The genomic alterations associated with cancers are numerous and varied involving both isolated and large-scale complex genomic rearrangements. Diffuse Intrinsic Pontine Glioma (DIPG) is a rare and fatal form of pediatric high-grade gliomas arising in the brainstem. Most pediatric gliomas exhibit complex genomic signatures with alterations in copy number, SNVs and structural rearrangements(Jones and Baker 2014). Here we present our analysis of the impact of SNVs on gene expression and alternative splicing in DIPGs. We first identified SNVs from three parallel sequencing platforms (whole genome, exome and transcriptome) and select correlated variants across the three platforms. We then study the cis-regulatory impact of these variants on the expression profiles and alternative splicing of downstream genes. By comparing these results in tumour and normal samples we have identified a set of SNVs that show significant impact in DIPGs.

Modulation of GATA3 binding to an enhancer at the *ESR1* locus (6q25. 1) underlies the association with breast cancer risk. *S. D. Bailey[1,2], K. Desai[3], P. Mazrooei[1,2], M. Lupien[1,2,4].* 1) Princess Margaret Cancer Centre, University Health Network, Toronto, ON; 2) Department of Medical Biophysics, University of Toronto, Toronto, ON; 3) Department of Genetics, Norris Cotton Cancer Center, Dartmouth Medical School, Lebanon, NH; 4) Ontario Institute for Cancer Research, Toronto, ON.

The identification of an association between variation at the estrogen receptor alpha (*ESR1*) locus and breast cancer (BCa) serves as a 'proof of principle' for BCa genome-wide association studies (GWAS). Although, *ESR1* has been implicated as the target gene, the causal variant(s) underlying the association have yet to be elucidated. Determining the variant(s) responsible for the association and how it promotes BCa risk may provide novel insight into BCa progression. Multiple risk-associated single nucleotide variants (raSNVs), originating from samples of different ethnic backgrounds (European & East Asian), have been identified at the *ESR1* locus. Using an integrative genomics approach that combines chromatin openness, histone modifications and transcription factor binding, while leveraging the patterns of linkage disequilibrium (LD) among the different ethnic groups, we identify a functional SNV that is shared between ethnicities and in strong LD with the original raSNVs. The variant allele of the SNV decreases the affinity of GATA3 for the chromatin by ~8-fold and is located within an active enhancer element specific to BCa cells. The functional enhancer physically interacts with the *ESR1* promoter, through a long-range chromatin interaction and the modulation of the enhancer by the SNV results in the allele-specific expression of *ESR1*. Although additional functional variants may exist at the *ESR1* locus, we demonstrate that a single SNV that acts by disrupting GATA3 binding can account for the multiple GWAS signals observed at the *ESR1* locus.

SMART-ddPCR: a novel method for accurate assessment of preferential allelic imbalance in tumor DNA. *A. J. de Smith[1], K. M. Walsh[2], H. M. Hansen[2], A. Endicott[1], J. K. Wiencke[2], C. Metayer[3], J. L. Wiemels[1,2].* 1) Department of Epidemiology and Biostatistics, University of California San Francisco, San Francisco, CA; 2) Division of Neuroepidemiology, Department of Neurological Surgery, University of California San Francisco, San Francisco, CA; 3) School of Public Health, University of California Berkeley, Berkeley, CA.

Genome-wide association studies have identified numerous SNPs associated with cancer risk. Tumor selection of SNP risk alleles, or preferential allelic imbalance (PAI), has been demonstrated in some cancer types. However, the extent to which heritable genetic variants affect tumor evolution, as opposed to tumor initiation, is underexamined. We developed a novel methodology termed Somatic Mutation Allelic Ratio Test using Droplet Digital PCR (SMART-ddPCR) for accurate assessment of tumor PAI. Using SMART-ddPCR, we investigated allelic imbalance (AI) at genomic loci associated with childhood ALL, including: *CDKN2A* (missense variant rs3731249 and tag SNP rs3731217) and *IKZF1* (rs4132601), genes frequently lost in ALL tumors; and *CEBPE* (rs2239633), *ARID5B* (rs7089424), *PIP4K2A* (rs10764338), and *GATA3* (rs3824662), all located on chromosomes gained in hyperdiploid ALL. Using constitutive DNA from SNP heterozygotes to establish thresholds, we measured allelic copy number in tumor DNA from 19-142 heterozygotes per SNP locus. We found significant tumor PAI for *CDKN2A* SNP rs3731249, with 14 subjects with preferential retention of the risk allele and only 3 subjects preferentially retaining the protective allele (p=0. 006). There was a trend towards tumor PAI favoring the risk allele for the *CDKN2A* tagging SNP (p=0. 17) and the *IKZF1* SNP (p=0. 23). We did not find significant tumor PAI in hyperdiploid ALL subjects heterozygous for SNPs in *CEBPE*, *ARID5B*, *PIP4K2A*, or *GATA3*. Using a genomic copy number control assay, we investigated somatic copy number alterations (SCNA) underlying AI at *CDKN2A* and *IKZF1*, revealing a complex range of alterations including homozygous and hemizygous deletions and copy-neutral loss of heterozygosity, with varying clonality. Copy number estimates from ddPCR showed high agreement with those from multiplex ligation-dependent probe amplification assays. We present SMART-ddPCR as a highly accurate method for investigation of tumor PAI and assessment of somatic alterations underlying AI, and demonstrate a direct interaction between heritable and somatic *CDKN2A* variation underlying leukemogenesis. Furthermore, analysis of the overlap of recurrent SCNAs from The Cancer Genome Atlas with cancer-associated SNPs from the NHGRI GWAS Catalog revealed 16/140 recurrent SCNA loci overlapping heritable variants associated with a matching cancer type, including at *TERT*, *MYC*, and *EGFR*. These loci represent candidate PAI regions warranting further investigation.

Annotation of functional impact of missense mutations in BRCA1. *P. Gaudet, I. Cusin, M. Zahn, A. Bairoch.* SIB Swiss Institute of Bioinformatics, Geneva, Switzerland.

