrillion sequenced bases from an Illumina HiSeq X Ten system. Efficient and thorough quality assessment of sequenced genomes in ultra-high-throughput scale is crucial for successful large-scale genetic studies, because delayed quality assessment in HiSeq X Ten can result in up to $100,000 of financial loss per day. Here we propose to develop a rapid and accurate set of algorithms and tools to produce comprehensive quality metrics directly from raw sequence reads prior to alignment. Our methods offer orders of magnitude faster turnaround time than existing alignment-based methods, while providing a truly comprehensive set of quality metrics, including estimates of genetic ancestry and contamination.

The key idea of our method is focusing on small regions of genome nearby known polymorphisms. Our method first extracts flanking sequences (250-1,000bp) around known variant sites and rapidly filters out more than99% of unalignable reads using Eland-like hashing technique. The filtered reads are aligned using computationally optimized version of bwa. As a result, compared to the widely used 1000 Genomes alignment pipeline, we now are able to reduce the computational time to generate thorough quality metrics on 30x genome from 160 hours to 43 minutes. Our results show that the quality metrics estimated our method is highly concordant to the quality metrics generated from the full-alignment pipeline.

Because our proposed methods collect information about genetic variation between individuals, it also provides accurate estimates of DNA contamination and genetic ancestry, in addition to the variety of typically quality metrics, such as base quality distribution, depth distribution, GC bias, and insert size distribution. By rapidly producing all these information together, our tool will help us detect potential problem in ultra-high-throughput sequence reads at a real-time speed, ensuring high quality sequence production and preventing unexpected loss in time and/or cost.

1733T

Identifying the underlying causal variants in associated regions in multiethnic meta-analysis. *A. B. Zhu[1], K. S. Burch[1], F. Hormozdiari[1], E. Eskin[1,2].* 1) Department of Computer Science, University of California, Los Angeles, California, 90095; 2) Department of Human Genetics, University of California, Los Angeles, California, 90095.

Meta-analyses combining the results of multiple genome-wide association studies (GWAS) have identified thousands of loci involved in dozens of human complex traits. A central challenge in the analysis of these data is to identify the actual causal variants which are responsible for these observed association signals. In many cases, there are multiple causal variants at each locus, and these variants themselves have different effect sizes in each GWAS study. Identifying these causal variants is complicated by complex patterns of linkage disequilibrium which may differ in each study. In this project, we present CAVIAR-Meta, a method for statistical fine mapping in meta-analyses. Our approach attempts to identify the minimum set of variants that, with high probability, contains all of the causal variants. Our method considers the possibility that each causal variant has a different effect size in each study by assuming a model closely resembling the random effects model, which is widely utilized in meta-analyses. We demonstrate the utility of our method through analysis of both simulated and real meta-analysis data.

1734F

Challenges in variant annotation for clinical genomic testing. *J. Yen, S. Garcia, S. Chervitz, B. Linebaugh, A. Montana, M. Morra, J. West, R. Chen, D. Church.* Personalis, Menlo Park, CA. , USA.

Sequencing based clinical testing is undergoing a revolution. While small gene panels have previously dominated the landscape, whole exome (WES) and whole genome (WGS) based strategies have recently emerged as valuable clinical tools, especially for diseases of unknown etiology or where there is extensive genetic heterogeneity. This expansion of WES and WGS based strategies in both scope and scale presents challenges for generating standard variant syntax, which is critical for building accurate and reliable resources for the clinical and scientific community. For example, the same indel can be represented in alternative ways in a VCF file. Analyses of dbSNP 142 identify over 350,000 variants that are represented in a non-normalized way (using software described by Tan et al. , 2015). Over 550 of these variants are also in ClinVar. In many cases, the normalization procedure reveals that the same variant can be represented in multiple ways, each with incomplete annotation. In addition to VCF file representation, challenges also arise in the translation of these variants to standard nomenclature recommended by the Human Genome Variation Society (HGVS), which was developed when sequence based testing was transcript rather than genome based. The same variant can have very different HGVS representation even on the same RefSeq transcript. In evaluating tools for generating HGVS nomenclature, we demonstrate challenges in providing variant syntax in a standardized, unambiguous format. We evaluated snpEff, Variation Reporter and Variant Effect Predictor (VEP) on a test set of 115 variants representing 5 variant classes with complex syntax representations at the genome, transcript and protein level, and their effect impact. While missense variants generally annotated correctly both at the transcript and protein level (all accurately described at least 28/32 of our test missense variants on all levels), the tools perform less far less robustly on frameshifting indels (one described 0/19 test variants correctly at the coding level). A closer look at the outputs reveal complexities in comparing preferred with non-preferred nomenclature, syntax representation across most indels and non-coding regions and where genomic reference differs from the RefSeq transcript. The results of our tests have significant implications for the search and annotation of variants during clinical testing and serve to inform the ongoing adoption and refinement of available tools.

1735W

Improving the annotation of splice-disrupting loss-of-function variants. *D. P. Birnbaum[1,2], K. J. Karczewski[1,2], D. G. MacArthur[1,2].* 1) Analytic and Translational Genetics Unit, Massachusetts General Hopsital, Boston, MA; 2) MacArthur Lab, Broad Institute, Boston, MA.

Disruption of transcript splicing underlies many cases of genetic disease, but identifying variants that alter splicing remains a challenging process. Much work has been done on developing probabilistic models for predicting how sequence variation will impact mRNA splicing, including tools such as MaxEntScan, Spliceman, and ESEfinder, but these tools have generally not been calibrated on large data sets of human genetic variation, and often cannot be scaled to the annotation of the many variants identified by modern large-scale sequencing studies. Here, we integrate splice variant prediction into the Ensembl Variant Effect Predictor (VEP) annotation framework. Specifically, we have written an improvement to LOFTEE, a loss-of-function annotation plugin to VEP, to identify the probability of splice disruption for variants outside the essential splice site, and also to check whether a putatively splice-disrupting variant may be rescued by a nearby alternative splice site. The plugin uses a probabilistic model to evaluate the usability of a potential "rescue" splice site by its local sequence context.

We validate these methods by applying them to variants from the Exome Aggregation Consortium (ExAC) as well as databases of known disease variants. Finally, we directly investigate the role of variants on splicing by intersecting exomes with matched RNA-Seq data from over 500 individuals from the GTEx consortium. The resulting tool can be readily scaled to the detection of candidate pathogenic splice variants in large datasets of human sequence variation.

1736T

Sequencing depth of coverage as a quality control metric in whole exome sequencing fails to identify multiple regions in which variant calling and genotyping cannot be accurately performed. *A. Naik, B. Kelly, P. White.* The Research Institute at Nationwide Children's Hospital , Columbus, OH.

Whole Exome Sequencing (WES) aims to identify potentially pathogenic variants in the protein coding regions of the genome, where it is estimated that 85% of the mutations responsible for Mendelian diseases are found. However, not all regions of the genome targeted are captured well, resulting in exonic regions that lack enough high quality read coverage to enable variant calling and accurate genotyping. A report of all poorly sequenced exons provides an important QC metric in clinical applications, where conventional Sanger sequencing may be needed to fill in for exons within clinically relevant genes. The conventional strategy is to use depth of coverage (DP) as the criteria for this purpose but we hypothesize that using genotype quality (GQ) would more accurately describe exonic regions missed by the assay. GQ is the Phred-scaled confidence that the predicted genotype is correct, considering the likelihood values of all possible genotypes. To create a report of missing exonic regions with both DP and GQ, we used the Churchill pipeline to efficiently perform variant calling, emitting genotypes for the entire genome in a genome Variant Call Format (gVCF) file. In combination with a manufacturer's targeted region BED file, the gVCF file is utilized to identify all regions that were targeted, but inadequately sequenced, at both no-confidence and low-confidence thresholds for DP and GQ. These regions are then annotated using NCBI's RefGene to obtain the specific targeted exons in genes not adequately and completely captured. The end-product is a detailed report of these exons, including annotations from OMIM, ClinVar and HGMD. Tests were run on the popular Coriell NA12878 reference sample captured using the Agilent SureSelectQXT Clinical Exome chemistry, sequenced to a depth of 100X. A total of 7,792 exons included at least one no-confidence base using GQ, as opposed to 6,809 exons using DP. This difference, 983 (3. 6% of the total exons targeted), represents exons with sufficient depth, but the quality of that depth was not such that confident genotypes could be called. Given GQ more adequately defines regions that cannot be accurately genotyped; it is our recommendation that DP not be used as a criterion for describing exonic regions missed by the assay.

1737F

Genotype Imputation Informed by both Kinship and Linkage Disequilibrium. *R. Wasiolek, J. Sinsheimer, K. Lange.* Biomathematics, UCLA, Los Angeles, CA.

Genotype imputation is increasingly important as more sequencing and genotyping technologies are developed and routinely employed. For example, GWAS analysis methods generally require large data sets with full SNP coverage. Genotype imputation fills in missing SNPs so that different genotyping sets can be used in the same study and untyped markers can be tested. Unfortunately, the majority of genotype imputation algorithms are slow. Another limitation is that these methods impute assuming individuals are unrelated, which leads to Mendelian inconsistencies when using data from families. A recently developed method by Chi et al employs a fast MM algorithm to impute missing SNP data based on matrix completion and linkage disequilibrium between neighboring SNPs by using a low rank approximation to the data but still assumes unrelated individuals. We extend this algorithm for family data by exploiting the kinship calculated using known pedigree relationships or from genetic relationship matrices. Our algorithm uses an MM algorithm and matrix completion to minimize an objective function that penalizes discordant genotypes among close relatives. Post-minimization, the singular value decomposition of the imputation matrix is taken and truncated after the *r* largest singular values to capture linkage disequilibrium. The values of r and the penalties are determined by cross-validation on a withheld subset of the observed data. Our preliminary results indicate that our algorithm is more accurate than the Chi et. al. MM algorithm, returning lower error rates and substantially fewer Mendelian inconsistencies with only minor losses in computational speed. Our algorithm also remains competitive in overall error rate and leads to substantiallyfewer Mendelian inconsistencies when compared with a second more accuratealgorithm that employs a Nesterov accelerated gradient method. Additionally, the inclusion of pedigree data allows us to employ a projection to nearest Mendelian consistency post-imputation which resolves more than 95 percent of the remaining Mendelian errors and further improves accuracy. Thus when imputing genotypes when family data are available, we recommend including kinship information to reduce Mendelian inconsistencies without sacrificing accuracy obtained from the LD. Our algorithm is currently implemented in Matlab.

1738W

Heterogeneity of Exome Methodology Causes Variability in CNV Predictions. *C. S. Hong[1], L. N. Singh[1], J. C. Mullikin[2,3], L. G. Biesecker[1,2].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Comparative Genomics Analysis Unit, Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 3) NIH Intramural Sequencing Center, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

As exome sequencing (ES) becomes widely used in research and clinical settings, the effort to accurately identify copy number variations (CNVs) from the ES has been increasing. While many algorithms have been published to discover CNVs from exomes, no study has examined how variation in ES methodology affects the variability of CNV calls. In this study, we hypothesized that three confounders (independently-derived datasets, sample sizes, and heterogeneity in capture kits) would lead to variable CNV predictions, measured by the true positive rate. Four CNV tools were tested: eXome Hidden Markov Model (XHMM), Copy Number Inference From Exome Reads (CoNIFER), EXCAVATOR, and Copy Number Analysis for Targeted Resequencing (CONTRA). The CNV callers were greatly influenced by all three hypothesized attributes of exome data. The call reliability was strongly associated with the data source (p-value < 0. 05). The sample size was positively correlated with the number of CNV calls (χ> 0. 38) and also was either positively or negatively correlated with the true positive rate, dependent of CNV callers. In addition, the reliability (TP) was strongly associated with the capture kits used (p-value<0. 05). The results demonstrate that due to the intrinsic attributes of exome data, each data set is unique and that the reliability of CNV calls based on one study cannot be generalized for others. We conclude that training and testing the CNV callers on multiple independent datasets, in addition to improvements in algorithm, is a must in further advancing the wide applicability of CNV discovery in exome studies.

1739T

Comparison of a Literature Search Algorithm and Curated Publication Database with the Literature Content of Other Locus Specific Databases. *L. Esterling, D. DiFrancesco, P. Nix, JP. De La O, B. Coffee, S. Manley.* Myriad Genetic Laboratories, Inc. , Salt Lake City, UT.

Background: Effectively searching the scientific literature for publications providing evidence for the pathogenicity of a variant is critical in variant classification. This evidence may be crucial to the classification of a novel variant as either pathogenic or benign. Searches for relevant citations are complicated by the use of alternative nomenclatures for variants, gene names, and reference sequences. **Methods:** To ensure the most exhaustive search possible, our laboratory has developed an automated literature search algorithm coupled with a curated, searchable publication database of over 9500 citations crucial to the classification of variants affecting 25 genes included in a pan-cancer panel. Our automated literature search includes broad parameters to identify all references for a variant, which include all combinations of alternate gene names and variant designations. These references are reviewed by scientific experts, annotated, and linked to individual variants found in each publication. More than 80,000 variant references with evidence pertaining to classification have been identified and have been compiled by actively monitoring new literature and applying this automated literature search algorithm for newly identified variants. Using these tools, information pertaining to a variant's classification, as well as literature regarding allelic and surrounding variants, can be retrieved instantly during the classification process. This method has been used to facilitate the classification of over 27,000 single nucleotide and copy number variants in the past six years. To assess how comprehensive and effective this method is compared to other Locus Specific Databases, we compared variant references identified via our method to publications referenced in locus specific databases for 1554 previously classified and newly identified variants. **Results:** A total of 852 citations were identified for these 1554 variants using our method and locus specific databases combined. Our method identified 334% more citations than the locus specific databases combined. **Conclusions:** These results confirm that our literature search method and algorithm is more comprehensive than publicly available databases and illustrates the significant amount of time and resources that need to be dedicated to variant classification to provide physicians and patients the most accurate test results for clinical decisions.

Augmenting public databases with ultra-deep clinical targeted sequencing data. *E. A. Evans[1], M. D. Rasmussen[1], J. Maguire[1], K. R. Haas[1], H. P. Kang[1], D. G. MacArthur[2], I. S. Haque[1].* 1) Counsyl, South San Francisco, CA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA.

Clinical interpretation of sequence variants requires a deep understanding of the distribution and frequency of genetic variation in the general population. ClinVar solicits information from clinical labs to report variant-level statistics and clinical interpretations, but lacks comprehensive frequency information on controls. Research data sets (e. g. , 1000 Genomes and the Exome Aggregation Consortium (ExAC)) provide control information for most human genes but have gaps in coverage for known disease genes and are usually sequenced at a depth that limits analysis to SNPs and indels. In contrast, targeted clinical sequencing data has narrower genomic coverage, but can be designed to fully cover the genes of interest with sufficient depth to call CNVs and rearrangements. Here we describe the analysis of data from >100,000 samples tested using a clinical panel of up to 102 Mendelian disease genes. We used hybrid capture followed by sequencing on the Illumina HiSeq 2500 with manual call review (guaranteed mean depth >150x; min 99% bases covered >20x). Our analysis augments standard tools (BWA/GATK) with methods for haplotype, CNV, and high-homology-region calling. We clustered all samples into one of 15 groups using self-reported and genetic ancestry. We present the first sensitivity analysis for literature pathogenicity curation in clinical gene-panel sequencing. We classified all detected variants in 41,530 patients by literature review consistent with ACMG guidelines. 23% of patients carried >=1 variant on a whitelist chosen for an existing genotyping-based screen. Adding known-deleterious variants detected an additional 9% of patients; adding likely-deleterious variants detected another 6. 1% of patients; and adding predicted-deleterious variants detected a further 2% of patients.

We present a catalog of novel CNVs found in Mendelian disease genes. While current sequencing databases are limited by their underlying depth (on our panel ExAC mean coverage ranges from 3. 29 to 77. 9), our ultra-deep data enable new findings.

Finally, we describe the integration of this deep clinical sequencing data into the ExAC browser, more than doubling the sample size in 100 clinically relevant genes and making this data available to the wider community. This is the first example of a clinical lab contributing a large amount of control variant frequency data to a public sequencing database, and outlines a process by which commercial data can be made accessible in an open system.

1741W

From genes to functional elements - enriching RefSeq annotation of the human genome. *C. M. Farrell, K. D. Pruitt, T. D. Murphy, D. R. Maglott, T. Goldfarb, S. H. Rangwala, RefSeq Group.* National Center for Biotechnology Information, NLM/NIH, Bethesda, MD.

The RefSeq database at NCBI (www. ncbi. nlm. nih. gov/refseq/) provides reference sequences for transcripts, proteins and genomes, and its diverse uses include genome annotation, gene identification, variation calling, and functional characterization. Human RefSeqs are used in clinical practice, with the RefSeqGene/Locus Reference Genomic (LRG) collaboration providing a foundation for reporting variants according to the Human Genome Variation Society (HGVS) standard. To date, the RefSeq group has primarily focused on defining the sequences of genes, pseudogenes and gene products, with each gene having a record in NCBI's Gene database (www. ncbi. nlm. nih. gov/gene/). However, genes occupy only a small fraction of the genome, and the sequences of non-genic functional elements need to be defined. Mutations in these elements can lead to human diseases, with many genome-wide association studies (GWAS) pointing to variants in non-annotated intergenic regions. Initiatives such as the ENCODE and Roadmap Epigenomics projects have provided ways to predict the presence of functional elements on the reference genome, but specialized research knowledge and the use of customized genome browsers or tracks are required to assess such elements. Thus, these elements may not be apparent to all users in biomedical research. The RefSeq group has therefore initiated a project to provide reference sequences for functional elements in both human and mouse, and to annotate them on the reference genome alongside our current gene annotations. The scope of this annotation is for elements that are experimentally validated in the literature, including known gene regulatory elements (e. g. , enhancers), elements involved in higher-order genome organization (e. g. , boundary elements), and elements that are otherwise considered to be of functional importance (e. g. , recombination hotspots). Curated records will also be provided for these elements in NCBI's Gene resource to include summaries, functional attributes, and various metadata from the literature and public databases. These functional elements will enrich the current scope of our genome annotation, they will be particularly useful for GWAS and variant interpretation outside of gene boundaries, they will be highly visible and accessible to a wide user base, and are expected to be valuable to research in general. This work was supported by the Intramural Research Program of the National Library of Medicine, NIH.

Curation of reference sequence (RefSeq) standards to support clinical applications and basic research. *K. Pruitt, C. M. Farrell, M. J. Landrum, D. R. Maglott, T. D. Murphy, RefSeq Curation Group.* NCBI, National Institutes of Health, Bethesda, MD.

The National Center for Biotechnology Information (NCBI) RefSeq project (www. ncbi. nlm. nih. gov/refseq/) provides reference sequence and annotation standards for genomes, transcripts, proteins, gene regions, and pseudogenes. The RefSeq project provides functional and structural annotation of viral, prokaryotic, and eukaryotic RefSeq genomes and supports myriad other investigations ranging from expression studies to clinical reporting of genetic mutations to variation calls. RefSeq records for human (and mouse) include genome annotation for reference and other assemblies, >50,000 (>25,000) curated transcripts and >37,000 (>22,000) proteins plus model transcripts and proteins inferred from protein and transcript data (including RNA-seq) aligned to genomes. The curated RefSeq dataset is of high quality following 15 years of sequence and gene curation by NCBI scientific staff and participation in international collaborations which provide additional scientific review of the data. RefSeq collaborates with the Genome Reference Consortium (GRC), which maintains and updates the human and mouse reference genome sequence (www. ncbi. nlm. nih. gov/projects/genome/assembly/grc/); RefSeq curators request GRC review of sequence regions that conflict with aligned transcripts or publications and review some GRC proposed sequence updates that may impact gene annotation. RefSeq proteins and their genome annotation coordinates are further reviewed by partner members of the Consensus CDS (CCDS) collaboration which aims to stabilize and reconcile conflicts between the human and mouse reference genome protein-coding gene annotation that is provided by the NCBI and Ensembl genome annotation pipelines (www. ncbi. nlm. nih. gov/CCDS/), both of which include curated content from the RefSeq and GENCODE projects. The CCDS project is engaged in ongoing review of conflicts and must reach consensus agreement to change annotation coordinates for proteins having a CCDS ID. In addition, the RefSeqGene/Locus Reference Genomic (LRG) collaboration defines genomic sequence regions for human genes which serve as a stable foundation for reporting mutations in HGVS format, for establishing conventions for numbering exons and introns, and for defining the coordinates of other variations (www. ncbi. nlm. nih. gov/refseq/rsg/). Over 5,400 RefSeqGene sequence records (576 with an LRG ID) are available. The presentation will describe RefSeq, our collaborative approach to providing it, and avenues for data access.

n_1n_2TrackAnnotator: Software for detection and annotation of tracks comprising user-defined two different nucleotides in genome sequence. *H. N. Singh, M. R. Rajeswari.* Biochemistry, All India Institute of Medical Sciences, New Delhi, Delhi, India.

Chromosomal DNA exists mainly as a right-handed double helix form known as B-DNA. However, other conformations, such as triplexes, tetraplexes, slipped structures with hairpin loops, cruciforms etc. are also known that were found to be primarily associated with gene regulation processes such as replication and transcription blocking as well as genetic rearrangements. Identification and annotation of these repeat sequence which leads to form non-B DNA structures, is the decisive task in order to understand the mechanisms of the genetic instability and disease correlations. Therefore, we developed **"n1n2TrackAnnotator",** a standalone software for genome-wide analysis to identify and annotate tracks containing two different nucleotides in the genome sequences. It provides a complete open-source pipeline on Windows platform comprising all steps from importing of raw data (genome sequence, annotation file: General Feature Format), pre-processing of data, annotation of the identified sequences. n1n2TrackAnnotator is written as a standalone tool using C# 4. 0 object oriented programming language at . NET Framework 4. 0 for Windows platform. In particular, it implements a knowledge based window-shift algorithm and supports NCBI/Genome database information patterns. .

A Bayesian test to identify variance quantitative trait loci. *B. Dumitrascu[1], G. Darnell[1], J. Ayroles[1,2], B. Engelhardt[3,4].* 1) Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ; 2) Department of Organismic and Evolutionary Biology, Harvard University,Cambridge, MA, USA; 3) Department of Computer Science, Princeton University, Princeton, NJ, USA; 4) Center for Statistics and Machine Learning, Princeton University, Princeton, NJ, USA.

Identifying genotypic variants that are associated with variation in quantitative traits is a primary focus of statistical genetics. However, few studies successfully address the problem of genome-wide identification of variants that have an effect on the variance of a trait instead of the trait mean across a population. Up to now, there has not been a general and robust approach to test for these variance controlling QTLs, or vQTLs. In this study, we develop BvQTL, a Bayesian framework for identifying vQTLs using a heteroskedastic linear regression model. We develop fast approximation algorithms for the statistical testing framework to scale the test to trivial genome-wide application. We show through simulations that our method outperforms classical statistical tests for covariates that affect variance such as the Levene and Brown-Forsythe tests in diverse genomic situations, including at loci with low minor allele frequency or mean effects. In particular, we show that BvQTL is a robust framework that produces fewer false negatives at a consistent false positive rate and performs well on small samples and on imputed genotypes. As empirical validation of our method, we apply BvQTL to data from the Cardiovascular and Pharmacogenetics (CAP) study to test for dependence between variance in gene expression levels and genotypes. We show that our approach works for arbitrary quantitative traits by finding vQTLs in methylation study data, representing genetic variants associated with variance of methylation levels at specific CpG sites, from 255 genotype-annotated samples from the HapMap2 study. We expect that, in the near future, genome-wide studies for quantitative trait association will include tests for vQTLs as part of the standard procedure.

1745T

An improved infrastructure and user interface for the NHGRI-EBI Genome-Wide Association Study (GWAS) Catalog. *J. A. L. MacArthur[1], T. Burdett[1], F. Cunningham[1], L. Gil[1], P. N. Hall[2], E. Hastings[1], L. A. Hindorff[2], H. A. Junkins[2], A. K. Klemm[2], J. Morales[1], D. Welter[1], H. Parkinson[1].* 1) European Bioinformatics Institute (EMBL-EBI), Cambridge, United Kingdom; 2) Population Genomics, NHGRI, NIH, Bethesda, MD.

The GWAS Catalog (Welter et al. , 2014) is a manually curated, publicly available resource of all published GWAS and trait-associations, containing over 2,000 studies and 17,000 SNP-trait associations, as of June 2015. It was originally created by the National Human Genome Research Institute (NHGRI) in 2008 and has been collaboratively produced and developed by the NHGRI and European Bioinformatics Institute (EMBL-EBI) since 2010. In March 2015 the GWAS Catalog was given a new website (http://www. ebi. ac. uk/gwas/) and infrastructure at EMBL-EBI to deliver an improved user experience and long-term support to the Catalog into the future. The new website includes a search interface driven by an ontology-enriched Solr index. Search results are displayed in interactive tables with dynamic links to related GWAS Catalog data and to external resources, such as Ensembl and Europe PubMed Central. Search results can also be sorted, filtered and downloaded. The redesign allows for the improved capture of complex GWAS study design and association data, such as the independent representation of loci in SNPxSNP interaction studies. A new curation platform has been developed, supporting the accurate recording of study design and results, improved quality control processes and scaling of data curation into the future. The increased curatorial capacity will improve our ability to tackle the current backlog of eligible studies. Several enhancements have been made to the scientific content of the Catalog: newly released ancestry information for 2011 studies onwards is available, while mapping information has been added for all GWAS Catalog SNPs to Ensembl genes, in addition to NCBI genes. Informatics improvements have facilitated the integration of GWAS Catalog data and will enable the development of tools to identify causal variants and understand functional relationships between variants and phenotypes. In the future we aim to allow users to define regions of association using linkage disequilibrium data and to explore genes and regulatory elements within these regions. The improved curation, modelling, querying and integration of GWAS Catalog data has vastly improved the utility of this resource in identifying and understanding disease loci. The improvements to curation efficiency and scalability will ensure that the resource is sustainable and can meet the demands of increasing data complexity and volume.

1746F

Meta-analysis of Complex Diseases at Gene Level by Functional Regression. *Y. Wang[1], W. Chen[2], D. E. Weeks[2], H. Ren[3], Y. Li[4], I. Lobach[5], C. I. Amos[6], J. H. Moore[7], M. Boehnke[8], M. Xiong[9], R. Fan[10].* 1) Food and Drug Administration (FDA), Silver Spring, MD; 2) University of Pittsburgh; 3) Regeneron Pharmaceuticals, Inc; 4) University of North Carolina, Chapel Hill; 5) University of California, San Francisco; 6) Dartmouth Medical College; 7) University of Pennsylvania; 8) University of Michigan, Ann Arbor; 9) University of Texas - Houston; 10) Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), National Institutes of Health (NIH).

We develop functional regression models (FRMs) to perform meta-analysis of multiple studies to evaluate the relationship of genetic data to quantitative or dichotomous traits adjusting for covariates by using functional data analysis techniques. Unlike the previously developed MetaSKAT methods, which are based on mixed effect models to model the major gene contributions from loci as a random effect, FRMs are fixed effect models and genetic effects of multiple genetic variants are assumed to be fixed. Based on the FRMs, we developed test statistics to test for an association between a complex trait and multiple genetic variants in one genetic region. We then performed extensive simulations to evaluate the empirical type I error rates and power performance of the proposed models and tests. The proposed test statistics control the type I error very well and are conservative, and have higher power than MetaSKAT in most cases. Specifically, we show: (1) the proposed test statistics have higher power than MetaSKAT for quantitative traits no matter some causal variants are rare and some are common or all causal variants are rare, (2) the proposed test statistics have higher power than MetaSKAT for dichotomous traits when some causal variants are common and some are rare, and (3) when the causal variants are all rare (i. e. , minor allele frequencies less than 0. 03), the proposed test statistics have similar or slightly lower power than MetaSKAT for dichotomous traits. For quantitative traits, one paper is accepted by ``Genetics", whichis available in Early Online, June 9, http://www. genetics. org/content/early/recent. In our unpublished work, the proposed methods were applied to analyze genetic data of 22 gene regions of type 2 diabetes data from a meta-analysis of eight European studies. These 22 genes are all from literature and each of them contains SNPs/variants which are related to the trait by single SNP/variant analysis in various studies. Hence, they can be treated as candidate genes and can be used to test the performance of gene based tests. The proposed methods detected significant association for 18 genes (p-values $< 3. 10 \times 10\text{-}6$) and tentative association for 2 genes (p-values around 10-5) and no association for 2 genes, while MetaSKAT detected none. The models and related test statistics can analyze rare variants or common variants or a combination of the two, and can be useful in whole genome-wide and whole exome association studies.

Churchill 2. 0: Making the Ultra-Fast Analysis Pipeline for Clinical and Population-Scale Genomics Faster, More Efficient, and More Comprehensive. *B. Kelly, J. Fitch, H. Kuck, P. White.* The Research Institute at Nationwide Children's Hospital, Columbus, OH.

Next generation sequencing (NGS) has revolutionized genetic research, enabling dramatic increases in the discovery of functional variants in syndromic and common diseases. Declining sequencing costs are enabling the study of many 1,000's of samples, and this exponential growth in data generation has created a computational bottleneck. Current analysis approaches can take days to complete, resulting in bioinformatics overheads that exceed sequencing costs and represent a significant limitation. Churchill is a computational approach that overcomes these challenges, fully automating the steps required to take raw sequencing data through the complex and computationally intensive processes of alignment through variant discovery. Compared with alternative analysis pipelines, Churchill is faster, deterministic and 100% reproducible. Through novel parallelization techniques, Churchill enables efficient whole genome sequencing analysis in less than two hours, ideal for clinical applications where turnaround time is paramount and data quality cannot be sacrificed. Churchill also enables population-scale analyses to be performed cost-effectively, efficiently distributing the analysis steps and processing data sets that would otherwise have been too large to analyze at a reasonable cost and in a practical time frame. Published in January 2015, Churchill is now being utilized by a large community within both the research and clinical domains. Since then we have made significant enhancements to the original release of the Churchill pipeline. Churchill 2. 0 expands the novel balanced subregional parallelization strategy to structural variant (SV) detection resulting in significantly reduced SV analysis time. Churchill 2. 0 has been redesigned to be highly modular, allowing users to incorporate different aligners, variant callers, and other components, creating custom pipelines that take advantage of Churchill's parallelism and speed. Churchill 2. 0 is more robust and fault tolerant, providing meaningful QC metrics and allowing a user to restart an analysis from the point at which an error occurred. As we look to the future, the era of the $1,000 genome will exponentially increase the size and number of genomic studies. Churchill 2. 0 makes significant and necessary improvements on an already fast, accurate and deterministic pipeline, enabling comprehensive, fully-automated analyses and eliminating the computational bottleneck in clinical and population-scale genomics.

1748T

NCBI resources for taking advantage of the GRCh38 reference genome assembly. *V. A. Schneider, V. Ananiev, N. Bouk, C. Clausen, M. DiCuccio, B. Holmes, A. Kuznetsov, P. Meric, T. Murphy, L. Phan, M. Ward.* IEB, NIH/NCBI, Bethesda, MD.

The Genome Reference Consortium (GRC) released GRCh38, the current version of the human genome reference assembly, in December 2013. The updated assembly contains many improvements, such as gap closures, path corrections and individual base updates, as well as new features, such as modeled centromere sequence representations. It also contains a large cohort of alternate loci scaffolds, which provide alternative sequence representations for more than 200 genomic regions. Despite a general recognition that the assembly update represents an improved substrate for analysis, the need to remap datasets to new coordinates, uncertainty about what regions have changed and unfamiliarity with alternate loci are challenges that have slowed the adoption of GRCh38 by scientists engaged in both basic and clinical research. Several NCBI tools exist to help users make the transition to GRCh38 and take advantage of the alternate loci. We will present features of NCBI resources such as Variation Viewer and MapViewer, used for genome browsing, that enable users to identify and view assembly differences and regions with alternate sequence representation. We will also discuss new browser features associated with track management and display, as well as support for viewing user uploaded data that improve the user experience with NCBI browsers in general. The NCBI Remapping Service allows users to project features not only between different assembly versions, but also between chromosomes and alternate loci scaffolds. We will describe recent updates to the Remapping Service that improve variant re-mapping and discuss features of the NCBI assembly-assembly alignment algorithm that were developed to specifically support the structure of the GRCh38 assembly with its alternate loci. We will illustrate how assembly-assembly alignment reports available from the remapping service provide users with a convenient catalog of differences between the current and previous reference assembly versions. Together, these and other NCBI resources will help researchers take advantage of the improvements offered in the current reference genome assembly.

1749F

High-accuracy imputation for *HLA* class I and II genes based on high-resolution SNP data of Japanese references and its application on Steven-Johnson Syndrome and Narcolepsy with cataplexy. *S. Khor[1], W. Yang[2], M. Kawashima[1], S. Kamitsuji[2], X. Zheng[3], N. Nishida[1,4], H. Sawai[1], H. Toyoda[1], T. Miyagawa[1], Y. Hitomi[1], M. Honda[5,6], M. Ueta[7], S. Kinoshita[7], N. Kamatani[2], K. Tokunaga[1].* 1) Department of Human Genetics, Graduate School of Medicine,, University of Tokyo, Tokyo, Tokyo, Japan; 2) StaGen Co. , Ltd. , Statistical Genetics Analysis Division, Tokyo, Japan; 3) Department of Biostatistics, University of Washington, Seattle, WA, United States; 4) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 5) Department of Somnology, Tokyo Medical University, Tokyo, Japan; 6) Sleep Research Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 7) Department of Frontier Medical Science and Technology for Ophthalmology, Kyoto Prefectural University of Medicine, Kyoto, Japan.

Statistical imputation of classical human leukocyte antigen (*HLA*) classes is becoming an indispensable tool for fine-mappings of disease association signals from case-control genome-wide association studies (GWASs). However, most currently available *HLA* imputation tools are based on European reference populations and are not suitable for direct application to non-European populations. Among the *HLA* imputation tools, the HIBAG R package is a flexible *HLA* imputation tool that is equipped with a wide range of population-based classifiers; moreover, HIBAG R enables individual researchers to build custom classifiers. Here, two datasets, each comprising data from healthy Japanese individuals of difference sample sizes, were used to build custom classifiers. *HLA* imputation accuracy in five *HLA* classes (*HLA-A*, *HLA-B*, *HLA-DRB1*, *HLA-DQB1*, *HLA-DPB1*) increased from the 82. 5-98. 8% obtained with the original HIBAG references to 95. 2-99. 5% with our custom classifiers. A call threshold (CT) of 0. 4 is recommended for our Japanese classifiers; in contrast, HIBAG references recommend a CT of 0. 5. Moreover, our classifiers could be used to identify the risk haplotypes for Japanese narcolepsy with cataplexy, *HLA-DRB1*15:01* and *HLA-DQB1*06:02*, with 100% and 99. 7% accuracy, respectively. Finally, the risk *HLA* alleles (*HLA-A*02:06* and *HLA-B*44:03*) for multiple population Steven-Johnson Syndrome (SJS) can be correctly imputed with an accuracy of 59/59 and 28/29 in 117 patients who carry the risk *HLA* alleles respectively. Therefore, these classifiers can be used to supplement the current lack of *HLA* genotyping data in widely available GWAS datasets.

1750W

PhenomeCentral: a portal for phenotypic and genotypic matchmaking of patients with rare genetic diseases. *O. J. Buske[1,2,3], M. Girdea[1,2,3], S. Dumitriu[3], B. Gallinger[3,4], T. Hartley[5], H. Trang[3,4], A. Misyura[3], T. Friedman[1], C. Beaulieu[5], W. P. Bone[6], A. E. Links[6], N. L. Washington[7], M. A. Haendel[8], P. N. Robinson[9], C. F. Boerkoel[6], D. Adams[6], W. A. Gahl[6], K. M. Boycott[5], M. Brudno[1,2,3].* 1) Computer Science, University of Toronto, Toronto, Ontario, Canada; 2) Genetics and Genome Biology Program, The Hospital for Sick Children, Toronto, Canada; 3) Centre for Computational Medicine, The Hospital for Sick Children, Toronto, Canada; 4) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario Canada; 5) Children's Hospital of Eastern Ontario Research Institute, Ottawa, Ontario, Canada; 6) Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, Maryland, USA; 7) Genomics Division, Lawrence Berkeley National Laboratory, Berkeley, California, USA; 8) Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, Oregon, USA; 9) Institute for Medical Genetics and Human Genetics, Charité-Universitàtsmedizin Berlin, Berlin, Germany.

The discovery of disease-causing mutations typically requires confirmation of the variant or gene in multiple unrelated individuals, and a large number of rare genetic diseases remain unsolved due to difficulty identifying second families. To enable the secure sharing of case records by clinicians and rare disease scientists, we have developed PhenomeCentral (https://phenomecentral. org), a restricted access portal for sharing de-identified patient phenotype and genotype data to find similar cases around the world. Each record includes a detailed phenotypic description (specified using HPO terms) and relevant genetic information (exome data and/or candidate genes). PhenomeCentral identifies similar patients in the database based on semantic similarity between clinical features, automatically prioritized genes from whole-exome data, and candidate genes entered by the users, enabling both hypothesis-free and hypothesis-driven matchmaking. Additionally, users can opt to include patient records in matchmaking across the Matchmaker Exchange, enabling them to see similar patients not only within PhenomeCentral but also within other patient databases (including GeneMatcher and DECIPHER). Users can then contact other submitters to follow up on promising matches. PhenomeCentral incorporates data for over 1,250 patients with rare genetic diseases, contributed by the FORGE and Care4Rare Canada projects, the US NIH Undiagnosed Diseases Program, the EU Neuromics and ANDDIrare projects, as well as numerous independent clinicians and scientists. Though the majority of these records have associated exome data, most lack a molecular diagnosis. PhenomeCentral has already been used to identify causative mutations for several patients, and its ability to find matching patients and diagnose these diseases will grow with each additional patient that is entered. The coordination with the Matchmaker Exchange further increases the number of potential matches. With additional sites planning to join the Matchmaker Exchange in the near future, storing deep phenotype and genotype data for all patients in PhenomeCentral will help ensure the maximum potential for matchmaking for these rare disease patients.

1751T

NCBI's database of Genotypes and Phenotypes: dbGaP. *M. Feolo, S. Pretel, Z. Wang, M. Bihan, S. Sherry, NCBI's dbGaP staff.* National Center for Biotechnology Information, National Institutes of Health, USA.

The explosion of data from genome scale studies is well underway and the need to archive these data is growing rapidly. The National Center for Biotechnology Information's database of Genotypes and Phenotypes (dbGaP) is an NIH sponsored repository charged to archive, curate and distribute information produced by genome scale studies investigating the interaction of genotype and phenotype. The data submitted to dbGaP includes: individual level molecular and phenotype data; analysis results; medical images; general information about the study; and documents that contextualize phenotypic variables, such as research protocols and questionnaires. The molecular data includes array-based, sequence-based or imputed genotypes; expression, as well as next-generation sequencing (NGS) performed to produce whole exome; whole genome; RNA seq; and epigenomic data. NGS sequence submitted to dbGaP, mostly in the form of BAM files, are archived and accession by NCBI's Sequence Read Archive (SRA). Phenotypic data pertaining to Clinical or Research study participants and their samples consists of any combination of cross-sectional or longitudinal demographic; clinical; laboratory; exposure; or treatment variables. Medical images such as CT; MRI; and retinal scans of the eye are also stored and distributed by dbGaP. Analysis results include summary-level statistical measures of the association between the phenotypic variables and the molecular data. All documents, analysis, phenotypic and molecular data are validated for consistency and format though a computational and human curatorial process. Validated submission are then accessioned with stable, unique identifiers that support update of the same study with successive genetic investigations. These identifiers make it possible to cite the data that were downloaded from dbGaP and used to generate new research results, in a very specific and stable way. The dbGaP provides unprecedented access to a vast array of genome scale studies, both funded by National Institutes of Health, and other funding agencies worldwide. Through controlled access, researchers from across the globe may obtain complete statistical analyses, subject-level phenotype and molecular measures of over 900,000 subjects. This presentation will describe the data content, access procedure and highlight several new features of dbGaP.

1752F

Development of a bioinformatics application for the assessment of genetic risk of complex diseases. *K. L. Valdés[1], F. F. González-Galarza[1,2], R. D. Arellano-PerezVertti[1], E. Ramírez-Ramírez[1], A. Y. García-Marín[2], D. Delgadillo-Guzmán[1], J. Morán-Martínez[1], J. E. Gaytan-Arocha[1], J. R. Argüello[1,2].* 1) Faculty of Medicine, Autonomous University of Coahuila, Torreon, Mexico; 2) Institute of Science and Genomic Medicine, Torreon, Mexico.

In recent years, the number of studies in the genomics field has increased at a rapid pace. Well-structured genome-wide association studies (GWAS) have determined a significant number of SNPs associated to different complex diseases and traits. However, there is still a gap on the translation of this information into medical practice. For instance, the role of low density lipoprotein (LDL), high density lipoprotein (HDL), and triglycerides in cardiovascular disease is well established. However, in the clinical context, the genetic component of these complex traits is commonly disregarded. In this study, we designed a bioinformatics application for the analysis of dyslipidemia-associated SNPs which were extracted from the Catalog of Published GWAS. To test our software, we analyzed one hundred randomly-selected individuals from the North Area of Mexico that were genotyped using the Illumina microarray technology with approximately 600,000 SNPs. Using an additive genetic risk score model, we calculated an accumulated odds ratio and an accumulated p-value for each individual and estimated a genetic risk factor for three complex traits: elevated levels of LDL and triglycerides, and decreased levels of HDL. Here, we provide a user-friendly bioinformatics application for the analysis of genetic risk which could be applied in clinical setting to different health conditions involving complex traits such as dyslipidemias. Ongoing investigations are being performed for futher validation of these algorithms, including the non-genetic components, such as clinical and environmental factors.

An empirical recombination for demographic inference and IDB detection. *T. Y. Wang, J. H. Loo, M. Lin.* Mackay Memorial Hospital, New Taipei City, Taiwan.

Genome-wide data facilitate the investigation of genomic relatedness between individuals within or across populations, providing an insight into demographic histories. Genomic regions of identity by decent (IBD) in individuals, co-inherited from common ancestors, can be detected and analyzed to reveal genetic relatedness for demographic inference. Many methods have recently been developed to detect IBD regions, aiming at detecting identical regions that are statistically unlikely to occur without common ancestors. Some employ coalescent or probabilistic models to identify such IBD regions with significantly low frequencies of occurrence; the others use non-coalescent and non-probabilistic models to detect IBD regions with long lengths, which serve as proxies for low frequencies. However, due to high computational cost of coalescent or probabilistic models, the first ones are usually not fit to large datasets, and because of no short IBD regions detected, the last ones cannot provide comprehensive information for demographic inference. We propose an empirical approach that is able to infer demographic histories and to detect IBD regions simultaneously. This approach comprises of an empirical model of recombination and an IBD detection algorithm. The empirical model builds coalescent trees with recombination events based on genomic similarities of individuals, and the detection algorithm incorporates the information of coalescent trees with recombination events to identify IBD regions. These two procedures can be executed iteratively till no new IBD regions found and no new changes in coalescent trees. In addition, the two procedures can be in parallel in each iteration to improve computational efficiency. We applied our method in simulated data and two real datasets: the 1,000 genomes and the HLA alleles in Taiwan populations. First in simulation analysis, our method is able to infer demographic histories and to detect short IBD regions with high accuracy while maintaining high computational efficiency. Second in the 1,000 genome dataset, our approach not only reveals recent demographic events based on long detected IBD regions, but also ancient histories from short IBD regions. Finally in the HLA alleles in Taiwan populations, we demonstrate the pure utility of the empirical recombination model for recent demographic inference. Therefore, our proposed method is capable of detecting IBD regions efficiently and making demographic inference comprehensively.

1754T

Smart multiple testing correction in eQTL studies. *D. B. Duong[2], B. Han[1], E. Eskin[2].* 1) Asan Institute for Life Sciences, University of Ulsan College of Medicine, Asan Medical Center, Seoul, Republic of Korea; 2) Computer Science , UC Los Angeles , Los Angeles , CA.

In expression quantitative trait loci (eQTL) studies, it is of tremendous interest to identify eGenes, the genes whose expression levels are associated with particular genetic variants. The common procedure for detecting eGenes is to test association of each nearby variant (cis variants) to the expression level, and select the minimum p-value among all p-values. As we perform multiple tests, the minimum p-value has to be corrected for multiple hypothesis testing. A widely used procedure for this correction is the permutation test. Recently, we proposed an approach called eGene-MVN that can obtain the same correction results as the permutation test in a dramatically reduced time (Sul et al. , AJHG 2015). However, this approach only improves the efficiency of the permutation test, but does not improve the p-values of the permutation test. The limitation of both the permutation test and eGene-MVN is that they do not incorporate prior information of the variants. For example, we have prior knowledge that variants near transcription start site (TSS) are more likely to regulate expressions. We propose a new multiple testing correction approach for eQTL studies, called eGene-Smart. Our approach learns how large an effect a variant would have for regulation from the observed data in a similar strategy to cross-validation. Then based on these learned prior parameters, our approach weights each variant differently in multiple testing correction. Specifically, the corrected p-value becomes more significant if the up-weighted variant is driving the association signal rather than the down-weighted variants. In simulations, we show that our approach gives better power than the previous approaches, while appropriately controlling the overall false positive rate. We apply our approach to the Genotype-Tissue Expression (GTEx) data and show that our approach dramatically improves eGene p-values for significantly associated eGenes. We expect that our approach will be widely used in future eQTL studies to improve p-values and effectively identify eGenes.

1755F

Kaviar: a comprehensive public catalog of human variant and genotype frequencies. *T. Farrah[1], D. E. Mauldin[1], N. Clegg[1], M. Robinson[1], J. Vockley[2], J. Niederhuber[2], L. Hood[1], G. Glusman[1].* 1) Institute for Systems Biology, Seattle, WA; 2) Inova Translational Medicine Institute, Falls Church, VA.

Kaviar, first released in 2010, is now the largest publicly available catalog of whole genome human allele frequencies. Obtaining established allele frequencies of observed genetic variants is a key step in genome interpretation, and allele frequency accuracy depends on the size and diversity of the source data. Kaviar combines data from 37 sources including 5000+ whole genomes sequenced by the Inova Translational Medicine Institute (inova. org/itmi) and the Institute for Systems Biology (familygenomics. systemsbiology. net). It provides allele frequencies for 168 million SNVs, twice as many as the 1000 Genomes Project. In addition to the private whole genomes, Kaviar includes whole genome data from the 1000 Genomes Project, the Alzheimer's Disease Neuroimaging Initiative (ADNI), the Simons Diversity Project, the Wellderly project, the UK10K, Genomes of the Netherlands, and the Personal Genomes Project, and also incorporates the 63,000 exomes from the Exome Aggregation Consortium (ExAC).

Kaviar uses a comprehensive pipeline to integrate sources in a manner that increases concordance, including normalization of all variants to enforce parsimony and left alignment. Based on 194 genomes sequenced on both Illumina and Complete Genomics platforms, we remap variants that are called frequently on one platform but never called on the other. Kaviar also reports population-specific frequencies computed by inferring the continent(s) of origin for each data source.

Kaviar now reports *genotype frequency* in addition to allele frequency, which can be useful in identifying genomic regions that require more inspection. Variants deviating from Hardy-Weinberg equilibrium may suggest errors in the genome reference, in sequencing, in analytics, or population structure. Such deviations may also point toward selection signatures. A variant never seen as homozygous may have a recessive effect. Differences in genotype distributions among different data sources may uncover differences in sequencing technology, differences in variant representation, or reference biases.

We propose Kaviar as the community's standard resource for human allele and genotype frequencies. Kaviar is available via web interface, downloadable VCF files, and GA4GH beacon at db. systemsbiology. net/kaviar.

Single Sample Imputation from Next Generation Sequencing (NGS) Exome data can improve genotypes in low-coverage regions. *H. Sicotte[1], N. Prodduturi[1], J. A. Johnson[2], Y. Lin[2], P. A. Decker[1], J. E. Eckel-Passow[1], R. B. Jenkins[3], M. P. Goetz[4,5], R. Weinshilboum[4], J. C. Boughey[6], L. Wang[4], K. R. Kalari[1], S. K. McDonnell[1], M. de Andrade[1], J. P. Kocher[1].* 1) Department of Health Sciences Research, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905; 2) Mayo Clinic Research and Education Support Systems, Information Technology Rochester, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905; 3) Laboratory Medicine and Pathology, Mayo Clinic College of Medicine, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905; 4) Department of Molecular Pharmacology & Experimental Therapeutics, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905; 5) Medical Oncology, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905; 6) Department of Surgery, Mayo Clinic, 200 First Street SW, Rochester, MN, 55905.

Background: In the research setting, the high cost of NGS whole genome sequencing (WGS) has driven the use of low-coverage sequencing or whole exome sequencing (WES). However, WES genotypes have large site to site variation because of the uneven coverage of the targeted exons, or complete lack of coverage outside of the target region. We wanted to determine the usefulness of genotype imputation to obtain genotypes in region of poor or non-existent coverage in WES data. NGS data is different from the typical input of imputation (microarray genotypes) and may require different quality control steps to insure accurate imputation. Also, because NGS data is usually delivered in small or single-sample batches, we wanted to study single-sample imputation to best fit imputation in current NGS processing workflows. **Results:** Single-sample imputation is made possible by a recent development in imputation, namely phasing using a haplotype reference. We added a single-sample imputation option to EZimputer, our imputation workflow based on Shapeit2 and Impute2. We evaluated the accuracy of imputation from exome genotypes using genotypes from an illumina OMNI array on germline samples from the Breast Cancer Genome Guided Therapy (BEAUTY). We found that both variable and homozygous reference variants from the imputation reference, such as the 1000 genomes, need to be used as input genotypes to the workflow. We found that imputation accuracy is improved by filtering genotypes used in the imputation. We found that single-sample imputation against the reference is more accurate than multi-sample imputation for small sample size. We also evaluated two tools (HARSH and Shapeit2) that take advantage of NGS-specific information, namely co-occurrence of variants on the same sequencing reads or fragments. Overall, these two tools did not improve the imputation when using our high coverage exomes as input. Lastly, we show that there is an imputation metric that can precisely predict the probability that any given imputed genotype (per sample) is accurate. **Availability and Implementation:** EZimputer is under the GNU public license athttp://www. mayo. edu/research/departments-divisions/department-health-sciences-research/division-biomedical-statistics-informatics/software/bioinformatics-software-packagesandhttp://code. google. com/p/ezimputer/.

Genetic and clinical predictors for asthma risk assessment among children in Taiwan. *J. Tseng[1,2], M. Su[1], C. Tsai[1], Y. Lee[1].* 1) Institutive of Epidemiology and Preventive Medicin, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Department of Pediatrics, Children Hospital, Changhua Christian Hospital, Changhua, Taiwan.

Background Asthma is the single most common chronic childhood disease affected by multiple genetic and environmental factors. Although many genetic variants have been noted to be associated with childhood asthma, up to the present, no risk assessment models that incorporate genetic and clinical predictors for asthma occurrence are currently available. **Methods** We analyzed 10 single nucleotide polymorphisms (SNPs) identified from 9 asthma-associated genes among subjects who participated in three children's cohort studies in Taiwan (TCHS, GBCA and TCCAS). The parents of all participants were interviewed regarding the information of asthma risk factors. Modified Asthma Predictive Index (mAPI) and genetic risk scores (GRSs) of 10 SNPs were used in prediction model assessment. The performance of prediction ability was assessed by discrimination and reclassification statistics, and calibration. Cross validation with leave-one-out cross validation method was also conducted. **Results**In total, 640 asthma cases and 1921 control subjects were included in current study. After controlling for age, sex and BMI, two environmental factors, moist and water damage of wall, were significantly associated with childhood asthma and all these covariates were incorporated into baseline model. The prediction ability of childhood asthma improved greatly in combined model composed of GRSs and mAPI compared with clinical model, demonstrating an increased AUC from 0. 748 to 0. 780 ($p \leq$ 0. 0001). Besides, the improvement in discrimination (IDI: 0. 022, $p \leq$0. 0001) and reclassification (continuous NRI: 0. 344, $p \leq$ 0. 0001) also showed while comparing clinical model and combined model. Considering the 18% general risk of asthma in children, the combined model concluded sensitivity, specificity, positive predictive value, and negative predictive value as 78. 8%, 59. 4%, 39. 5%, and 89. 3%, respectively. **Conclusion**We have successfully constructed a prediction model composed of genetic and clinical factors in asthma risk assessment. Adding GRS into clinical factor-based prediction model would increase the prediction ability substantially in predicting the occurrence of childhood asthma.

1758F

A cloud based in-silico research platform for disease genomics: G-DOC *Plus*. *K. Bhuvaneshwar, Y. Gusev, A. Belouali, V. Singh, R. M. Johnson, L. Song, A. Alaoui, M. Harris, S. Madhavan.* Innovation Center for Biomedical Informatics, Georgetown University, Washington, DC.

Our flagship web platform G-DOC was first deployed in 2011 enable the practice of a translational-based approach to research and medicine in cancer. In fall 2014, we released G-DOC *Plus* to enable integration of multiple data types to understand mechanisms of cancer and non-cancer diseases for precision medicine. G-DOC*Plus*was developed using our in-house architectural framework to support over 1100 users and 10,000 patient and cell line samples. Our data collection includes whole genome sequencing (WGS) data from the 1000 Genomes Project and Complete Genomics; multi-omics data from the NCI-60 data collection; numerous breast, GI, and pediatric cancer studies; and non-cancer studies. In Spring 2015, G-DOC *Plus* became the official host of the well-known REMBRANDT data (Repository of Brain Neoplasia Data). Itincludes a broad collection of bioinformatics and systems biology tools for analysis and visualization of many 'omics' types including DNA, mRNA, miRNA, metabolites, DNA copy number analysis using our original Chromosomal Instability Index (CIN) algorithm in addition to WGS and clinical data. Users can also explore medical images, somatic mutations and perform pathway enrichment analysis using Reactome database. G-DOC *Plus* enables researchers to easily mine existing datasets to gain fundamentally new insights into complex diseases in an effort to improve survival and therapeutic outcomes. In this submission, we report in-silico analysis case studies done using clinical, gene expression and copy number data on four different types of brain tumors in the REMBRANDT dataset. We compared Astrocytoma (low-grade glioma) with Gliobastoma (GBM, high-grade glioma) patients. The most under expressed gene in this analysis, RHOF, was six fold under-expressed in the GBM group. This gene is known in literature to be down regulated in GBM patients through the over expression of their activators. We also examined copy number data using the CIN tool in G-DOC *Plus* and found higher chromosomal instability in the Astrocytoma group in chromosome 8q, which is also well known in literature. G-DOC *Plus* tools have been leveraged in cancer and non-cancer disease studies for hypothesis generation; multi-omic in-silico analysis and population genetics analysis. The long-term vision for G-DOC *Plus* is to extend this systems medicine platform to hospital networks to provide more effective clinical decision support. G-DOC *Plus* is available at: https://gdoc. georgetown. edu.

Can functional data assess genetic risk? – A polygenic risk score approach. *M. Butkiewicz[1], W. S. Bush[1], M. A. Pericak-Vance[2], W. K. Scott[2], J. L. Haines[1].* 1) Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) John P. Hussman Institute for Human Genomics University of Miami Miller School of Medicine, Miami, FL.

Polygenic genetic risk scores (PGRS) have been previously applied to characterize genetic effects for groups of SNPs in GWA studies where individual SNPs may not reach a significance (p-value) threshold. However, because most of the SNPs have no known functional impact and likely serve as surrogates for the actual functional variant, their explanatory effect may be blunted, reducing the accuracy of the score. To circumvent this limitation and as a proof of principle, we hypothesize that a polygenic functional risk score (PFRS) based on functional expression quantitative trait loci (eQTL) data can function like a PGRS because it can capture actual functional effects. Using quantified expression levels of mRNAs instead of GWAS related p-values, a SNP is chosen only if characterized as eQTL. If true, then known associated genes should generate a better predictive set of eQTL SNPs than genes not associated with that trait. In this study, we analyzed subject samples within the Amish assessed for age-related macular degeneration (AMD) comprised of 112 cases and 463 controls. Functional eQTL data was accessed through the Fantom5 database. We started with known AMD-associated genes. Genotype data was parsed to include only SNPs that had matching eQTL data. The resulting SNPs, weighted by the eQTL effect size estimate (beta value), were aggregated by gene to assemble a gene-weighted feature dataset for each subject. Next, machine learning algorithms were trained to distinguish cases from controls. The resulting 5-fold cross-validated classifier, achieved a prediction accuracy average of 81%, with a data split of 80% for training and 20% for testing. Subsequently, a different, distinct set of genes associated with Alzheimer's disease (AD) was chosen and the training protocol was repeated. Based on the same subject samples but using a different target gene set, the resulting classifier only achieved a reduced average prediction accuracy of 58%. These preliminary results demonstrates that classification performance differs depending on the gene set used, and supports our hypothesis that functional eQTL data can capture correlations between trait-associated SNPs and the trait itself, here AMD and AD. Next, we will identify larger case/control cohorts and compare our approach to existing PGRS. With systematic selection of new SNP sets, we anticipate that this ongoing study will reveal novel eQTL SNP combinations correlated with traits specific to human cell types.

Polycomb Repressive Complex 2 epigenomic signature defines age-associated hypermethylation and gene expression changes. *M. Dozmorov.* Biostatistics, Virginia Commonwealth University, Richmond, VA.

Although age-associated gene expression and methylation changes have been reported throughout the literature, the unifying epigenomic principles of aging remain poorly understood. Recent explosion in availability and resolution of functional/regulatory genome annotation data (epigenomic data), such as that provided by the ENCODE and Roadmap Epigenomics projects, provides an opportunity for the identification of epigenomic mechanisms potentially altered by age-associated differentially methylated regions (aDMRs) and to find regulatory signatures in the promoters of age-associated genes (aGENs). Here we show that aDMRs and aGENs identified in multiple independent studies share a common Polycomb Repressive Complex 2 signature marked by EZH2, SUZ12, CTCF binding sites, repressive H3K27me3 and activating H3K4me1 histone modification marks, and a "poised promoter" chromatin state. This signature is depleted in Pol II-associated transcription factor binding sites, activating H3K79me2, H3K36me3, H3K27ac marks, and an "active promoter" chromatin state. The PRC2 signature was shown to be generally stable across cell types. When considering the directionality of methylation changes, we found the PRC2 signature to be associated with aDMRs hypermethylated with age, while hypomethylated aDMRs were associated with enhancers. In contrast, aGENs were associated with the PRC2 signature independently of the directionality of gene expression changes. These results suggest that the PRC2 signature is the common epigenomic context of genomic regions associated with hypermethylation and gene expression changes in aging.

1761F

Population scale human genome analysis on the cloud. *J. Fitch[1], B. Kelly[1], P. White[1,2].* 1) The Research Institute at Nationwide Children's Hospital, Columbus, OH; 2) Department of Pediatrics, The Ohio State University, Columbus OH.

Advancing sequencing technologies have made population scale whole genome sequencing a possibility. However, current strategies for analysis of this data rely upon approaches that have limited scalability, lack reproducibility and are complex to implement, requiring substantial investment in specialized IT solutions. To overcome these challenges we developed a highly accurate and deterministic analysis solution, named Churchill, which fully automates the analytical process required to perform the complex and computationally intensive process of alignment, post-alignment processing, local realignment, recalibration and genotyping. Our parallelization strategy enables division of each analysis step across multiple compute instances, enabling whole genome variant discovery and genotyping to be completed in under 90 minutes. In addition to rapid analysis of a single sample, Churchill optimizes utilization of available compute resources and scales in a near linear fashion, enabling population scale genome analysis to be performed cost-effectively using cloud resources. To demonstrate this, we analyzed the 1000 Genomes Project dataset of 2,504 whole genome and exome sequenced individuals. Starting from FASTQ raw input data, we were able to fully automate the complete analysis process, ultimately performing multi-sample variant calling and generating population allele frequencies in seven days. We identified approximately 75 million variants in common with those released in the 1KG Phase 3 analysis of this dataset, with highly similar minor allele frequencies, demonstrating the efficacy of our rapid approach. In addition, through utilizing a highly sensitive method for variant detection that calls SNPs and indels simultaneously via local re-assembly of haplotypes in an active region, in combination with joint genotyping across the entire population, we discovered 5. 6 million indels not reported in the original analysis. Our approach demonstrates the feasibility of generating population allele frequencies specific to a given unified analysis approach, critical for accurately filtering datasets for discovery of rare pathogenic variants. Moreover, through use of on demand cloud computing resources, our method represents a solution for the genomics computational bottleneck and will keep pace with the magnitude of data generated by population scale sequencing.

1762W

Functional long-range regulatory interactions harbor co-occurring ancestry specific variants. *D. L. Gibbs[1], C. Humphries[1], N. Chambwe[1], T. Knijnenburg[1], B. Bernard[1], J. Roach[1], J. Vockley[2], J. Niederhuber[2], I. Shmulevich[1].* 1) Institute for Systems Biology, Seattle , WA; 2) Inova Translational Medicine Institute, Inova, Fairfax, Virginia.

Populations are defined by genetic isolation. This isolation results in differences in genetic variants and different patterns of gene expression. Variants falling within regulatory regions can affect the control of gene expression by altering binding motifs. These influences include long-range three-dimensional chromatin interactions crucial to the control of expression. This work examines the idea that variant pairs, co-segregating in populations, could affect the three-dimensional regulatory structure and alter expression patterns. Using whole genome sequences, we mapped common variants (>1% MAF) from 791 women and 788 men of diverse backgrounds into publicly available ChIA-PET derived chromatin interaction data. Statistical testing determines if variant pairs appear at a higher rate and associate with altered gene expression for a given population. In total, 78,982 variants fell within the genomic interactions; 2,215 interactions contained variants on both sides of the interaction. Significant variant pairs allowed for a comparison between populations, showing varying degrees of agreement. All population groups were observed to have unique variant pairs, but the European group was found to have the largest number of unique variant pairs with 74, followed by the African group with 19 unique variant pairs. Using UCSC and ENCODE annotation databases, such as RegulomeDB, variant pairs were annotated for gene structure and regulatory elements. While many variant pairs are found in insulator regions, 157 pairs are found in combinations of active promoter and strong enhancer regions. Lastly, using RNAseq data derived from women in the study, variant pairs are assessed for impact on the control of gene expression. This work helps to explain observed differences in gene regulation across populations, and contains the potential for clinical application.

1763T

Network-based meta-analyses of multiple gene expression profiles with BMD variations in females. *H. He[1], S. L. Cao[2], Y. Zhou[1], L. Zhang[1], T. H. Niu[1], Y. P. Wang[2], H. W. Deng[1].* 1) Biostatistics and Bioinformatics, School of Public Health and Tropical Medicine, New Orleans, LA; 2) Department of Biomedical Engineering, Tulane University, New Orleans, LA, 70118, USA.

Existing microarray studies of bone mineral density (BMD) are important parts of the efforts to understand the pathology of osteoporosis and have identified a number of candidate genes. However, these studies were limited to small sample size and usually analyzed individually. We proposed a network-based meta-analysis approach that combined meta-analysis across six microarray datasets and functional module identification from human protein-protein interaction (PPI) to highlight differentially expressed genes (DEGs) and a functional module that may play important roles in BMD regulation. Expression profiling studies were identified by searching PubMed database, GEO and ArrayExpress. Two meta-analysis approaches were applied across the preprocessed datasets. The first nonparametric meta-analysis combined p-values by Fisher's method from individual experiments to identify genes with a large effect size in all datasets. The second approach combined effect sizes from each dataset into a meta-effect size to estimate the amount of change in expression across all datasets. Genes with *Q* test's p-value less than 0. 05 or *I2* value higher than 50% were assessed by Random Effects Model, otherwise by Fixed Effects Model . Functional modules were identified through the integrated analysis of microarray data in the context of large biological protein–protein interaction (PPI) networks by using Fisher's combined p-values. KEGG pathway enrichment analysis on module genes was performed by a hypergeometric test. Six gene expression datasets were identified and raw CEL files were downloaded from GEO and ArrayExpress. In total there were 249 female subjects. A consensus module was identified containing 58 genes (nodes) and 83 edges. KEGG pathway enrichment analysis of 58 module genes revealed that genes were enriched in several important pathway like Osteoclast differentiation and B cell receptor signaling pathway. Meta-analyses by combining effect size and by combining p-values were both applied to the individual gene level to prioritize more important candidate genes. Five candidate genes (*ESR1*, *MAP3K3*, *PYGM*, *RAC1* and *SYK*) were identified and their associations with BMD were all validated by a BMD meta-analysis study. In summary, our network-based meta-analysis not only identified important DEGs but also discovered functional modules biologically related to osteoporosis pathology. Our study may provide importantly potential therapeutic targets for osteoporosis.

1764F

AnthOligo: Automated design of hybridization oligonucleotides for region-specific extraction of large contigious DNA fragments. *P. Jayaraman[1], K. Mackiewicz[3], P. M. Clark[3], M. Sarmady[1], D. Monos[2,3].* 1) Bioinformatics Group, Division of Genomic Diagnostics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology and Lab Medicine, Perelman School of Medicine, University of Pennsylvania; 3) Immunogenetics Lab, Division of Genomic Diagnostics, Dept. of Pathology and Lab Medicine, Children's Hospital of Philadelphia.

Region-specific extraction(RSE) of DNA is an increasingly utilized solution-based technique for enrichment and targeted resequencing of defined genomic regions of interest by next-generation sequencing(NGS). The captured contiguous fragments of DNA are particularly amenable to PacBio Single Molecule Real-Time Sequencing(SMRT) platforms, which can produce elongated reads, enabling long-range haplotype phasing across complex regions of the genome, such as the MHC. AnthOligo is a web application developed to automate the integrated process of designing capture oligonucleotides for such emerging sequencing platforms. This program facilitates the design of oligos for any locus of interest based upon user-defined constraints. The final set of optimal oligos resulting from such a complex process needs to satisfy numerous requirements (melting temperature, self/cross dimerization, entropy and putative off-target hybridization loci etc.). While countless tools exist to perform a subset of the desired tasks, they do not automatically retrieve genomic sequence and design the oligos. AnthOligo integrates several tools including Primer3, UCSC Genome Browser utilities and UNAFold to design oligos and analyze their properties. For given regions of interest, it extracts the reference sequence from UCSC Genome Browser (hg19) and breaks it down to 6Kb windows. To ensure optimal design of capture oligos, the 6Kb window is shifted towards the 3' end of the target locus at 3Kb intervals, producing overlapping windows. For each unique window, the Primer3 application is run based on user-defined configurations to generate raw oligos. UCSC BLAT, hairpin, and self/cross-dimer analyses are then run to further refine the oligos based on uniqueness, temperature, and entropy parameters. To select final list of oligos, a sliding window is used to select oligos that are ~8Kb apart from each other to ensure significant coverage of the target region. Previously designed oligos were used to successfully validate AnthOligo results. By streamlining the process of selecting an optimal set of oligos, this application is estimated to reduce considerable hands-on time. Program parameters can be customized for each individual run, making AnthOligo flexible for a wider range of applications (e. g. the design of internal oligos to be used as baits for gene panel analysis or as probes for large-scale CgH array processes). AnthOligo is publicly available as a web application at http://antholigo. chop. edu.

1765W

miR-96 targets a network of transcription factors and cell cycle regulators associated with prostate cancer progression. *M. D. Long[1], P. K. Singh[2], M. J. Campbell[1].* 1) 1Department of Pharmacology and Therapeutics, Roswell Park Cancer Institute, Elm & Carlton Streets, Buffalo, NY 14263, USA; 2) New York State Center of Excellence in Bioinformatics and Life Sciences, State University of New York at Buffalo, 701 Ellicott St, Buffalo, NY 14203 USA.

MicroRNAs often target gene expression to multiple members of the same network. The nuclear receptor (NR) superfamily of transcription factors forms one such network that is relevant to prostate cancer (PCa) progression and therapy. Previously, we used bootstrap permutation approaches on TCGA PCa cohorts (prad_mskcc and prad_tcga) to reveal that NR superfamily members were more commonly down-regulated at the mRNA level than predicted by chance. The retinoic acid receptor gamma (RARγ) was the most commonly lost NR (reflecting prostatic metaplasia in Rarγ knockout mice, reported by others). Rather than mutations or deletions correlating with NR expression loss, a cohort of 65 miRNA targeting NRs were elevated in expression, more than predicted by chance. The most significant negative correlation was between miR-96 and RARg mRNA. Both miR-96 transfection and *RARG*-3'UTR luciferase assays validated that miR-96 regulated RARγexpression. Expression analyses revealed miR-96 gain and RARγ loss during murine PCa development and elevated miR-96 levels significantly associated with worse disease free survival in the prad_tcga cohort. To identify miR-96 targets we used a biotinylated miR-96 (bi-miR-96) pull down approach. Non-malignant RWPE-1 prostate cells and LNCaP prostate cancer cells were transfected with bi-miR-96 or *c. elegans* bi-cel-miR-67 prior to microarray analyses. These analyses revealed both unique and shared targets between the two cells. Focusing on LNCaP cells, we identified nearly 400 genes enriched significantly with bi-miR-96. Hypergeometric tests revealed these genes were significantly enriched in miR-96 targets predicted by miRWalk (p<1. 3e-16) and GSEA (P<2e-27). Kolmogorov–Smirnov tests established these genes were significantly negatively correlated with miR-96 in prad_tcga cohort (p< 5. 2e-7). PCR validation confirmed miR-96 interacted with established (*FOXO1*, *RARG*) and novel targets (*SLC6A9*, *GCNT1*). Annotation of these genes revealed that the most enriched class of genes was transcription factors (~10%) including *CEBPA*, *ARID3B* and *SMAD4.* GO term analyses revealed a very significant enrichment for cell cycle regulation and reflecting this, miR-96 mimics increased the growth of LNCaP cells by reducing cells in G1 phase. Together these findings suggest that miR-96 is significantly associated with aggressive prostate cancer in part by regulating RARγ and a network of transcription factors associated with cell cycle control.

1766T

Examining lost reads to survey the microbiome and immune components of the human body across 43 human sites from 175 individuals. *S. Mangul[1], N. Strauli[2], H. Yang[1], R. Hernandez[2], R. Ophoff[3], E. Eskin[1,3], N. Zaitlen[4].* 1) Computer Science Department, University of California, Los Angeles; 2) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco; 3) Human Genetics, Los Angeles, University of California, Los Angeles; 4) Department of Medicine, University of California, San Francisco.

In this work we aim to profile the lost reads to study immune system function across tissues directly from RNA-seq data. We use 1641 RNA-Seq samples corresponding to 175 individuals and 43 sites from GTEx project : 29 solid organ tissues, 11 brain subregions, whole blood, and two cell lines, LCL and cultured fibroblasts from skin. . We use the unmapped reads to obtain a detailed profile of the microbial and immune components of the human body. We filtered out 54. 68%±7. 28% of the unmapped reads, which were low-quality and/or low complexity as well as 33. 18%±4. 82% of the unmapped reads that mapped to the human reference sequence (MegaBLAST, edit distance 10). The remaining high-quality unique reads are used to perform a survey of the microbiome and immune components. To profile the microbiome we used phylogenetic marker genes to assign candidate microbial reads to the bacterial and archeal taxa. A total of 713 taxa were assigned with Phylosift, with 8 taxa on the phylum level. No microbial organisms were observed in heart, pituitary and adrenal gland. All other tissues contain at least one bacterial or archeal phyla (0. 79+-0. 55 phyla per sample). We observe two viruses harbored in multiple tissues. EBV virus is present in 20% of the skin samples and 66% of the liver samples but it is not present in any of the brain samples. Enterobacteria phage phiX174 virus is present in 20% of the skin samples but is not present in liver and brain tissues. To profile B and T cells across tissues candidate immune reads were mapped to the V(D)J regions of the Ig loci. We compared normalized read counts of V(D)J mapped reads between tissues in order to determine the related abundances of immune cells. As a positive control we confirm that abundances of V(D)J reads in LCLs are significantly greater than thyroid and brain. Consistent with its role as an interface to environmental exposure, lung also contained and increased abundance of V(D)J reads relative to thyroid and brain (p-value < 10-6). We next measured the genetic diversity of V(D)J variants by examine number of gene alleles expressed per sample We observed a lower diversity of gene alleles in the lung and thyroid compared to LCLs (p-value < 10-16). Examining immune and microbial genes in GTEx can help define typical profiles for a healthy tissue. It is essential to monitor microbial and immune diversity, and this work may eventually help diagnose immune and microbiome imbalance in a tissue specific manner.

1767F

The feasibility test of fetal fraction estimation in targeted sequencing using fragment size in the case of Duchenne Muscular Dystrophy (DMD). *J. Park[1], D. Y. Park[1], B. Lee[1], T. Yun[1], J. Lee[1], J. H. Chae[2,3], B. C. Lim[2,3].* 1) Molecular diagnostics R&D Team, IVD Business Division, SK telecom, Seongnam, Kyunggi, South Korea; 2) Departent of Pediatrics, Seoul National University College of Medicine, Seoul National University Children's Hospital, Seoul, Korea; 3) Institute of Reproductive Medicine and Population, Medical Research Center, Seoul Natinal University, Seoul, Korea.