Characterization of the phenotypic effect of mutations provides evidence on which variants of unknown significance (VUS) can be evaluated. We have annotated the phenotypes caused by missense mutations in BRCA1 associated with increase susceptibility to breast and ovarian cancers. Using the information derived from 87 publications, the functional impact of 488 variants was captured, resulting in 1300 different annotations. Each annotation is supported by detailed experimental evidences. Well characterized and assessed functions of BRCA1 includes its ubiquitin-protein ligase activity and its role in DNA repair, as well as its transcriptional regulation activity, response to DNA damage, and UBE2D1, BARD1 and BRIP1 binding. These data provide the most comprehensive resource on phenotypes of BRCA1 variants. We are expanding this work to other disease-causing genes, including BRCA2, as well as genes implicated in Lynch syndrome (MSH2, MSH6, MLH1).

2633W

Extending the prediction of pathogenicity for genetic variants in the DNA double-stranded break repair pathway. *J. Loke[1], K upadhyay[1], M. Groden[1], A. Pearlman[1], S. Klugman[2], H. Ostrer[1].* 1) Pathology, Albert Einstein Sch Med, Bronx, NY; 2) Montefiore Med Ctr, Bronx NY.

Introduction. An average woman's lifetime risk for developing breast cancer is 11%. Among these women, 5-10% come from families at high risk for breast or other cancers and 20% have a mutation in the genes, *BRCA1* and *2.* Others have mutations in genes that, along with *BRCA1* and *2,* play a role in the repair of DNA double-stranded breaks (DSB). Previously, we showed functional effects of mutations in DSB repair genes based on the nuclear localization of BRCA1 in response to radiomimetic agents, changes in the binding of cofactors (BARD1, BRCA2, FANCD2 and PALB2) and phosphorylation of p53. Here, we demonstrate that these effects are observed for mutations in other DSB genes. Functional changes can be used to identify pathogenic mutations in these genes, especially those with negative *BRCA1* and *2* genetic tests. **Methods and Methods.** Lymphoblastoid cells (LCLs) were collected from individuals with four different sets of variants, including known *BRCA1* pathogenic mutations, benign variants (normal), *ATM, BRCA2*, *FANCC*, *FANCG FANCD2, and NBN* mutations and a cohort of 16 subjects with negative *BRCA1* and *2* genetic tests. Flow variant assays (FVAs) were used to determine whether pathogenic variants in DSB repair genes disrupt the nuclear localization of BRCA1, the phosphorylation of p53 and the nuclear p53 regulation by MDM2 in response to the combination of DNA crosslinking and breakage drugs, diepoxybutane, mitomycin C, and bleomycin. All LCLs had DNA sequencing that was analyzed for mutations. **Results.** Mutations in *BRCA1* and *ATM, BRCA2*, *FANCC*, *FANCG*, *FANCD2, and NBN* (phenocopies) decreased nuclear localization of BRCA1 in response to the drug combination (p=3. 9 x10-81 for *BRCA1* and 3. 4 X10-93 for phenocopies), reduced phosphorylation of p53 (p=3. 6 X10-81 for *BRCA1* and 7. 5x10-90 for phenocopies) and increased nuclear MDM2 (p=1. 2 X10-27 for *BRCA1* and 2. 2 X10-44 for phenocopies). Unsupervised analysis of all of these assays demonstrated two apparent clusters, high-risk *BRCA1* and phenocopy mutations and normal sequenced controls. Three subjects with negative *BRCA1* and *2* genetic tests and fully sequenced genomes fell into the high-risk cluster. **Conclusion.** FVAs distinguish mutations in *BRCA1* and phenocopy genes in the DSB repair pathway from benign variants. When applied to a small, high-risk, *BRCA1* and *2* negative genetic test cohort, ~19% had positive results. FVAs of circulating cells may represent a fast and effective tool for assessing breast cancer risks.

2634T

Functional characterization of *BARD1* missense variants. *A. Toland[1,2], C. Lee[3], T. Banerjee[3], J. Gillespie[1], L. Starita[4], J. Parvin[3].* 1) Molecular Virology, Immunology & Medical Genetics, Ohio State University, Columbus, OH; 2) Divison of Human Genetics, Ohio State University, Columbus, OH; 3) Biomedical Informatics, Ohio State University. , Columbus, OH; 4) Genome Sciences, University of Washington, Seattle, WA.

Clinical testing of *BRCA1* and *BRCA2* for susceptibility to hereditary breast and ovarian cancer (HBOC) has been available for 20 years. Recently, due to identification of new HBOC genes, companies that offer BRCA1/2 testing have expanded the number of genes being tested for breast cancer predisposition. Truncating and nonsense mutations in BARD1 are associated with an increased risk of breast cancer. The exact penetrance and lifetime risk of mutations in these genes is not well characterized. Nonetheless, genetic testing of *BARD1* is being offered clinically, and many missense variants of uncertain clinical significance have been identified. BARD1 and BRCA1 proteins heterodimerize, and BARD1 function is critical for BRCA1 function in homology directed repair. Because we have previously shown that functional assays, such as those that measure homology directed repair, have a high sensitivity and specificity for prediction of known *BRCA1* missense mutations, we hypothesized that this assay could have utility in classifying missense variants in *BARD1*. To test this, we assayed the effect of 29 *BARD1* missense variants on BARD1 function in homology-directed repair. Unlike *BRCA1*, we did not have any "known" pathogenic missense variants in *BARD1*. To this end, we used a "synthetic" mutation, L44R, that had been reported to disrupt BARD1/BRCA1 binding. We also included known neutral variants that had high population frequencies. From our assay we identified four variants, L44R, C53W, C71Y and G623E that were defective in DNA repair and one variant that showed intermediate repair capabilities. Two of these variants, C53W and C71Y, may result in loss of function by making the BARD1 protein insoluble. All variants with allele frequencies greater than 1% in dbSNP behaved functionally as wildtype BARD1. These results do not rule out potential effects on splicing. It will be important to integrate this functional data with additional segregation or evolutionary conservation data to provide further support for these four variants as being pathogenic. In summary, the HDR assay may be a robust tool for characterization of variants in genes important in homologous recombination.

2635W

Germline mutations in *ETV6* confer risk of acute lymphoblastic leukemia and thrombocytopenia. *S. Topka[1, 8], V. Joseph[1, 8], MF. Walsh[2], L. Jacobs[1], A. Maria[1], D. Villano[1], P. Gaddam[1], G. Wu[2], RB. McGee[2], E. Quinn[2], H. Inaba[2], C. Hartford[2], CH. Pui[2], P. Steinherz[1], M. Edmonson[2], M. Zhang[3], K. Schrader[5], A. Lincoln[1], P. Stepensky[4], S. Lipkin[6], Y. Goldgur[7], M. Harit[4], ZK. Stadler[1], C. Mullighan[2], M. Weintraub[4], A. Shimamura[3, 9], J. Zhang[2], JR. Downing[2], KE. Nichols[2], K. Offit[1, 6, 8].* 1) Department of Medicine, Memorial Sloan Kettering Cancer Center (MSKCC), New York, NY; 2) St Jude Children's Research Hospital (SJCRH), Memphis, TN; 3) Fred Hutchinson Cancer Research Center and University of Washington, Seattle, WA; 4) Pediatric Hematology/Oncology Department, Hadassah-Hebrew University Medical Center, Jerusalem, Israel; 5) University of British Columbia, Vancouver, B. C; 6) Weill Cornell Medical College, New York, NY; 7) Structural Biology Program, Memorial Sloan-Kettering Cancer Center, New York, NY; 8) Cancer Biology and Genetics Program, Memorial Sloan Kettering Cancer Center, New York, NY; 9) Seattle Children's Hospital, Seattle, WA.

Somatic mutations affecting *ETV6* often occur in acute lymphoblastic leukemia (ALL), the most common childhood malignancy. The genetic factors that predispose to ALL remain poorly understood. Here, we identify a novel germline *ETV6* p. L349P mutation in a kindred affected by thrombocytopenia and ALL. A second *ETV6* p. N385fs mutation was identified in an unrelated kindred characterized by thrombocytopenia, ALL and secondary myelodysplasia/acute myeloid leukemia. Leukemic cells from the proband in the second kindred showed deletion of wild type *ETV6* with retention of the *ETV6* p. N385fs. Enforced expression of the *ETV6* mutants revealed normal transcript and protein levels, but impaired nuclear localization. Accordingly, these mutants exhibited significantly reduced ability to regulate the transcription of *ETV6* target genes. Our findings highlight a novel role for *ETV6* in leukemia predisposition.

Systematic prioritization of druggable mutations across 16 cancer types using a structural genomics-based approach. *J. Zhao[1], F. Cheng[1], Y. Wang[1], Z. Zhao[1,2,3,4].* 1) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN 37203, USA; 2) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN 37232, USA; 3) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN 37232, USA; 4) Vanderbilt-Ingram Cancer Center, Vanderbilt University School of Medicine, Nashville, TN 37232, USA.

The progress of several large-scale cancer genome sequencing projects such as The Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium projects has accumulated a large number of somatic mutations. However, how to address the biological impacts of these mutations to distinguish damaging 'driver' from neural 'passenger' and prioritize druggable mutations remain important but challenging problems in cancer genomics research. Fortunately, the rapid advancements of structural genomics technologies (e. g. X-ray) have made a wealth of protein structure data available, providing an opportunity to interrogate somatic mutations in the context of protein functional features (i. e. , protein-ligand binding sites) to determine their pathophysiological roles in cancer and prioritize druggable mutations that may have the potential to mediate drug binding at the atom resolution. In this study, we proposed a structural genomics-based method SGDriver that incorporates the protein structural information into somatic missense mutations to detect significantly mutated protein-ligand binding sites which we assume are likely to be druggable targets. Applying SGDriver to 746,631 missense mutations from 4,997 tumors across 16 cancer types from TCGA, we detected 14,471 potential druggable mutations in 2,091 proteins (including 1,516 recurrently mutated proteins) across 3,558 cancer genomes, and further identified 298 proteins bearing significantly mutated ligand binding sites (adjusted p-value < 0. 05). we also implemented drug-target network analysis suggesting 98 known and 126 repurposed druggable anticancer targets (e. g. *SPOP* and *NR3C1*). Furthermore, our integrated analysis indicated that 13% of patients harbored known druggable mutations and could benefit from current targeted therapy, and this fraction would increase to 31% after considering drug repositioning strategy. This study demonstrates a novel approach for interpreting somatic mutations and prioritizing druggable mutations for precision cancer medicine research.

2637W

An intronic indel variant confers melanoma risk through *PARP1* expression regulation. *J. Choi[1], M. Makowski[1,2], T. Zhang[1], M. Law[3], C. Sutherland[4], W. Kim[1], M. Kovacs[1], H. Parikh[1], L. Aoude[3], M. Gartside[3], J. Trent[5], L. Hurley[4], M. Vermeulen[2], S. Macgregor[3], N. Hayward[3], M. Xu[1], K. Brown[1].* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Department of Molecular Biology, Faculty of Science, Radboud Institute for Molecular Life Sciences, Radboud University Nijmegen, The Netherlands; 3) Queensland Institute of Medical Research, Brisbane, QLD, Australia; 4) College of Pharmacy, University of Arizona, Tucson, AZ; 5) Translational Genomics Research Institute, Phoenix, AZ.

Recent genome wide association studies identified several new loci for melanoma susceptibility including chr1q42. 1 locus encompassing Poly [ADP-ribose] polymerase 1 (*PARP1*). As an effort to identify effecter genes and functional risk variants from this locus we performed expression quantitative trait loci (eQTL) analysis in 62 melanoma cell lines. Among the genes in 1Mb area eQTL was identified for *PARP1* and subsequently validated by qPCR, where increased *PARP1* levels are significantly correlated with the risk allele (p=0. 03, copy number adjusted). Further allele discrimination qPCR of *PARP1* transcripts in 14 melanoma cell lines heterozygous and of neutral copy for the lead SNP indicated significantly higher proportion for the risk allele (p=. 0001). Same allelic imbalance was also observed in 51 heterozygous melanomas with neutral copy numbers from The Cancer Genome Atlas (p=. 028). To identify functional risk variants mediating these effects we annotated thislocus using six melanoma relevant cell types available from ENCODE and Roadmap database. Based on recent fine mapping data suggesting single-SNP model for this locus we prioritized high LD variants for nomination. Among 65 SNPs of high LD with the lead SNP or imputed best SNP (r2>0. 6 using 1000 Genomes phase3), four exhibited strong evidence as potential transcriptional enhancers. Electro Mobility Shift Assays and luciferase assays on these four variants demonstrated that one of them, a six-base pair indel (-/GGGCCC) in the first intron, displayed strong allelic functionality. Consistent with the expression data melanoma-associated deletion allele results in higher luciferase activity while protective insertion allele binds a group of proteins with higher affinity. Subsequent comparative mass-spectrometry for these insertion-binding proteins identified a striking collection of Guanine-quadruplex binding proteins including RECQL as potential inhibitors of *PARP1* expression. Consistent with this hypothesis RECQL knockdown leads to increased *PARP1* expression in melanoma cell lines carrying insertion allele. Over-expression of RECQL also results in more pronounced allelic difference in luciferase activities indicating that RECQL contributes to allelic *PARP1* expression. These data demonstrate that increased *PARP1* expression is correlated with melanoma risk and an indel variant mediates differential *PARP1* expression possibly through secondary DNA structure binding proteins including RECQL.