Background:In noninvasive prenatal testing (NIPT), targeted deep sequencing is used to detect micro insertion and deletion for screening Mendelian disorders. In this study, fetal fraction estimation method based on DNA fragment size was applied to targeted sequencing data. The feasibility of DNA fragment size based fetal fraction estimation was already shown in whole genome shallow sequencing (Stephanie Yu et. al). From the comparison of other conventional methods, DNA fragment size based method shows comparable results. Thus, DNA fragment size based method is more cost effective and can be applied for quality control of data. This method works well without any extra gene information and SNP information. Method:Customtargeted panel(Agilent SureSelect) was designed to cover the entire DMD gene region. Targeted sequencing was performed using 9maternal plasma DNA at varying gestational weeks from 5 mothers. Fetal genomic DNA obtained from either chorionic villi sampling or amniocentesis and genomic DNA from 5 mothers was used to validate the results. Using mean read depth of two Zinc Finger genes with a minimum mapping quality score of 20 and base quality score of 20, the fractional fetal DNA concentration was calculated as previous study (S. Yoo et. al). Also a size ratio indicating the relative proportions of short and long DNA fragments was calculated for each sample for the comparison ofZinc Fingermethod (Stephanie Yu et. al.). For more information, we compare the AB allele frequency ratio of hetero SNP sites of mother to confirm the fetal DNA was shorter than maternal DNA. Linear regression was used to compare two methods. Results:- From the comparison of AB allele frequency ratio based fetal fraction estimation and size ratio based one, the proposed method shows positive correlation (r=0. 85, p=3. 896x10-8). Similar result is also obtained from the comparison of Zinc Finger based estimation (r=0. 67, p=0. 09). In addition, our linear model is similar to the previously published whole genome sequencing data (Stephanie C. Y. Yu et. al). Thus fragment size based fetal fraction estimation can be extendible to targeted sequencing. ReferenceStephanie C. Y. Yu et. al. Predicted effect of single nucleotide polymorphisms affecting skin/hair coloration and/or 4-6 KHz hearing loss in young adults on secondary protein structure of melanocortin-1 receptor (MC1R). *C. B. Pudrith[1], S. L. Phillips[1], V. C. Henrich[2].* 1) Communication Sciences and Disorders, University of North Carolina at Greensboro, Greensboro, NC; 2) Center for Biotechnology, Genomics, and Health Research, University of North Carolina at Greensboro, Greensboro, NC.

In a recent study (Phillips et al. 2015), we found that young adult musicians carrying 1 of several minor alleles in the melanocortin receptor 1 (MC1R) gene had bilateral notching (BN), a 15 db or greater loss of hearing acuity at 4-6 KHz in both ears. A case-control study (N=252) included 84 subjects with BN, along with 2 control groups (unilateral notching and no notching). Eight MC1R SNPs were identified for all 252 subjects, and 25 (9. 9%) individuals had at least 1 minor allele. Of these 25 carriers, 18 (72%) had BN. Bilateral notching is a possible phenotype for identifying genetic variants associated with susceptibility to noise induced hearing loss. Because there are numerous SNPs with a relatively low frequency within the MC1R gene, a statistical analysis for any single polymorphism could not be performed. The purpose of this study is to determine if non-synonymous SNPs (NS-SNPs) in MC1R including those that are prevalent in BN subjects, also are predicted to affect the secondary structure of MC1R, using a protein structure-modeling program, Raptor X. The analysis included 5 SNPs associated with BN in the Phillips study (rs1110400, rs117952179, rs2229617, rs34090186, and rs34158934), one that was not (rs885479) and 8 other previously studied MC1R SNPs. The predicted structure of the wild type sequence was compared to the predicted structure of each polymorphic sequence. The variance between each sequence pair was calculated at each amino acid site, and then totaled throughout the protein. The overall variances for the NS-SNPs had a bimodal distribution. Of the 14 NS-SNP tested, 4 were not predicted to affect MC1R secondary structure (Group 1) and 10 did (Group 2). Two of the 5 NS-SNPs associated with BN (rs2229617 and rs34090186) led to a predicted change in secondary structure and all 8 SNPs from previous studies predicted a change. An unexpected finding was that the specific amino acids affected by Group 2 substitutions were nearly identical. This indicates that MC1R has several polymorphic sites that lead to similar secondary structural changes, regardless of their location in the MC1R sequence. It also suggests the possibility that some SNPs of MC1R can affect hearing acuity even though a predicted change in MC1R secondary structure is not discernible by computer modeling. This work was supported in part by the National Institutes of Deafness and other Communication Disorders grant R21DC009296-01.

Carrier Risk Estimation using Single Nucleotide Polymorphism-based Measures of Relatedness. *R. Shraga, M. Gold, A. Manoharan, S. Yarnall.* Recombine, Inc. , New York , NY.

Background: Genome wide measures of human relatedness have been used in a wide variety of applications. The goal of this study was to evaluate localized genetic relatedness in specific clinically relevant regions. We focused on DNA regions surrounding genes related to Cystic Fibrosis, Sickle-Cell Anemia, and Smith-Lemli-Opitz Syndrome. **Methods:** We created three different cohorts of patients by selecting carriers of the 3 disorders and adding randomized control patients who were known non-carriers of the same ethnicity. In order to study the relatedness of each group of patients, we selected single nucleotide polymorphisms (SNPs) in the region of the genes implicated in each disease. We used PLINK to prune the initial set of SNPs and kept those that are in approximate linkage equilibrium. We created genetic similarity matrices for each cohort using six different SNP-based measures of relatedness. These measures differ in how they score heterozygous matches and account for minor allele frequency (MAF). Additionally, we used different windows for SNP selection ranging from 1 to 10 Mbp upstream and downstream of the gene. We compared average relatedness within the case groups, within the control groups, and between the case and control groups. This research led to the development of an initial carrier risk classifier for Cystic Fibrosis mutation DeltaF508, which modifies the k-Nearest Neighbor (KNN) algorithm to use our SNP-based relatedness measure instead of Euclidean distance. We tested the performance of our classifier using repeated random sub-sampling cross validation. **Results:** We found that carriers of all 3 disorders appear more similar to each other than they do to controls. This observation was more pronounced in the measures that give a stronger weight to SNPs with low MAF. We also found that inter-group relatedness between sets of patients that are carriers of different mutations for the same disease varies widely. Using the modified KNN classifier, we randomly sub-sampled our cohort into training and testing sets 20 times, and found that 95. 28% of cases get classified as at risk compared to 25. 54% of controls. **Conclusion:** These results indicate it may be feasible to classify carrier risk even when direct observation of a mutation is not possible, especially if our observations hold true for rare variants. This may be useful for improving sensitivity in cases where direct testing is difficult or error prone.

Childhood Asthma Clusters Reveal Different Clinical Characteristics and Gene Signatures. *M. W. Su[1, 2], C. H. Tsai[1], Y. F. Wu[1], B. L. Chiang[3], Y. H. Yang[3], Y. T. Lin[3], L. C. Wang[3], J. H. Lee[3], C. C. Chou[3], W. C. Wu[1], Y. L. Lee[1, 2].* 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan; 3) Department of Pediatrics, National Taiwan University Hospital, Taipei, Taiwan.

Childhood asthma is a heterogeneous disorder that comprises distinct disease subphenotypes with complex pathophysiology. Asthma subphenotypes would evoke different clinical characteristics and various responses to medications. We want to identify different clusters of childhood asthma and achieve better therapeutic strategies. We applied k-means cluster analysis of twelve objective clinical examinations to 351 children with asthma in the Taiwanese Consortium of Childhood Asthma Study (TCCAS). Using microarray of peripheral blood mononuclear cell (PBMC) from children with different asthma subphenotypes, we develop a gene expression signature that predicts neutrophil-predominant asthma by logistic regression model. Five clusters of childhood asthma were identified and can be characterized by either predominant eosinophilic or neutrophilic, or even mixed eosinophilic and neutrophilic inflammatory pattern. A six-gene signature discriminates children with neutrophil-predominant asthma from other subphenotypes, including aquaporin 9 (AQP9), lipocalin 2 (LCN2), carcinoembryonic antigen-related cell adhesion molecule 6 and 8 (CEACAM6 and CEACAM8), orosomucoid 1 (ORM1), and peptidoglycan recognition protein 1 (PGLYRP1). The performance was evaluated by leave-one-out cross-validation, and the area under ROC curve (AUC) was 0. 93. Clustering can be helpful to identify clinically relevant patients and develop personalize asthma therapeutic strategies. Gene expression signatures of asthma subphenotypes not only improve our knowledge about childhood asthma, but provide guidance on future therapeutic strategies.

1771W

Reducing Off-Target Rate in Targeted Sequencing. *L. Teng, C. L. Hsieh, C. Lin, H. Y. Chuang.* Illumina, 5200 Illumina Way, San Diego, CA.

Targeted sequencing involves isolation of genomic regions of interest in a sample library, enabling cost-effective and systematic detection of germline and somatic variants. There are a wide variety of targeted approaches, ranging from biochemistry assays to NGS platforms and analysis tools. One of the major obstacles shared across the various approaches is the significant amount of sequenced reads eaten by off-target genomic regions. Targeted sequencing generally achieves only 40%~60% efficiency [1]. The off-target reads not only wastes sequencing yield but also potentially compromises variant calling for somatic mutations of low frequency. In this study, by utilizing peak calling techniques commonly used in ChIP-seq [2], we found that under the same experimental condition, a large majority of the off-target reads were systematic, highly reproducible across different samples and replicates. Many regions that were highly enriched with the systematic off-target reads were inside gene bodies. The similarity between the off-target regions and capture probes suggested that a great portion of off-target reads were likely pulled down by non-specific probes. To improve the on-target rate, we designed specific blockers or probes that bind to the identified off-target genomic regions. Different enrichment protocols which make use of the off-target blockers or probes were explored and the result showed promising reduction on the off-target rate.

1772T

Pathway Based Targeted Sequencing and Meta-Genomic Analysis of Preterm Birth. *A. Uzun[1,2], J. Schuster[1,2], B. Mcgonnigal[1,2], C. Schorl[3], A. T. Dewan[4], J. F. Padbury[1,2].* 1) Pediatrics, Women and Infants Hospital, Providence, RI; 2) Pediatrics, Brown Medical School, Brown University,Providence, RI; 3) Molecular, Cellular Biology Biochemistry, Brown Medical School, Brown University,Providence, RI; 4) Department of Chronic Disease Epidemiology, Yale School of Public Health, Yale University, New Haven, CT.

Preterm birth is a major public health problem. It occurs in 1 in 8 women. Classical estimates from twin studies suggest that the heritability of preterm birth is up to 40%. Pedigree analysis puts all of the risk on the maternal side. Previously, we analyzed a genome-wide case/control study, with approximately total of 2,000 term preterm mothers from the Danish National Birth Cohort to test the validity of the genes for Preterm birth. We identified 329 genes nested within 69 gene sets and 132 haplotype blocks that are highly associated with preterm birth. **1)** We performed targeted sequencing on these genes and genomic regions on 23 women with 2 generations of preterm birth, 9 women with 3 generations of preterm birth and 16 term controls. We found over 23,200 variants. **2)** We applied zygosity testing where we compared the variants of cases and controls for their abundance of homozygosity and/or heterozygosity. Statistical comparisons yield around 400 significant ($p<0.05$) variants on 200 genes. **3)** Meta-genomic analysis: We built a gene list for each mother (total of 48) where variants with $p<0.1$ were included and applied Gene Set Enrichment Analysis (GSEA) for each. Next, we transformed the gene set results for each mother into binary gene set profiles and applied an iterative binary bi-clustering algorithm (iBBiG) to identify groups of gene sets that are coordinately associated with groups of mothers and their phenotypes (preterm, term) across the GSEA results. We identified 5 significant ($p<0.05$) and overlapping clusters (modules) of shared genes and variants associated with preterm birth. These 5 modules included 34 genes with 217 variants were contributed. This meta-genomic approach is readily adaptable to incorporation of sequencing results from other projects on preterm birth.

1773F

Determine the contribution of genomic structure variation to the etiology of Tourette syndrome using whole-exome sequencing. *Y. Zhang[1], T. Fernandez[2], R. King[2], M. State[3], J. Tischfield[1], G. Heiman[1], J. Xing[1], The TIC Genetics Collaborative Group.* 1) Rutgers, the State University of New Jersey, Department of Genetics and the Human Genetics Institute of New Jersey, Piscataway, NJ, USA; 2) Yale Child Study Center and Department of Psychiatry, Yale University School of Medicine, New Haven, CT, USA; 3) Department of Psychiatry, University of California, San Francisco, USA.

Copy number variation (CNV) is a major component of human genetic variation. CNVs have been associated with many neuropsychiatric disorders, such as Schizophrenia, Autism, Autism spectrum disorder, and obsessive–compulsive disorder (OCD). Tourette syndrome (TS) is a neurodevelopmental disorder characterized by repetitive, stereotyped, involuntary movements and vocalizations called tics. Despite the strong evidence that genetics play a significant role in Tourette syndrome etiology, little is known about the genetic basis of TS. For this reason, whole-exome sequencing (WES) data has been generated by the Tourette International Collaborative Genetics (TIC Genetics) study to identify disease causal variants. To date, the TIC Genetics study has completed WES on 325 simplex families. We hypothesize that rare genic CNVs contribute to TS. Compared to microarray-based approach, WES offers several advantages for CNV detection, including higher sensitivity for smaller CNVs and higher enrichment for genic CNVs. To identify CNVs, we evaluated existing WES-based CNV computational approaches, including FishingCNV, CoNIFER and EXCAVATOR. We are also developing a novel computational approach to identify *de novo* genic CNVs in TS patients. Overall, our analysis will shed light on the genetic causation of TS related to genomic structural variation.

1774W

Accelerating pancreatic cancer drug screening by leveraging genomics to select better *in vitro* models. *R. Kusko[1], Y. Cha[1,2], J. Perez-Rogers[1,3], A. Lysaght[1], B. Weiner[1], S. Kolitz[1], F. Towfic[1], J. Funt[1], K. Fowler[1], B. Vardarajan[1,4], M. Artyomov[1,5], B. Zeskind[1].* 1) Immuneering, Cambridge, MA; 2) MIT, Cambridge, MA; 3) Boston University, Boston, MA; 4) Columbia University Medical Center, New York, NY; 5) Washington University in in St Louis, St Louis, MO.

The projection that pancreatic cancer will be the second leading cause of cancer related death by 2020 compounded by the numerous clinical trial failures precipitates the need for increased progress in new medicine development. Cell lines used for screening pre-clinical compounds prior to animal or human testing are selected for ease of access and literature prevalence. However, the constellation of genomic derangements in cell lines commonly used for *in vitro* studies may not be representative of pancreatic cancer tumors. In this study, we leveraged a wealth of publically available data from The Cancer Genome Atlas (TCGA) and the Cancer Cell Line Encyclopedia (CCLE) to predict optimal cell lines. We estimated the popularity of each CCLE profiled pancreatic cancer cell line using literature search and compared this to genomic similarity metrics. To start, we compared median per gene CNV values in TCGA pancreatic cancer tumors to pancreatic cancer cell lines in CCLE. Contrary to our expectation, the top five cell lines by CNV correlation with TCGA pancreatic tumors represented only 6% out of all literature search hits for all CCLE pancreatic cancer cell lines, indicating the availability of more optimal cell lines from a genomics perspective. Additionally, we used publically available algorithms to filter targeted sequencing data from TCGA and CCLE pancreatic cancer cell lines. Using clustering based on the presence or absence of these 7 mutations which passed filter, we showed that some pancreatic cancer cell lines readily clustered amongst TCGA pancreatic tumors (such as L33), while others occupied discrete branches of the dendrogram exclusive of most TCGA tumors (such as PK1 and PANC1). Lastly, we conducted an integrative analysis comparing the overall mutational burden in pathways between pancreatic cancer cell lines and tumors. Cluster analysis revealed that the majority of cell lines are highly similar to each other, but a handful of cell lines such as L33 cluster in branches mostly occupied by tumors. These results together imply that while some cell lines mimic pancreatic tumor genomes closely, others represent genomic constellations not commonly observed in patients. In summary, our work reports that many popular pancreatic cancer cell lines harbor distinct genomic aberration patterns from pancreatic cancer tumors in patients and highlights the emerging role of genomics in advancing the clinical success of therapeutic trials.

1775T

Using genome-wide genotyping and genome-wide gene expression profiles to perform integrative analyses of neutrophilic asthma. *C. H. Tsai[1], M. W. Su[1], B. L. Chiang[2], Y. H. Yang[2], C. C. Chou[2], Y. J. Chang[3], Y. F. Wu[1], Y. L. Lee[1,3].* 1) Institute of Epidemiology and Preventive Medicine, College of Public Health, National Taiwan University, Taipei, Taiwan; 2) Department of Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 3) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Background:Asthma is a heterogeneous airway disease. Neutrophil predominance in asthmatics has been reported to be associated with poor lung function and disease outcomes, as well as sudden asthma fatalities. Genome-wide association studies (GWAS) and genome-wide gene expression have been used to detect susceptibility gene for asthma. However, the results of GWAS generally are weak effects and wide variations in gene-expression microarrays. Therefore, the objective of this study is to integrate genome-wide genotyping and genome-wide gene expression profiles to investigate the genetic markers and pathway in neutrophilic asthma. Methods:Absolute neutrophil counts in peripheral blood from 535 asthmatics were used to find the cut-off point to discriminate neutrophilic asthma from Taiwanese Consortium of Childhood Asthma Study (TCCAS). We examined the whole genome genotyping and expression profiles from 30 cases of neutrophilic asthma and 29 non-neutrophilic asthma of peripheral blood mononuclear cells. Differentially expression gene were be defined, then Gene Set Enrichment Analysis (GSEA) and Ingenuity Pathway Analysis (IPA) were be applied to find potentially biological pathway. We preformed Gene Set Association Analysis (GSAA) and expression quantitative trait loci (eQTL) to integrate multiple genomic analysis platforms. Results:Higher neutrophil counts were found to be associated with poor pulmonary function, higher lung illness and without controlled asthma. We identified 592 differentially expression genes (FDR<0. 05) which were associated with defense and immune responses, including biology of immune system process. Production of nitric oxide and relative oxygen species in macrophages was the most significantly canonical pathway by IPA. Using integrative analysis, we found 14 leading edge genes by GSAA and 20 SNP-gene pairs by eQTL. A total of 3 genes, *BCL6 (B-Cell Lymphoma 6)*, *PPARG (Peroxisome proliferator-activated receptor gamma)* and *CDA (Cytidine Deaminase)*, were also reported on GSEA or IPA analysis. Conclusion:Our results indicate that neutrophil predominance is an important subphenotype in asthma. We could identify SNPs that affect gene expression level altering biological function in neutrophilic asthma. It is a practicable approach to combine SNP and gene expression information to investigate the important genetic markers and biological pathway on complex diseases.

1776F

Detecting the influence of genetic variants on personality. *K. Wolffhechel[1], H. Jarmer[1], S. M. van den Berg[2], M. H. M. de Moor[3], J. J. Hottenga[3], D. I. Boomsma[3].* 1) Center for Biological Sequence Analysis, Department of Systems Biology, Technical University of Denmark, Kongens Lyngby, Denmark; 2) Department of Research Methodology, Measurement and Data Analysis, University of Twente, Enschede, Netherlands; 3) Department of Biological Psychology, VU University Amsterdam, Amsterdam, Netherlands.

Personality has for many decades been known as partly hereditary, but the genetic basis for the development of our personality is still mostly unknown. In this work we attempt to classify personality traits from genetic variants using state-of-the-art machine learning algorithms on 60-item NEO-FFI measurements and over 8 million SNPs from 2946 unrelated Dutch participants. First, we choose pathway genes known to influence brain function and in a repeated nested 5-fold cross-validation we then select by genome-wide association for pathways associated with personality types and use these as predictors to classify to the two sides of a given personality trait. We find a classification better than random to the two ends of the scale for some of the Big Five traits. Next steps will be to get a better understanding of the found pathways and to look into possible gene-environment effects not captured by our model. Getting a clearer understanding of how exactly genetics influence our personality development would give us a huge advantage in predicting and perhaps preventing the onset of genetically caused personality disorders.

1777W

Diagnostic Role of Exome Sequencing in Immune Deficiency Disorders. *S. E. Brenner[1], A. N. Adhikari[1], J. P. Patel[2], A. Y. Chan[3], D. Punwani[3], H. Wang[3], A. Kwan[3], T. A. Kadlecek[3], M. J. Cowan[3], M. Mollenauer[3], J. Kuriyan[1], S. M. Fu[4], U. Sunderam[5], S. Rana[5], A. Chellappan[5], K. Kundu[5], A. Mulder[6], F. H. J. Claas[6], J. A. Church[7], A. Weiss[3], R. A. Gatti[8], J. M. Puck[3], R. Srinivasan[5].* 1) University of California, Berkeley, CA, USA; 2) Children's Hospital of Los Angeles, Los Angeles, CA, USA; 3) University of California, San Francisco, CA, USA; 4) University of Virginia School of Medicine, Charlottesville, VA, USA; 5) Innovation Labs, Tata Consultancy Services Hyderabad, India; 6) Leiden University Medical Centre, Leiden, The Netherlands; 7) University of Southern California, Los Angeles, CA, USA; 8) University of California, Los Angeles, CA, USA.

We developed an analysis protocol for individual genome interpretation and used its distinctive features to diagnose numerous clinical cases. We applied the protocol to exomes from patients with undiagnosed primary immune disorders, with a particular focus on infants with absent or low T cell receptor excision circles (TRECs), a marker for T-cells, at birth. To yield high quality sets of possible causative variants, we used multiple callers with multisample calling and integrated variant annotation, variant filtering, and gene prioritization. Our first cases involved two unrelated infant girls with low TRECs at birth that were not eligible for a bone marrow transplantation because no abnormalities were found in genes related to severe combined immunodeficiency (SCID). We discovered compound heterozygous variants in the *ATM*gene for both the infants. After clinical confirmation, this discovery offered a very early diagnosis of Ataxia Telangiectasia (AT), allowing for avoidance of undue irradiation and live vaccinations as well as revealing a new potential role for TREC screening in AT diagnosis. In another case, the affected siblings had early onset bullous phempigoid, a chronic autoimmune disorder. Our analysis revealed compound heterozygous mutations in ZAP70, a gene associated with profound primary immunodeficiency, the opposite phenotype. Cellular immunological studies indicated that one variant was hypomorphic and the other was hyperactive. These combined to yield a novel presentation, adding to the existing phenotype repertoire of ZAP70 in humans. Our analysis protocol focuses on genomic features that may be overlooked by other methods. In the case of a female with severe influenza pneumonia, our annotation tool, Varant, flagged variants in *PRKDC* apparently occurring after the genomically-encoded stop codon. This stop codon in the reference genome was correctly identified as premature due to a rare single base deletion. But accounting for the proband being normal at this position, we correctly annotated the proband's two variants as nonsynonymous mutations likely causative for the phenotype. Our protocol has been similarly revealing in other SCID and CID cases including Nijmegen Breakage Syndrome and BCL11B, which highlight unique features of the analysis framework that facilitate genetic discovery. These help provide crucial information to offer prompt appropriate treatment, family genetic counseling, and avoidance of diagnostic odyssey.

OMIM at 50: the nexus for knowledge on human genes and genetic disorders. *A. Hamosh[1], C. Bocchini[1], J. Amberger[1], N. Sobreira[1], F. Schiettecatte[2], A. F. Scott[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins Univ Sch Med, Baltimore, MD; 2) FS Consulting, LLC. Salem, MA.

The 2015 ASHG meeting launches a one-year celebration of Online *Mendelian Inheritance in Man*, OMIM's 50th anniversary. As of June 11, 2015, OMIM has curated over 7,800 phenotype and 15,000 gene entries. Among these are 3,405 genes recognized as causing 5,500 phenotypes. Between May 1, 2014 and April 30, 2015, there were a total of 2. 4 million visitors to OMIM. org, over 10,000 registered users of the ftp download, and close to 3,000 users of the API. Over the past 50 years, OMIM(http://OMIM. org) has grown from a series of books comprised primarily of descriptions of Mendelian phenotypes to a comprehensive interactive resource of knowledge on human genes and phenotypes that serves clinical and research genetics. OMIM classifies and names genetic disorders described in the published literature with consideration given to both clinical and molecular aspects of disease. For those not familiar with a particular gene or phenotype, the OMIM entry text provides a descriptivesummary and a jumping point to additional references and connections to context-specific information in other resources(for a comprehensive list, see external resources at OMIM. org). Discrete clinical features of a disorder or phenotype are represented in Clinical Synopses and are mapped to HPO and SNOMED CT terms thus facilitating incorporation into computational research. The OMIM Phenotypic Series provide a unique view of the genetic heterogeneity of many Mendelian disorders and facilitate bioinformatic research across networks of related disorders. OMIM provides data to the NCBI Clinical Variation Database, ClinVar, NCBI Gene databases, and controlled vocabularies such as HPO and the UMLS. OMIM is working with the ClinGen Project to establish community standards for phenotyping, disease gene curation, and variant annotation. In addition, OMIM encourages collaboration among clinicians and researchers through MIMmatch, a tool that allows users to follow entry updates and find colleagues with similar research interests. By providing unique expertly curated information on the relationship between genes and disease that is critical to overlapping and diverse communities of clinicians, molecular biologists and genome scientists, as well as students and teachers of these disciplines, OMIM stands at the nexus of clinical genetics, genomics and translational science.

1779F

Investigation of rare variants in complex disorders by using pooled DNA sequencing. *J. Wang[1], T. Skoog[1], H. Laivuori[2,3], P. Gerdhem[4], H. Lohi[5,6], J. Kere[1,6], H. Jiao[1].* 1) Department of Biosciences and Nutrition, Center for Innovative Medicine, Sciences for Life Laboratory, Karolinska Institutet, Stockholm, Sweden; 2) Medical Genetics and Obstetrics and Gynecology, University of Helsinki and Helsinki University Hospital, Helsinki, Flnland; 3) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 4) Department of Orthopedics, Karolinska University Hospital and Department of Clinical Sciences, Intervention and Technology (CLINTEC), Karolinska Institutet, Stockholm, Sweden; 5) Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 6) Molecular Neurology Research Program, University of Helsinki, and Folkhälsan Institute of Genetics, Helsinki, Finland.

BackgroundNext generation sequencing technologies have revolutionized genetics studies by providing an opportunity to detect rare variants associated with complex diseases. However, sequencing thousands of individuals in population-based association studies is costly and laborious. Sequencing pooled DNA samples could reduce the effort, but the question is if rare alleles are detected and if minor allele frequencies (MAF) estimated using pooled samples are correct. We aimed at evaluating the accuracy of MAF calculated using pooled DNA sequencing data. **Method**Whole genome sequencing (WGS) was performed with 20 untagged bullterrier DNA samples distributed into two pools, ten in each. A similar pooling strategy was applied on 100 scoliosis and 100 preeclampsia patient samples, ten in each pool using exome-sequencing. We tested different variant calling tools, e. g. SAMtools, GATK and FreeBayes, and compared the discovery of alleles and MAFs called by different software. Furthermore, the MAFs estimated by the three tools were evaluated by the MAFs obtained from individual-based genotyping data using microarray or Sequenom platform. **Result**We did not find large difference among the variants identified by three different tools, suggesting high discovery rate. For 20 bullterrier samples, 67867 of 69061 autosomal SNPs detected from Illumina Canine chip were detected by whole genome sequencing. The pooled MAF of around 50% shared SNPs was identical between WGS and microarray, and 35% had only one allele difference by direct allele counting. The rate of identical allele estimates was larger than 73% for rare variants (MAF≤0. 05). For exome-sequencing, 48 low frequency variants in preeclampsia study and 43 rare variants in scoliosis study were validated by genotyping individually. Except four monomorphic cases, MAFs estimated from pooled DNA sequencing data showed high concordance (R2= 0. 86) with those from genotyping data. **Conclusion**Pooled DNA sequencing data captured with high accuracy the alleles and MAFs as compared to individual genotyping data. The pooling strategy could be a rapid and cost-effective alternative approach for evaluating rare variants in association studies.

Distribution of unique sequences in the human genome. *K. Misawa[1,2], K. Kojima[2,3], Y. Kawai[2,3], M. Nagasaki[1,2,3].* 1) Department of Cohort Genome Information Analysis, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Graduate School of Medicine, Tohoku University, Sendai, Miyagi, Japan; 3) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan.

Targeted nucleases are useful tools for genome alteration with high precision. The RNA-guided Cas9 nuclease from the microbial clustered regularly interspaced short palindromic repeats (CRISPR) adaptive immune system can be used as an efficient genome engineering tool in eukaryotic cells including human cells (*1*). CRISPR requires a 20-bp targeting sequence (*2*). When studying large genomes, however, the design of oligonucleotides for CRISPR is complicated by the redundancy of sequences. Such non-unique sequences cannot be CRISPR targets, because they cause off-target reaction. Thus, the distribution of unique sequences in the genome is of interest. We describe the development of a novel method, UF, for detecting unique 20-bp sequences in entire genomes (*3*). UF stands for "Unique Finder. " By using UF, the distribution of unique sequences in the human genome was investigated. It was found that 60% of the human genome is unique on average as shown in the previous study (*4*). It was found that non-unique regions of human genome are concentrated on centromeres and terminal regions of the chromosomes. The proportions of unique sequences are about 80% in the rest part of the genome. ToMMo processed the whole genome sequences of 1,070 healthy Japanese individuals. We are now investigating genetic variations of non-unique sequences in the Japanese population. The program for obtaining unique sequences is available at https:// sourceforge. jp/projects/parallelgwas/releases/. Reference1. P. D. Modular transcriptional repertoire, network community structure, and microRNA target analyses in thymic tissue of Down syndrome infants. *C. A. Moreira-Filho[1], S. Y. Bando[1], F. B. Bertonha[1], F. N. Silva[2], L. F. Costa[2], L. R. Ferreira[1], M. Carneiro-Sampaio[1].* 1) Pediatrics FMUSP, University of São Paulo, São Paulo, São Paulo, Brazil; 2) Instituto de Física de São Carlos, Universidade de São Paulo, São Carlos, SP, Brazil.

Trisomy 21- driven transcriptional alterations in human thymus were characterized through gene coexpression networks (GCNs) - obtained for differentially expressed (DE networks) and for all valid GO annotated transcripts (CO networks) - coarse-grained community structure and microRNA-target analyses. We used whole thymic tissue (corticomedullar sections) - obtained at heart surgery from Down syndrome (DS) and karyotipically normal individuals (CT) - and a network-based approach for GCN analysis that allows the identification of modular transcriptional repertoires and the interactions between all the system's constituents through community detection. Changes in the degree of connections observed for hierarchically important hubs/genes in CT and DS gene networks corresponded to sub-network changes, i. e. module (communities) changes. Distinct communities of highly interconnected gene sets were topologically identified for DS and CT networks. Coarse-grained community structure revealed distinct functional interactions between gene communities for CT and DS networks. The role of microRNAs in modulating the expression of highly connected genes in CT and DS was revealed through microRNA-target analysis. Our results show that thymus global hypofunction in Down syndrome correlates with distinctive GCN topology and node hierarchy. The comparative genetic and topological analysis of DE networks disclose how significant is the impact of trisomy 21 on thymus functioning. The high modularity of DS-DE network contrasts with its reduced connectivity, thus indicating a certain degree of disorganization of modular interactions caused by gene dosage imbalance. Coarse-grained community analysis confirmed these data. Since the CO networks are more similar in their connectivity and modularity (although not in hubs' hierarchy), the DS-DE network may represent the "ground zero", where trisomy-driven gene dysregulation strongly impacted the normal gene-gene interactions, with the derived "shock-waves" reflecting on the DS-CO network. In conclusion, alterations observed in DS networks regarding connectivity, modularity, and communities' structure reflect chromosome 21 dysregulation and its consequences. As a whole, the results indicate that GCNs' functional and topological modules correspond, and that trisomy 21 may be interpreted as the breakdown and altered reorganization of functional modules. This mechanism is coherent with the network-based model of human disease.

Longitudinal prediction of the infant gut microbiome with dynamic bayesian networks. *M. J. McGeachie[1], J. E. Sordillo[1], T. Gibson[1], G. M. Weinstock[2], Y. -Y. Liu[1], D. R. Gold[1], S. T. Weiss[1], A. Litonjua[1].* 1) Channing Div Network Med, Dept of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT.

BACKGROUNDSequencing of the 16S rDNA gene allows comprehensive assessment of microbial community composition from human body sites. Emerging evidence suggests that differences or aberrations in the microbiome can lead to various diseases and chronic conditions. Dynamic Bayesian Networks (DBNs) have been used in other settings to successfully model time series data and obtain accurate predictions of future behavior as well as identify salient connections and relationships within the data. METHODSWe modeled extant infant gut microbiome time series data using DBNs to demonstrate ability to predict progression of microbiome taxa and to identify important relationships among those taxa. Previously published and publicly accessible data on 58 preterm infants in the Neonatal Intensive Care Unit who underwent frequent stool collection for a month was used. We constructed DBNs from the data and analyzed predictive performance and network characteristics. RESULTSA DBN model of the infant gut microbial ecosystem explicitly captured relationships observed previously. Relationships identified between age and *Clostridia*, and between *Clostridia*, *Gammaproteobacteria*, and *Bacilli* were among the strongest relationships identified. In general, with increasing infant age, the DBN predicted increasing amounts of *Clostridia*, residual amounts of *Bacilli*, and increasing amounts of *Gammaproteobacteria* that then give way to *Clostridia*. Decreasing amounts of *Bacilli* over time were dependent upon increasing *Clostridia* and *Actinobacteria*, when present. Prediction performance of DBNs with fewer edges were overall more accurate, although less so on harder-to-predict subjects (p = 0. 016). The DBN provided quantitative likelihood estimates for rare, dramatic, sudden shifts in microbiome population ("abruptions") observed in some infants. Iterative prediction, while less accurate that sequential prediction (p < 0. 001), showed remarkable insensitivity to initial conditions and indicated convergence to a mix of *Clostridia*, *Gammaproteobacteria*, and *Bacilli* for all tested initial microbiome populations. CONCLUSIONSDBNs were able to identify important relationships between microbiome taxa and predict future changes in microbiome composition from measured or synthetic initial conditions. DBNs also provided likelihood estimates for sudden, dramatic shifts in microbiome composition, which may be useful in guiding further analysis of those samples.

Structural and functional investigation of pathogenic mutations of IL10RA gene by computational methods. *B. Babajan[1], M. Kaleemuddin[3], E. Ramu[1], Y. A. Jumana[1,2], S. Noor Ahmadh[1,2].* 1) Princess Al-Jawhara Al-Brahim Centre of Excellence in Research of Hereditary Disorders (PACER-HD) , King Abdulaziz University Jeddah 21589 Kingdom of Saudi Arabia; 2) Department of Genetic Medicine, Faculty of Medicine King Abdulaziz University Jeddah 21589 Kingdom of Saudi Arabia; 3) Department of Biochemistry, King Abdulaziz University Jeddah 21589 Kingdom of Saudi Arabia.

ObjectiveThe advent of genome wide association studies, whole - genome and - exome studies has started to uncover known/novel pathogenic variations in interleukin-10 receptor alpha (IL10 RA) gene in several autoimmune diseases. However, the structural and functional impact of these genetic mutations is not well identified. Hence, this study has performed the computational analysis of clinically potential missense and untranslated region mutations of human IL10RA gene. **Methodology**In this study a combination of empirical rule and support vector machine based insilico algorithms were employed to predict the pathogenic potential of non-synonymous mutations of 1L10 gene. Additionally, molecular modeling and secondary structure analysis was performed to confirm their impact on the stability and secondary properties of IL10RA protein. **Results**Besides, the mutations corresponding to p. Y57C, p. T84I, p. Y91C, p. R101W, p. R117C, p. R117H and p. G141R in exonic region; c. *1537T>C, a regulatory region variant was also found to potentially influence the structural and functional deviations of IL10RA activity. Moreover, the molecular docking analysis of IL10RA with substrate (IL10) and mutated forms of IL10RA was found to be three mutated proteins of IL10RA are (p. Y57C, p. R117C and p. G141R) most interesting residues for mutagenesis and affect the selectivity and affinity of IL10RA towards IL10. **Conclusion**Our findings are expected to help in narrowing down the number of IL10RA genetic variants to be screened for auto immune disease association studies and also to design a better competitive inhibitors for mutated forms IL10RA protein. **Keywords**Insilico analysis, IL10 Gene, Pathogenic Mutations.

Forecasting a renal prognosis of IgA nephropathy using machine learning. *H. Lee[1], J. Noh[2], H. Kim[3], W. S. Yang[3], G. Kim[2], Y. S. Kim[1], D. K. Kim[1].* 1) Internal Medicine, Seoul National University Hospital; 2) Computer Science and Engineering, Seoul National University College of Engineering; 3) Internal Medicine, Asan Medical Center, University of Ulsan College of Medicine.