2638T

Breast cancer pedigree exome sequencing reveals inherited Rad52 truncation mutation implicated in breast cancer susceptibility. *H. A. Costa[1], M. Sikora[2], K. Hastak[1], J. M. Ford[1], L. C. Laurent[3], C. D. Bustamante[1].* 1) Stanford University School of Medicine, Department of Genetics, Stanford, CA, 94305, USA; 2) Natural History Museum of Denmark, Centre for GeoGenetics, 1350, Copenhagen, Denmark; 3) University of California, San Diego, Department of Reproductive Medicine, La Jolla, CA, 92037, USA.

BRCA1/2 mutations have been the most exhaustively elucidated mechanism for inherited breast cancer cause, however only an estimated 25% of cases are atributable to mutations in these two genes. We have sequenced the exomes of a non-BRCA breast cancer pedigree and have identified a shared truncation mutation in the Rad52 protein. We have performed cellular based assays to functionally characterize this truncation mutation and demonstrate it results in the mis-localization of Rad52 during double strand break repair. This observation gives credence to the growing body of work regarding the complex involvement of Rad52 in breast cancer etiology and progression, and suggests that genetic background can modulate the effect of common or perceived ''benign" mutations among different populations.

2639W

RNA functional studies for the classification of germline variants of uncertain significance that may impair splicing. *M. B. Warf[1], E. Goosen[1], D. Mancini-DiNardo[1], J. Willmott[2], Y. Qian[1], M. Landon[2], K. Rushton[2], K. R. Bowles[1], B. B. Roa[1].* 1) Myriad Genetics, Inc. , Salt Lake City, UT. , USA; 2) Myriad Genetic Laboratories, Inc. , Salt Lake City, UT, USA.

Background: RNA splicing is the process by which non-coding intronic regions of a gene are removed after transcription. Genetic variants within introns may impair splicing, resulting in an RNA molecule that does not encode a functional protein. Depending on the sequence context, certain positions within an intron or exon cannot tolerate changes without functional splicing consequences, while other positions can tolerate a variety of genetic variation without impairing splicing. In these studies we establish an IRB approved research process to enroll and collect samples from selected patients after clinical testing has been performed. These patients carry certain variants of uncertain significance (VUS) that may alter splicing. Using the collected sample, we generate and interpret functional RNA splicing data to aid in the reclassification the variant. **Methods:** RNA is extracted from blood samples acquired from a patient(s) carrying a variant of interest. cDNA is synthesized and PCR is performed, amplifying regions within the gene to be assessed. Splicing patterns are visualized on an agarose gel, and all splicing products are identified via sequencing. The wild-type splicing pattern is confirmed in age/gender matched blood derived control samples, and preferably also within RNA extracted from normal tissue (i. e. breast, ovarian, or colon, etc). Further analysis is performed to determine whether the allele carrying the variants of interest can produce any wild-type splice product. **Results:** We analyzed multiple variants within genes in which pathogenic variants cause an increased cancer risk. In one case, *MLH1* c. 306G>T (which is the last base of an exon), the data indicated the variant fully impaired proper splicing of the mutant allele, and the variant was reclassified as Likely Pathogenic. In another case, *CDH1* c. 715G>T (which creates a cryptic splice acceptor), the data showed the variant only partially impaired proper splicing of the mutant allele, and a wild-type splice product was still made from the mutant allele; this variant remained a VUS. **Discussion:** These studies demonstrate that precise and specific functional RNA studies are helpful to differentiate variants that fully impair splicing and those that only partially impair splicing. Variants that fully impair splicing can be reclassified, while variants with intermediate splicing defects may require additional data to determine if the splicing defect is sufficient to cause increased cancer risk.

2640T

Breast cancer risk variants at 11q13 alter the activity of transcriptional enhancers of novel long noncoding RNAs, *CUPID1* and *CUPID2,* implicated in DNA repair. *J. D. French[1], J. A. Betts[1], M. Clark[2], A. Wiegmans[1], M. Moradi Marjaneh[1], B. Gloss[2], M. Ghoussaini[3], G. Chenevix-Trench[1], D. F. Easton[3], A. M. Dunning[3], T. Mercer[2], M. E. Dinger[2], S. L. Edwards[1].* 1) QIMR Berghofer Medical Resesarch Institute, Brisbane, Queensland (QLD), Australia; 2) Garvan Institute of Medical Research, Sydney, Australia; 3) Department of Oncology, Centre for Cancer Genetic Epidemiology, University of Cambridge, Cambridge CB1 8RN, UK.

One of the strongest breast cancer associations identified via GWAS is with SNP rs614367, which lies in a 350kb intergenic region on 11q13. As part of the iCOGs project, we have previously fine-mapped this locus and identified three independent sets of correlated, highly trait associated variants (iCHAVs) associated with estrogen receptor positive (ER+) breast cancer and showed that the strongest iCHAV1 lies in a transcriptional enhancer of *CCND1* [MIM168461], located 125kb away (French et al, 2013). In the current study, we have performed targeted RNA CaptureSeq using capture arrays covering the 11q13 intergenic region and identified two novel lncRNAs, *CUPID1* and *CUPID2,* transcribed from the region. RNA CaptureSeq from a range of tissues demonstrated that *CUPID1* and *CUPID2* expression is highly tissue specific, restricted to breast and kidney. Both lncRNAs are estrogen regulated and overexpressed in ER+ cell lines and tumors. Using chromosome conformation capture (3C) and reporter assays we show that, in addition to the *CCND1* promoter, iCHAV1 acts as a strong enhancer on the *CUPID1* and *CUPID2* promoters. In a breast cancer cell line heterozygous for the iCHAV1 haplotype, we demonstrate by allele-specific 3C that the protective alleles preferentially bind CTCF and participate in chromatin interactions with the *CUPID1* and *CUPID2* bidirectional promoter. Knockdown of *CUPID1* and *CUPID2* decreased *CCND1* and reduced RAD51 foci formation after treatment with ionizing radiation suggesting the both lncRNAs are implicated in HR-mediated DNA repair. In summary, we suggest that in addition to reducing the expression of *CCND1*, breast cancer risk variants at 11q13 reduce the expression of *CUPID1* and *CUPID2* causing impaired DNA damage repair. .

Multi-modal report summary for AML: Combining NGS and Cytogenetics Data to Enable Therapeutic Decision Making. *C. E. Carmack, T. Natarajan, C. J. Miller, B. Parikh, I. Maurer, M. J. Glynias.* GenomOncology, Cleveland, OH.

IntroductionAcute myeloid leukemia (AML) is a clonal disorder of the blood forming cells characterized by accumulation of immature blast cells in the bone marrow and peripheral blood. It is a heterogeneous disease, and as such, its molecular footprint varies. It is therefore important to test for key genetic biomarkers for both prognostic and predictive (treatment) purposes. Patients can benefit greatly utilizing genetic markers for risk stratification. Given the nature of the various genetic markers, several different molecular methodologies are used to evaluate the patient. Evaluation of mutational status of molecular markers like NPM1, CEBPA, KIT and FLT3 has been shown to help refine the prognosis. For example, if a patient is found to have a normal karyotype and a favorable fusion, he/she may qualify for conventional therapy. However, the physician may decide to further test the tumor for FLT3 ITD, and which, if present, would change the prognosis to unfavorable risk. Now the physician can instead decide to consider the patient for transplant, or clinical trial, as the patient is least likely to benefit from conventional therapy. Karyotype analysis, fluorescence in situ hybridization (FISH) and next generation sequencing (NGS) are all used to evaluate AML patients. By employing all of the molecular data, a better diagnostic can be made. **Methods/Results**Clinical molecular results from patient . bam and . vcf files were filtered through over 200 treatment rules contained in the GenomOncology (GO) Clinical Workbench. Of these 150 were based on SNV only; 45 came from fusion rules; and 14 based on amplification rules. Patient results along with clinical interpretation were reported in a lab configured pathology report. **Conclusions**Currently, DNA-Seq data sets (e. g. Illumina and Ion Torrent Hotspot Panels) are rich sources of clinically relevant information which include SNVs, indels, etc. Even more complex data sets are on the horizon (e. g. RNA-Seq, copy-number, LOH, etc.). The ultimate utility of multi-modal clinical tests lies in being able to provide a comprehensive view of complex genomic alterations that work in tandem to drive tumor growth, response to therapy and disease course. Software that pulls complex data sets together into a single record along with providing clinical rules-based medicine prioritization, helps communicate all the useful genetic information and value contained in precision medicine testing like NGS, and microarrays.

2642T

The correlation between the expression level of has-miR-338-3p with the rate of breast cancer metastasis to lymph nodes. *A. Abak[1], E. Sakhinia[2], S. Amini[2].* 1) Tabriz University of Medical Sciences, Tabriz, East Azerbaijan, Iran; 2) Biotechnology Research Center,Tabriz University of Medical Sciences,Tabriz,Iran.

Breast canceris the most common female malignancies in the world which seriously impacts the female health. In recent years, various studies have been reported to determine the relevance of miRNAs to human cancer. microRNAs (miRNAs) have been demonstrated to be important gene regulators with critical roles in diverse biological processes, including tumorigenesis. miR-338-3p is a recently discovered miRNA and is involved in cell differentiation. Previous studies suggested microRNA-338-3p (miR-338-3p) was down-regulated and play tumor suppressor roles in gastric cancer, colorectal carcinoma ,lung cancer and hepatocellular carcinoma. Knocking downmiR-338-3p in breast cancer cells led to mesenchymal-like changes. MiR-338-3p influenced the expression of the EMT-associated proteins by upregulating the epithelial marker E-cadherin and downregulating the mesenchymal markers, N-cadherin, fibronectin, and vimentin. However, the role ofmiR-338-3p in breast cancer tissues is still unclear. The aim of this study was to investigate the expression level of miR-338-3p in breast cancer and its relationship with the clinicopathological features of patients. Total RNA was first isolated from 40 pairs of breast cancer tissues and adjacent non-tumor tissues. Afterwards cDNAs were synthesized and the expression level of microRNA-338-3p was quantified by real time PCR. The Correlation between the expression level of microRNA-338-3p and clinicopathological features was studied and the capability of microRNA-338-3p to function as a breast cancer tumor marker was also explored. The expression of microRNA-338-3p was significantly down-regulated in breast cancer tissues in comparison with those in the adjacent non-tumorous tissues, and the value was negatively related to advanced tumor, node, metastasis stage and local invasion. The expression of microRNA-338-3p in breast cancer cells transfected with pre-microRNA-338-3p was significantly increased. Furthermore, over-expression of microRNA-338-3p showed obviously suppressed invasion and migration ability in breast cancer cells. Therefore, we conclude thatmiR-338-3p acts as a novel tumor suppressor gene in breast cancer. miR-338-3pcan decrease migratory, invasive, proliferative and apoptotic behaviors, as well as breast cancer EMT. Therefore, targeting with themiR-338-3p might serve as a novel therapeutic application to treat breast cancer patients.

2643W

Acquired Telomere Shortening in Women Diagnosed with Breast Cancer is Associated with Chemotherapy and Depressive Symptoms. *A. Alhareeri[1], D. Lyon[2], M. Dozmorov[3], R. K. Elswick[3,5], TP. York[1], D. Lynch Kelly[2], C. Jackson-Cook[1,4,6].* 1) Department of Human and Molecular Genetics, Virginia Commonwealth University School of Medicine, Richmond, VA; 2) Biovehavioral Nursing Science, University of Florida School of Nursing, Gainesville, FL; 3) Department of Biostatistics, Virginia Commonwealth University School of Medicine, Richmond, VA; 4) Department of Pathology, Virginia Commonwealth University School of Medicine, Richmond, VA; 5) Department of Family and Community Health Nursing, Virginia Commonwealth University School of Nursing, Richmond, VA; 6) Massey Cancer Center, Virginia Commonwealth University, Richmond, VA.