Previous studies of IgA nephropathy (IgAN) patients have focused on risk factor evaluation. We aimed to develop individual outcome prediction models in IgAN patients using machine learning methods. We reviewed clinical and pathologic characteristics of adult IgAN patients from Seoul National University Hospital (SNUH, n = 1,540) and Asan Medical Center (AMC, n = 1,044) at the time of renal biopsy. They were divided into development (followed up ≥10 years) and prediction (follow up <10 years) sets, respectively. The outcome was 10-year renal survival (10YRS) probability. We developed prediction models from SNUH test set by using logistic regression (LR) with Lasso method, a classification and regression tree (CART), and neural network (NN) using 16 clinico-pathologic variables. We also used bagging, random forest (RF) and boosting for ensemble learning. Finally, those models were validated internally in SNUH prediction set and externally in AMC development and prediction sets. Considering missing data, 1,514 and 847 patients were included from SNUH and AMC cohorts. In the LR model, estimated glomerular filtration rate (eGFR), hemoglobin, proportions of GS and SS, interstitial fibrosis were selected as predictors for ESRD. In the CART model, eGFR 53. 3 ml/min/1. 73m2 was proved to be a watershed for 10YRS, followed by, proportion of GS (≥ 39. 2%) and SS (≥ 28. 5%), tubular atrophy (≥ moderate), hemoglobin (<11. 9 g/dL) and proteinuria (≥ 1. 39 g/g), sequentially (accuracy, 0. 849). In the NN, variables were selected including eGFR, proportions of SS, hemoglobin, proportion of GS, albumin, and interstitial fibrosis, sequentially (accuracy, 0. 862). In addition, the ensemble learners showed good performance (accuracies of bagging, 0. 868; RF, 0. 874; boosting, 0. 862). Those individual learners were validated internally with good performance (sensitivities of LR, 0. 855; CART, 0. 921; NN, 0. 952; bagging, 0. 857; RF, 0. 921; boosting, 0. 921). And finally, we proved the robustness of those models from external validation. Good performances of both development (sensitivities of LR, 0. 847; CART, 0. 867; NN, 0. 855; bagging, 0. 852; RF, 0. 872; boosting, 0. 851) and prediction sets (sensitivities of LR, 0. 980; CART, 0. 902; NN, 0. 941; bagging, 0. 882; RF, 0. 902; boosting, 0. 922) were showed. We developed robustness of prediction models using machine learning for the individual's likelihood of 10YRS in IgAN with both internal and external validation.

1785F

Identification of genetic interactions involved in Dyslexia pathogenesis. *N. Karbalai[1,2], D. Czamara[1,2], B. Pütz[1], C. Wolf[1], T. Kam-Thong[1], A. Gialluisi[11], R. Malik[2,17], F. Dyslexia is a highly prevalent disorder in children, characterized by severe deficits in learning to read and/or spell. Several cognitive endophenotypes like phonological awareness and auditory short-term memory were correlated with core dyslexia phenotypes. However, the underlying neurobiological processes of these different cognitive abilities suggest a highly heterogeneous genetic architecture contributing to susceptibility for dyslexia, which can obscure single-locus associations. We therefore went beyond established single-locus methods to analyse higher-order genetic interactions, which are essential components of genetic processes. Within a sample of 862 dyslexics from France, Germany, USA, and UK we conducted a genome-wide two-locus interaction scan via the tool GLIDE. We identified genetic interactions affecting susceptibility for altered cognitive skills (single-word reading, phonological awareness, nonword reading, and spelling), previously ascertained for each individual. Our survey revealed interactions at highly relevant genomic sites, comprising both novel and previously known candidates for dyslexia susceptibility. Strong associations ($p \leq 9*10\text{-}14$) for single-word reading were obtained for interactions between variants on chr9q31. 3 and intronic variants of *FOXP2* (chr7q31. 1). This transcription factor gene has been implicated in a severe form of speech and language disorder, and recent studies have suggested that it may also contribute to etiology of dyslexia. Among others, we also observed significant interactions ($p \leq 9*10\text{-}13$) for phonological awareness between variants on chr18q11. 2, a genomic region linked to various dyslexia endophenotypes, and intronic variants of *NCAM1* (chr11q23. 2). This neural cell adhesion gene is known to be involved in nervous system development and has been associated with risk of ADHD, and Bipolar Disorder. Gene-set enrichment analysis of all loci with an endophenotype association of $p \leq 1*10\text{-}10$ highlighted processes, that were previously implicated in dyslexia, as significantly enriched e. g. axon guidance, locomotory behaviour, development of the cerebral cortex and nervous system. Furthermore, we found an accumulation of transcription factor binding sites and/or DNaseI hypersensitivity sites annotated by ENCODE at the chromosomal regions of our significant loci. Our results suggest multi-genetic mechanisms like allelic interactions play an important role in etiology of dyslexia.

Systematic and integrative analysis of a gene-set involved in prostate cancer: a bioinformatics study. *J. Pani[1], K. Gautam Singh[2], A. Narayan Singh[3], F. Kumar Pandey[4], H. Narayan Singh[5].* 1) cytogenetics, MTA Infotech, New Delhi, New Delhi, India; 2) Bioinformatics Division, MTA Infotech, New Delhi; 3) IT Division, MTA Infotech, New Delhi; 4) I. T. S Paramedical College, Ghaziabad, India; 5) School of Sciences, Noida International University, Gautam Budh Nagar, India.

The etiology of prostate cancer (PC) is multifactorial, including genetic and non-genetics factors. However, the etiology of the disease is yet to understand completely. Development of any cancer reflects a progressive accumulation of alterations in various genes and their effect on various pathways. Therefore, identification of genes and study of the molecular basis of their corresponding pathways will definitely provide insights into the etiology and prognosis of the disease. List of genes involved in the PC were extracted from gene-disease association databases. Genes were classified and further, pathway enrichment analysis was also done at FDR<0. 01. 27 genes were found to be reported for the disease pathogenesis. These gene products belong to 12 different categories based on their function viz. Signaling molecule (13 genes), Enzymes (11), Receptor (8 genes), Transcription factor (5 genes), Nucleic acid binding (5 genes), Enzyme modulator (4 genes), Defense/immunity protein(3 genes), Extracellular matrix protein (2 genes), Calcium-binding protein (2 genes), Transporter (2 genes), Cell adhesion molecule (1 genes), Surfactant (1 genes), however, some genes belong to more than one categories. Pathway enrichment analyses (FDR < 0. 01) of these genes clearly show their involvement with signaling pathways. These genes belong to various protein function categories; however, signaling molecules are prominent in disease progression. HMGB1 involve in transactivation of androgen receptor; VEGFA implicated in the angiogenesis that occur in PC via VEGF signaling pathway; IL-6, 7, 15 differentially regulates androgen receptor transactivation via various signaling pathways; ERG, a protooncogene involve in translocation leading to cancer; KLK3, also known as prostate-specific antigen and androgen control its expression; KLK4 is androgen-regulated molecule which is reported to be overexpressed in PC; CD82 inhibit metastatic process; dysregulation of TGFB1 activation and signaling may result in apoptosis, IGF1 is a marker of tumor progression, VIP activates adenylyl cyclase in prostate gland; NRG1 can accumulate in specific subnuclear compartments. The present study gives valuable insights into pathogenesis of PC and suggests important interventions to ameliorate this disorder. It reveals that PC is a multifactorial complex disease which involves many genes and multiple pathways; however, androgen-receptor signaling pathway is most prominent mediator of the PC progression.

1787T

Implications for cell type-specific transcriptomics in the developing human brain from next-generation sequencing of subcellular RNA fractions. *A. J. Price[1,2,3], D. Kim[1,2], R. Tao[1], D. R. Weinberger[1,2], A. E. Jaffe[1,2].* 1) Lieber Institute for Brain Development, Baltimore, MD; 2) Johns Hopkins University School of Medicine, Baltimore, MD; 3) McKusick-Nathans Institute of Genetic Medicine, Baltimore, MD.

Post-mortem human brain tissue is an essential substrate for understating the molecular pathology of brain disorders and their risk. Many risk genes for schizophrenia and related disorders are likely dysregulated within individual cell populations, resulting in reduced signal when studying homogenate brain tissue. The most popular solution to the issue of cellular heterogeneity when using human frozen postmortem brain is currently to isolate cell nuclei from homogenate tissue, label the nuclei with cell-type specific fluorescent antibodies and sort out different cell types using fluorescence-activated cell sorting. This solution is well suited for DNA-based epigenetic studies but is limiting in terms of RNA, since a large part of the transcriptome is discarded with the cytosol. To determine the impact of profiling nuclear RNA in lieu of the whole transcriptome, we isolated nuclear and cytosolic RNA from three fetal and three adult human brains, prepared libraries from each RNA fraction for next-generation sequencing using both rRNA-depletion methods (Ribozero) and PolyA selection methods (PolyA+), and performed RNA sequencing on these 24 samples. In line with previous reports, we found that Ribozero library preparation highly enriched the proportion of reads aligning to introns particularly in the nuclear RNA fraction (6. 18% for PolyA+ and 47. 03% for Ribozero). Likewise, reads spanning splice junctions were highly enriched in polyA+ library samples regardless of cell fraction (p<10-6), suggesting enrichment for pre-mRNA in Ribozero nuclear samples. We found that library type had a larger impact on measurement of gene expression than RNA fraction overall, and that differences in gene expression between the nucleus and cytosol were mitigated by using polyA+ library preparation. On a cautionary note, the top differentially expressed genes across brain development only partially overlapped between library type in both the nucleus and cytosol. Investigators should therefore consider these results before deciding on library preparation method when undertaking transcriptome studies using human brain nuclei.

A Computational Protein Phenotype Prediction Approach to analyze the deleterious mutations of human med12 gene. *R. Elango[1,5], B. Banaganapalli[1,5], M. Kaleemuddin[1,3,5], J. Y. Al-Aama[1,2], I. Khan[4], N. Shaik[2].* 1) Princess Al-Jawhara Al-Brahim Center of Excellence in Research of Hereditary Disorders (PACER-HD), King Abdullaziz University, Jeddah, Saudi Arabia. , Jeddah, Saudi Arabia; 2) Department of Genetic Medicine, Faculty of Medicine, King Andullaziz University, Jeddah, Saudi Arabia; 3) Department of Biochemistry, Faculty of Science, King Abdulaziz University, Jeddah, Saudi Arabia; 4) Department of Clinical Laboratory Sciences, College of Applied Medical Sciences, King Saud University, Riyadh, Saudi Arabia; 5) Equal contribution.

Objective: MED12is a subunit of the multiprotein complex Mediator, an evolutionary-conserved regulator of transcription. Somatic mutations in MED12gene have been described in benign and smooth muscle cell tumors. The underlying basis if any mutation elicit the in protein phenotype changes remains unclear. The computational investigation on mutation effects on protein structure found to be an effective alternate method to traditional *in-vivo* and *in-vitro* approaches. Hence, we have performed the *in-silico* structure analysis of clinically potential missense mutations of human MED12 gene. Methodology: The MED12 gene mutations were collected from different databases and by text-mining. Combination of empirical rule and support vector machine based *in-silico* algorithms were employed to screen the pathogenic non-synonymous genetic mutations based on their nucleotide sequence conservation across species. Both native and conserved region specific 3-D MED12 mutant protein structures were built by integrative *ab-initio* and homology modeling methods. Solvent accessibility, secondary structure analysis, change in stability and other structural deformities of the protein due to mutation were analyzed. Results: The concordant predictions of SIFT, PolyPhen2 and I-Mutant 3. 0 have attributed the pathogenicity to 47 (28. 31%) missense mutations that span the gene. Our analysis showed that protein structures with amino acid substitutions between 1-100 amino acids- aa (Q43P, G44S, G44D, G44F) and 1800-1969aa (N1845T and S1969P) are structurally less divergent (0. 51Å -0. 59Å) compared to the substitutions between 350-550aa (P353H, R356W, E446A, D499H, R521H, R540H, K550N), with high structural divergence (0. 60Å -0. 89Å). Interestingly, these results confirm the protein stability and solvent accessibility findings. Conclusion: Missense mutations showing high structural divergence are likely to be more deleterious to protein and contribute to disease. Our findings are expected to help in narrowing down the number of MED12 variants to be screened for association studies. The *in-silico* based mutation analysis, being helpful in providing information about the nature of mutations, may also function as a first-pass filter to determine the candidates worth pursuing for further research in other coagulation disorder causing genes.

Diagnostic sequencing in mosaicism and heteroplasmy: allele detection and base calling by graph analysis. *S. Bang[1], J. Chae[1,2,3], K. Hwang[4].* 1) Biomedical Research Institute, Seoul National University Hospital, Seoul, Korea; 2) Department of Pediatrics, Division of Neurology, Seoul National University Children's Hospital, Seoul, Korea; 3) Seoul National University College of Medicine, Seoul, Korea; 4) School of Computing, Soongsil University, Seoul, Korea.

Identifying mosaicism in nuclear DNA and heteroplasmy in mitochondrial DNA are challenges in diagnostic sequencing, as both yield sequences with superimposed peaks of variable height and shape. Many base calling algorithms are not adequately equipped to accurately call such positions, as the tallest peak is usually considered the 'dominant' peak, and smaller peaks are handled as background noise. Visual evaluation of each sequence is generally accurate at these locations, but low- to mid-level superimposition can yield minor peaks that are difficult to distinguish from noise based on height alone. An in-house base calling algorithm has been developed to identify alleles with superimposed peaks more accurately. The algorithm serially interpolates polynomial functions of the trace graphs and represents peaks with best-fit Gaussian distributions, allowing fine evaluation of the morphologic characteristics defining the size and shape of each peak. The rates of detection of superimposition between this algorithm and the base callers PHRED and ABI have been compared for sequences gathered from the mitochondrial DNA of 42 pediatric patients with suspected mitochondrial disease and 57 healthy controls. For 92 positions showing superimposition, our algorithm, ABI, and PHRED correctly identified 60/92 (65%), 11/92 (12%), and 0/92 (0%) positions, respectively. Positive linear correlations between the algorithm's peak profile score ratios and the quality scores given by ABI and PHRED were observed (ABI, r = 0. 667; PHRED, r = 0. 690). Graph analysis provides more accurate base calling at superimposed positions and also shows potential for distinguishing minor peaks from baseline noise, thus improving base calling accuracy not only for heteroplasmy but also for low-level mosaicism.

1790T

Morphling: a likelihood based Mobile Element Insertion (MEI) caller for whole genome sequencing data. *S. Chen[1], G. Abecasis[2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI 48109; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109.

Mobile Element is a type of DNA sequences than can change their location or copy numbers in the genome. Previous studies have reported that an individual genome contains around 1,500 novel Mobile Element Insertions (MEIs). These MEIs, like other types of structure variation, might be present in regulatory or coding sequences, and might be associated with certain genetic disorders. Thus, identifying MEIs from sequencing data is of great importance to statistical genetics research. Here, we developed an MEI detector, Morphling, which automatically adjusts its parameters from remapping a small portion of reads back to a modified genomic sequence. Sample coverage and mapping status is also taken into account in this adjustment. With the adjusted parameters, Morphling converts split-read and read-pair information to genotype likelihood estimate of each potential MEI event. The genotype likelihood estimate will be of great use in following analysis. In simulated data, Morphling shows better performance compared to other callers, in terms of detection power, false discovery rate and break point accuracy. In real data, Morphling has more stable performance across samples with different coverage and mapping status. Also, Morphling is well-designed perform joint calling on multiple samples, and utilize population-scale information to improve its performance. It is quite useful for population-based studies with lower sample coverage but larger sample size. Currently we're applying Morphling to multiple sequencing studies to obtain a high quality MEI call set. We're also performing PCR validation followed by Sanger sequencing on some samples to evaluate Morphling's performance in real data.

1791F

Benchmarking well know bioinformatics aligners and variant callers using the Pilot Genome (NA12878) and Ashkenazim Father-Mother-Son trio. *A. B. Diallo, A. Carroll, B. Hannigan, S. Ma, M. Kinsella.* DNAnexus, Mountain View, CA.

Next Generation Sequencing cost is decreasing continuously and clinical applications are taking advantage of the technology. Nevertheless the standards to assess confident variant calls are limited, and improving this is important to assessing clinical utility and reproducibility. The "Genome in a Bottle Consortium" is working on the development of widely accepted reference materials and performance metrics to provide a foundation to address theseconcerns. Building on that foundation,here we present benchmark results using well know bioinformatics aligners and variant callers on the Pilot Genome (NA12878) and Ashkenazim Father-Mother-Son trio. We focus on the variant calls results qualityby using different variety of coverage depths of Illumina reads and parameters tuning to understand the costs and benefits of sequencing to higher coverage. We detail tools for comparisons of the VCF results and investigate the benefits of assembling across different methods. The pipelines, datasets, and tools are openly available on DNAnexus.

1792W

A realistic simulation for benchmarking germline and somatic mutation detection with long read sequencing. *B. Lau, J. C. Mu, M. Mohiyuddin, L. T. Fang, N. B. Asadi, H. Y. K. Lam.* Bina Technologies, Roche Sequencing, Redwood City, CA.

In response to recent advances in third generation sequencing technologies, an increasingly mature arsenal of bioinformatics software has been developed to analyze long reads with high error rates. For example, Pacific Biosciences (PacBio) long-read sequencing and software suite have demonstrated power to resolve long haplotypes in difficult regions of the genome. Such demonstrations have mostly been sample-specific; however, a controlled simulation-validation study of various toolsets can provide valuable insights into the general applicability of existing methods. To date, simulation has been hampered by a lack of a realistic yet versatile long-read simulator. For example, PBSIM does not generate data in the H5 format required by PacBio processing tools. We also found that the Alchemy simulator generates H5 format for a particular, older chemistry of PacBio and produces spurious artifacts. In this study, we have developed a generic and realistic long-read simulator and an automated framework for systematic evaluation of sequencing and variant calling accuracy, in the context of long-read sequencing for germline and somatic mutations. Our simulator works by first extracting a sequencing error profile from real data followed by read generation using the specified genome reference. The output is stored in both FASTQ and H5 formats, allowing downstream processing by pipelines which work exclusively with either format. The simulator is then used in conjunction with the VarSim framework which synthesizes synthetic genomes based on real variations and evaluates germline and somatic variant calling for diploid organisms. This results in an unbiased evaluation platform for a wide variety of tools when applied to long reads. We report an evaluation based on reads simulated with the error profile of PacBio public CHM1 human data. Our simulator will aid researchers in benchmarking tools to extract the most out of their long-read sequencing data.

Fast and accurate variant calling of thousands of human genomes for clinical applications. *G. A. Lunter, A. Rimmer, E. L. S. Sanders, H. T. Tonkrova, S. Trygubenko, S. Weller, G. McVean, M. A. Simpson.* Genomics plc, 52 Cornmarket Street, Oxford, United Kingdom.

Whole-genome and -exome sequencing is fast becoming a standard tool in clinical practice, and many clinical sequencing projects are underway aimed at populating large databases with patient data and their associated genomes. To help unlock the potential of these large data collections, Genomics plc is buildingthe infrastructure to analyze genomic data in a range of healthcare settings. Recognising the need for a highly efficient algorithm to enable processing of hundreds of thousands of genomes using reasonable resources while making no sacrifices to accuracy, we present a haplotype-based variant caller written in C++11 that combines high accuracy with very low CPU, memory and I/O usage. Calling a 30X human genome on a single CPU core takes 4 hours, uses 60 Mb of RAM, and requires just a single pass over the input BAM file, considerably better than other existing tools. We tested our algorithm on several community-standard data sets, including the Genome In A Bottle data, Illumina's Platinum genomes and the naturally haploid hydatiform mole data. The tool's sensitivity and specificity for SNPs andindels exceed those of other community-standard callers. We achieve this performance by usingbespoke error models for homopolymers and other repetitive regions, and for error modes typical of Illumina X10 data,the preferred platform for large-scale whole-genome sequencing. In addition the tool has the functionality to integrate a knowledge base of known variation and systematic data problems to further improve sensitivity and specificity. The tool includes integrated modulesof keyinterestforclinical genome sequencing projects, including modules forcalling of germline de-novo mutations andsomatic variants in cancer samples, the ability to genotype a pre-defined set of variants, and theability to call reference bases toconvey the confidence ofthe absence of mutations known to contribute to disease risk. Variants are reported in standard VCF / gVCF format.

1794F

Whole read overlap assembly accurately detects structural variants now in GRCh38. *A. Mangubat[1], B. Drees[1], J. Bruestle[1], N. Spies[2, 3], E. E. Eichler[4], M. Malig[4], S. N. Shekar[1].* 1) Spiral Genetics, Seattle, WA; 2) Stanford University School of Medicine, Stanford, CA; 3) National Institute of Standards and Technology Genome in a Bottle, Gaithersburg, MD; 4) Genome Sciences, University of Washington School of Medicine, Seattle, WA.

Until now, variant calls for structural variants (SVs) in whole human genome data have been prone to imprecision and high rates of false discovery. Here we show how read overlap assembly to detect variantshas the ability to detect indels and SVs (including larger insertions) with considerable precision and few false discoveries in NA12878 and an Ashkenazi Jewish trio. .

In simulated data and in a previous study using real data by English et al (2015, accepted), the method has been shown to have high sensitivity compared to other bioinformatic SV callers and a false discovery rate of less than 5% when detecting SVs.

Using the Anchored Assembly method on Illumina HiSeq NA12878 data, we detect variants previously reported in the results of the 1000 genomes project, as well as variants that have now been incorporated into the new human reference (GRCh38). In addition, we detect a number of novel SVs, which were confirmed using PacBio sequencing of fosmids (Eichler et al, 2015, in preparation). This confirms that the method can be used to detect variants not otherwise normally detected by other bioinformatic methods on Illumina data.

Using Anchored Assembly on the Ashkenazi Jewish trio sequenced by Personal Genome Project (PGP), we used the tool SVViz to validate the SVs by segregation within the family. Of 10 SVs in the offspring selected at random, all showed consistency of calls and logical segregation within the trio. Anchored Assembly detected a 3. 4kb insertion inherited in the offspring that is a match to an alternate allele assembly now in GRCh38. Given the resolution of this insertion, it was possible to identify the 5 SNPs and an indel within the insertion that were inherited from the father as well as a single SNP inherited from the mother. This level of precision makes Anchored Assembly useful for analyses of a family.

Whole read overlap assembly allows for accurate and precise calls of SVs with low false discovery rates. The ability to compare across samples is particularly useful for identifying variants associated with autism and rare genetic disorders.

1795W

A comprehensive genomics resource for assessingvariant calling accuracy. *M. Mohiyuddin[1], J. C. Mu[1], P. T. Afshar[2], X. Chen[3], N. Baniasadi[1], M. B. Gerstein[4], W. H. Wong[3, 5], H. Y. K. Lam[1].* 1) Bioinformatics, Bina Technologies, Redwood City, CA; 2) Electrical Engineering, Stanford University, Stanford, CA; 3) Statistics, Stanford University, Stanford, CA; 4) Computational Biology and Bioinformatics, Yale University, New Haven, CT; 5) Health Research and Policy, Stanford University, Stanford, CA.

Precision medicine based on high-throughput sequencing requires accurate sequencing algorithms. This necessitates the development of high-confidence and comprehensive human variant sets to accurately assess their performance. Recent works have attempted to provide such resources containing variants of high-confidence but they fail to encompass all major types of variants including structural variants (SVs). For example, the current gold sets of the NA12878 genome contain only SNVs and Indels up to couple hundred base-pairs while the HS1011 male genome gold set only incorporates SVs. To address these limitations, we leveraged the publicly available massive high-quality Sanger sequences of relatively high (9x) coverage for the HuRef genome to construct by far the most comprehensive gold set. We cross validated the gold set with deep Illumina sequencing of 140x coverage, population datasets, and well-established algorithms. Since the published variants for HuRef were mostly reported five years ago with the primary aim of obtaining its genetic makeup, we found multiple issues involving compatibility, organization, and accuracy which prevented their direct use in benchmarking. This necessitated our thorough reanalysis and validation of the HuRef genome which resulted in a gold set with high specificity and sensitivity. Our gold set contains around 3. 5M SNVs, 560K Indels, and 5K SVs (including long insertions) up to a hundred thousand base-pairs, which makes it comprehensive not only in terms of the number of variants but also for the kinds of variants over a large size range. As a demonstration of the HuRef gold set's utility, we use it to benchmark the accuracy of several published SV detection tools. Our gold set as well as related data have been released to public repositories. We further enhanced the comprehensiveness of the call set by identifying thousands of tandem repeats using the Sanger reads. We successfully identified the previously found uVNTR (upstream variable number of tandem repeats) in HuRef's MAOA gene which is associated with antisocial behavior, alcoholism, and impulsivity. As a negative control, we confirmed in our HuRef genome there is no expansion of the polymorphic trinucleotide (CAG)n repeat in the HTT gene which is involved in Huntington disease.

1796T

Utilizing the Genome Analysis Toolkit's (GATK) CalculateGenotypePosteriors to refine sequencing genotype calls based on external population and trio information. *E. Pugh, K. Hetrick, P. Zhang, K. Doheny.* Center for Inherited Disease Research, Institute of Genetic Medicine, The Johns Hopkins School of Medicine, Baltimore, MD.

GATK 3. 3-0 can use population allele frequency data and/or trio information to refine the posterior probability of the genotypes generated by HaplotypeCaller. We hoped to use this to reduce the number of false positive de novo variants seen without losing 'real' de novo variants utilizing a set of 767 whole exome (WES) samples (Agilent® SureSelect™ XT Human All Exon v4, Illumina® HiSeq™ 2000/2500) sequenced as part of our work for the Baylor Hopkins Center for Mendelian Genomics (http://www. mendelian. org/) containing a variety of ethnicities and family structures, as well as whole genome (WGS) data for a Hapmap trio. BAM files were generated using GATK 3 and bwa mem 0. 7. 8. gVCF files were created with GATK 3-3. 0 HaplotypeCaller on baited regions (79 Mb), joint called with GenotypeGVCFs, variant sites filtered with Variant Quality Score Recalibration (VQSR) using Best Practices and then genotypes refined with CalculateGenotypePosteriors using different combinations of supporting external population information (1KG and Exome Aggregation Consortium) and/or pedigree information. Concordance and sensitivity to genotypes generated on a SNP array was calculated for each sample. Mendelian errors were calculated using PLINK. For the WGS data, we compared Mendelian error rate before and after genotype refinement observing a decrease from 0. 6% to 0. 08% and 6% to 0. 15%, for SNVs and indels, respectively. For the trio subset of WES families, the combination of trio and frequency refinement reduced the SNV Mendelian error rate from 0. 20% to 0. 03%, while with trio refinement alone it was 0. 002%. Unexpectedly, for nuclear families with two or three children sequenced frequency and trio refinement reduced the error rate but trio refinement alone did not. Trio refinement alone also resulted in lowering a subset of sequencing quality metrics for a subset of samples. Mean sensitivity to heterozygotes and homozygote concordance were similar across permutations at ~98% and ~99. 5% respectively but mean homozygote concordance dropped significantly for 9 samples when only trio refinement was used. A similar pattern was seen for percent of SNPs in dbSNP 138 with a mean of ~98% with 85 samples falling below 96. 5% for trio refinement alone. Our preliminary investigation suggests that the combination of frequency and trio based genotype refinement may help reduce false de novo calls and we are continuing to explore the application of genotype refinement to WGS and WES data.

1797F

Comparison of alignment strategies for allelic expression imbalance. *C. K. Raulerson[1], M. L. Buchkovich[1], A. Ko[2,3], Z. Xu[1,4], Y. Li[1,4], M. Laakso[5], P. Pajukanta[2,3], T. S. Furey[1,6], K. L. Mohlke[1].* 1) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 3) Molecular Biology Institute at UCLA, Los Angeles, USA; 4) Department of Biostatistics, University of North Carolina, Chapel Hill, NC; 5) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland;; 6) Department of Biology, University of North Carolina, Chapel Hill, NC.

Allelic expression imbalance (AEI) analysis identifies genetically-affected cis-acting regulatory elements at loci implicated in complex diseases. Accurate detection of AEI depends on correctly aligning reads to heterozygous sites. Most aligners only consider mapping to the reference allele at a given locus, leading to an artificially inflated mapping rate for the reference allele. Allele-aware aligners consider both alleles at each heterozygous site, providing equal opportunity for correctly mapping reads containing the alternate allele. The extent to which reference-mapping bias affects RNA-seq alignment is not fully understood. To assess the aligner's contribution to detection of AEI, we evaluated a genotype-independent aligner, STAR (allowing two mismatches), and an allele-aware aligner, GSNAP, by comparing reads mapped both to a reference genome and a complement genome. We used genotypes and adipose tissue RNA-seq data (50 bp paired-end, avg. ~45 million reads) from 8 individuals from the METSIM study. We first aligned reads to the hg19 human reference genome using each aligner. We then created a complement reference genome by converting alleles at heterozygous sites to the non-reference allele and realigned the reads. Reads that aligned uniquely to different locations in these two alignments must be incorrectly mapped in at least one of them. STAR and GSNAP mapped a similar average percentage of reads (89 and 88% of reads, respectively), with greater than 99% of reads mapped to the same location in the two genomes. Using STAR, an average of 0. 19% (±0. 27) of reads mapped to different locations in the reference and the complement genomes, while using GSNAP, an average of only 0. 007% (±0. 0015) of reads mapped differently. This represents a nearly 30-fold decrease in detectable incorrect alignments. In our study, GSNAP required 6-fold more analysis time compared to STAR due to GSNAP's inclusion of known genotypes in the analysis. At disease-associated loci, where allele counts inform our understanding of underlying biology, the increased accuracy at heterozygous sites may prove useful in examining the contribution of regulatory variants. Although the analysis time increased using GSNAP, this allele-aware strategy showed a 30-fold increase in accurate alignments to a subset of heterozygous sites and presumably will detect AEI with greater accuracy.

Decision Tree Machine Learning Approach to Identify Clinically Actionable Copy Number Events. *S. Shams, A. O'Hara, Z. Che, V. Wasnikar.* BioDiscovery, Inc. , Hawthorne, CA.

Clinical case review is focused on identification of potentially pathogenic copy number alterations while excluding common benign copy number alterations (CNA) and frequently observed array-specific artifacts. This includes comparison of the proband sample results with public databases and in-house archived sample results to exclude copy number polymorphisms and to identify previously observed pathogenic changes. Depending on the quality of the results and the complexity of the sample DNA, call classification can become a time-consuming process. We have developed a Variant Interpretation Assistant (VIA) system that uses a decision tree machine learning approach to set up rules for automatic pre-classification of CNA. This sophisticated tool includes pre-classification of CNA based on user specified designations (defaults include benign, likely benign, VUS, likely pathogenic, pathogenic and artifact); The VIA system then uses region specific functions, such as SIMILARITY, OVERLAP, PREVIOUS_SIMILAR_CASES, and POSITION to allow the user to set up lab specific rules. Benign and likely benign regions are pre-classified based on public copy number polymorphism databases and publications, and previous in-house case classification results. Pathogenic and likely pathogenic regions are pre-classified based on overlap with known pathogenic alterations in previously classified in-house case results, as well as public database and publication records. Alterations over a certain length or those which cover specific genes/exons of interest are pre-classified accordingly. VIA tracks results in real time from previously annotated samples to allow for interpretation of newly uploaded samples based on the evolving in-house results archive. Microarray results on mixed array platforms from normal and affected samples were tested with VIA. A set of previously reviewed samples with a mix of benign and pathogenic classified calls was imported into the system. VIA then pre-classified these same samples and the results were compared. All pre-classification results were annotated with the logic used by VIA to keep a complete audit trail of calling. This system was able to correctly identify pathogenic results for affected samples while finding benign results for normal samples. Final results were then auto-reported in ISCN nomenclature. VIA is capable of quickly and reliably classifying CNA from microarray and includes an extensive audit trail for potential regulatory demand.

Modeling *Pseudomonas* DNA Integrations into Stomach Adenocarcinoma. *K. B. Sieber[1], P. Gajer[1,2], N. Kumar[1], J. C. Dunning Hotopp[1,2,3].* 1) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD 21201; 2) Department of Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD 21201; 3) Greenebaum Cancer Center, University of Maryland School of Medicine, Baltimore, MD 21201.

The integration of exogenous DNA into the human genome can produce disease causing somatic mutations. For example, human papillomavirus (HPV) caused ~490,000 cases of cervical cancer in 2002. The integration of HPV DNA into the human genome is a key step to promoting carcinogenesis. In contrast to viral integrations, the instances and repercussions of bacterial DNA integrations into the human genome are less clear. Given that there are 10× more bacterial cells in our bodies than human cells, there is ample opportunity for integration of bacterial DNA into somatic genomes. Previously, using publicly available Illumina sequence data from The Cancer Genome Atlas (TCGA), we identified putative integrations of bacterial DNA in cancer genomes, defined as >4× coverage on the human genome of Illumina paired-end reads with one read mapping exclusively in the human genome and the other read mapping exclusively to bacteria. These data support the specific integration of *Pseudomonas* 16S & 23S DNA into four proto-oncogenes. Here, in order to better understand the structure and sequence of these integrations, we have modeled the most likely configuration of these integrations. These models rely on using the Jensen-Shannon Distance to compare the insert size of the models of bacterial DNA integration with the insert size of the sequencing library. These data support that the integrations are into the 5χUTR near the transcriptional start site of the human genes. Using the model of the bacterial DNA integration into *CEACAM5*, we have constructed the bacterial DNA integration into the human *CEACAM5* promoter in a luciferase reporter construct to test if the bacterial DNA integration may alter transcriptional regulation of *CEACAM5.* Preliminary results suggest *CEACAM5* promoter with the bacterial DNA integrations have altered expression compared to the native *CEACAM5* promoter. This is consistent with our previous observation of higher expression of genes with integrations relative to the same genes without integrations in other stomach adenocarcinoma samples. Further experiments are needed to characterize the other putative bacterial DNA integrations before more general conclusions can be drawn about the effects of bacterial DNA integrations on transcriptional regulation.

SNooPer: a machine learning-based method for somatic variant identification from next-generation sequencing. *JF. Spinella[1], R. Vidal[1], V. Saillour[1], P. Cassart[1], C. Richer[1], M. Ouimet[1], J. Healy[1], D. Sinnett[1,2].* 1) University of Montreal, Centre Hospitalier Universitaire Sainte-Justine Research Center, Montreal, Quebec, Canada; 2) Department of Pediatrics, Faculty of Medicine, University of Montreal, Quebec, Canada.

The advent of next-generation sequencing has allowed unbiased, in-depth interrogation of cancer genomes. Many somatic variant callers have been developed yet accurate ascertainment of somatic variants remains a considerable challenge as evidenced by the consistently weak overlap between algorithms. Statistical model-based algorithms that are currently available perform well under best-case scenarios, e. g. high sequencing depth, homogenous tumor samples, high somatic variant allele frequency (VAF), but only show limited performance with sub-optimal data such as low-pass whole-genome sequencing data. We propose SNooPer, a highly versatile machine learning approach that uses Random Forest classification models to accurately call somatic variants in low-depth sequencing data. SNooPer uses a subset of variant positions from the sequencing output for which the class is known, either true variation or sequencing error, to train the data-specific model. This implicitly requires that a subset of positions be validated on an independent NGS platform or using orthogonal technology. During the training phase, multiple features including measures of quality, coverage and strand bias are extracted from the mpileups files. Features are ranked by information gain and only informative features are used to build the classification model. Using a real dataset of 40 childhood acute lymphoblastic leukemia patients, we show how the SNooPer algorithm outperforms benchmarked algorithms (JointSNVMix2, VarScan2, MuTect), is not affected by limited sequence coverage or low VAFs, and can be used to reduce overall sequencing costs while maintaining high specificity and sensitivity to somatic variant calling, particularly in low-depth sequencing data. While the goal of any cancer sequencing project is to identify a relevant, and limited, set of somatic variants for further sequence/functional validation, the inherently complex nature of cancer genomes combined with technical issues directly related to sequencing and alignment can affect either the specificity and/or sensitivity of most callers. The flexibility of SNooPer's random forest protects against technical bias and systematic errors, and is appealing in that it does not rely on user-defined parameters. The SNooPer source code is freely available for acadamic users, upon request.

Toward assembly-based variation discovery from highly divergent regions. *S. Tian, H. H. Yan, S. Slager.* Mayo Clinic, Rochester, MN.

Whole exome sequencing (WES) has been widely used to identify variants implicated in disease. However, current variant discovery approaches often rely on mapped reads alone and whose efficiency is limited by the gaps, misassemblies and underrepresentation of alternative loci in the reference sequence. Obviously, their performance deteriorates in regions with high sequence variation and large INDELs. The human leukocyte antigen (HLA) at 6p21. 3, for example, is associated with over 100 diseases and well known for its extreme divergence. Fully cataloging variants from such highly divergent regions (HDRs) is clinically important but challenging in practice. A few assemblers have been developed to identify variants through direct variant calling, microassembly or whole genome assembly. Nevertheless, these tools mainly focus on whole genome sequence and their feasibility on WES data remains largely unknown. Here we utilize WES de novo assembly for variant discovery in HDRs. Using exonic regions from Chr6, seven 100-bp datasets were simulated at 0. 05-15% divergence rates that reflect the whole spectrum of genome variation. We compared three popular variation-aware de novo assemblers, Cortex, Fermi and String Graph Assembler (SGA), on simulated data and the 150-bp NA12878 exome data released by the Illumina Inc. In parallel, three haplotype-based callers, GATK HaplotypeCaller, FreeBayes and Platypus, were tested together with BWA or BWA-MEM mapping. On the simulated data, the three mapping-based approaches showed 97% SNP calling sensitivity at low (<=1%) divergence but performed poorly (median 61%) at high divergence. Compared to the mapping-based methods, Cortex had much lower sensitivities, even at low divergence (median 78%). We implemented key enhancements to SGA that was originally designed for the assembly of consensus sequence. Remarkably, SGA achieved excellence in both sensitivity (93. 7-95. 6%) and speed. It showed superior performance across all the divergence rates and over a wide range of coverage depths. Fermi was clearly less sensitive than SGA, especially when coverage is under 100x. We recapitulated our findings on the NA12878 exome data, in which SGA achieved comparable SNP calling sensitivity in the HLA (93. 8%) and non-HLA (94. 1%) regions and identified large INDELs from the capture regions. We conclude that SGA represents an ideal platform for variant discovery in HDRs using WES data and should be generally applicable to the entire genome.