Breast cancer (BC) is one of the most commonly diagnosed malignancies in females. The 5-year survival rate for women with early stage BC is about 90%; however, the quality of life for many of these women may be adversely affected due to treatment/cancer-related side effects, including a constellation of symptoms (pain, depression, fatigue, stress, sleep disturbance and cognitive dysfunction) collectively termed psychoneurological symptoms (PNS). The primary aim of this study is to test the hypothesis that these PNS are correlated with alterations in telomere length (TL) that may lead to acquired changes in the methylation status of juxtaposed genes. To date, we have longitudinally studied 64 women (ages 23-71) with early stage breast cancer (I to IIIA) at 2 time points: prior to chemotherapy (baseline) and 4 weeks following the first chemotherapy treatment (mid-treatment). Measures quantified include TL (using both a monochrome multiplex qPCR assay and a semi-quantitative chromosome-specific FISH assay); genome-wide methylation (Illumina 450K); and depression (using HADS). Mean TLs (based on T/S ratios; qPCR) at mid-treatment were not significantly different from those at baseline (p=0. 493), but chromosome-specific shortening at mid-treatment was observed for 1p; 9q; 12q; 18p; 18q; 21p; and 22p (p=0. 019 to 0. 048). Also, a non-random distribution of significant differentially methylated sites was observed for regions juxtaposed to distal 1p (p<2. 2e-16), 9q (p<2. 2e-16) and 12q (p=6. 314e-12), the latter of which are rich in CpGs. Analyses of TL with depressive symptoms showed significant negative correlations (higher depressive symptom scores with shorter telomeres) for 35 of the 46 telomeres (1p, 2p, 2q, 3p, 3q, 4p, 4q, 5p, 5q, 6p, 6q, 7q, 8p, 8q, 9q, 10p, 11q, 12p, 12q, 13p, 13q, 14q, 15p, 15q, 16p, 17q, 18p, 18q, 19p, 19q, 20p, 20q, 21p, Xp and Xq) (p=0. 001 to 0. 041). Model fitting showed chemotherapy to be predictive of TL changes for a subset of telomeres (p=0. 017 to 0. 049). Collectively, the results of this study show that telomere shortening for a subset of chromosomes is associated with chemotherapy, methylation alterations and depression. Knowledge gained from this study provides a plausible biological basis, at least in part, for the development/persistence of PNS following chemotherapy and offers hope for the future development of therapeutic interventions that could alleviate undesirable side effects in patients receiving treatment for BC.

Molecular basis of the resistance to X-rays of chondrosarcomas. *J. Aury-Landas[1,2], N. GIRARD[1,2], M. BARREAU[1,2], E. LHUISSIER[1,2], K. BOUMEDIENE[1,2], C. BAUGE[1,2].* 1) Normandie Université, France; 2) UNICAEN, EA4652 MILPAT, Caen, France.

Chondrosarcomas are malignant tumors of bone that produce cartilage matrix. Primary chondrosarcoma is the second most frequently primary malignant tumor of bone after osteosarcoma, and represents about 25% of bone sarcomas. Chondrosarcoma is considered as resistant to both chemotherapy and radiation, making surgical resection the only curative treatment. However, mechanisms of resistance are not well understood. This project aims to investigate resistance mechanism to radiotherapy. We compared the response to X-rays radiation of five different cell lines derived from human chondrosarcomas. They can be classified according to their sensibility to X-rays within 3 groups: X-rays induced both apoptosis and senescence in the most sensitive group, whereas they induce only apoptosis or senescence for the intermediate group. No death could be detected for the most resistant group. To understand the molecular basis of theses different responses to X-rays, we performed whole-exome sequencing on the five cell lines. On average, 60 000 variants were identified per exome, including 1700 new variants. After filtration, 245 to 476 coding or splice variants per cell line were predicted as somatic variants with deleterious functional impact on the protein. Interestingly, we found ten commonly mutated genes in the cell lines in which apoptosis is observed after X-rays radiation. Their putative role in radioresistance is under investigation. In conclusion, we show that chondrosarcoma cell lines respond differently to X-ray. In addition, our study is the first one which extensively characterizes commonly used human chondrosarcoma cell lines by exome sequencing. Our preliminary results provide essential genetic information on radioresistance mechanisms through the identification of genes potentially involved in the response to radiation.

Significance of maspin protein expression in prognosis of gallbladder cancer. *K. Baghel[1], HR. Kazmi[1], S. Raj[3], A. Chandra[1], RN. Srivastava[2].* 1) Surgical Gastroenterology , King George's Medical University, Lucknow, Uttar Pradesh, India; 2) Orthopaedics Surgery, King George's Medical University, Lucknow, Uttar Pradesh, India; 3) M S Ramaiah Medical College, Bangalore.

Introduction: Gallbladder cancer (GBC) is highly fatal gastrointestinal malignancy with poor prognosis in northern India. Prognostic significance of Maspin has reported in various cancers but has not been evaluated for GBC. We investigated maspin protein expression in normal, cholelithiasis and GBC patients along with its prognostic importance in cancer patients. **Methodology:** We investigated maspin protein expression in gallbladder tissue of subjects with cholelithiasis (n=36), GBC (n=46) and controls (n = 25). Clinicopathological parameters and prognosis of patients with GBC were correlated with the expression of maspin protein by ELISA. Kaplan- Meier method was performed for survival analysis. **Results:** Significant increased (P<0. 0001) expression of maspin protein was observed in GBC as compared to cholelithiasis, whereas no expression was found in normal tissues. Increased maspin expression was significantly associated with higher tumor stage (stage III vs. stage II; P <0. 0001) and cellular differentiation (poor and moderate vs. well differentiated; P<0. 0001) in GBC. Significant correlation (Pearson's coefficient(r)=-0. 617;P<0. 0001) was observed between maspin protein expression and survival of cancer patients after surgery. Overall survival was significantly shorter (P=<0. 0001; hazard ratio [HR] for death= 2. 84; 95% Confidence interval [CI] = 0. 09865 to 0. 3683) in patients of GBC with maspin expression > 169. 56 pg/mg (median survival; 10 months) as compared to those with expression < 169. 56 pg/mg (median survival; 16 months). Statistically significant difference (P=0. 03) in overall survival was observed for stage II patients with maspin expression > 169. 56 pg/mg (median survival; 11 months) as compared to those with expression < 169. 56 pg/mg (median survival; 18 months). Similarly, for stage III, there was significant difference (P=0. 04) in overall survival between patients with maspin expression > 169. 56 pg/mg (median survival; 9. 5 months) and with expression < 169. 56 pg/mg (median survival; 13 months). The HR for stage II and III disease was 3. 45 (95% CI = 0. 09247 to 0. 9088) and 3. 21 (95% CI = 0. 1010 to 0. 9598) respectively. **Conclusion:** Up-regulation of maspin mRNA may play an important role in malignant progression and is correlated with a poor prognosis. Maspin expression can be useful as a clinical marker in the management of this disease.