1802T

SuperVario: a Common Repository for Variant Data. *A. S. Wenocur[1], L. Tian[1], K. Nguyen[1,4], P. M. Abou-Sleiman[1,2,3], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Center for Dynamic Data Analytics, Rutgers University, Piscataway, NJ.

In many bioinformatic analysis pipelines, nucleic acid reads are mapped, then submitted to a variant caller. Typically, the variant data are stored in flat files, difficult to use and query by multiple investigators. A common problem encountered is that CNVs, point mutations, indels, SNPs, structural, and other variants are tagged for specific analyses and are not easily shared or retrieved for new *insilico*experiments. A solution to this is a centralized repository for genomic variants, which can accommodate multiple classes of variant data. We have developed a database of variants, allowing researchers to apply custom filters and visualize by frequency in a specialized genome browser. The initial prototype was an instance of Exac Browser, modified to load VCFs produced at our institution. The next phase of development for this repository shall be to integrate it with a more fine-grained filtering framework, allowing it to be extended by a developer on-demand. Currently, SuperVario is an evolving framework unifying several bioinformatics tools into a user-friendly querying and visualization platform. SuperVario will store variant annotations and clinical metadata in RDF format, using a SPARQL framework for querying. This currently supplements the MongoDB data store used by the Exac Browser; however, these two data stores ultimately shall be unified. Subsequent releases of SuperVario are to include a system for load-balancing on the cloud, and a custom binary data store and index format for compact storage and rapid querying.

1803F

Analysing the technical sensitivity of indel detection for molecular diagnostics. *N. Whiffin[1,2], R. Govind[1,2], S. Wilkinson[1,2], E. Edwards[1,2], P. J. Barton[1,2], J. S. Ware[1,2], S. A. Cook[1,2].* 1) National Heart and Lung institute, Imperial College, London, UK; 2) NIHR Cardiovascular BRU, Royal Brompton and Harefield NHS Trust, London, UK.

While insertions and deletions (InDels) are known to play a large part in the genetics of human disease, they remain difficult to identify accurately from short-read sequencing data. Different InDel callers have small overlap and particularly struggle with repetitive stretches of DNA. This issue is of particular importance in a diagnostic setting where high sensitivity of variant calling is crucial. To elucidate which of the constantly expanding catalogue of calling algorithms should be used in our diagnostic pipeline, we compared the sensitivity and specificity of six commonly used algorithms (GATK UnifiedGenotyper, GATK HaplotypeCaller, Pindel, Platypus, VarScan2 and Scalpel) across 169 genes sequenced in 89 individuals. In total, 510 InDels were identified in protein coding regions, with 29. 8% identified by all six callers, and 15% identified by only one. Of 22 InDels found uniquely in one sample, 10 (45. 5%) were consistently called by all six callers. The remaining 12 InDels were significantly longer than those universally identified by all algorithms (9. 6 and 3. 5 bp respectively; Wilcoxon P=0. 028), reflecting known difficulties detecting larger InDels. Validation by Sanger sequencing revealed 10 of the 12 inconsistently called InDels to be true variants, including two InDels over 20 bps long. Only HaplotypeCaller and Pindel successfully identified these two large InDels. Overall, HaplotypeCaller showed the best performance, calling all 10 validated InDels (100% sensitivity) and only one false positive. Currently, a barrier to using HaplotypeCaller in diagnostics is the commercial licence fee. Here, we find that using a combination of other callers, including Pindel, the same high sensitivity can be achieved. Previous comparisons of indel callers have often been based on only two callers. We present a comprehensive analysis of up-to-date software solutions. Furthermore, we use real, rather than simulated, data and specifically focus on InDel calling in a diagnostic setting. It is hoped this work will guide scientists in both research and diagnostic settings when choosing a variant caller to identify InDels in sequencing data. *This abstract presents independent research commissioned by the Health Innovation Challenge Fund (HICF-R6-373), a parallel funding partnership between the Department of Health and Wellcome Trust. The views expressed in this publication are those of the authors and not necessarily those of the Department of Health or Wellcome Trust. .*

1804W

ScanIndel: a hybrid framework for indel detection via gapped alignment, split reads and *de novo* assembly. *R. Yang[1], A. C. Nelson[2], C. Henzler[1], B. Thyagarajan[2], K. A. T. Silverstein[1].* 1) Supercomputing Institute for Advanced Computational Research, University of Minnesota, Minneapolis, MN; 2) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN.

Comprehensive identification of indels across the full size spectrum from second generation sequencing is challenging due to the relative short read length inherent in the technology. Different indel calling methods exist but are limited in detection to specific sizes with varying accuracy and resolution. We present ScanIndel, an integrated framework for detecting indels with multiple heuristics including gapped alignment, split reads and *de novo* assembly. Using simulation data, we demonstrate ScanIndel's superior sensitivity and specificity relative to several state-of-the-art indel callers (including Pindel, GATK HaplotypeCaller, Platypus and Scalpel) across various coverage levels (10X, 20X and 50X) and indel sizes (1 bp to 1 kbp). ScanIndel yields higher predictive accuracy with lower computational cost compared to Pindel for both targeted resequencing data from tumor specimens and high coverage whole-genome sequencing data from the human NIST standard NA12878. Thus we anticipate ScanIndel will improve indel analysis in both clinical and research setting.

1805T

ConVarCal: A Reliable and Robust Platform for Next-Generation Sequencing Variants Identification. *Y. Zheng[1], T. F. Yoshimatsu[1], A. Rodriguez[2], R. K. Madduri[2], P. J. Dave[2], O. I. Olopade[1].* 1) Department of Medicine, The University of Chicago, Chicago, IL 60637; 2) Computation Institute and Argonne National Laboratory, The University of Chicago, Chicago, IL 60637.

Background: In the era of next-generation sequencing (NGS), enormous volume of single nucleotide variants (SNVs), insertions and deletions (Indels), and structural variants (SVs) can be identified at both individual and population levels. To minimize the false positive/negative detection rates, to gain better variant annotation, and to curtail the bottleneck inherent to processing of Big Data, we developed ConVarCal (Confident Variant Calling), a platform for NGS variants identification. **Methods:** ConVarCal integrates multiple NGS reads aligners, variant callers and annotator in a malleable manner using the elastic computing capability of Globus Genomics built upon Amazon Web Services. Raw data (e. g. FASTQ) can be safely transferred via Globus Online and automatically fed into ConVarCal for BWA-MEM or Bowtie2 alignment. The resulting BAM files can be processed by highly parallelized variant calling pipelines, including GATK HaplotypeCaller, Platypus, FreeBayes, SAMtools mpileup, and Atlas2. To realize dynamic parallelization of some callers, wrapper scripts using Swift language are implemented. The output VCF files can then be normalized before employing the Consensus Genotyper to select a set of highly confident SNVs and Indels. SVs can also be detected using tools such as Delly and CONTRA. Variants can be further annotated on ANNOVAR. **Results:** Here we elucidate the performance of ConVarCal by analyzing germline BROCA cancer risk panel sequencing data (Illumina 2500 paired-end, 1. 3Mbp targeted regions, ave. depth of 260x) in a test dataset of 200 Nigerian breast cancer patients with family history and/or early age at onset. FASTQ files (ave. 1. 65 GB per sample) were transferred across continental USA in about 3 minutes per sample at each interval. The entire analysis of 200 samples on ConVarCal were completed in one to two days, depending on the configuration and resource availability of cloud computing. Among 5 callers, ConVarCal confidently identified 14 deleterious SNVs and 11 damaging Indels (*BRCA1*: 15, *BRCA2*: 4, *PALB2*: 2, *BRIP1*: 1, *CHEK2*: 1, *NBN*: 1, *TP53*: 1) in 29 subjects, including the 16 previously known mutations detected by Sanger sequencing. **Conclusion:** ConVarCal takes full advantage of Globus Genomics for NGS variant detection in a reliable and robust manner. It is scalable for larger tasks, and modular to adapt more tools. New tools like FermiKit, VarScan2, Lumpy, and MetaSV are currently being optimized to further enhance our platform.

A comprehensive SomaticSeq workflow to prioritize biologically relevant somatic mutations in cancer. *L. T. Fang, A. Chibber, M. Mohiyuddin, J. C. Mu, G. Gibeling, S. Barr, N. Bani Asadi, H. Y. K. Lam.* Bina Technologies, Roche Sequencing, Redwood City, CA 94065.

Cancers are diseases of the genome. Accurately identifying somatic variants between the tumor and matched normal tissue is critical in understanding cancer biology. There is a plethora of software tools designed to detect many types of somatic changes occurring in tumor-normal sequencing experiments, such as somatic single nucleotide variations (SNVs), small insertions/deletions (INDELs), copy number aberrations (CNAs), and structural variations (SVs).

We previously presented SomaticSeq, a workflow that incorporates an ensemble of algorithms for SNV and INDEL detection. It implements a stochastic boosting machine learning algorithm to drastically improve accuracy of the combined call sets, and have achieved excellent results in a variety of simulated and real data. We obtained F1 score above 95% in partially synthetic DREAM Challenge data and recalls above 90% in publicly available data from European Genome Archive (EGA), better than any individual algorithm that we have incorporated.

In this study, we expandSomaticSeq to detect somatic copy number aberrations and structural variations in tumor-normal whole genome sequencing data. It incorporates methods such as Control-FREEC, OncoSNP-SEQ, Seq2C, CNVkit, and CREST. It also merges the somatic SV/CNA results with SNV/INDEL to reflect different somatic changes to the same gene. Control-FREEC and OncoSNP-SEQ are designed to detect large-scale somatic CNAs (10 kbps to whole chromosomes) in whole genome sequencing, whereas Seq2C and CNVkit are better suited for whole exome or targeted sequencing. CREST is capable of detecting medium-scale SVs (> 50 kbp) with exact breakpoints in whole genome sequencing. Thus, the comprehensive SomaticSeq workflow has tools capable of detecting somatic variants of any scale.

The comprehensive SomaticSeq allows cancer researchers to specifically prioritize for genes with somatic changes of different types, or where multiple changes have occurred within the same gene. For each gene, the researchers can find somatic mutations, copy number aberrations, structural variations, and use these genetic contexts to infer its biological significance. We have used a number of publicly available datasets from TCGA and EGA as test cases to demonstrate its ability and accuracy performance.

Identification of novel tumor suppressor candidates in familial cholangiocarcinoma using sequencing-based Megabase-scale haplotypes from germline and cancer genomes. *S. Greer[1], L. Nadauld[2], B. Lau[1], E. Hopmans[1], C. Wood[3], J. Bell[1], H. Ji[1,3].* 1) Stanford Genome Technology Center, Stanford University, Stanford, CA; 2) Intermountain Healthcare, Salt Lake City, UT; 3) Dept of Med/Oncology, Stanford University, Stanford, CA.

Cholangiocarcinoma (bile duct cancer) is an epithelial malignancy originating from the bile duct that connects the liver to the small intestine. Only recently has the molecular genetic underpinnings of this cancer been explored with a number of genome sequencing studies of a limited number of primary tumors. In this study, we sought to identify potential susceptibility genes that have not yet been described and whose germline variants are associated with an increased familial risk of cholangiocarcinoma. We characterize the genome wide variants from multiple members of an extended pedigree with an early onset of cholangiocarcinoma and an inheritance pattern phenotypically consistent with autosomal dominance. As haplotype-resolved genomes of pedigrees would provide higher confidence of Mendelian segregation patterns, we demonstrate for the first time the application of experimentally-derived Megabase-scale haplotypes and phased genome analysis to identify Mendelian disease loci. Our approach relies on a novel technology where individual high molecular weight DNA molecules up to and greater than 50 kb in size are used to experimentally derive haplotypes from whole genome sequencing. This phasing technology uses droplet-partitioned barcodes to tag individual DNA sequence reads. Thus, these barcode sequences can be linked to individual DNA molecules of high molecular weight. This approach enables the genetic phasing of large groups of variants (“phase blocks”) on a Megabase scale. This approach also provides a means to validate structural variant (SV) and copy number variant (CNV) calls from whole genome short-read data. Using this phasing approach in combination with traditional whole genome shotgun sequencing, we analyzed the extended pedigree for germline variants as well as some primary cholangiocarcinomas. We identify haplotypes that co-segregate with affected family members and several novel candidate genes with germline mutations with a predicted deleterious effect. These represent novel loci. Somatic variant analysis of the tumor samples, specifically considering SVs and CNVs, was used to identify driver mutations that may work in concert with candidate germline mutations to initiate and maintain tumorigenesis. Overall, our study has significant implications by shedding light on the genetic basis of cholangiocarcinoma, as well as providing a general method for discovering novel variants and determining its haplotyped segregation in pedigrees.

Towards reliably detecting structural variants with nanopore sequencing. *A. L. Norris[1], R. E. Workman[2], J. R. Eshleman[1], W. Timp[2].* 1) Pathology and Oncology, The Sol Goldman Pancreatic Cancer Research Center, Johns Hopkins School of Medicine, Baltimore, MD; 2) Biomedical Engineering and Medicine, Center for Epigenetics, Johns Hopkins School of Medicine, Baltimore, MD.

Despite advances in 2nd generation DNA sequencing (e. g. Illumina), structural variants (SVs) are difficult to reliably detect due to the short read length (<300bp). Not only do the reads – or paired-end reads – need to straddle a breakpoint,but repetitive elements often lead to ambiguities in the alignment of 2nd generation sequencing's short reads. Given that repetitive DNA regions (including centromeres, telomeres, and other repetitive elements) encompass over half (56%) of the human genome, this is a significant concern when mapping SVs. We propose to use the long-reads (~20kb) available via 3rd generation sequencing, specifically nanopore sequencing on the MinION, to detect SVs. Nanopore sequencing relies on a similar concept to a Coulter counter, reading the DNA sequence from the change in electrical current resulting from a DNA strand being forced through a nanometer size pore embedded in a membrane. Though 3rd generation sequencing has a high mismatch rate, precluding base substitution and small frameshift mutation detection, the long reads are superior to 2nd generation sequencing for SV detection. We have tested nanopore sequencing for detection of a series of previously characterized SVs, including large deletions, inversions and translocations that inactivate the *CDKN2A* (*p16*) and *SMAD4* (*DPC4*) tumor suppressor genes. Using PCR amplicon mixes, we have demonstrated that nanopore sequencing can detect large deletions, translocations and inversions at dilutions as low as 1:100, with as few as 500 reads per sample. Given the speed, small footprint and low capital cost of nanopore sequencing, nanopore sequencing could become the ideal tool for the low-level detection of cancer-associated SVs needed for molecular relapse, early detection of cancer, and therapeutic monitoring.

1809F

Finding the fastest route to the right answer: optimizing detection of mutations, copy number changes, and loss of heterozygosity in a single sequencing assay. *B. Peter[1], K. S. Jeong[2], A. Ashutosh[2], C. Le Cocq[2], A. Vadapalli[2], D. Joshi[2], D. Roberts[2], J. Ghosh[2].* 1) Agilent Laboratories, Agilent Technologies, Santa Clara, CA; 2) Diagnostics and Genomics Group, Agilent Technologies, Santa Clara, CA.

Although the cost of Next Generation Sequencing has fallen, there remains a need to improve extraction of the most actionable information, in a more cost and time efficient manner. Different genome variations have different requirements for detection. Sensitive and accurate detection of Single Nucleotide Polymorphisms and Variants (SNPs, SNVs) requires deep coverage with a high number of sequencing reads. However, detection of Copy Number Variation (CNV) and of Loss-of Heterozygosity (LOH) requires broad coverage across the genome. Whole Genome Sequencing (WGS) has the potential to detect the full range of aberrations, but the cost, data analysis burden, and slow turnaround time of deep coverage WGS prevent it from being efficient for clinical research. Target enrichment panels can concentrate sequencing data on regions of interest, but any aberrations falling outside those regions are missed. We created OneSeq, a single sequencing assay combining broad and deep coverage, to generate the most relevant information in the shortest amount of time. First we introduce a genome-wide target enrichment strategy which allows deep coverage on specific regions of interest, while detecting CNVs and LOH across the entire genome. This assay compares an experimental sample to a known diploid reference sample to detect copy number changes. Specific regions of interest, such as disease associated genes, can be targeted by custom SureSelect panels added to the catalog SureSelect backbone panel for higher coverage, allowing sensitive detection of mutations and indels. Second, new computational methods vastly improve the analysis pipeline and reduce result turnaround time from days to hours. Starting with the sequence files, the SureCall desktop software performs an extremely parallelized pipeline composed of optimized BWA-MEM (Li H. 2013), pre-processing, SNP calling and other Agilent algorithms. Typical processing time on a Windows workstation (3GHz/12GB RAM) for a 175M read pairs data set (2x4GB) is only two hours, including alignment, file conversions, SNV, CNV, and LOH calling, annotations, and report generation. We validated this new method on samples with various sizes of known chromosomal aberrations, and compared results to data obtained by low-pass WGS and several microarray platforms. The OneSeq assay, using the fast analysis pipeline, accurately detected the confirmed aberrations in every sample, and simultaneously provided information on SNPs and LOH regions.

Next-Generation Sequencing Carrier Screen for Alpha Thalassemia Identifies Both Common and Rare Variants. *J. R. Maguire, K. M. D'Auria, H. H. Lai, X. Wang, C. S. Chu, I. S. Haque, E. A. Evans, H. P. Kang, D. Muzzey.* Counsyl, South San Francisco, CA.

INTRODUCTION: Alpha thalassemia (AT)—one of the most common recessive diseases—is characterized by deficient production of alpha globin from the *HBA1* and *HBA2* genes, which have identical tandem coding sequences. Carrier status depends not just on the total number of *HBA* copies in the genome, but also on copy number per chromosome. Current screening methods for AT are low-throughput and high cost, plus they either cannot reflect the underlying locus architecture or have a low signal-to-noise ratio that makes them error prone. We developed an NGS-based assay that identifies all of the major large deletional variants—including the phase and copy number of *HBA1* and *HBA2* genes—as well as SNPs and short indels, giving it a detection rate near 100%. The assay is entirely automated and could, in principle, process thousands of AT samples on a single Illumina RapidRun flow cell.

METHODS: We designed both specific and degenerate hybrid-capture probes that tile the *HBA* locus on Chr16. Depth at each *HBA* probe was normalized to the depth at probes out of the *HBA* region, where average copy number is two, yielding a copy-number profile. *HBA* phase and copy number was resolved by comparing the observed profile against the set of expected profiles for all common deletional variants. The copy number at each position informed which allele frequency to expect during SNP- and indel-finding. During validation, we confirmed results using MLPA.

RESULTS: A validation study with normal, carrier, and affected samples showed perfect concordance between our NGS assay and MLPA. We have since run the assay on nearly 150,000 clinical samples with carrier rates consistent with published literature. For carriers with two *HBA* copies, the assay resolves cis vs trans orientation of the *HBA* genes and, in the cis case, identifies the best-matching ethnic origin of the deletion. Further, it reveals silent carriers who nevertheless have four total *HBA* copies, where the duplicated and deleted genes have different chromosomal offsets. Finally, though most samples have four copies of the *HBA* genes, many have far more copies, and we have observed more than six copies in several samples.

CONCLUSIONS: AT carrier status can be assessed at a nearly perfect detection rate with an automated, inexpensive NGS-based assay. The confidence of calls is substantially greater than MLPA can achieve, and obtaining the same confidence from a SNP array would require that fully half of the chip be devoted to AT alone.

1811T

Confirming Variants Discovered by Next Generation Sequencing (NGS) with Sanger Sequencing Using Innovative Bioinformatics Tools. *E. H. Schreiber, S. Berosik, M. Wenz, S. Chang, J. Zhu, J. Zhang, P. Brzoska.* Genetic Sciences Division, Thermo Fisher Scientific, South San Francisco, CA.

Next-generation sequencing (NGS) analyses have revolutionized our understanding of biological processes. In many basic science or applied research studies, substantive insights have been made by comparing the primary DNA sequence of genes in different groups of subjects. In such studies, researchers attempt to identify the role that variations of nucleotide sequence between the groups may play in disease susceptibility, disease progression, or phenotypic variation. The accurate identification of sequence variants is therefore instrumental in insuring successful experimental outcomes. However, the library preparation and chemistries used in NGS technologies are prone to low, but detectable, levels of sequencing errors that can lead to confusing or incorrect interpretations. Therefore, many labs confirm potential variants identified by NGS by using an orthogonal method such as Sanger-based sequencing: polymerase termination with fluorescent dideoxynucleotides followed by sequence collection on automated Capillary Electrophoresis (CE) instruments. This is a robust and inexpensive method with chemistries and analysis tools that are easy to use and well understood – and due to its high accuracy and ease of data interpretation is considered as the gold standard for DNA sequence analysis. It is therefore an ideal system for validating variant calls made on NGS platforms. To streamline the validation workflow we have developed a web-based Primer Designer tool for PCR and Sanger sequencing that provides pre-designed PCR primer pair sequences for almost all exons in the human exome in an easy to search format. Using these primers researchers can readily PCR amplify and Sanger sequence variants of interest discovered by NGS. The resulting Sanger sequencing data (. ab1 files) can then be analyzed and compared against the NGS vcf variant file using a novel software termed NGC (next generation confirmation). The software aligns the NGS variant finding directly with the variant found in the Sanger sequencing trace for visual inspection and produces a consolidated report for matches or mis-matches as well as a joint vcf file with genome coordinates for downstream bioinformatic processing. In conclusion, the Primer Designer and NGC analysis tools enable a seamless workflow for NGS variant confirmation by traditional Sanger sequencing.

Detecting Single Exon Deletions in Clinical Whole Exome Sequencing. *T. Chiang[1], P. Liu[2], T. Gambin[2], S. White[1], S. Matakis[4], M. Dahdouli[1], P. Panchal[1], Y. Ding[1], C. Shaw[2], S. Wen[2], W. Bi[2], F. Xia[2], N. Zhiyv[2], R. Person[2], M. Walkiewicz[2], J. Scull[2], J. A. Rosenfeld[2], Z. H. C. Akdemir[2], A. Hawes[1], W. Salerno[1], N. Veeraraghavan[1], D. M. Muzny[1,2], S. E. Plon[1,2], J. R. Lupski[2], C. Eng[2], A. L. Beaudet[2], M. Bainbridge[1], E. Boerwinkle[1,3], Y. Yang[2], R. A. Gibbs[1,2].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, 77030; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, 77030; 3) Human Genetics Center, University of Texas Health Science Center, Houston, TX 77030; 4) Baylor Miraca Genetics Laboratories, Baylor College of Medicine, Houston, TX 77021.

Clinical Whole Exome Sequencing (WES) is becoming routine for the identification of pathogenic variants underlying genetic diseases. Copy Number Variation (CNV) is also often associated with human genetic disease, but routine detection of CNVs in WES remains a challenge. Even the conceptually more straightforward problem of reliable detection of homozygous or hemizygous deletions is not fully solved. We therefore developed methods to reliably detect exon deletions from WES data in a clinical setting. Previous read depth-based approaches for calling WES CNVs have either utilized a match-control set of samples as a reference baseline, or employed analysis on a cohort of samples as a single independent study. Here, we observed that the growing collection of samples from our clinical laboratory that were sequenced with identical methods could be used as the baseline sample of reference. Incoming new samples are therefore added to the reservoir and analyzed within this context. We used a dual normalization approach, consisting of PCA-XHMM intermediates and RPKM Read Depth (RD) values to call deletions. The former is centered by exon on a z-score scale whereas the latter is normalized at the sample level. Both methods remove exons with GC and low complexity biases from the analysis. Complete homozygous/hemizygous exon deletions are called using a strict filtering criterion. In sum, 6477 exomes were analyzed and a total of 2440 single exon deletions (1110 genes) were called in 11% of the samples (median:11 genes/sample). OMIM disorders are associated with 195 of these candidate genes (18%). The majority of samples (80%) contained deletions in only one gene. Incorporating the deletion analysis in known disease genes has boosted the diagnostic rate. In addition, new disease gene discoveries can potentially be made from these data. To extend these methods to reliable detection of heterozygous deletions, we profiled a subset of samples and found that while most exons displayed a normal RPKM distribution, a subset of exons displayed a bi-modal distribution, which is suggestive of polymorphic heterozygous deletions or duplication events. They were flagged as candidate CNVs for further investigation. In a profile screen of 1825 exomes, we report 7335 such candidate genes (22% are OMIM genes) in 1683 samples (92%). Current efforts are aimed at fully resolving these events in order to obtain higher specificity and sensitivity of the overall routines.

1813W

BioNano nanochannel-based genome mapping can detect large pathogenic CNVs on chromosome 22q11. 2 and describe genome architecture in humans. *R. R. Haraksingh, A. E. Urban.* Depts. of Psychiatry and Genetics, Stanford University, Palo Alto, CA.

We used nanochannel-based mapping of 150+ kb fragments of genomic DNA (Bionano Irys platform) to detect large, disease associated CNVs in the human 22q11. 2 locus. The protocol involves linearizing, nick-labeling and uniformly stretching extremely long fragments of unamplified genomic DNA into nanochannels, thereby preserving the long-range architecture of the genome without amplification bias. Massively parallel single molecule visualization via optical flow-through imaging of these DNA molecules is used to create a physical map of the genome and resolve CNVs even within segmental duplications (SegDups). Bionano mapping has been used previously for a variety of bacterial, plant, normal human and cancer genomes, but not yet in cases of large CNVs associated with developmental disorders. Detecting large-scale CNVs in the human genome is paramount for biomedical research and clinical cytogenetics. Currently, CNVs are detected using hybridization-based methods and short-read sequencing-based methods. These methods are largely adequate but have limited detection power in highly repetitive regions of the genome and are subject to genome amplification, hybridization, and coverage biases. Further, current methods often do not provide sufficient positional context for large CNVs, in particular novel insertions or CNVs with breakpoints in SegDups. Determining the relative positions of large-scale structural variants in the genome is necessary to elucidate their functional impact. We used the Bionano protocol to assemble genome maps for three patients in the NIMH Molecular Genetics of Schizophrenia cohort. Two of these genomes are known to contain 2. 5 Mbp duplications and the third contains a 2. 9 Mbp deletion at chromosome 22q11. 2. Large CNVs in this locus are strongly associated with morphological abnormalities and neuropsychiatric disorders such as Schizophrenia and Autism. Bionano analysis resolved the structure of the 22q11. 2 locus in all three genomes. DNA molecules that unambiguously mapped to the reference genome were used to determine copy number by a computational approach analogous to read depth analysis to resolve the duplications and deletion. Molecules that did not uniquely map to the reference genome were retained for 'split read' analysis to further determine the genome architecture at this locus. Nanochannel based genome analysis represents a novel tool for detecting large disease-associated CNVs, even in complex regions of the human genome.

1814T

panelcn. MOPS reaches clinical standards as a CNV detection tool for targeted panel sequencing data. *V. Haunschmid[1], G. Povysil[1], J. Vogt[2], K. Wimmer[2], G. Klambauer[1], S. Hochreiter[1].* 1) Institute of Bioinformatics, Johannes Kepler University Linz, Linz, Austria; 2) Division of Human Genetics, Medical University Innsbruck, Innsbruck, Austria.

Targeted panel sequencing is becoming increasingly important as a cost-effective strategy to identify disease-causing variants in clinical and research applications. While various copy number variation (CNV) detection methods exist for whole-genome and whole-exome sequencing data, highly accurate methods for panel sequencing data that are suitable for clinical purposes are still missing. The challenges with this kind of data are the small size and number of target regions as well as their uneven coverage. For clinical applications a method should furthermore be able to detect both short CNVs affecting only single exons or even just parts thereof as well as longer CNVs that affect multiple exons or even an entire gene. We present panelcn. MOPS for copy number detection which extends our previously developed method cn. MOPS to targeted panel sequencing data. The method is well suited for this type of data since it can estimate technical and biological characteristics influencing the read counts of each targeted region by a mixture of Poissons model. The design of the count windows, the read counting procedure, the parameters of the model and the segmentation algorithm have been optimized for targeted panel sequencing. cn. MOPS supplies integer copy numbers together with probabilities which inform users about the reliability of the copy number estimates. We have tested panelcn. MOPS on simulated and real sequencing data. On 240 simulated data sets, that resembled the characteristics of targeted panel sequencing data, panelcn. MOPS has reached an average accuracy of 99. 96%. The real sequencing data was enriched with the TruSight cancer panel that targets 94 cancer predisposition genes including NF1/2, BRCA1/2 and APC. panelcn. MOPS detected 100% of CNVs known from previous MLPA analyses without any false positives. The size of the CNVs ranged from an 80bp deletion starting in the intron and affecting only part of one exon over duplications of several exons to deletions of 350kb affecting the entire gene. These results show that CNVs in targeted panel sequencing data can accurately be predicted with panelcn. MOPS. Consequently additional biotechnologies to detect CNVs, such as MLPA, can be omitted in order to reduce time and costs.

1815F

***i*PsychCNV: A robust method for copy number variation detection on dried blood spots.** *J. H. Thygesen[1,2], M. Bertalan[1], S. Weinsheimer[1], W. Mazin[1], T. Sparsø[1], T. Werge[1].* 1) Mental Health Centre, Sct. Hans and, Roskilde, DK, Research Institute of Biological Psychiatry, Psychiatric Center Sct. Hans, Roskilde, Denmark; 2) Neuroscience of Mental Health Department, Division of Psychiatry, University Collage London.

Dried blood spot (DBS) has been collected in Denmark for over 30 years, offering uncountable possibilities for population genetics studies. However, DBS genomic analysis offers unusual challenges, which current methods for copy-number variation (CNV) detection are not designed to handle. Existing methods predict large number of false positive CNVs on DBS data, making association analysis infeasible. Here we describe a novel methodological approach, *i*PsychCNV, the first tool designed to predict and analyze CNVs from DBS genomic data obtained via Illumina SNP array. *i*PsychCNV outperforms the widely used algorithm PennCNV on three datasets with different source of genomic DNA: whole blood, DBS and mock data (simulating DBS). Direct comparison of matched whole blood vs. DBS data from four samples reveals that PennCNV and *i*PsychCNV have a ratio of 0. 75% and 45% of true positives, respectively. To evaluate the methods specificity and sensitivity, we generated mock data that simulates 800 different CNV combinations found in Infinium PsychArray BeadChip (Illumina) from DBS data. On mock data, PennCNV has poor performance with 0. 65 area under the ROC curve (AUC), when compared to *i*PsychCNV which has excellent performance of 0. 92 ROC AUC. Traditional CNV prediction methods perform poorly because they rely mostly on Log R ratio signal, which on DBS data can have three times higher standard deviation than observed from whole blood. *i*PsychCNV takes full advantage of B allele frequency distribution, whereby false positive CNVs are reduced. The *i*Psych project includes 80,000 DBS samples from five psychiatric diseases and controls; therefore program functions are designed to manage large datasets, like searching for CNV hotspots, which summarize genomic regions that are more relevant for a specific disease. A support vector machine (SVM) model can be constructed using selected variables from CNV hotspot regions, increasing true positive calls. *i*PsychCNV can improve existing CNV call from other programs by using B allele frequency, hotspots and SVM. *i*PsychCNV is a R package easily installed, implemented and efficiently executed using multiple cores. It performs well for different datasets, offering a robust alternative to the existing CNV prediction methods. *i*PsychCNV is publicly available on Github as an open source project: https://github. com/mbertalan/iPsychCNV.

1816W

The NIH Undiagnosed Diseases Program approach to prioritizing variants from genome-scale sequencing. *D. R. Adams[1,2], C. Lau[2], B. N. Pusey[2], W. Bone[2], E. Valkanas[2], C. Tifft[1,2], C. Toro[2], W. A. Gahl[1,2], T. Markello[2].* 1) NHGRI, NIH, Bethesda, MD; 2) Undiagnosed Diseases Program, NIH, Bethesda, MD.

The NIH Undiagnosed Diseases Program (UDP), now its 8th year, uses a wide variety of resources to make diagnoses and nucleate research for individuals with challenging undiagnosed diseases. Genome-scale sequencing has proven to be a valuable tool for both pursuits. Typical UDP study participants have been evaluated extensively before arrival. Prior evaluations often include targeted sequencing, gene panels and/or clinical exomes. As a result, most genome-scale sequencing results produced by the UDP do not have readily interpretable clinical significance. Instead, they form a body of starting points for research into new diseases and atypical disease presentations. Prioritization of these promising but non-diagnostic DNA sequence variants remains a persistent challenge. Our approach to the selection of research candidates incorporates individualization of cases beginning with the selection of target family members. A particular emphasis is placed on phenotyping genetically informative relatives. SNP chip data is used extensively both for copy number variant detection, recombination mapping and other procedures. Once sequencing is complete, called variants are culled by automated analysis followed by manual curation of BAM file data for each finding. The list of manually curated variants is then sorted by senior bioinformatics staff based on known-disease implication of the associated gene and other bioinformatic characteristics. Finally, a multidisciplinary meeting is used to discuss each variant. The meeting includes the clinicians who evaluated the patient, the bioinformatics staff who processed the data and selected members of the UDP translational laboratory who will be tasked with performing follow up validation experiments. Variants are ranked based on multiple parameters including potential phenotypic match, research tractability, resource utilization, and expertise availability (both local and via collaboration). Finally, variants are placed into one of three categories: high interest variants suitable for immediate action, medium interest variants suitable for promotion through match-making websites and low interest variants that will be included in routine dbGaP submissions only. We present a case-based description of our ongoing efforts to optimize this process and hope that it will contribute to a generalized discussion of frameworks for evaluating research-level sequencing findings.

Background: Whole-exome sequencing (WES) is a useful method for identifying disease-causing mutations. However, often no candidate mutations are identified using the commonly available targeted probe sets. In a recent analysis, we also could not find candidate mutations for 20. 9% (9/43) of our pedigrees with a congenital neurological disorder using pre-designed capture probes (SureSelect V4 or V5). One possible cause is that standard WES does not sequence all protein-coding sequences (CDS) due to capture probe design and regions of low coverage, which account for approximately 10% of all CDS regions. **Methods:**We combined a selective circularization-based target enrichment method (HaloPlex) with a hybrid capture method (SureSelect V5; WES) to increase the coverage of CDS regions and identify pathogenic mutations for pedigrees with no candidates through standard WES analysis. We designed a probe set for complementary custom CDS sequencing (CCCS), and applied this combination approach to 7 (SureSelect V5) of the 9 pedigrees. These 7 pedigrees are families with a congenital neurological disorder (microcephaly,lissencephaly,ventricular dilatation,bilateral perisylvian polymicrogyria(BPP) and/or hydrocephaly). **Results:**The combination method predicted a 98. 6% coverage of CDS regions by probe design and produced an observed coverage, with read depth $\geq$10, of 97. 4%. We identified novel pathogenic mutations in one pedigree with microcephaly (OMIM #608716) using this combination method. The mutation was composed of two nonsense variants in *ASPM* gene, c. 8098C>T [p. R2700*] and c. 10168C>T [p. R3390*], identified through WES and CCCS analysis, respectively. The variant call of latter locus was missed in standard WES as the region had low read depth (<10) in all samples. The variants were validated for all six individuals in the family using Sanger sequencing. The parents were carriers of one variant each, the unaffected children showed no mutations and the mutations were identified in both the affected children. **Conclusion:**Our combination method of WES and CCCS contributed to an increase in the coverage of CDS regions (97. 4%) and successfully identified a novel pathogenic mutation. We believe that this combination method will contribute to the identification of novel causative mutations, which are inaccessible by current pre-designed standard WES analysis, and to a greater understanding of mechanisms behind, and therapies for, disease.

Trans-ethnic analysis of complex traits: analysis approaches by the Population Architecture Using Genetics and Epidemiology (PAGE) II Study. *S. Rosse[1], N. Zubair[1], A. Martin[2], R. Walker[3], J. Kocarnik[1], G. Wocjik[2], C. Gignoux[2], M. Graff[4], L. Xia[5], N. Franceschini[4], C. Haiman[5], U. Peters[1], R. Loos[3], C. Kooperberg[1], E. Kenny[3], C. Carlson[1], Population Architecture using Genomics and Epidemiology Phase II (PAGE II).* 1) Public Health Genetics, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 3) Preventive Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Gillings School of Global Public Health, University of North Carolina, Chapel Hill, NC; 5) Keck School of Medicine, University of Southern California, Los Angeles, CA.

The Population Architecture using Genomics and Epidemiology, Phase II (PAGE II), Study was initiated in 2013 by the National Human Genome Research Institute to expand our understanding of well-replicated genetic disease associations in several large, ethnically diverse and well characterized population-based studies. PAGE II investigators harmonize phenotypes across studies and perform genetic analyses on a variety of outcomes. Approximately 1. 5 million variants will be genotyped in up to 51,750 DNA samples from African-American, Hispanic/Latino, Asian/Pacific Islander, and American Indian participants. Our objective was to design a genotyping platform that would allow genetic characterization of multiethnic samples in order to refine genetic associations with metabolic, cardiovascular, renal, inflammatory, anthropometric, and lifestyle traits. While PAGE II will perform 'agnostic' genomewide scans, we also customized the MultiEthnic Genotyping Array (MEGA Chip), for functional discovery by prioritizing known risk loci, clinically relevant mutations, putative risk alleles, and other functionally important variants. The custom content included on the MEGA Chip will allow researchers to prioritize likely functional variants for laboratory follow-up and identify new independent alleles positioned in known disease loci. MEGA Chip is comprised of a backbone containing Illumina's Humancore array with approximately 300,000 variants, the standard Illumina exome content of approximately 240,000 variants, the African Diaspora chip (700,000), a multiethnic GWAS scaffold (360,000), multiethnic exomic content (200,000), and over 50,000 custom content variants. Here we describe both the custom content of the MEGA Chip and the PAGE II consortium, including its goals, methods, and study design, highlighting how PAGE II can contribute to understanding the genetic architecture of confirmed associations across populations.

Use of whole genome sequence analysis following uninformative exome sequencing to uncover potential causal variants in siblings with interstitial lung disease. *B. A. Ozenberger[1,2], D. C. Koboldt[1], T. J. Nicholas[1], D. Wegner[3], J. Wambach[3], R. Fulton[1], R. K. Wilson[1,2], J. Coldwell[4], F. S. Cole[3].* 1) McDonnell Genome Institute, Washington University, Saint Louis, MO; 2) Department of Medicine, Washington University, Saint Louis, MO; 3) St Louis Children's Hospital, Department of Pediatrics, Washington University, Saint Louis, MO; 4) Department of Genetics, University of Oklahoma at Tulsa, Tulsa, OK.

The diagnosis of rare inherited pediatric disease often includes candidate gene sequencing assays, but these assays have limitations which often result in the absence of a definitive etiology. In genetically complex disorders, gene panel testing can be used to examine simultaneously many genes known to be potentially associated with a phenotype. More recently, the entire protein-coding territory (exome) may be interrogated in cases for which other diagnostic assays have failed to reveal a cause. The success rate of gene panel and exome assays depends on many factors, such as the phenotype, the specific assay, and the availability of family members for segregation analysis, but is disappointingly low, averaging <25% across diverse phenotypes. The absence of a diagnosis in some cases may be due to technical limitations of the sequencing method employed. Exome capture analysis can effectively reveal single-nucleotide variants but only in the genomic regions targeted. Furthermore, large structural variants (copy number alterations, insertions, deletions) are not readily measured during exome analysis. Whole genome sequencing (WGS) may be a more attractive option in cases of undiagnosed disease because the genome is investigated to maximal extent and WGS methods allow for effective interrogation for all variant types including structural alterations. Regardless, WGS analysis for clinical diagnosis remains uncommon at present. Full siblings presented with severe respiratory symptoms during infancy, underwent chest computed tomography (CT) scan and lung biopsy, and were diagnosed with interstitial lung disease. Parents were healthy without respiratory symptoms and family history was negative. The occurrence of affected siblings with healthy parents suggested a genetic etiology with possible recessive inheritance. Exome sequencing of both affected siblings was unrevealing. The family (siblings and parents) subsequently consented to participate in a WGS study. We present a comprehensive analysis for candidate causal variants using Illumina X WGS data and discuss the advantages of WGS over exome or gene panel strategies for the investigation of rare inherited diseases.

High speed, low cost processing of WGS data in Alzheimer's disease patients along with integrative analyses enables novel insights into risk mechanisms. *N. D. Beckmann[1], B. Tolhuis[2], J. Karten[2], T. Karten[2], Z. R. Giles[1], H. Shah[1], R. Tanzi[3], E. E. Schadt[1].* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) GENALICE, Deventerweg 9d, 3843 GA Harderwijk, the Netherlands; 3) Massachusetts General Hospital-East Aging and Gen. Research Unit, Bldg. 149, 6th Fl. 149 13th Street Charlestown, MA 02129.

Alzheimer's Disease (AD) is a neurological disorder characterized by progressive memory loss. It is the leading cause of dementia, with an estimated incidence of 22 million cases that is projected to double in the next 20 years. Senile plaques in the brain consisting of accumulated Amyloid Beta and neurofibrillary tangles (hyperphosphorylated Tau protein) are the hallmarks of AD. AD is highly heritable, with several known strong genetic components of the disease already identified, but smaller-to-moderate sized effects remaining to be discovered. Here, we compose a database of over 3000 whole genome sequences (WGS) establishing the largest cohort of WGS for AD to date. Variant calling on large cohorts of WGS is impractical with standard variant calling methodologies. A novel proprietary pipeline, GENALICE MAP, is used to uniformly call variants across all samples. GENALICE is a single stream process that offers a significant improvement over standard pipelines employing GATK (>80 hours on one core per genome) in a more traditional high performance compute cluster, both in terms of computing time (6 minutes per genome), memory usage and disk space, while keeping high variant sensitivity (99. 5% on benchmark NA12878 genome). We were able to process all 3000 genomes in 3 days with a cost-reduction of more than an order of magnitude compared to GATK on Amazon EC2. An extensive comparison of variants called with GATK versus GENALICE demonstrated both pipelines performed similarly (93% concordance). Given the drastically reduced computing requirements, we can uniformly call variants in large cohorts of whole genomes, significantly reducing confounds and batch effects from multiple calling algorithms to increase the power of variant detection. With the rapid processing of large numbers of whole genomes, we identified broader sets of candidate AD variants than could be identified in single datasets processed independently. We used an integrative biology annotation strategy that involved calculation of CADD scores and eQTLs in disease relevant tissues from the AMP-AD consortium, assessing significance in single variant association studies for more common variants, gene-based and gene-set enrichment analyses, and causal network models of AD to identify novel genes and pathways implicated in AD. These uniformly called and annotated variants placed in an appropriate molecular context provide novel insights into the risk mechanisms of AD.

1821F

Utilization of PacBio long-read sequencing in comprehensive genomics. *H. Doddapaneni[1], A. English[1], M. Wang[1], C. R. Beck[2], W. J. Salerno[1], Q. Meng[1], Y. Han[1], E. A. Boerwinkle[1, 3], J. R. Lupski[1, 2], D. M. Muzny[1], R. A. Gibbs[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, 77030, USA; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, 77030, USA; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX, 77030, USA.

Accurate identification of chromosomal alterations ranging from single nucleotide variants (SNVs) to large structural variants (SVs) is essential for comprehensive understanding of genomic architecture and disease mechanisms. At the Baylor College of Medicine Human Genome Sequencing Center (HGSC) we have developed applications for PacBio long-read sequencing technology to detect SVs. A novel method, Pacific Biosystems large Insert targeted capture-sequencing (PB-LITS) combines DNA target-capture enrichment technology with PacBio large-insert library preparation procedures for studying SVs at specific chromosomal regions (Wang et al. PMID: 25887218). This method provides deep sequence coverage with PacBio long reads at substantially reduced cost compared to whole genome PacBio sequencing. We have successfully analyzed target-capture reads through our analysis pipeline PBHoney (described below) to delineate the breakpoint junctions of low copy repeat (LCR)-associated complex SVs on chr17p11. 2 in patients diagnosed with Potocki–Lupski syndrome (PTLS; MIM#610883). PBHoney is a long-read SV detection software that leverages multiple detection and evaluation approaches to report SVs (English et al. PMID: 24915764). In addition to calling SVs with PacBio data from targeted sequencing, the method has also been applied to whole genome human haploid and diploid sequencing experiments. For the cell-line CHM1-tert, PBHoney made 9,496 SV calls between 50 bp and 100 kbp from 40x haploid PacBio coverage. When compared to the previously reported 12,047 SV calls from the same data (Chaisson et al. PMID: 25383537) and Illumina SVs generated from our multiple caller method, Parliament (English et al. PMID: 25886820), we found that PBHoney has a sensitivity of 66. 8%, and the highest positive predictive value at 70. 3%. When applied to a well characterized diploid human sample (HS1011), the software identified 9k deletions, 15k insertions, and 338 inversion calls with 20x coverage (i. e. , 10x per haploid genome) data input. By comparing PBHoney's results with SVs identified from Illumina short-reads and other methodologies, we illustrate the additive value of PBHoney and PacBio data. All of these newly accrued research and development experience has demonstrated that use of long-read sequencing alone or as a complementary data source for SV detection can provide a comprehensive assessment of genomic architecture and enhance our understanding of genetic disease mechanisms.

1822W

Integrative calling of short indels encompassing a wide spectrum of tandem repeats via fuzzy left-right alignment. *H. M. Kang, A. Tan.* Biostatistics Dept, Univ Michigan, Ann Arbor, Ann Arbor, MI.

Statistical models and computational approaches for detecting short insertions and deletions (indels) have rapidly evolved to accurately detect simple biallelic indels mostly located in >97% of non-repetitive regions of the genome. However, ~50% of indels reside in <3% of repeat-rich regions of the genome, mostly in the form of variable nucleotide tandem repeats (VNTRs). Due to increased sequencing errors, alignment errors, and PCR slippages in repeat-rich regions, calling indels in these regions of genome is extremely challenging and has not been the major focus of most indel calling algorithms. Here we propose novel methods to detect or integrate indels encompassing repeat-rich regions systematically. The key idea of our method is to use the difference between left-alignment and right-alignment of indel alleles to systematically classify VNTR based on repeat tract length and repeat units. To model VNTRs with inexact repeats (due to sequencing errors and/or true variants within repeat tract), we extend this method into "fuzzy left-right alignment" algorithm that allows mismatches in left- and right- alignment to when repeat tract length can be substantially increased. Repeat units can be determined by prefix tree implemented in a computationally efficient manner. Compared to the methods relying only on reference sequences, such as *lobSTR* or *RepeatSeq*, our method substantially improves the sensitivity to identify inexact VNTRs and VNTRs located outside of repeat-rich regions focused by lobSTR. We applied our algorithm to deeply sequenced 1000 Genomes samples. The concordance across three different calling algorithms – *HaplotypeCaller*, *Platypus*, and *samtools* - were 56% and 90% within and outside repeat-rich regions of genome (defined by *TandemRepeatFinder* and *mDUST*), respectively. Our VNTR-aware normalization on the same call sets increased the concordance to 75% and 95%, respectively. Recalling the variants with our VNTR-aware variant detection algorithm increased the sensitivity of VNTR detection by 11% compared to *HaplotypeCaller*, when evaluating based on the VNTRs overlapping with *lobSTR* calls. Our proposed VNTR-aware variant normalization and detection methods are implemented in our public sequence analysis software packages *GotCloud* and *vt*.

Mitigating Batch Effects in Whole Genome Sequencing. *J. Tom, W. Forrest, J. Reeder, J. Hunkapiller, T. Bhangale.* Bioinformatics and Computational Biology, Genentech, South San Francisco, CA.

With the arrival of the 1000 dollar whole genome sequence (WGS) for humans, large WGS datasets are now feasible. Unfortunately, not all sequencing is directly comparable – not even sequencing run solely using Illumina technology. Batch effects from chemistry changes, number of PCR cycles, and type of sequencer can all impact variant calling. Systematic biases in variant calling between batches complicate downstream analysis e. g. by producing false positive disease association. Often only genotype data is available for analysis (as opposed to the raw read or alignment data) and it's necessary to characterize batch effects based on genotypes alone. We have analyzed WGS data with target coverage of 30X for 1245 samples sequenced using Illumina technology. These samples are from five different vendors spanning at least four major differences in library prep and chemistry. We have computed various metrics using genotype data such as transition transversion ratio (Ti/Tv), percent confirmed in 1000 genomes, and ancestry coefficients to identify batch effects and have tested filters that can be applied to mitigate them. Ancestry coefficient estimation is necessary to disambiguate observed differences in metrics due to heritage from those due to batch effects. We have determined that removing calls with genotype quality less than 90 is the most effective filter for mitigating batch effects. In our samples we found, on average, improvements in Ti/Tv in coding regions from 2. 97 to 3. 09 and increases in percent confirmed in 1000 genomes from 80. 4% to 84%. Heterozygote concordance in technical replicates improves from 90. 88% to 99. 8%. Imposing this filter removes a modest percent of variants (16. 8% on average). We have implemented our method to compute these metrics in an R package genotypeeval that will be available from Bioconductor.

Challenges and approaches to genotyping large biobank projects. *T. Webster[1], J. Brodsky[1], D. Oliver[1], D. Petkova[2], C. Freeman[2], C. Bycrof[2], J. Gollub[1], A. Ollmann[1], A. Qiu[1], L. Reynolds[1], B. Eynon[1], J. Schmidt[1].* 1) Affymetrix, Santa Clara, CA; 2) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

As part of major national healthcare initiatives, recent biobank projects are designed to genotype large numbers of individuals. The UK Biobank is a prospective cohort study of over 500,000 individuals from across the United Kingdom. The custom UK Biobank Axiom® Array, with over 800,000 markers, was designed for the project. Due to the size of the study, genotyping was performed in batches of approximately 4,700 individuals who were genotyped on approximately 50 Axiom® 96-sample array plates, for a total of approximately 100 batches. This genotyping strategy, while beneficial for intra-batch consistency and computational tractability, increases the probability that a fraction of the markers will have inconsistent or missing genotypes in some of the dataset. However, the availability of multiple batches processed under the same strict guidelines, provides opportunities for new analytical workflows to improve the accuracy of all genotypes obtained as part of a large sample cohort. We have developed a workflow to increase accuracy and batch-to-batch consistency and reduce the amount of missing data in very large genotyping projects. The workflow consists of two rounds of genotyping. After the first round of standard genotyping, all batches are analyzed to select an exemplar batch for each probe set (the probes that interrogate a marker) as the source of SNP Specific Prior (SSP) information. These SSPs are used by the AxiomGT1 algorithm to improve consistency and accuracy in the other batches in the second round of genotyping. Other probeset specific modifications to the genotyping algorithm, such as modification of algorithmic parameters or advanced normalization to attenuate effects such as plate-to-plate variation, are applied to selected probesets, as well. A final round of analysis excludes a small percentage of probesets that produce sub-optimal clusters, and also probe sets with cluster patterns consistent with complex genetics at the marker site, resulting in more than three genotype clusters. We show that the new workflow decreases the missing information per batch from approximately 3% to less than approximately 2%, increases the ability to detect rare genotypes, and increases the consistency of allele frequencies across multiple batches.

1825W

Description Extractor: Automated HGVS-recommended sequence variant description. *P. E. M. Taschner[1], J. Vis[2,3], M. Vermaat[4], J. N. Kok[3], J. F. J. Laros[4,5].* 1) Generade Center of Expertise Genomics, University of Applied Sciences Leiden, Leiden, Netherlands; 2) Department of Molecular Epidemiology, Leiden University Medical Center, Leiden, The Netherlands; 3) Leiden Institute of Advanced Computer Science, Leiden University, Leiden, The Netherlands; 4) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 5) Leiden Genome Technology Center, Leiden University Medical Center, Leiden, The Netherlands.

The Mutalyzer sequence variation nomenclature checker1 was developed to promote error-free reporting of sequence variants. Mutalyzer applies the Human Genome Variation Society's (HGVS)2 standard nomenclature, which is recommended by the ACMG for variant descriptions. Nonetheless, construction of variant descriptions still requires basic knowledge of the standard nomenclature and manual comparison of reference and variant sequences. This leaves room for errors in reporting, which is highly undesired in relation to the diagnosis of genetic disease. The chance of finding a complex variant increases with the rise of long read sequencers. The newly developed Description Extractor3 helps users to describe complex variants. The algorithm closely follows the human approach for sequence comparison. It will first find the "region of change". Within this region it finds the largest overlap, producing two regions that need to be described in a similar way. This process is repeated until a compact description is found. The tool ensures that the same description will be generated for the same observed variant. The significant advantage: knowledge of the HGVS nomenclature is no longer required to generate correct descriptions. This not only helps clinicians to generate correct descriptions, but its implementation also allows automation of the description process. Database curators can use the tool to describe complete alleles or haplotypes. In addition, they can list the differences between reference sequence versions or even complete genome builds. The Description Extractor and Mutalyzer are freely accessible via the internet and available for download for local installation. 1) https://mutalyzer. nl/2) http://www. hgvs. org/mutnomen/3) https://mutalyzer. nl/description-extractorThis work was supported by the Dutch national program COMMIT.

Accuracy of Variant detection in Next-generation sequencing: a comparison between exome and RNA seq. *I. trotta, h. almusa, m. lepistö, a. palva, s. hannula, a. vaittinen, p. mattila, p. ellonen, c. heckman, j. saarela.* Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finl, Helsinki, Finland.

NGS approaches are currently widely used in clinical genetics for the rapid detection of rare deleterious variants in monogenic disorders. In order to assess the limitations of the methods for a reliable detection of variants in a diagnostic perspective we compared whole-exome (WES) and RNA sequencing in 27 samples. We examined only the coding variants included in the WES target (*Ensembl v75* genomic sequence) with sequencing depth >20X. We identified 14,772 positions (4,937 unique variant sites) in which the 2 methods produced a different call. We excluded the cases with a putative biological explanation (monoallelic expression), which left 1,340 discrepancies (527 unique) for further analysis, including the follow up by Sanger sequencing of 30 variants. The variant calling process was performed using GenomeAnalysisTK-3. 1-1 (GATK, BWA 0. 6. 2 aligner) in WES, and Tophat v2. 0. 6 and Samtools 0. 1. 18 (Bowtie2 2. 0. 2 aligner) in RNA sequencing. We showed that **15. 6%** of differences (n=209/1,340) could be explained by errors in the alignment or variant calling: 44 missed calls in WES and 165 in RNA seq. Indeed, we observed some variant caller specific challenges: the co-occurrence of heterozygous SNPs and short deletions in the same position prevented GATK to call the SNPs (n=4), while TopHat failed to call short indels located in proximity of the exon-intron boundaries (n=55). We further examined the putative non-unique mapping of the regions flanking the discordant variants (100bp seeds) and found 694/1,340 sites (**51. 8%**) to map in more than one location in the genome. The remaining **32. 6**% of the discrepancies (n=437, 248 unique) could not be explained by evident technical faults. Of them, 40 (4 unique) had been identified as RNA editing sites based on the *RADAR* database. In a total of 62 unexplained discordances we observed at least 3 reads with the alternative allele in WES with a frequency under the threshold required for the call, but in 329 cases no reads with the alternative allele seen in the transcripts sequence were observed in WES despite of >100x coverage of some of the sites. A total of 68 identified discordances referred to genes reported in the OMIM database (in association with 39 disorders), of which two were defined as pathogenetic according to the ClinVar classification. Altogether, these considerations suggest a thorough evaluation of the disease genes targets for NGS, considering the potential drop of causal variants for technical limitations.

1827F

Genotype Imputation Using Sparse Partial Least Squares Analysis. *H. Koh[1], D. V. Conti[2].* 1) New York University, New York, NY; 2) University of Southern California, Los Angeles, CA.

Genotype imputation techniques have been widely used for genetic researchers to obtain denser genetic data for the analysis of genome-wide association studies (GWAS) with much less financial and temporal burden than when they use higher coverage sequencing procedures. Here, we introduce a new model-based genotype imputation method using sparse partial least squares discriminant analysis (SPLS-DA) logistic regression models, termed as 'SPLS-IMPUTE'. The family of sparse partial least squares (SPLS) analysis tools has recently been developed by employing variable selection along with dimension reduction built in the traditional partial least squares (PLS) methods. We noticed that this additional variable selection property for SPLS analysis has facilitated much faster and more accurate analysis in the context of regression-based modeling using high-dimensional data. Taking such advantages of SPLS analysis, the SPLS-DA logistic regression model is used for the machinery of SPLS-IMPUTE by examining the association structure, linkage disequilibrium, among SNPs to tie underlying genotypes in a reference panel and a GWAS study sample. We emphasize that SPLS-IMPUTE does not require haplotype estimation, also known as phasing, for a reference panel or a GWAS study sample which is a major time component required from two benchmark methods, MACH and IMPUTE2. As a result, SPLS-IMPUTE can be used more computationally efficiently especially in a situation where a phased reference panel is not immediately available. We also observe a near perfect agreement of best guessed imputed genotype calls with true genotypes in our leave-one-out simulation experiment (Discordance rate: 3. 98% for SPLS-IMPUTE (K=10) and 3. 76% for SPLS-IMPUTE (K=15).

De novo and somatic indel variant analysis of whole genome and exome capture sequencing experiments with Scalpel. *H. Fang[1,3,4], E. Grabowska[2], K. Arora[2], V. Vacic[2], M. Zody[2], I. Iossifov[1], J. O'Rawe[3,4], G. Lyon[3,4], M. Wigler[1], M. Schatz[1], G. Narzisi[1,2].* 1) Simons Center for Quantitative Biology, Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) New York Genome Center, New York, NY; 3) Stanley Institute for Cognitive Genomics, One Bungtown Road, Cold Spring Harbor Laboratory, NY; 4) Stony Brook University, 100 Nicolls Rd, Stony Brook, NY.

Insertions and deletions (indels) are the second most common of variation in human genomes and the most common structural variants. Despite their biological relevance, indels of more than five bases are still challenging to discover. Scalpel is an open-source algorithm (http://scalpel. sourceforge. net/), which combines read mapping and assembly for sensitive and specific discovery of indels in whole genome and exome data. A detailed repeat analysis coupled with a self-tuning *k*-mer strategy allows Scalpel to outperform other state-of-the-art approaches for indel discovery, particularly in regions containing near-perfect repeats. We showed that accuracy of indel detection with WGS is greater than WES even within the targeted regions. Short tandem repeats, especially homopolymer A/T runs are a major source of errors, and they are highly enriched in the WES data. PCR-free protocols help reduce such biases and improve the accuracy of indel calling. Further, common practice of sequencing WGS at 30X using the HiSeq platform is not sufficient for sensitive indel discovery, resulting in at least 25% false negative rates. Scalpel has been successfully used to identify novel candidate genes for autistic spectrum disorder. We analyzed 593 families for inherited and de novo indels from the Simons Simplex Collection, demonstrating Scalpel's power to detect de novo (PPV= 82%) and long transmitted events (PPV= 78%). Consistent with Iossifov *et al*. 2015, we confirm a significant two-fold enrichment for likely gene-disrupting (LGD) indel mutations: 35 frameshifts in autistic children versus 16 in unaffected siblings (P-value = 0. 01097). We found a notable overlap between the LGD target genes and the 842 FMRP-associated genes. We have recently extended Scalpel to detect somatic mutations from tumor and matched normal data and compared its performance to other widely used somatic callers such as SomaticIndelDetector, Strelka, Pindel, Platypus, using data from the DREAM challenge. We characterized false positive and false negative calls in the context of sequence composition and VAFs distributions. . Our results show that Scalpel has the best overall balance between sensitivity and specificity, and recovers somatic indels across the whole length spectrum while keeping a low FDR. Other recent improvements include improved support for highly variable coverage regions, such as targeted sequencing panels, as well as greatly improved runtime performance.

1829T

Platinum Genomes: A comprehensive package for assessing variant calling performance on GRCh37 and GRCh38. *E. Fritzilas[1], M. A. Bekritsky[1], P. Krusche[1], M. A. Eberle[2].* 1) Illumina Cambridge Ltd. , Chesterford Research Park, Saffron Walden, Essex, CB10 1XL, UK; 2) Illumina Inc. , 5200 Illumina Way, San Diego, CA 92122, USA.

Advances in high-throughput sequencing technology now make it possible to rapidly sequence individuals and call variants ranging from single base substitutions to large structural events. Since these sequencing technologies will likely be widely used for clinical applications in the near future, it is essential that we have the means to systematically assess the accuracy of the resulting variant calls. By sequencing a large, three generation pedigree, the Platinum Genomes exploits Mendelian inheritance to create a set of phased high-confidence variant calls, thereby enabling researchers worldwide to characterize the human genome more accurately. Using pedigree phasing in addition to having a replicate analysis allows us to cover a substantial portion of the genome with gold-standard calls, enabling researchers worldwide to characterize variant calling in the human genome accurately. In December 2013 the GRCh38 reference sequence was published, with several improvements over GRCh37. Here we present a new version of Platinum Genomes built using GRCh38, providing researchers with a much-needed resource to assess variant calling performance in the latest version of the human reference genome. Having truth sets for both GRCh37 and GRCh38 also enables us to perform a detailed comparison of the consequences of switching to the new reference, as it allows accurate benchmarking of individual variant calling pipelines on both reference versions. Moreover, analyzing the high-confidence calls unique to either assembly will reveal cases where the changes introduced in GRCh38 have resolved alignment artefacts and led to more accurate variant calling. Overall, we observe ~3. 6 million platinum SNP calls and ~590,000 indel calls per individual in the platinum truth set, comparable to the number of platinum variant calls from GRCh37. In addition to comparing the overall numbers, we lift over the variants from each truth set to quantify the causes and locations where variants fail to occur in both genome builds. VCF files with high-confidence Platinum Genomes variant calls are publicly available on www. platinumgenomes. org. Illumina also offers a companion open source tool that enables benchmarking of a query VCF against the Platinum Genomes truth data in terms of sensitivity and specificity: github. com/sequencing/hap. py.

1830F

Enforcing high quality variant calling in large scale whole genome sequencing. *Z. Huang[1], N. Rustagi[1], L. A. Cupples[2], R. Gibbs[1], E. Boerwinkle[1,3], F. Yu[1].* 1) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 3) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX.

Discovery of rare SNPs and novel genes is of critical importance in the disease associationstudy and whole genome sequencing (WGS) with thousands or larger sample size isindispensible. However, large scale WGSvariant calling has many challenges scientifically and computationally. In this work, we addressed the challenge in achieving high quality variant calling. The calling quality is affected by caller specific bias, population substructure, and the sequencing and mapping errors amplified by the sample size. These factors hamper the detection power of population specific rare variants. In order to call high quality rare variants, we developed 1) a novel ensemble calling approach, goSNAP, which employs multiple callers (each in joint calling mode) and features a consensus filter to ensure high quality site discovery, 2) a step-by-step quality control procedure following site discovery, genotype likelihood calculation and imputation, and 3) the optimal strategy to apply site level Hardy Weinberg exact test (HWE) which filters common sites affected by mismapping but keeps the population specific rare variants intact. We apply these methods tothe SNP calling of5297 WGS samples (36% African Americans (AfAm) and 64% European American (EuAm)) with 6-10x coverage in theCHARGEproject(theCohortsfor Heart and Aging Research in Genomic Epidemiology). The whole process only took 6 weeks and 5. 2million CPU hours. We called 72. 2 millionSNPs witha transition-to-transversionratio(Ti/Tv)of2. 14. With large sample size per population, we obtain high novel SNP rate, 49. 4% compared to 1000 Genomes Project (phase3) and 59. 9% compared to dbSNP (b141). Taking CHARGE WES SNPs as gold standard, our WGS call set has 63. 9% sensitivity, 99. 8% specificity and 2. 98% FDR, outperforming any single caller. Therediscovery rate of singleton, doubleton and common SNPs (AF>5%) are 43. 1%,72. 2% and 95. 0%, respectively. We obtain high genotype concordance, 98. 7%(Ref/Ref), 84. 1%(Ref/Alt) and 99. 3%(Alt/Alt), compared to CHARGE cSNP array. By choosing HWE p-value cutoff 10-15 in AfAm and 10-17 in EuAm, we keep all rare SNPs in each population with AC<10 and further filter 0. 8% of SNPs (Ti/Tv=1. 22) after imputation purification, most of which have AF>10%. 92% of the filtered sites have excess of HETs. We hope future large scale WGS projects may benefit from our high quality variant calling methods and practices.

1831W

A Bayesian framework for *de novo* mutations calling in nuclear families. *Q. Wei[1,2], R. Chen[1,2], X. Zhan[3], X. Zhong[4], W. Chen[5], B. Li[1,2].* 1) Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN; 2) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 3) Quantitative Biomedical Research Center, University of Texas Southwestern Medical Center, Dallas, TX; 4) Department of Biostatistics, Vanderbilt University, Nashville, TN; 5) Department of Pediatrics, University of Pittsburgh, Pittsburgh, PA.

Increasing evidence shows that de novo mutations play an important role in genetic etiology of both complex and Mendelian diseases. Although a common design is to sequence proband-parents trios, sequencing additional unaffected siblings provides natural controls to characterize disease-causing de novo mutations identified in probands. Current state-of-the-art methods were designed to handle offspring-parents trios and for nuclear families with multiple offspring such methods are inefficient in de novo mutation calling due to the ignorance of the family relatedness. In this study, we develop a Bayesian framework to jointly model the sequencing data in a family, leveraging the identity-by-descent (IBD) allele sharing among offspring, to optimize the de novo mutation calling accuracy. Through extensive simulations we showed that the new method is superior to the existing state-of-the-art method, especially for moderate sequencing coverage. This will be particularly beneficial for whole genome sequencing, as it is still prohibitively expensive to perform high-depth whole genome sequencing. Breaking down by IBD sharing categories, we observed that the greatest accuracy was achieved for de novo mutations in regions of IBD=2, and for IBD=0 and 1 the performance is comparable. Application of the new method to an exome sequencing dataset of quartet nuclear families showed increased sensitivity and specificity of de novo mutation calling over existing methods.

1832T

Resizing N-Base Gaps in the Human Reference Genome. *Z. Dzakula, A. Hastie, A. Pang, E. T. Lam, W. Andrews, Z. Zhu, X. Zhou, T. Liang, T. Anantharaman, H. Cao.* BioNano Genomics, Inc. , San Diego, CA.

With our Irys® genome mapping platform and NanoChannel technology, we have collected whole genome mapping data on an ensemble comprising over 30 euploid human genomes. We then used the resulting *de novo* assembled genome maps to estimate the sizes of the N-base gaps in the human reference. The ultra-long DNA molecules (ranging from 150 kb to 2. 5 Mb) enabled us to bridge a large fraction of N-base gaps present in the human reference and to accurately measure their widths. The corrected gap widths were evaluated by averaging the corresponding segment lengths observed in the euploid assemblies. The arbitrary sizes of N-base gaps currently present in the human reference significantly differ from our ensemble-based estimates, in sharp contrast with the high degree of consistency among the *de novo* assembled genome maps originating from different individuals. Our assemblies also suggest existence of an internal structure within a subset of N-base gaps. Using genome mapping data to this subset of gaps, we were able to accurately place sequence motifs inside a portion of the human genome previously considered “The Dark Matter. ” In addition, we analyzed reference regions surrounding N-base gaps that disagree with all our euploid assemblies. We are proposing an alternative structure for those regions, consistent with our observations both in terms of the number and the locations of the relevant sequence motifs. Finally, our genome maps reveal diversity among the individuals included in the ensemble, suggesting presence of haplotypes both inside and in the vicinity of the N-base gaps.

1833F

Characterization of the microDNome and its impact on the differential sensitivity to cancer treatments. *P. Mehanna[1], V. Gagné[1], M. Lajoie[1], D. Sinnett[1,2], I. Brukner[3], M. Krajinovic[1,2].* 1) Centre Hospitalier Universitaire Sainte-Justine Research Center, University of Montreal, Montreal, Canada; 2) Department of Pediatrics, Faculty of Medicine, University of Montreal, Montreal, Canada; 3) Molecular Diagnostics Laboratory, Jewish General Hospital, McGill University, Montreal, Canada.

A novel form of extrachromosomal circular DNA, microDNAs, has recently been identified within normal and tumor tissue. MicroDNAs are characterized as small fragments (200-400bp) of extra-chromosomal circular DNA and are derived from unique and non-repetitive genomic sequences that are enriched in exonic regions, CpG islands and 5'UTRs. These entities seem to be generated during DNA replication leaving behind microdeletions at different genomic loci that could modify a cell's transcriptomic profile when a regulatory region is altered, or result in a gain/loss of function of a particular gene if the coding region is modified. Furthermore, in the event of selective pressures, such as those induced by treatment in a cancer setting, these alterations could be fixed in the cell if they present a selective advantage and therefore contribute to cancer development and drug resistance. In this study, we set out to investigate whether and how the formation of microDNAs and concomitant chromosomal microdeletions can shape resistance to chemotherapeutic drugs in cancer, more specifically childhood acute lymphoblastic leukemia (cALL). To identify microDNA signatures we used a panel of 20 human lymphoblastoid cell lines (LCLs): 10 that were previously shown to be resistant (higher IC50) and 10 that were sensitive (lower IC50) to two major chemotherapeutic drugs used to treat cALL patients (methotrexate and asparaginase). Following treatment of LCLs with respective IC50 drug concentrations, microDNAs were extracted using methods that are adapted for the extraction of circular DNA molecules followed by enrichment through rolling circle amplification and high throughput sequencing using Ion Torrent technology. Reads were then mapped to the reference genome using Torrent Mapping Alignment Program. The identity of microDNA clusters was confirmed by validating their circularity (control of nucleotide repeats between soft-clips), their location in the genome (outside of repetitive sequences) and their size using third-party softwares such as BedTools and custom in-house scripts. We defined the genomic distribution of microDNAs and assessed their eventual drug-resistance specific enrichments. Genomic counterparts of microDNA were then prioritised for sequencing based on their function and redundancy. Ultimately, this study will provide insight into possible novel mechanisms of genomic variability underlying resistance in cancer chemotherapy.

1834W

Updates in the human reference genome assembly (GRCh38). *T. Rezaie[1], V. A. Schneider[1], T. Graves-Lindsay[2], P. Flicek[3], R. Durbin[4] for the Genome Reference Consortium.* 1) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD; 2) The Genome Institute at Washington University, St. Louis, MO; 3) European Molecular Biology Laboratory, European Bioinformatics Institute, Hinxton, Cambridge, UK; 4) The Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK.

Continued improvement and modernization of the human reference genome assembly, together with a growing catalog of human genomic diversity, is promoting the advancement of biological research. The Genome Reference Consortium (GRC), the group responsible for updating the reference genome assemblies for human, mouse and zebrafish, provides users with improvements even between major assembly releases. These improvements are comprised of fix and novel patches, which represent assembly corrections and alternate sequence representations, respectively. Patches are standalone scaffold sequences placed in chromosome context via alignment. Released quarterly, there have now been 4 patch releases associated with GRCh38, including 38 assembly corrections and 19 new alternate sequence representations. We will demonstrate how our recent analysis of assembly-assembly alignments as part of an effort to integrate missing sequences into the reference resulted in representation of several new structural variants. We will discuss how the availability of several individual genome assemblies derived from long-read WGS sequencing efforts has enabled us to further improve the reference assembly. We will also describe how use of the NCBI Remapping Service contributed to these analyses and can serve as a tool for making assembly updates. We will discuss how this GRC effort not only continues the ongoing curation of the reference, but is also driving development of new GRC tools and protocols for assembly improvement. The GRC strives to make its curation activities accessible to the public and we will present recent improvements to public GRC websites. These include an interactive page for finding and viewing issues under GRC review. Users now have access to more information about issues, and improvements in navigation make it easier for users to pinpoint issues relevant to their research interest. Moreover, the GRC also provides tracks that describe GRC curation efforts and details of assembly construction and quality. We will show how to access these tracks on the GRC's website, NCBI's 1000 Genomes or Variation Viewer browsers, as well as via the GRC track hub used by the genome browsers at UCSC and Ensembl. You may contact the first author (during and after the meeting) at Tayebeh. Rezaie@nih. gov.

1835T

A Single-Tube NGS Library Prep Workflow Integrating Enzymatic Fragmentation Results in High Yields and Low Sequencing Bias. *S. Liu-Cordero[1], B. Miller[2], M. Appel[1], V. Van Kets[2], B. van Rooyen[2], H. Whitehorn[2], M. Ranik[2], P. Jones[2], A. Geldart[1], R. Kasinskas[1], E. van der Walt[2].* 1) Kapa Biosystems, Wilmington, MA; 2) Kapa Biosystems, Cape Town, South Africa.

The use of whole exome sequencing (WES) through next-generation sequencing is accelerating as clinical application of the technique becomes more prevalent. WES is increasingly being applied for elucidating the genetic etiology of human disease in research areas such as inherited disease, personalized genomics, and drug discovery. These types of projects show the need for faster and more scalable NGS library preparation methods while providing a level of sequence quality and coverage that allows for rare genetic variants to be revealed. Accurate determination of a comprehensive set of variants in coding regions requires deeper and more uniform sequencing coverage and a reduction of bias across all steps in the sequencing workflow. Fragmentation of sample DNA for input to the NGS workflow is often an essential, but laborious step at the beginning of the library preparation process. Current techniques involve either enzymatic methods that exhibit a high degree of sequence bias and sensitivity to DNA input amounts, or mechanical shearing systems that are not scalable to meet growing throughput demands. We describe a novel enzymatic fragmentation formulation that provides a streamlined workflow and dramatically reduces sequencing bias relative to current methods, approaching the performance of mechanical shearing but with improved workflow and automation. We compare this enzymatic fragmentation method to current fragmentation solutions in WES workflows for high and low quality DNA input, including FFPE. We show that, when combined with a highly efficient library preparation, this method provides a powerful tool for optimizing these workflows and increasing throughput.