Association of *CDH1* gene polymorphisms -472delA and -160C>A with diffuse and intestinal gastric cancer in Mexican population. *A. R. Bustos-Carpinteyro[1,2], N. Delgado-Figueroa[2], S. Luna-Ernesto[3], M. T. Magaña[2], J. Y. Sánchez-López[2].* 1) Instituto de Genética Humana, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) División de Genética. Centro de Investigación BioMédica de Occidente, Instituto Mexicano del Seguro Social. Guadalajara, Jal. México; 3) Servicio de Endoscopía, Hospital de Especialidades, Centro Médico Nacional de Occidente, Instituto Mexicano del Seguro Social. Guadalajara, Jal. México.

Introduction. Gastric cancer (GC) constitutes the third cause of cancer death in Mexico and worldwide. Due to its histological characteristics, GC can be classified as diffuse and intestinal. It has been observed that diffuse GC has a reduced expression of the E-Cadherin cell adhesion protein, encoded by the *CDH1* gene. A reduction on *CDH1* gene transcription has been reported whenever the mutated alleles -472delA (rs5030625) and -160C>A (rs16260) are present. The aim of this study was to determine the association of *CDH1* -472delA and -160C>A polymorphisms with diffuse and/or intestinal gastric cancer in Mexican patients, as well as to determine the frequencies of these polymorphisms in Mexican healthy population. **Methods.** Four groups of genomic DNA samples were analyzed: diffuse gastric cancer (n=24), intestinal gastric cancer (n=23), controls (n=48), and healthy blood donors (n=93). Genotyping of SNPs was performed by PCR followed by RFLPs through *Ban*II (-472delA) and *Hinc*II (-160C>A) enzymes. The restriction fragments were observed on 6% polyacrylamide gels. The data were analyzed through SPSSv11 and Arlequin 3. 1 statistic programs. **Results.** The frequency of the mutated allele of -472delA SNP was 0. 326, 0. 318 and 0. 284 in the diffuse-gastric-cancer, intestinal-gastric-cancer and control groups, respectively. For the -160C>A SNP, the frequencies of the mutated allele were 0. 174, 0. 318 and 0. 313 for each respective group. Comparison of the genotypic and allele frequencies of both polymorphisms among the three groups shows no significant differences (p>0. 05). Three haplotypes were observed: 1) delA-C: 52. 3%, 42. 5% and 39. 8%, for diffuse-gastric-cancer, intestinal-gastric- cancer and control groups, respectively; 2) delA-A: 18. 2%, 25% and 31. 8%; and 3) A-C: 29. 5%, 32. 5% and 28. 4%, for each group respectively. The haplotypes frequencies were similar among the studied groups. Both polymorphisms showed linkage equilibrium (r2<0. 33, p>0. 05). Hardy-Weinberg Equilibrium was observed for -472delA and -160C>A SNPs in healthy Mexican population. **Conclusions.** The -472delA and -160C>A SNPs are not associated with gastric cancer in patients from western Mexico. However, further studies are required in order to increase our understanding of the role that these polymorphisms play in the development of this disease.

High Grade Glioblastoma Patients have Increased Levels of Systemic Chromosomal Instability, detected by High Resolution Flow Cytometry in Circulating Reticulocytes. *M. Camargo[1], LM. Barrera-Arenas[1], LD. Ortiz[2].* 1) University Research Center - Biology, University of Antioquia, Medellin, Antioquia, Colombia; 2) Cancerology Institute, Clinica Las Americas, Medellin, Colombia.

The automatic detection of genetic damage by advanced flow cytometry of micronucleated (MN) reticulocytes, has increased the speed and sensitivity of *in vivo* detection of cytogenetic damage. This has been possible through the refinement of the original three color fluorescence labeling technique (Dertinger et al. , 2011) that includes antihuman-CD71-FITC for the immature fraction of reticulocytes, anti-human-CD61-PE to exclude platelets, and PI for nuclear DNA. We have applied this methodology with the aim of exploring chromosomal instability in circulating cells in a population of cancer patients with newly diagnosed high grade glioblastomas (WHO IV), measuring the frequency of MNCD71+ cells immediately before therapy. The study included 50 patients and 25 healthy controls, paired by gender and age matched by decils. Basic confounding factors that may affect the backgrounds levels of genotoxicity were controlled. Samples were analyzed with a flow cytometer FACS CANTO II (BD Biosciences). To our knowledge this is the largest group of patients with glioblastomas in whom, this has been studied. In healthy controls the mean frequency of MNCD71+ was 0. 098 ± 0. 019%. (CI: 0. 058-0. 139%, 95%) while in patients was 3. 060 ± 0. 625 (CI:1. 802-4. 318, 95%). These observations suggest an association between elevated levels of micronucleated reticulocytes and the risk of this particular type of aggressive tumor. They also lso support the intriguing observation made by others about a possible systemic effect of cytogenetic instability associated with a localized tumor. In fact, a number of studies have found elevated levels of MN formation or increased cytogenetic abnormalities in the peripheral blood lymphocytes of cancer patients prior to chemotherapy or radiotherapy. Despite the fact that, to our knowledge, this is the largest group of patients with glioblastomas in whom this has been studied, our findings should be replicated in largest cohorts of patients, carefully looking for parameters such as hidden confounding factors, tumor-derived DNA in circulating blood, oxidative stress in circulating blood and/or in blood cells, among others, before proposing that the MNCD71+ endpoint represents a valuable biomarker for glioblastomas. FUNDING by Sostenibility Grant (01740), University of Antioquia. Note: Authors (1) contributed equally to this work.