1836F

TruSeq Rapid Exome: A new improved exome enrichment strategy using a mutant transposase. *D. Schlingman[1], A. Kia[1], A. Khanna[1], J. Burgess[1], H. Grunenwald[1], V. Ruotti[1], A. Tan[1], M. He[1], T. Osothprarop[1], M. Costello[2], A. Cheney[2], J. Decker[1], R. Vaidyanathan[1].* 1) Illumina Inc, Madison, WI; 2) Broad Institute, Cambridge, MA.

Rapid expansion of studies and knowledge on the human exome has led to a myriad of scientific discoveries in recent years. Transposase-based Nextera facilitated many of these breakthroughs by utilizing an innovative methodology that combines an efficient and robust workflow with impressive performance. Nextera enables users to fragment and adaptor-tag an entire genome in minutes, dramatically improving workflow speed vs. the traditional ligation-based strategies. The adaption of Nextera for exome enrichment applications has furthered the impact of such technology. In continuing to improve and optimize transposase-based strategies, we have re-engineered a highly efficient bacterial transposase with a lowered AT/GC insertional bias, leading to more uniform coverage, therefore, reducing the amount of sequencing required to cover the genome at the same depth when compared to the 1st generation Nextera. In addition, this new transposase delivers consistent library insert size over a range of input DNA, allowing up to a tenfold variance from the 50 ng input recommendation. Such capability for input tolerance translates to workflow flexibility, robustness and is independent of quantification inaccuracies. For a fast, streamlined exome enrichment workflow, we incorporated significant optimizations to reduce the hybridization time, enabling a 1-day workflow. In addition, we have introduced a modified buffer to reduce sample mutation due to oxidation. These combined improvements of a new mutant transpose and hybridization conditions demonstrate an impressive > 80% read enrichment at 4 GB sequencing and > 85% exome coverage at 10x. Variant calling analysis against the Genome-in-a-Bottle reference data set (National Institute of Standards and Technology), demonstrated exome workflow precision of >99. 5% and recall of >91% at ~100x coverage. Overall, this new and improved 1-day exome workflow with a re-engineered transposase demonstrates better on-target performance and more accurate SNP/variant calling, which in turn holds promise to further applications with exome target enrichment.

1837W

Missing coverage of ACMG genes in clinical exome and genome sequencing. *R. L. Goldfeder[1,2], D. M. Waggott[2], E. A. Ashley[2].* 1) Biomedical Informatics Program, Stanford University, Stanford, CA; 2) Stanford Center for Inherited Cardiovascular Disease, Stanford University, Stanford, CA.

The human genome is complex; pseudogenes and other repetitive sequences, which comprise roughly half of the genome, create challenges in sequencing, alignment, and variant interpretation. Despite these challenges, clinical-grade genome sequencing and interpretation requires accurate and complete genotype calls across the entire genome. Of note, the American College of Medical Genetics and Genomics (ACMG) recommends pathogenic variant discovery, review, and reporting for 56 genes that are known be associated with disease. Since we consider this gene set to be a minimum set of genes where performance must meet medical standards, we sought to examine the read depth for each base in each ACMG gene for 12 clinical exomes (including Personalis ACE Exome, Agilent Clinical Research Exome, and Baylor Clinical Exome) and 39 clinical genomes (including several versions of the Illumina HiSeq platform). We observe that coverage of these important genes varies by sequencing approach. In particular, exome sequencing methods perform better than whole genome sequencing for coding bases. However, UTR bases are better covered by whole genome sequencing approaches. Adequate read depth is required to make accurate genotype calls; therefore, insufficient coverage of any base in a disease gene is problematic as DNA sequencing becomes incorporated into clinical decision-making. Further understanding of the parameters that contribute to variability in coverage will aid the development of new technologies and analysis approaches for clinical genome sequencing.

1838T

***De novo* assembly of a diploid Asian genome.** *Y. Guo, K. Wang.* Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA.

The arrival of second-generation sequencing enables us to rapidly re-sequence human genome in a matter of hours, at reasonable prices. However, re-sequencing-based studies are performing poorly in GC-rich areas, segmental duplication regions, repeat regions with length more than read length; furthermore, reference-guided alignment process is inherently biased towards known sequences. With increasing throughput and read length from third-generation sequencing, e. g. SMRT (single-molecule real-time) technology, *de novo* assembly has become fast, accurate and affordable. Here we present results from *de novo* assembly of an Asian subject. We sequenced the genome with an average coverage of 80X by third-generation sequencing technology. The N50 of read length is above 12kb. We were able to generate a *de novo* assembly of ~2. 8 Gbp using Falcon assembler. We compared the genome assembly with several other assemblies generated on subjects of European and Asian ancestry, and evaluated the completeness of the assembly by several bioinformatics approaches. Next we used Illumina HiSeq data and Illumina Omni SNP array for detecting CNVs, by comparing to GRCh37. We then used the de novo assembly to see whether these CNVs can be found or validated by de novo assembly. Initial analysis revealed that long reads were able to capture large-scale CNV events, for example, a common 14,199 bp deletion. We will present the latest results on the genome assembly and discuss lessons learned from this study.

1839F

Initial characterisation of 125 whole-genome sequenced trios from four ethnic groups in the Gambia. *Q. S Le[1], EM Leffler[1], KJ Kivinen[2], GBJ Busby[1], Muminato Jallow[3], Fatou Sisay-Joof[3], Jim Stalker[3], Kirk Rockett[1], G Band[1], DP Kwiatkowski[1,2], CCA Spencer[1], GGDP The Gambia Genome Diversity Pr[1,2,3].* 1) Wellcome Trust Centre for Human Genetics, Oxford University, Roosevelt Drive, Oxford. OX3 7BN; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge. CB10 1SA; 3) MRC Unit, The Gambia, Atlantic Boulevard, Fajara, The Gambia.

We describe the initial construction of a haplotype reference panel based on 125 trios from four major ethnic groups in Gambia sequenced to 10X coverage, alongside read data obtained from the LWK and YRI sample collections sequenced by the 1000 Genomes project. Our pipeline is similar to one used by the 1000 Genomes project and uses GATK, SNPTOOLS and Beagle to detect, filter, and refine variant calls, and SHAPEIT 2. 0 to phase incorporating pedigree information. Overall we call 23. 8 million SNPs and 1. 7 million INDELs across the autosomal chromosomes, including 7. 1 million SNPs that are not present in dbSNP, and therefore represent putatively novel human variation. Using new methods we also identify parts of the genome where new haplotypes are found, using variation at the malaria associated sickle-cell locus as an example. Exploiting the new haplotype reference panel, we imputed SNPs in a large cohort of severe malaria cases and population controls from the Gambia, and demonstrate improved imputation quality and power to detect association at known risk loci. We also use the data to look at the structure of genetic diversity within and between the four Gambian groups. We highlight regions of the genome which appear to be shaped by natural selection and harbour new functional variation.

1840W

Comparison of exome and genome sequencing platforms for the complete capture of protein coding regions. *S. H. Lelieveld[1], M. Spielmann[2,3], S. Mundlos[2,3], J. A. Veltman[1,4], C. Gilissen[1].* 1) Department of Human Genetics, Radboud Institute for Molecular Life Sciences, Nijmegen, Netherlands; 2) Institute for Medical Genetics and Human Genetics, Charité Universitàtsmedizin Berlin, Berlin, Germany; 3) Max Planck Institute for Molecular Genetics, Berlin, Germany; 4) Department of Clinical Genetics, Maastricht University Medical Centre, Maastricht, Netherlands.

For next-generation sequencing technologies sufficient base-pair coverage is the foremost requirement for the reliable detection of genomic variants. We investigated whether whole genome sequencing (WGS) platforms offer superior coverage of coding regions compared to whole exome sequencing (WES) platforms, and compared single-base coverage for a large set of different exome and genome samples (24 Agilent V4 (at 78x and 160x coverage), 12 Agilent V5 (100x), 12 NimbleGen V3 (95x), 24 Complete Genomics (44x and 87x), 11 Illumina HiSeq (28x), 12 Illumina X-Ten (40x)). We find that WES platforms have improved considerably in the last years, but at comparable sequencing depth, WGS outperforms WES in terms of covered coding regions. At higher sequencing depth (95x-160x) WES successfully captures 95% of the coding regions with a minimal coverage of 20x, compared to 98% for WGS at 87 fold coverage. A comparison to published gene panel studies shows that these perform similar to WES and WGS in terms of coverage. Three different assessments of sequence coverage bias showed consistent biases for WES but not for WGS. We found no clear differences for the technologies concerning their ability to achieve complete coverage of 2,759 clinically relevant genes. We show that WES performs comparable to WGS in terms of covered bases if sequenced at 2-3 times higher coverage. This does, however, go at the cost of substantially more sequencing biases in WES approaches, which may impact applications such as the identification of copy-number variants and somatic variation. Our findings will guide laboratories to make an informed decision on which sequencing platform and coverage to choose.

1841T

The International Genome Sample Resource: Beyond the 1000 Genomes Project. *X. Zheng-Bradley, L. Clark, J. Khobova, A. Datta, I. Streeter, D. Richardson, P. Flicek.* The European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, United Kingdom.

The 1000 Genomes Project provides an essential reference catalog of human variation. It includes more than 80 million variant sites ranging from single nucleotide polymorphisms to structural variant events including inversions and duplications. Global allele frequencies and genotypes for 2504 individuals are also provided; these samples are from 26 different populations across Europe, Africa, East and South Asia and the Americas. This resource has enabled many other projects to better interpret their results. Primary uses for the 1000 Genomes data sets include serving as imputation panels to derive whole genome variant sets from exome or array-based genotypes; as filters of shared variation in rare disease or cancer sequencing projects; and for exploring demography and selection in human populations and evolution. Although the 1000 Genomes Project has reached its goal and finished successfully, the use of the resulting data sets and analysis results remains high. The International Sample Genome Resource (IGSR), launched in January 2015, will maintain, update and expand this valuable reference data set. The IGSR will maintain the FTP site (ftp://ftp. 1000genomes. ebi. ac. uk/vol1/ftp) and the project website (http://www. 1000genomes. org) to ensure the community can access both the raw data and the documentation about the 1000 Genomes Project. We will establish a stable version of the 1000 Genomes Browser and the tools it hosts (http://browser. 1000genomes. org) based on the project's final date release, which is based on the GRCh37 assembly of the human reference genome. IGSR will also extend and expand the 1000 Genomes dataset to ensure it remains useful to the community. These plans fall into three main categories. 1) Remap the existing data to the new human assembly GRCh38. The majority of the phase 3 data is now available mapped to GRCh38 from our FTP site. 2) Draw in other data created on the Coriell Cell lines such as the RNA-Seq data created by the Geuvadis project, whole genome sequencing at a deeper level or from new technologies. 3) Add new open population collections sequenced using the same strategy to expand the diversity of the public catalog. We aim to build new tools to improve data discoverability and allow people to view the data alongside other genomic annotation in Ensembl.

1842F

***De Novo* Assembly of the First Human Diploid Genome with Single-molecule Sequencing for Asian Genome Project.** *M. Sohn[1,2,4], A. Rhie[1,2,4], SJ. Lee[1,3], JS. Kim[1,3], SK. Yoo[1,2,5], DS. Lee[1,2,4], J. Baek[3], M. Roh[3], JY. Shin[1,3], KS. Yang[3], C. Kim[3], JS. Seo[1,2,3,4,5].* 1) Genomic Medicine Institute(GMI), Seoul National University; 2) Department of Biomedical Sciences, Seoul National University College of Medicine, Seoul 110-799, Korea; 3) Macrogen Inc. Seoul 153-781; 4) Department of Biochemistry and Molecular Biology, Seoul National University College of Medicine, Seoul 110-799, Korea; 5) Interdisciplinary Program in Bioinformatics, Seoul National University, Seoul 110-799, Korea.

Through the Asian Genome Project, we wish to uncover the genetic variation within the Northern Asian population that is responsible foradaptationand Mendelian diseases. The Asian Genome Project is divided into two phases. In the first phase, we have sequenced 158 Mongolians, 67Kazakhstans, 150 Koreans, 62Chinese's and Japanese fromHapMapsamples. In the second phase, we wishto sequence another ten thousand Asian genomes. It has come to our attention that we require a reference genome tailored for the Asian population. To pursue this goal, we assembled the Altai Korean (AK1) diploid genome usingPacBioRSII with P6C4 chemistry (>100X) and 100,000 BAC clones. The assembled-contigshad a total sequence length of 2. 811 Gb and had a N50 of 7. 3 Mb. Ourcontigscovered 91% of the GRCh38 reference genome with gaps, and furthermore, we were able to close 250 gaps and extend 180 gaps out of 604 gaps existing in GRCh38. We were able to find 196 novel insertions and 260 novel deletions in Chr20, which may explain certain geneticsusceptibilityin Asians. We will also be utilizing the data fromBioNanoto further refine our assembly and use BAC clones to resolve many highly complex regions, with the goal of creating the most accurate Asian reference genome for clinical application and population genetics.

1843W

SHIELD: an integrative gene expression database for inner ear research. *J. Shen[1,2], D. I. Scheffer[3,4], K. Y. Kwan[5], D. P. Corey[2,3,4].* 1) Department of Pathology, Brigham and Women's Hospital; 2) Harvard Medical School Center for Hereditary Deafness; 3) Department of Neurobiology; 4) Howard Hughes Medical Institute, Harvard Medical School, Boston, MA; 5) Department of Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ.

The inner ear is a highly specialized mechanosensitive organ responsible for hearing and balance. Its small size and difficulty in harvesting sufficient tissue has hindered the progress of molecular studies. The protein components of mechanotransduction, the molecular biology of inner ear development, and the genetic causes of many hereditary hearing and balance disorders remain largely unknown. Inner-ear gene expression data will help illuminate each of these areas. For over a decade, our laboratories and others have generated extensive sets of gene expression data for different cell types in the inner ear using various sample preparation methods and high-throughput genome-wide approaches. To facilitate the study of genes in the inner ear by efficient presentation of the accumulated data and to foster collaboration among investigators, we have developed the Shared Harvard Inner Ear Laboratory Database (SHIELD: https://shield. hms. harvard. edu/), an integrated resource that seeks to compile, organize and analyze the genomic, transcriptomic, and proteomic knowledge of the inner ear. Five datasets are currently available. These datasets are combined in a relational database that integrates experimental data and annotations relevant to the inner ear. The SHIELD has a searchable web interface with two data retrieval options: viewing the gene pages online or downloading individual datasets as data tables. Each retrieved gene page shows the gene expression data and detailed gene information with hyperlinks to other online databases with up-to-date annotations. Downloadable data tables, for more convenient offline data analysis, are derived from publications and are current as of the time of publication. The SHIELD has made published and some unpublished data freely available to the public with the hope and expectation of accelerating discovery in the molecular biology of balance, hearing and deafness.

1844T

aRrayLasso: a network-based approach to microarrayinterconversion. *A. S. Brown[1], C. J. Patel[2].* 1) Cancer Immunology and AIDS, Dana-Farber Cancer Institute, Boston, MA; 2) Center for Biomedical Informatics, Harvard Medical School, Boston MA.

Summary: Robust conversion between microarray platforms is needed to leverage the wide variety of microarray expression studies thathave been conducted to date. Currently available conversion meth-ods rely on manufacturer annotations, which are often incomplete, oron direct alignment of probes from different platforms, which often failto yield acceptable gene-wise correlation. Here, we describe aRray-Lasso, which uses the Lasso-penalized generalized linear model tomodel the relationships between individual probes in different probesets. We have implemented aRrayLasso in a set of five open-sourceR functions that allow the user to acquire data from public sourcessuch as GEO, train a set of Lasso models on that data, and directlymap one microarray platform to another. aRrayLasso significantly pre-dicts expression levels with higher fidelity than technical replicates ofthe same RNA pool, demonstrating its utility in the integration of datasets from different platforms. **Availability and Implementation**: All functions are availa-ble, along with descriptions, at https://github. com/adam-sam-brown/aRrayLasso.

1845F

Sequencing File Mover: A Tool for the Management of Sequencing Data. *K. A. Duerr, M. Z. Mawhinney, K. N. Hetrick, S. M. L. Griffith, A. M. Sanchez, A. B. Robinson, B. D. Tibbils, B. D. Craig, J. L. Goldstein, L. Watkins, Jr. , K. F. Doheny.* Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD.

The Center for Inherited Disease Research (CIDR) provides high quality sequencing and genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to disease. The Sequencing File Mover is a Java desktop application created to aid lab management in filtering, moving, copying, and deleting large quantities of files of diverse types. The application features a custom set of file manipulation modes that have been designed around the needs of sequencing lab managers. To match the dynamic needs of lab data interpreters, the application's performance parameters can easily be altered. Originally operating solely to copy or move a specific set of files from a selected directory, the application evolved to accept additional metadata, to be used during file management. For example, using pedigree information, the application can sort files by family. The application also contains multiple options to clean up vestigial sequencing data files and directories. Each option has been customized to delete residual files and transfer desired files to a compressed archive based on the type of data generated within a specific time period. Before the files are manipulated, the application gives counts of file type or directory size, specific to the mode selected, giving the user a clear view of what will happen upon submission. Before submission, the application will first check if the selected destination already contains any of the chosen files and will display a warning if needed. Upon submission, to gauge wait time, the application displays a progress bar, estimating the time remaining. If the user wishes to cancel the submission, the user has the option to revert any changes that have been made. The application will then either replace moved files or delete copied files. Previously, the amount of time taken to move or remove terabytes worth of data manually on a monthly basis was prohibitive and error-laden. With the help of this application, lab management can submit their mass file manipulation request in a few minutes, resulting in significant time savings and fewer errors.

1846W

A flexible pipeline that extracts full ClinVar data set. *X. Feng, A. Jackson, S. Paithankar, A. Baker, S. Plon, A. Milosavljevic.* Baylor College of Medicine, Houston, TX.

The ClinVar database, maintained by the National Center for Biotechnology information (NCBI), provides information about medically important variants with associated phenotypes and effects of sequence changes. With the help from the NIH Clinical Genome Resource (ClinGen) project, ClinVar is becoming an authoritative resource for medical variants submission and interpretation.

ClinVar's content can be accessed in several ways: the website for live queries and release file download for integrated data analysis. Users can also access it via NCBI's Eutils application programming interface (API). However, ClinVar's full content is only available in its Extensible Markup Language (XML) release. The XML release is structured using deeply nested nodes that requires memory-efficient parsing algorithms. Consequently many existing pipelines that extract data from Clinvar use the alternative Variant Call Format (VCF) version that has incomplete data but easier to parse. Moreover, the data reported by ClinVar can be organized in many ways. Consequently, much redundant effort is spent by multiple groups performing the same data warehousing effort in order to extract the parts of data of interest from the complete ClinVar release.

To address these issues and enable local warehousing of ClinVar data, here we report our design and implementation of a memory-efficient flexible pipeline that extracts full ClinVar dataset on a regular desktop with typical hardware configuration. We invented a user-editable map file format that specifies the portion of the ClinVar's XML file targeted for extraction. By editing this map file, the users can extract various portions of ClinVar without modifying the pipeline code. The pipeline outputs ClinVar variants as javaScript Object Notation (JSON) files for direct consumption by document oriented databases. We implemented the map processor in Ruby and designed an example map file that models the official example release file. Using this map, our flexible pipeline automatically extracted about 150,000 (as of May 2015) ClinVar variants from the XML release into JSONs. We then validated the pipeline using a series of different maps. The pipeline has been published on github (https://github. com/clingendb/clinvar_xml_pipe). The full set of ClinVar JSON files generated from the pipeline is hosted at the GenboreeKB repository(http://genboree. org/genboreeKB/genboree_kbs?project_id=test_clingen&coll=clinvar_xml0. 8) that can be accessed via APIs.

An integrated RNA and DNA approach to unravel genetic regulation in cancer. *V. Hedatale, S. Ramachandrula, P. Tata, R. Gupta.* Strand Life Sciences, Bangalore, India.

Background: Clinically meaningful applications like cancer studies benefit from analyzing genomic and transcriptomic anomalies simultaneously in personalized oncology. Mutations in the genome result in diverse transcriptional aberrations that can be missed in a whole genome/exome analysis. The analysis of low allele fraction variants, RNA editing events and allele specific expression is possible only in an integrated analysis. This necessitates the development of biologist friendly tools like Strand NGS to provide an integrated platform for easy and accurate analysis of multiple next generation sequence (ngs) data and perform multi-omic pathway analysis. **Results:** We used a publicly available tumor-normal paired genome and transcriptome ngs dataset from a patient with aggressive prostate cancer (APCa) rapidly progressing towards castrate resistance. A comprehensive analysis of the primary and metastatic prostate cancer was carried out using Strand NGS for possible small and large structural variants, expression alterations, RNA editing events and allele specific expression. Large amplifications with a concomittantly higher expression of genes like MSI2, KLK3, AR was observed in both primary and metastatic prostate cancers and corroborated with a TCGA provisional dataset of 499 aggressive prostate cancer samples. The hybrid luminal-neuroendocrine tumor had a number of copy number aberrations and gene fusion events and expressed both luminal markers (*MSI2, NKX3-1, AR, KLK3*) and neuroendocrine markers (*CHGA, CHGB, NSE, CGA)*. We identified multiple A-to-I RNA editing events within the 3' UTR region of H6PD. Based on known interactions we generated a Natural Language Processing-based network of androgen-independent prostate cancer and overlayed genomic and transcriptomic data in a multi-omic pathway analysis. Androgen receptor interacting proteins EIF4E, ERG, MAPK, AKT in this network were highly upregulated in the tumors suggesting that with disease progression, these proteins are active even in androgen-depleted conditions. **Conclusion:** Overall, this case study highlights the importance of integrated analyses of genome and transcriptome for basic tumour biology, RNA-editing events and identification of potential biomarkers. We also demonstrated that Strand NGS is an excellent platform for the effortless analysis, integration, visualization and downstream analysis of different ngs data.

The PhenX Toolkit: A Genomic Resource for Collaborative and Translational Biomedical Research. *W. Huggins[1], H. Pan[1], D. S. Nettles[1], T. Hendershot[1], D. R. Maiese[1], D. C. Brown[1], J. Levy[1], M. Phillips[1], N. Gaddis[1], V. Bakalov[1], Y. Qin[1], R. P. Troiano[2], J. Himes[3], P. Byers[4], N. Butte[5], S. Smith[6], P. A. Harris[7], M. L. Marazita[8], C. A. McCarty[9], G. K. Farber[10], K. L. Wanke[11], B. Iglesias[12], E. M. Ramos[12], C. M. Hamilton[1].* 1) RTI International, Research Triangle Park, NC; 2) National Cancer Institute, Bethesda, MD; 3) University of Minnesota, Minneapolis, MN; 4) University of Washington, Seattle, WA; 5) Baylor College, Houston, TX; 6) Florida Hospital, Orlando FL; 7) Vanderbilt University, Nashville, TN; 8) University of Pittsburgh, Pittsburgh, PA; 9) Essentia Institute of Rural Health, Duluth, MN; 10) National Institute of Mental Health, Bethesda, MD; 11) Office of Disease Prevention, National Institutes of Health, Bethesda, MD; 12) National Human Genome Research Institute, Bethesda, MD.

To help investigators identify opportunities for collaborative biomedical research and improve the consistency of data-collection, the Web-based PhenX Toolkit (consensus measures for **Phen**otypes and e**X**posures, https://www. phenxtoolkit. org/) is a catalog of 395 standard measures with browse and search capabilities and bioinformatics support. PhenX phase I established a consensus process and a bioinformatics pipeline, and generated 349 measures relevant to common complex diseases with additional depth in substance abuse and addiction. PhenX measures and protocols are included in the Cancer Data Standards Repository (caDSR) Common Data Elements (CDE) Dictionary and the NIH Common Data Element (CDE) Resource Portal. PhenX phase II, now underway, is assembling Expert Review Panels (ERPs) to review and update Toolkit content. The ERPs are evaluating the protocols and supporting information for all PhenX Phase I measures. The first ERP reviewed 74 protocols from 4 related research domains. As a result of their review, the ERP recommended replacing 4 protocols and adding 3 new measures and 6 new protocols to the PhenX Toolkit. In Phase II, measures suitable for inclusion in the Toolkit extend beyond primary utility in genome wide association studies to other study designs, including clinical and translational research. The PhenX Steering Committee prioritized expansion of the Toolkit to include measures relevant to rare genetic conditions, including a crowdsourcing annotation effort, and to address obesity. To support investigators who want to collect data via the Web, PhenX protocols are being made available as REDCap Instrument Zip files. To help users find comparable data, a team of curators is combining programmatic and manual approaches to map the ~16,000 PhenX variables to all completed studies in dbGaP. Variable mappings for selected PhenX measures will be presented to demonstrate utility. In supplemental efforts new measures are being added to support mental health research, tobacco regulatory research, and sickle cell disease research. PhenX is managing change, expanding the scope, and increasing the utility of the Toolkit. These efforts will ensure that the PhenX Toolkit will continue to provide the biomedical research community with easy access to standard measures with the potential to increase the overall impact of individual studies by facilitating cross-study analysis. *Funding provided by NHGRI, co-funding from NIDA: U01 HG004597 and U41 HG007050.* .

Interpreting a migraine GWAS using gene expression in healthy human brain. *S. M. H. Huisman[1,2], E. Eising[3], A. Mahfouz[1,2], L. Vijfhuizen[3], B. de Vries[3], B. P. F. Lelieveldt[2], A. M. J. M. van den Maagdenberg[3,4], M. J. T. Reinders[1], International Headache Genetics Consortium.* 1) Department of Intelligent Systems, Delft University of Technology, Delft, Zuid Holland, The Netherlands; 2) Department of Radiology, Leiden University Medical Center, Leiden, Zuid Holland, The Netherlands; 3) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 4) Department of Neurology, Leiden University Medical Center, Leiden, The Netherlands.

Genome Wide Association Studies (GWAS) are frequently used to find common variants with small effect sizes. However, they often provide researchers with short lists of single nucleotide polymorphisms (SNPs) with uncertain connections to biological functions. We present an analysis of GWAS data for migraine, where the full list of SNP statistics is used to find groups of functionally related migraine-associated genes. For this end we make use of gene co-expression in the healthy human brain. We performed genome wide clustering of genes, followed by enrichment analysis for migraine candidate genes. In addition, we constructed local co-expression networks around high-confidence genes. Both approaches converge on distinct biological functions and brain regions of interest. Materials & MethodsMigraine GWAS data was obtained from the International Headache Genetics Consortium, with 23,285 cases and 95,425 controls. Genes were scored by SNP load and divided into high-confidence genes, migraine candidate genes, and non-migraine genes. Spatial gene expression data in the healthy adult human brain was obtained from the Allen Brain Institute. It contains microarray expression values of 3702 samples from 6 donors. Robust gene co-expressions were used to cluster genes into 18 modules, which were then tested for enrichment of migraine candidate genes, and functionally characterized. In a second approach, local co-expression networks were built around the high-confidence migraine genes. These local networks were then compared to the modules of the first approach. ResultsThe genome wide analysis revealed several modules of genes enriched in migraine candidates. Two modules have preferential expression in the cerebral cortex and are enriched in synapse related annotations and neuron specific genes. A third module contains oligodendrocytes and genes preferentially expressed in subcortical regions. The local co-expression networks converge on the same pathways and expression patterns, even though the high confidence genes lie mostly outside of the modules of interest, which improves our confidence. DiscussionThe analyses confirm the previously observed link between migraine and cortical neurotransmission. They also point to the involvement of subcortical myelination, which is in line with recent tentative findings. These results show that more relevant information can be extracted from GWAS results, using (publicly available) tissue specific expression patterns.

Deploying a next-generation informatics infrastructure for genomic medicine: the Ohio State University and Ohio Supercomputer Center experience. *D. D. Kinnamon[1], D. Johnson[2], F. Oriyo[1], R. E. Hershberger[1].* 1) Division of Human Genetics, Department of Internal Medicine, The Ohio State University Wexner Medical Center, Columbus, OH; 2) Ohio Supercomputer Center, Columbus, OH.

Genomic medicine requires informatics infrastructure that facilitates integrated storage and high-throughput processing of phenotypic, laboratory, and genomic data. Such infrastructure presents a major implementation challenge; genomic data storage and processing require scalable high-performance computing resources not generally available within an academic medical center. Meeting this challenge by deploying these resources at the medical center is often fiscally and operationally untenable. While this challenge could also be met by moving all data management from medical center systems to an external cloud or shared high-performance computing resource, such systems may not fully comply with federal, state, and institutional regulations pertaining to confidential health information. To overcome these obstacles, the Division of Human Genetics at the Ohio State University Wexner Medical Center (OSUWMC) partnered with the Ohio Supercomputer Center (OSC), a shared high-performance computing resource funded by the State of Ohio, to design and deploy a comprehensive solution using the BC|Enterprise genomic data integration software platform from vendor BC Platforms. The platform is deployed on a dedicated server hosted at OSC and provides tools for managing and linking phenotypic, laboratory, and genomic data. These tools transparently leverage OSC's shared storage pool and compute clusters for high-volume storage and high-throughput processing of genomic data at low cost. In addition, the project team designing and implementing the platform worked closely with OSUWMC Information Security and the Ohio State University Office of Responsible Research Practices throughout all project phases to ensure full compliance with all applicable regulations, including for system components using shared OSC resources. The resulting platform provides end-to-end data management and analysis capabilities for a single patient, minimizes movement of genomic data for analysis, and provides scalable storage and processing to accommodate anticipated growth in genomic data. End-users at OSUWMC are able to access these features through web applications that do not require local installation of specialized software or knowledge of high-performance computing. Our platform provides a template for academic medical centers seeking to partner with shared high-performance computing resources to establish cost-effective software-as-a-service solutions that support genomic medicine.

1851F

Sequence and structural variability at the whole population scale for the Influenza Virus type A. *G. Mazzocco[1,3], P. Migdał[1], M. Łaś;niewski[1], J. Radomski[2], D. Plewczyński[1].* 1) Centre of New Technology, University of Warsaw, Warsaw, Poland; 2) Interdisciplinary Centre for Mathematical and Computational Modelling, University of Warsaw, Warsaw, Poland; 3) Institute of Computer Science, Polish Academy of Sciences, Warsaw, Poland.

Influenza type A viruses are commonly known for their extreme genetic variability, which represent a true virological challenge. The Hemagglutinin (HA) protein plays a crucial role in the mechanism of action of the virus, defining the likelihood of the interaction between the host cells (avian, human, swine, etc.) and the infecting viruses. The specific nature of the binding site within a given HA protein is in fact responsible for the differential recognition of some host-specific sialic acid derivatives. Hence the analysis of HA variability at molecular level is crucial for the correct understanding of the influenza problem at the population level. Although the analysis of HA genetic variability is classically applied to sequence and serological data, a comparative structural procedure can potentially provide additional insight. In order to perform such analysis, we initially selected a pool of 1198 HAs expressing the genetic variability of ~22k different HAs. We compared these proteins in terms of sequences, protein structures and electrostatics potentials (ESP), generating three layers of comparable information that were after used to generate three graph-based relational representations respectively. Metadata information (e. g. year, geographic location, virus host, etc.) was included, allowing the exploration of possibly interesting evolutionary patters.

1852W

Integrating coding variants and regulatory variation to improve the power of identifying disease-associated genes in complex human diseases. *A. Mezlini[1,2], A. Shlien[2], A. Goldenberg[1,2].* 1) Computer Science, University of Toronto, Toronto, Ontario, Canada; 2) SickKids Hospital. Toronto. Ontario. Canada.

Identifying genes associated with complex human diseasesis one of the main challenges of human genetics and computational medicine. Adisease causing abnormalityin a proteincan be due to protein-coding SNVsor due to regulatory changes, such asstructural DNA aberrationsor epigenetic variation,leading to theabnormalitiesin the quantity of the produced protein. The same disease in different patients may be due todifferent types of abnormalities. In complex diseases,the problem is compounded since these different types of abnormalities are likelyaffectingmultiple proteins making the discovery of the underlying disease mechanism very challenging.

To capture various types of abnormalities and to increase the power of the disease mechanism detection, we propose a novel method that integrates different types of data such asexomesequencing, gene expression and/or DNA methylation. Our approach utilizes a probabilistic graphical model to infer genes associated with complex diseases. Our method also incorporates external biological knowledge including gene networks and variant harmfulness predictions as Bayesian priors to improve the accuracy of gene detection.

Our extensive simulations show that our method has far superior sensitivity and precision compared to variant-aggregating (CAST, C-Alpha, SKAT, SKAT-O,dmGWAS) and differential expression methods. We show that integratingmultipledata typesand biological annotationshasagreaterpositive impact on the power of ourmethodthanthe sum of individualcontributions ofeach source of information, indicating the effectiveness of thesynergy of differenttypes of data in our model.

Our integrative approach was able to identify important genes in breast cancer, recovering the genes that were previously associated with different breast cancer subtypes and identifying novel candidate genes. Importantly, our analysis shows that many associated genes had coding aberrations in some patients and regulatory abnormalities in others, emphasizing the importance of data integration to explain the disease in a larger number of patients. For every patient in our cohort, we were able to analyze the posterior distribution overassociated genes, which enabledus tofurthercharacterize patientheterogeneity within the breast cancer subtypes. .

Integrated database and knowledge base for genomic prospective cohort study in Tohoku Medical Megabank toward personalized prevention and medicine. *S. Ogishima, T. Takai, K. Shimokawa, S. Nagaie, H. Tanaka, J. Nakaya.* Dept. of Bioclinical Information, Tohoku Medical Megabank Organization, Tohoku University, Sendai-shi, Miyagi, Japan.

To revitalize medical care and realize personalized prevention and medicine in the disaster area of Great East Japan Earthquake, the Tohoku Medical Megabank Organization has been established aiming at becoming a center for the reconstruction of the entire Tohoku region by conducting prospective genome-cohort study and developing the large-scale genome biobank toward personalized prevention and medicine. In our prospective cohort study, we will recruit 150,000 people at Tohoku university, satellites, health clinics, and Iwate medical university, and have collected biospecimen (blood, urine), blood and urine test, questionnaire, physical measurement as baseline and follow-up investigation. As for pathogenesis investigation follow-up, we will collect clinical data as electronic health records provided by Miyagi Medical and Welfare Information Network (MMWIN). MMWIN is expected to develop regional electronic network of medical records of most hospitals in Miyagi prefecture. Collected data will be de-identified and stored in the integrated database of Tohoku Medical Megabank. Researchers in universities, institutes, and companies can apply withdrawal of biospecimen and data. Integrated database is a database for integration of genomic (omics), specimen, baseline & follow-up and clinical data. On the other hand, knowledge base is a database for integration of existing and novel knowledge by large-scale correlation analysis on integrated database. It is a RDF store implemented by Virtuoso. Our database is is too huge to to grasp characteristic of data. Therefore, integrated database not only provides integration of data but also provides statistical significance and related knowledge in cooperation with knowledge base. Statistical significance of selected data is provided in integrated database to characterize selected cohort; e. g. , selected population has statistically significant bias in sex and alcohol intake. This characterization is expected to lead to hypothesis. Related knowledge of selected data is also provided in integrated database in cooperated with knowledge base; e. g. , breast cancer is known to have a highly linked and causative SNPs. This provision of related knowledge is expected to accelerate studies. We hope our integrated database and knowledge base which will be key database for realizing personalized prevention and medicine.

Phoenix Web: Presenting Relevant Lab Data and Receiving Feedback from Outside Sources. *A. M. Sanchez[1], K. A. Duerr[1], D. R. Leary[2], J. D. Newcomer[3], M. Adams[1], T. Shelford[1], C. M. Ongaco[1], I. A. McMullen[1], M. Z. Mawhinney[1], J. Romm[1], S. M. L. Griffith[1], J. L. Goldstein[1], L. Watkins, Jr. [1], K. F. Doheny[1].* 1) Center for Inherited Disease Research, Johns Hopkins University, Baltimore, MD; 2) The New York Genome Center, New York, NY; 3) The Johns Hopkins Applied Physics Lab, Laurel, MD.

The Center for Inherited Disease Research (CIDR) provides high quality sequencing and genotyping services and statistical genetics consultation to investigators working to discover genes that contribute to disease. Phoenix Web is an application that allows investigators secure and indirect access to portions of CIDR's Phoenix Laboratory Information Management System (LIMS). The Phoenix software, from which Phoenix Web extends, was designed and built at CIDR to organize project data; and orchestrate and track the flow of a project's samples as they move through CIDR's labs. While Phoenix was originally designed solely for internal use within CIDR, two significant portions of Phoenix's workflow, Principal Investigator File Handling (PIFH) and Problem Handling, require direct input from investigators remote from CIDR. The PIFH workflow handles processing and storage of investigator-provided project files (typically spreadsheets). The Problem Handling workflow is composed of two main sections: the tracking of issues discovered at CIDR that pertain to an investigator's project, and the generation of problem reports to be presented to an investigator for resolution. Such problems include, for example, insufficient quantities of DNA for a given assay or contaminated materials. Because of the timepotentially spent waiting for investigator feedback, both PIFH and Problem Handling cancreate workflow bottlenecks. Additionally, because these workflows require direct interaction with the investigator, easy-to-use software wouldyieldmorepositive investigator relations. Previously, the information exchanged with investigators was done exclusively via email communication with spreadsheet attachments. As a result, the entire process was both susceptible to human error and time consuming. Phoenix Web improves on this process by automatically and securely presenting relevant and up-to-date data to the investigator directly from the Phoenix system as well as providing automatic feedback from the web interface. This eliminates the need for slow email exchanges while still providing the investigator with feedback on their uploaded project files and problem resolution responses in an easy to access way. Furthermore, Phoenix Web presents more data to CIDR's investigators than before, allowing for a more transparent experience. Phoenix Web is flexible enough to allow even further transparency to investigators in the future.

1855W

Integrating Big Data to Make Biological Sense of Statistical Models. *S. Verma[1], A. Frase[1], S. Pendergrass[2], M. Hall[1], D. Kim[1], R. Li[1], M. Ritchie[1,2].* 1) Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Biomedical and Translational Informatics - Geisinger Health System, Danville, PA.

Researchers in human genetics have spent the last several decades searching for the genetic factors that influence susceptibility for complex disease, which has resulted in an outburst of biological data. Millions of research participants have been analyzed to identify thousands of single genetic variants associated with hundreds of common diseases. The search for complex gene-gene interactions and pathway/polygenic models has led to an even greater number of genetic variants in our pool of "putative disease variants". Making sense of all of these statistical associations in terms of underlying biology and disease etiology is the main objective for the transition from basic science in human genetics to translational science in precision medicine. Thousands of publicly available databases exist with biological knowledge, dozens of bioinformatics tools for functional predictions, and petabytes of functional genomics data from projects like ENCODE, GTeX, Roadmap Epigenome and others which can be integrated with these genetic variants to begin to put the pieces of the puzzle together. These databases can be used to prioritize results from association studies for functional validations in model organisms or they can also be used to prioritize variants/genes/omic regions that can be tested further to investigate interactions or regulatory networks associated with diseases. We have developed a unified framework, which is an integration of multiple public databases along with relevant annotation and visualization tools (Biofilter and iPhenoGram), allowing us to create a complete workflow to perform higher-level biological interpretation of association results. Recently we have extended this workflow by incorporating additional data on chromatin states from ENCODE. Using this workflow for specific genes (e. g. *PCSK9*), we can identify how variants associated with disease traits can be interpreted based on the activity and expression of each region. With this pipeline, we have improved the interpretation of results from novel and previously associated variants in glaucoma, type 2 diabetes, age-related macular degeneration and hypothyroidism by annotating them based on activity map of regions of genome (in most cases represented as repressed or transcribed regions). In conclusion, we present data visualization workflows to facilitate the integration of big data from biology with genetic association results to elevate ongoing human genetics studies to the next level.

1856T

RAPiD - An Agile and Dependable RNA-Seq Framework. *Y. Wang, R. Z. Castellanos, C. Pandya, H. Shah.* Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

RNA-Seq is a widely used technology for transcriptome analysis and rapid software development is underway for better analysis tools and algorithms. However, among numerous tools available in the literature, choosing tools of interest and integrating them as a seamless pipeline requires significant effort. There is an unmet need for a software suite that covers the breadth of available RNA-Seq algorithms. We present RNA-Seq Advanced Pipeline Deployment (RAPiD), an agile and dependable RNA-Seq framework that automates alignment (STAR and TopHat), quality control (FastQC, HTSeq and RNA-SeQC), expression analysis (featureCounts, Cufflinks, Kallisto and RSEM), variant calling (GATK), alternative splicing analysis (MISO) and fusion/chimera discovery (deFuse, Chimera, ChimeraScan, FusionCatcher, FusionMap, InFusion, OncoFuse and TopHat-Fusion). RAPiD is easily configurable with a recipe file that defines the set of tools/algorithms, corresponding parameters and dependency management. Integration of RAPiD with a high-performance computing cluster enables high-throughput computations with pipeline monitoring and manipulation capabilities. RAPiD runs are automatically tracked and visualized via a web-based dashboard through our in-house workflow management platform - APOLLO. RAPiD has been used for quality control, expression analysis, variant calling and fusion discovery. In total, RAPiD has processed tens of thousands of samples for a diverse set of clinical and research studies including The Cancer Genome Atlas (TCGA), Genotype-Tissue Expression (GTEX), CommonMind, PsychENCODE and LINCS. .

Piloting Methods for Integrating Neuroimaging and GWAS Data in Bipolar Disorder Studies. *H. Cao, MA. Brotman, N. Akula, W. Guo, L. Donahue, A. Oakes, B. Lehrman, FJ. McMahon, E. Leibenluft, Y. Yao.* National Institute of Mental Health, NIH, Bethesda, MD.

Background: Several functional magnetic resonance imaging (fMRI) studies have suggested that patients with bipolar disorder (BD) and youth at familial risk present amygdala dysfunction. Additionally, one genome-wide association study (Liu et al. , 2010) nominated a few genes influencing the magnitude of amygdala activation during face processing in BD patients. Our ultimate goal is to test whether there is a high level of correlation between BD-targeted neuroimaging phenotypes and genotypes. Toward that end, we compared the performance of two methods, a correlation method and a spares representation based variable selection (SRVS) method, in terms of the capability of finding the SNPs highly correlated with the fMRI phenotypes. **Methods:** Both task fMRI data (emotional/neutral faces processing task) and SNP data (712,077 SNPs after quality control) were acquired from 73 subjects, including 48 healthy controls, 15 adult bipolar patients and 10 children at risk for BD. Traditionally in case/control studies, the phenotype is quantitatively expressed as to represent disease status; however, here we used the averaged amygdala fMRI scores from both hemispheres for each subject as the quantitative phenotype in the form of . To detect significant association between the phenotype and the genotype data, we employed two methods including SRVS method and a SNP-wise -SNP-correlation analysis. The recently developed SRVS algorithm (Cao et al. , 2014) is proposed to solve sparse linear systems and select significant variable sets associated with the phenotype y. **Results:** In addition to the genes previously reported as BD candidate genes (e. g. AKAP13, DAOA, HTR2A, NRG1, SGK1), both statistical approaches nominated the MTR gene which has not been previously reported. Furthermore, the potentially significant SNP-fMRI phenotype association signals detected by both methods were different (overlap less than 25%). For example, CAMTA1 was only detected by the SRVS method; whereas, DISC1 and ODZ4 were identified by the correlation analysis. **Conclusions:** This is one of the first efforts to integrate fMRI and GWAS data with the aim of exploring the underlying mechanisms of BD using two statistical approaches. This preliminary analysis indicates the feasibility of using both methods for integrating GWAS and fMRI data. However, depending on the data structure, the performance of these two methods may be different. More studies are needed.

1858W

Accessing genomic evidence for clinical variants with new NCBI services. *S. Sherry, C. Xiao, D. Slotta, K. Rodarmer, M. Feolo, M. Kimelman, G. Godynskiy, C. O'Sullivan, E. Yaschenko.* National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD.

NCBI provides many resources for evaluating and declaring evidence of pathogenicity for an increasing number of human sequence variants. Primary details about a genetic test's analytical validity and clinical utility are reported in the Genetic Test Repository, and evidence for inferences of variant pathogenicity are summarized in ClinVar. NCBI has developed several tools that integrate these high level records with the more basic factual data describing them as population level variants (dbSNP/dbVar), and deeper still as individual-level observations with called genotypes (the NCBI Genotype Server), phenotypes (dbGaP), whole genome/exome sequences (SRA) and finally as positions on the reference genome (GRC human reference assemblies). Traversing the connections between variant-level records, e. g. GTR, ClinVar and dbSNP, and individual-level data (e. g. genotypes, sequnces, samples, and phenotypes) is a computationally intensive activity, and NCBI has developed several new services to pre-compute these relationships and permit users to quickly move from summary records to individual level data. This presentation will introduce several of these services including variation reporter, variation viewer, beacon search, and the genome browser with particular emphasis on how users can access and review individual level data for clinical variants or *ad hoc* genomic positions of particular interest. Examples of use include the review of ClinVar submissions by expert panels, research into the existence of specific sequence alleles, automatic notification when new data for specific potential alleles of interest are submitted to NCBI, confirmation of variant properties during manuscript review, and research in general questions of human genetic architecture.

1859T

A visual semantic similarity guided approach to variant prioritization and discovery in genome-wide diagnostics. *R. James[1], E. Chen[2], I. Campbell[2], P. Boone[2], M. Rao[2], M. Bainbridge[2,3], J. Posey[2], Y. Yang[2,4], C. Eng[2,4], C. Shaw[2,5].* 1) Structural and Computational Biology and Molecular Biophysics Program, Baylor College of Medicine, Houston, TX; 2) Molecular and Human Genetics Dept, Baylor College of Medicine, Houston, TX; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Baylor Miraca Genetics Laboratories, Houston, TX; 5) Statistics Dept, Rice University, Houston, TX.

Genome-wide data are increasingly important in the clinical evaluation of human disease. However, the large number of variants observed in individual patients challenges the efficiency and accuracy of diagnostic review. Recent work has shown that systematic integration of clinical phenotype data with genotype information can improve diagnostic workflows and prioritization of variants. We have developed visually interactive, analytically transparent analysis software that leverages existing disease catalogs, such as the Online Mendelian Inheritance in Man database (OMIM) and the Human Phenotype Ontology (HPO), to integrate patient phenotype and variant data into ranked diagnostic alternatives. Our tool, "OMIM Explorer" (http://www. omimexplorer. com), extends the biomedical application of semantic similarity methods beyond those reported in previous studies. The visual approach collapses high-dimensional phenotypic and genotypic feature data of an individual into a graphical format that contextualizes the patient within a low-dimensional disease map. This visual approach indicates differential diagnoses and algorithmically suggests potential alternatives for phenotype and gene queries. The tool also implements an adaptive approach for gene discovery based on patient phenotypes. We retrospectively analyzed pilot cohort data from the Whole Genome Laboratory at Baylor College of Medicine, demonstrating performance of the tool and workflow in novel visual display of clinical exomes, rapid matching of cohort cases to known diseases, and accurate prioritization of causative variants. Our tool assigned to clinically reported causal variants in disease genes a median rank in the top 1% of filtered candidates (4/463) across the 41 cohort cases with reported molecular diagnoses of exome variants in OMIM Morbid Map genes. Additionally, a novel semantic similarity method we developed asigned a median rank of 3/463, with 90% within the top 10,to the reported cohort variant host genes. This integrative paradigm can improve the quality of genomic medicine by more effectively utilizing available phenotype information, catalog data, and genomic knowledge.

1860F

Tracking data provenance at the ENCODE DCC. *E. T. Chan[1], J. M. Davidson[1], T. R. Dreszer[1], B. C. Hitz[1], M. Ho[1], B. J. Lee[2], V. S. Malladi[1], N. R. Podduturi[1], L. D. Rowe[1], M. Simison[1], C. A. Sloan[1], J. S. Strattan[1], F. Tanaka[1], E. L. Hong[1], W. J. Kent[2], J. M. Cherry[1].* 1) Department of Genetics, School of Medicine, Stanford University, Stanford, CA; 2) Center for Biomolecular Science and Engineering, University of California, Santa Cruz, CA.

The provenance of experimental reagents and transparency of computational analyses are essential to compare, reproduce, and interpret experimental data. The task of tracking this information consistently across diverse sequencing assays can be especially challenging in large projects like the ENCODE (ENcyclopedia Of DNA Elements) Consortium that perform 40+ genomic assays using 400+ cell and tissue types. The identification of a transcription factor binding site or the quantification of transcript's expression level is dependent on the software versions, and the parameters used when running the software, as well as the library preparation methods, and how the biological samples were obtained. To capture the provenance of experimental methods and computational results, the ENCODE DCC (Data Coordination Center) has created a rich data model that represents how experiments were performed, what software and pipelines were used, and which files were analyzed. These details of the experimental and computational methods, known as metadata, can then be used to identify related data for further analysis, interpret the results of the assays, and allow reproducibility of pipelines. All metadata and data generated by the ENCODE Consortium are freely available at at the ENCODE Portal(https://www. encodeproject. org/).

1861W

Facilitating Data Sharing through a Cloud-Based Data Platform. *M. Kaganovich, D. Gross, P. George, X. Xu, J. Cohen, L. Cherney, J. Hull, D. Caplan.* SolveBio, New York, NY.

High throughput generation of genomics data has led to an explosion in the breadth and quantity of reference data generated. Data sharing, theoretically, should be easy, rewarding for the data producer, and pervasive. Instead, the lack of systems and technologies to index, standardize, and share data, and the lack of interoperability and machine-readable standards means that critically important data remains in "silos", or walled off data repositories. Most individuals and institutions have little incentive to share data when sharing costs significant amounts of time and computing resources. Data sharing is crucial for genomics research and clinical genetics, as a source of reference data, for transparency, efficiency, and research reproducibility.

We have created a cloud-based data platform that indexes genomics-related reference data and a data integration pipeline that efficiently and systematically integrates different file types and sources. As of June 2015, our Data Library has integrated 25 publicly available and 4 commercially licensed data sources with 150+ independent data sets (consisting of over 1. 2 billion independent records and 28 billion data points) into one single platform. All data on our platform is versioned and dated, fully documented in terms of content and provenance, harmonized across the platform for common identifiers such as gene symbol and genomic position, and made accessible via a browser interface and an Application Programming Interface (API). The purpose of creating this data platform is to facilitate data sharing within and between organizations to advance genomics research and the practice of clinical genetics.

Here, we present our best practices, current models, and technical and logistical challenges involved in genomics data integration and data sharing. We present and contrast specific and real use cases of intra-institutional sharing, inter-institutional/intra-consortium sharing, variations on commercial licenses, and freely publicly available data sharing models. We also provide a calculation of the expenses (human hours and cloud-computing costs) of data integration and continued maintenance. We will show that our efforts improve the efficiency of data sharing by lowering the technical, logistical, and legal barriers associated with it.

A new publicly accessible resource for comprehensive recessive-disease variant curation: the GenePeeks Research Browser (GPRB). *R. M. Lim[1], M. J. Silver[1], C. Borroto[1], M. P. Hearing[1], A. J. Silver[1,2], J. L. Larson[2], L. M. Silver[1,2,3,4].* 1) GenePeeks, Inc. , New York, NY, USA; 2) GenePeeks, Inc. , Cambridge, MA, USA; 3) Department of Molecular Biology, Princeton University, Princeton, NJ, USA; 4) Woodrow Wilson School of Public and International Affairs, Princeton University, Princeton, NJ, USA.

Purpose: The science and human genetics communities have developed publicly available tools such as the UCSC Genome Browser, ClinVar, OMIM, and GeneReviews to further the understanding of the human genome. GenePeeks introduces the first publicly accessible browser that introduces two new features in addition to incorporating links to these resources: 1) Variant-specific Gene Dysfunction (VGD) scoring and 2) a dynamic graph displaying variants based on VGD score and Exome Aggregation Consortium (ExAC) allele frequency.

Methods: Gene-specific information was gathered from OMIM and RefSeq. Analytic gene targets were principally defined by Illumina's TruSight Inherited Disease Gene List. Variant-specific clinical information was gathered from ClinVar and OMIM. Population-specific allele and genotype frequencies were derived from 60,706 exomes processed and made publicly available by ExAC. Every variant described in ClinVar or present in the ExAC dataset within the targeted intervals defined by Illumina's TruSight One Sequencing Panel is analyzed and displayed. VGD scoring is described elsewhere (Silver, M. et al. , 2015 ASHG Abstract Submission). Updates to the GPRB are made continuously as new releases from data sources and interface improvements arise.

Results: The GPRB employs a user-friendly search tool that can respond to gene- and variant-specific searches. Gene pages host a dynamic display of variants graphed by their VGD score (x-axis) and ExAC allele frequency (y-axis, logarithmic scale). All variants are listed below the graph with brief variant information. Filters can be added to a query, thus applied to both the graph and the list. Each displayed variant links to a comprehensive variant page. Variant pages include general information such as genomic locus, ClinVar accession ID, OMIM allele ID, HGVSp and HGVSc; VGD information such as final VGD score and pathogenic predictor inputs; frequency information such as ExAC regional allele and genotype frequency; and clinical information such as ClinVar clinical significance and OMIM disease ID association. Sourced IDs such as ClinVar accession ID are hyperlinked to their respective pages on external sites; locus information links to the corresponding region in the UCSC Genome Browser. The GPRB is available at research. genepeeks. com.

Conclusion: The GPRB delivers novel functionality and content in a publicly available resource that is designed to adapt and improve based on the needs and feedback of users.

Bitmap indexing of genotyes improves functionality of an in-house distributed data query system. *H. Qiu[1], H. HAKONARSON[1,2].* 1) Center for Applied Genomics, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Bitmap indexing has been proven very efficient for query of static, low cardinality columns in data warehouses. Recent studies by other research groups applied bitmap index to large scale genomic variant datasets. Analyst Portal is our in-house distributed and integrative data query system where users, through web interface, perform complex query on Electronic Medical Records (EMR), laboratory workflow information, genotyping and next generation sequencing data. In order to support query into actual genotype calls of high-density SNP array, we first build bitmap indexes from existing source genotype files in plink PED format. Then the bitmap indexes are compressed using CPU friendly word-aligned hybrid (WAH) encoding scheme. Query of genotypes are performed using bitwise operations on the compressed bitmap indexes. The bitmap indexing package is deployed as a web service and made available to the relational database management system (RDBMS) on which Analyst Portal runs. Analyst Portal composes a query string based on user's search terms and makes API calls through the bitmap index web services. A user search term like "only return subjects with a list of known SNP mutations associated to a disease" can be effectively accommodated as a part of a more complex query. We conclude that WAH compressed bitmap indexing adds important genotype query functionality to our existing data query system.

Extending data access at the EGA. *D. Spalding[1], J. Almeida-King[1], C. Y. Gonzalez[1], J. Kandasamy[1], G. Saunders[1], A. Senf[1], I. Lappalainen[1], S. Ur-Rehman[1], M. Alberich[2], A. Carreno-Torres[2], J. Rambla[2], F. J. Lopez[1], J. M. Mut[1], R. Easty[1], O. M. Llobet[2], M. Sitges[2], S. de la Torre[2], A. Navarro[2,3,4], P. Flicek[1], J. Paschall[1].* 1) European Molecular Biology Laboratory, European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Hinxton, Cambridge, CB10 1SD, UK; 2) Centre for Genomic Regulation (CRG), Dr. Aiguader 88, 08003 Barcelona, Spain and Universitat Pompeu Fabra (UPF), Barcelona, Spain; 3) Institute of Evolutionary Biology, Barcelona, Spain; 4) Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

The European Genome-phenome Archive (EGA) is a controlled-access collection of human genomic and phenotypic data, for the purpose of biomedical research. Our collection includes major reference datasets for rare and common diseases, for example UK10K, Blueprint and the International Cancer Genome Consortium (ICGC), as well as control datasets, such as the data generated by the Wellcome Trust Case-Control Consortium (WTCCC). These data include over 1000 studies, 270,000 samples and comprise over 2PB of genomic data. In order to improve access and discoverability of the data within our archive, we have implemented a three tier Beacon that is fully compliant with the GA4GH specifications. At tier one, the public EGA beacon confirms allele existence within a subset of EGA datasets; the tier two registered access beacon increases the number of data sets and adds extra information where consent exists, such as allele frequency, whereas the tier three controlled access beacon allows full access to all authorised datasets. EGA is working with ELIXIR to share this technology across ELIXIR nodes. For registered users the facility to automate the application for full access to datasets with allele of interest is planned. The full GA4GH variant API is being developed for authorised users as EGA moves towards a secure cloud compute environment. This utilises the EGA's new data streaming download service that streams slices of encrypted data from the archive. Additional new services also enable the user to query all EGA metadata through a REST API, with the associated links to ENA, EVA, and BioSamples, both placing these data in the correct context and integrating these data with associated public data, for example UK10K and GoNL aggregated public data at EVA. These changes demonstrate how we at the EGA are implementing fundamental changes to facilitate data discovery and improve data dissemination to enhance the experience of EGA users. The EGA is jointly maintained by European Bioinformatics Institute (EMBL-EBI) and the Center for Genomic regulation (CRG), and this collaboration is motivating further developments towards a geographically distributed and federated archive, facilitating access across differing legal boundaries world-wide. The EGA is available at both www. ebi. ac. uk/ega/ and https://ega. crg. eu/.

An empirical evaluation of redundant annotations in common reference sources for tertiary analysis. *J. Warren, J. Li, A. Chhibber, E. Colak, A. Kiani, N. Bani Asadi, S. Barr, H. Y. K. Lam.* Bina Technologies, Roche Sequencing, Redwood City, CA.

After obtaining the genetic variants from next generation sequencing data, a precursory step in tertiary analysis is to annotate each variant with available relevant information. There is no standardized compendium for this purpose; researchers are instead required to compile data from a motley of annotation tools and public datasets. These annotation sources are quite diverse, with separate references providing information about different domains such as predicted functional impacts, known disease associations and population allele frequencies. Once assembled, the resulting data is subsequently analyzed to identify potential causative variants for the disease in question.

The choice of annotations sources accordingly has a direct impact on the results of the analysis, but the selection process is fraught with potentially overlooked complications. Many datasets provide the same information, but there is no guarantee of consistency in the reported data. Moreover, many public datasets are the result of studies of specific diseases or conditions, and the study selection criteria can bias the dataset contents. Predictions from functional impact tools also vary due to differences in assumptions and underlying data models. In sum, variants identified as potentially causative in one analysis could be omitted in another using a different set of annotation sources.

We have performed an empirical study of the quality and consistency of redundantly reported information to understand the impacts of selecting different annotation sources. We specifically examined differences in degree of agreement, predicted functional impacts, reported prevalence in populations, identified exonic regions and error rate. As anticipated, concordance of redundantly reported information is high, but data inconsistencies and errors are observed in effectively all aspects.

To illustrate the characteristics of using different datasets beyond reporting statistics, we also provide a funnel analysis of the NA12878 trio using different annotation sources. In this analysis, we filter the genomic variants using multiple criteria (e. g. rare variant, predicted damaging, associated with disease) using different data sources, reporting cardinality and overlap and each stage. This study illustrates the potential issues researchers may encounter during tertiary analysis.

Integrated analysis of germline, omic and disease data. *Z. Yang[1], D. C. Thomas[1], D. V. Conti[1,2].* 1) Department of Preventive Medicine, University of Southern California, Los Angeles, CA, USA; 2) Zilkha Neurogenetic Institute, University of Southern California, Los Angeles, CA, USA.

The availability of various omics data, such as metabolites, expression, and somatic profiles, facilitates potentially new insights into the underlying etiologic mechanism of disease. However, such data presents many analytic challenges including effect heterogeneity and high dimensionality. Recently proposed methods for omic data often ignore the underlying causal relationships of the various data types and focus mostly on data reduction by estimating underlying clusters. Here, we present a novel approach for the integrated analysis of germline, omic and disease data. Via a specific directed acyclic graph (DAG), we use a latent variable to relate information from germline genetic data to either a continuous or binary disease outcome. Within a measurement error framework, the omic data is viewed as a flawed measure of underlying latent clusters, categorized to simplify interpretation. We use an expectation-maximization (EM) algorithm to simultaneously estimate the unobserved latent clusters and model parameters, including genetic effects on the latent cluster and the impact of the cluster on omic patterns and on the disease outcome. Additionally, we incorporate penalized methods for variable selection in a high dimensional setting for both the genetic data and the omic data. Using simulations, we demonstrate the ability of our approach to accurately estimate underlying clusters and their corresponding genetic, omic and disease effects. Moreover, we demonstrate the feasibility of the variable selection to identify genetic and omic factors as both the means and correlational structures are varied. We discuss extensions to accommodate ascertainment and missing data.

Estimating Components of Heritability Explained by Gene Expression. *L. J. O'Connor, A. L. Price.* Harvard University, Cambridge, MA.

GWAS have identified many noncoding variants that contribute to disease risk, and it is increasingly clear that the genetic component of disease risk is largely driven by regulatory variation. It remains an open problem to quantify the proportion of SNP-heritability (*hg2*) that is explained by gene expression in a given tissue. We introduce a new method, called χ^2 regression, to estimate this proportion. Instead of using gene expression and phenotype measurements in a single cohort, we use disease χ^2 statistics and eQTL χ^2 statistics from separate cohorts; this SNP-centric approach eliminates environmental confounders, and it allows a gene-expression cohort to be analyzed in conjunction with GWAS summary statistics at much larger sample size. In order to integrate the two datasets, we use a simple idea: if gene expression impacts disease risk, then the effect size of a SNP on gene expression will impact its effect size on disease risk accordingly. More precisely, we regress disease χ^2 statistics on eQTL χ^2 statistics, summed across genes, to obtain the phenotypic variance explained by gene expression. The eQTL χ^2 statistics (which are proportional to squared effect sizes) are shrunk, so that they equal the posterior expected value of the true effect size; this shrinkage not only eliminates downward bias in the estimator but also reduces its variance, exploiting the fact that *cis* variants have much larger expected effect sizes. The method distinguishes genetic effects that are not mediated by gene expression, and it can partition explained variance by gene set or tissue type. We show that the proposed method is accurate and unbiased in simulation studies, and we apply it to real datasets.

Standardized analysis and sharing of genome-phenome data for rare disease research through RD-Connect's platform. *S. Beltran[1], D. Piscia[1], S. Laurie[1], A. Cañada[2,13], J. M. Fernández[2,13], J. P. Desvignes[3,4], M. Thompson[5], R. Kaliyaperumal[5], E. van der Horst[5], S. Lair[6], P. Sernaleda[7], C. Kingswood[1], M. Girdea[8], M. Brudno[8], A. Blavier[6], R. Thompson[9], H. Lochmüller[9], M. Bellgard[10], J. Paschall[11], P. Lopes[7], M. Roos[5], P. A. C. 't Hoen[5], V. de la Torre[2,13], A. Valencia[2,13], D. Salgado[3,4], C. Béroud[3,4,12], I. Gut[1], RD-Connect Consortium.* 1) Centro Nacional de Análisis Genómico, Barcelona, Catalonia, Spain; 2) Centro Nacional de Investigaciones Oncológicas (CNIO) , Madrid, Spain; 3) Aix-Marseille Université, Marseille, France; 4) Inserm, UMR_S 910, Marseille, France; 5) Department of Human Genetics, Leiden University Medical Center, Leiden, The Netherlands; 6) Interactive Biosoftware, Rouen, France; 7) DETI/IEETA, University of Aveiro, Portugal; 8) Centre for Computational Medicine, Hospital for Sick Children and University of Toronto, Toronto, ON, Canada; 9) Institute of Genetic Medicine, MRC Centre for Neuromuscular Diseases, Newcastle University, UK; 10) Centre for Comparative Genomics, Murdoch University, Perth, Western Australia; 11) European Molecular Biology Laboratory , European Bioinformatics Institute (EMBL-EBI), Wellcome Trust Genome Campus, Cambridge, United Kingdom; 12) APHM, Hôpital TIMONE Enfants , Laboratoire de Génétique Moléculaire, Marseille, France; 13) Instituto Nacional de Bioinformática (INB), Spain.

RD-Connect (rd-connect. eu) is an EU FP7 funded project building an integrated platform to narrow the gaps in rare disease research, where patient populations, clinical expertise and research communities are small in number and highly fragmented. RD-Connect's system securely integrates -omics data with biosample and clinical information using standardized analysis pipelines and terminologies such as the Human Phenotype Ontology, providing not only a centralized data repository but also a sophisticated and user-friendly online analysis platform. Although the system is being developed in a close collaboration with two EU flagship omics research projects, NeurOmics and EURenOmics, several other projects have already committed to providing data and RD-Connect gladly accepts submission proposals. Raw genomic data (from Whole Genome, Exome or gene panel NGS) is deposited at the European Genome-phenome Archive (EGA) and the corresponding clinical information is entered into a PhenoTips instance. The data is then processed by RD-Connect's standardized mapping, variant calling and annotation pipeline, which has around 99% precision and sensitivity when compared to the NA12878 reference set of calls from the NIST. The results are made available to authorized users through the platform, which runs on a Hadoop cluster and uses technologies such as ElasticSearch, Postgres, Scala and Angular. js, making it highly configurable and efficient. The user-friendly interface enables filtering and prioritization of variants using the most common quality, genomic location, effect, pathogenicity and population frequency annotations, including CADD and ExAC. Additional tools can be integrated at several levels: DiseaseCard, Alamut Functional Annotation (ALFA), UMD Predictor and gene-disease relationships in nanopublication format are already available. Current focus is on the integration of Exomiser (including PhenIX) to prioritize variants through genotype-phenotype queries, the provision of reliable allele frequencies, the lighting of a GA4GH beacon and patient matchmaking. A pre-release of 367 exomes was made available to selected users for beta-testing at platform. rd-connect. eu. A first official release including data from ~1000 exomes and access by any authorized researcher is expected by 2015 Q4.

Integrative longitudinal analysis of ribosome occupancy and protein synthesis during chemotherapeutic response reveals complex translational dynamics. *T. -Y. Liu[1], H. H. Huang[2], D. D. Wheeler[2,3], J. A. Wells[3], Y. S. Song[1,4,5], A. P. Wiita[2].* 1) Computer Science Division, University of California, Berkeley; 2) Dept. of Laboratory Medicine, University of California, San Francisco; 3) Dept. of Pharmaceutical Chemistry, University of California, San Francisco; 4) Dept. of Statistics, University of California, Berkeley; 5) Dept. of Integrative Biology, University of California, Berkeley.

Dynamic changes in the cancer proteome control tumor growth, proliferation, metastasis, and response to the therapy. Hence, it is important to understand the translational regulation in cancer cells during chemotherapeutic response. We studied multiple myeloma cells exposed to a low dose of bortezomib, designed to elicit a drug-induced stress response but not lead to widespread translational shutdown and cell death. mRNA-seq, ribosome profiling, and pulse-chase isotopic labeling mass spectrometry-based proteomics were integrated to directly monitor the synthesis of new proteins and degradation of existing proteins across a time course. The longitudinal study enabled us to describe translation rate as a function of transcript abundance and footprint density. We modeled the dynamic changes with a system of differential equations and solved the equation using functional data analysis. The pulse-chase mass spectrometry technique enables us to extract the degradation rate constant to disentangle the degradation process from the synthesis process. And the translational rate parameter is modeled as a time varying function. While it is widely assumed that ribosome footprint occupancy directly reflects protein synthesis, to our knowledge this assumption has not been previously tested in the same experimental system across a time course. We directly compared measurements of translational efficiency from ribosome profiling and the estimates of translational rate parameter using our proposed quantitative model. Results showed that they are imperfectly correlated. However, by incorporating a gene-specific modulation factor, a function of active ribosomes bound to transcript were incorporated into the quantitative model, we were able to correlate the translational efficiency and translational rate parameter. Our model implies gene-specific modulation factors that govern the relationship between footprint density and protein synthesis. These factors are found universal during chemotherapeutic response in our experiments. Our work offers a novel quantitative framework to understand translation using a combination of emerging technologies. Taking advantage of this model with concurrent biochemical and genetic experimentation may allow us to identify these factors that govern translational regulation in cancer and potentially eukaryotes more broadly, and shed light on targeted therapies.

Structural variation discovery in dogs using whole-genome sequencing. *M. Arumilli[1], MK. Hytönen[1], E. Salmela[1], J. Salojärvi[2], H. Lohi[1].* 1) Department of Veterinary Biosciences and Research Programs Unit, Molecular Neurology, University of Helsinki, Finland; 2) Department of Biosciences, University of Helsinki, Helsinki, Finland.

Background: Copy number variation (CNV) contributes to genetic and phenotypic diversity within and between species. CNVs in domestic dog have been correlated with many phenotypes, which are of comparative interest in humans. A reduced genetic variation in dog breeds than humans makes it feasible to study complex genetic traits in dogs with smaller sample sizes. In dogs, only four CNV studies using comparative genomic hybridization arrays (aCGH) and one CNV screen using CanineHD 170K genotyping array have been previously reported presenting a catalogue of CNVs. However, these approaches suffer from hybridization noise, limited coverage of genome, low resolution and inaccurate detection of breakpoints. Here, we expand from the earlier studies by carrying out the first Structural Variation (SV) study in dogs based on the whole-genome sequencing technology to a) catalogue the SV in dogs across breeds at ultra-high resolution b) compare the accuracy of CNV detection with genotyping array methods. In addition, we aim to perform an association study to identify CNVs associated with osteochondrosis phenotype in Border Collie breed. **Results:** SVs were detected using the Lumpy and GenomeSTRiP from whole-genome sequences of 159 dogs from 53 breeds. Many of the CNVs appeared to be highly breed-specific and previously known CNVs were generally replicated by our analysis. Furthermore, the comparison of CNVs from SNP genotype data of 22 individuals from IlluminaHD array with the same set of sequenced individuals showed that sequencing-based approach detected CNVs with more precise breakpoint detection than array based methods. In addition, comparing 13 affected individuals with osteochondrosis and 9 healthy individuals from Border Collie suggested CNV regions that can possibly contribute to the phenotype. **Conclusions:** This study provides a comprehensive analysis of canine CNVs cataloguing the CNV regions in different breeds to identify CNVs that contribute to breed specific phenotypes. The CNV regions identified for osteochondrosis may provide novel insights to study the complex genetics of the disorder in humans.

1871T

The Human-Mouse Disease Connection (HMDC) Portal: recent updates enabling discovery. *J. T. Eppig, S. M. Bello, J. A. Kadin, J. E. Richardson, C. L. Smith, MGI Staff.* Jackson Laboratory, Bar Harbor, ME.

The laboratory mouse is used extensively as a model system to investigate the eitopathogenesis of human disease and to test new clinical therapeutics. The Mouse Genome Informatics (MGI, www. informatics. jax. org) resource has recently added new features to its human-mouse translational tool, the Human-Mouse: Disease Connection (HMDC, www. diseasemodel. org). This tool, which provides simultaneous search and access to human and mouse genomic, phenotypic, and genetic disease information, assists researchers in identifying and evaluating candidate genes and mouse genotypes modeling a spectrum of clinically relevant phenotypes. Users can search the HMDC portal from a human or mouse standpoint, using (1) genes or gene IDs for either species, (2) genome locations from either species, and (3) mouse phenotype or human disease (OMIM) terms. Alternatively, data can be uploaded from human or mouse VCF files or text files of gene symbols or IDs. The HMDC phenotype and disease search has been updated to allow Boolean search expressions and includes an optional autocomplete feature. Initial search results display in an interactive grid for visual comparison of phenotypes and diseases across multiple genes, phenotypes, and diseases. A hybrid of HomoloGene and HCOP homology relationships is used to relate human and mouse genes in the grid. This hybrid maximize the number of homology groups including both human and mouse genes. The grid employs color cues that reflect the depth of human and mouse annotations. Grid cells are dynamically linked to underlying MGI data, including phenotypic detail, model-relevant publications, and global availability of mouse resources via IMSR (www. findmice. org). Alternate HMDC views include gene- and disease-centric information presented in tabular format. We will present examples of current content and capabilities of the HMGC Portal, including (1) display of known mouse model data for human disease, (2) potential human candidate genes for disease based on mouse phenotypes, (3) and potential target genes for developing new human disease models in mice. Supported by NIH grant HG000330.

Homology curation at SGD: Yeast and yeast research inform genetic medicine. *S. R. Engel, M. C. Costanzo, R. S. Nash, E. D. Wong, J. M. Cherry, The SGD Project.* Genetics, Stanford University, Palo Alto, CA.

The foundation for much of our understanding of basic cellular biology has been learned from the budding yeast*Saccharomyces cerevisiae*,and studies with yeast have provided powerful insights into human genetic diseases and the cellular pathways in which they are involved. This utility of yeast as a model for human disease arises from the biochemical unity that underlies all forms of life. Yeast has become extremely useful in the study of various diseases that afflict humans, such as cystic fibrosis, kidney disease, mitochondrial diseases, and neurodegenerative diseases such as Parkinson's. Recent work with humanized yeast (in which yeast genes have been replaced with human orthologs) and humanized yeast proteins (in which key residues have been altered to match the human sequence) has demonstrated extensive conservation of ancestral functions through time and across taxa. We will present an update on new developments at the*Saccharomyces*Genome Database (SGD;www. yeastgenome. org), the premier community resource for budding yeast. In order to promote and support the ways in which yeast and yeast research can inform genetic medicine, we are providing comprehensive curation for human disease-related genes and their yeast orthologs, including high quality manually curated information regarding functional complementation and conserved function. We also associate sequence changes with variations in yeast phenotypes and corresponding human disease manifestations. Curated information for yeast genes will be displayed on new Homology pages at SGD. Curated information for human genes will be available from the new "Yeast to Human Portal" knowledge center athumanportal. org. This new information is provided in ways that allow data mining and encourage innovation, for researchers studying both yeast and other organisms. These expanded efforts are part of our continuing mission to educate students, enable bench researchers, and facilitate scientific discovery. This work is supported by a grant from the NHGRI (U41 HG001315).