The Prevalence of CYP2D6 Gene Polymorphisms among Filipinos and Their Use as Biomarkers for Cancer Risk among Those with Lung Cancer. *E. Cutiongco de la Paz[1], C. Ngelangel[2], C. Padilla[1], A. Wang[3], J. Nevado[1], R. Ceniza[3], L. Simpao[3], L. Beratio[3], E. Dominguez[3], A. Albay[3], C. Silao[1], F. Rocamora[1], R. Luna[1], The Philippine Cancer Study Group.* 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila; 2) Institute of Clinical Epidemiology, National Institutes of Health, University of the Philippines Manila; 3) Section of Pulmonology, Department of Medicine, College of Medicine, Philippine General Hospital, University of the Philippines Manila.

The highly polymorphic nature of the CYP2D6 gene and its central role in the metabolism of commonly used drugs make it an ideal candidate for pharmacogenetic screening. However, the relevance of such screening depends primarily on the presence of significant variation within a target population. This study aims to determine the prevalence of CYP2D6 polymorphisms among Filipinos. It also aims to determine if such variants are associated with the occurrence of lung cancer, as tobacco-derived procarcinogens are metabolized by CYP2D6 to their carcinogenic derivatives. Utilizing a candidate gene approach, 47 single nucleotide polymorphisms (SNPs) of the CYP2D6 gene were genotyped from DNA samples of 115 cases with lung cancer and age- and sex-matched 115 controls. The samples were genotyped using the Illumina GoldenGate Genotyping assay. Results show that 18 out of 47 polymorphisms have significant genotypic variability (>1% for at least 2 genotypes). No variant is associated with lung cancer. However, rs1135840, rs16947 and rs28360521, were found to be highly variable among Filipinos and these findings may have clinical implications. Both rs1135840 and rs16947 are associated with cancer; rs16947 with timolol-induced bradycardia; and rs28360521 with lose-dose aspirin-induced lower gastrointestinal bleed. This study demonstrates that CYP2D6 polymorphisms are present among Filipinos, which, although not found to be associated with lung cancer, can be useful biomarkers for future pharmacogenetic studies.

Germline variant analysis and ancestry inference of 2,153 high-depth whole genomes of patients afflicted with diverse cancers. *F. M. De La Vega[1,2], D. Y. Wu. [1], S. Shringarpure[2], S. M. Waszak[3], S. Iakhnin[3], T. Shmaya[1], G. Wojcik[2], C. Gignoux[2], J. Korbel[3], C. D. Bustamante[2], The PCAWG Network.* 1) Annai Systems, Inc. , Burlingame, CA; 2) Stanford University, Stanford, CA; 3) EMBL, Heidelberg, Germany.

Numerous studies have shown a relationship between ancestry, penetrance of disease variants, and effectiveness of therapies. Unfortunately, ethnicity is often not accurate or present in the metadata of cancer research cohorts and thus is ignored in analysis. We aim to explore the relationship between ancestry, cancer etiology and outcomes analyzing 2,153 samples from the TCGA and ICGC projects for which whole genome sequencing data of the germline is available. Samples were sequenced with Illumina technology and realigned to the extended GRCh37 (hs37d5) reference as part the ongoing ICGC PanCancer Analysis of Whole Genomes Project. We performed variant calling using the rtgVariant software, yielding high sensitivity (98. 6%) and non-reference genotype concordance (99. 7%) with SNP genotyping arrays. About 47% of variants are novel as compared with dbSNP and 1000 Genomes Project (v3) data. We developed a maximum likelihood method that uses a previously selected set of 4,235 ancestry-informative-SNPs and their frequency across populations to assign continental ancestry to each donor. For those individuals that appear recently admixed we apply the RFmix software, a fast discriminative modeling approach, to identify ancestral chromosomal segments along the genome. Our results show that most donors are from European or Asian descent in concordance with their source. However, some population diversity is found in particular in the US cohorts. For example, in the US Breast Cancer cohort about a third of donors are from African ancestry, which is highly relevant given the higher prevalence of the triple-negative type of the disease in this population. Other ancestries, such as South-East Asian and Native American, are present although to a much lesser extent. These results highlight the need to recruit other populations for genomic studies to benefit these groups from the advances in personalized medicine. We identified loss of functions (LoF) variants across cancer and other medically relevant genes and stratified by ancestry. A linear relationship exists between cohort size and rate of LoF variant discovery in cancer genes. Interestingly, 58% of cancer genes are found to be mutated in more than two tumor types, suggesting pleiotropic effects. Our variant resource identifies rare human gene knock-outs, enhance imputation panels and the assessment of variant pathogenicity for clinical applications, and is helping to clarify the role of ancestry in cancer outcomes.

Comparing Heterogeneity across Biomarkers in Cancer Stem Cells and Side Populations in Breast Cancer Cell Lines. *D. Dhawan.* Institute of Life Sciences, Ahmedabad University, Ahmedabad, Gujarat, India, India.

Cancerous epithelial cells are confined to a primary site by the continued expression of adhesion molecules and the intact basal lamina. However, as the cancer progresses some cells are believed to undergo an epithelial-mesenchymal transition (EMT) event, leading to increased motility, invasion and, ultimately, metastasis of the cells from the primary tumour to secondary sites within the body. These disseminated cancer cells need the ability to self-renew, as stem cells do, in order to establish and maintain a heterogeneous metastatic tumour mass. Identification of the specific subpopulation of cancer stem cells amenable to the process of metastasis is highly desirable. In this study, we have isolated and characterized cancer stem cells from luminal and basal breast cancer cell lines (MDA-MB-231, MDA-MB-453, MDA-MB-468, MCF7 and T47D) on the basis of cell surface markers CD44 and CD24; as well as Side Populations (SP) using Hoechst 33342 dye efflux. The isolated populations were analysed for epithelial and mesenchymal markers like E-cadherin, N-cadherin, Sfrp1 and Vimentin by Western blotting and Immunocytochemistry. MDA-MB-231 cell lines contain a major population of CD44+CD24- cells whereas MCF7, T47D and MDA-MB-231 cell lines show a side population. We observed higher expression of N-cadherin in MCF-7 SP cells as compared to MCF-7NSP (Non-side population) cells suggesting that the SP cells are mesenchymal like cells and hence express increased N-cadherin with stem cell-like properties. There was an expression of Sfrp1 in the MCF7- NSP cells as compared to no expression in MCF7-SP cells, which suggests that the Wnt pathway is expressed in the MCF7-SP cells. The mesenchymal marker Vimentin was expressed only in MDA-MB-231 cells. Hence, understanding the breast cancer heterogeneity would enable a better understanding of the disease progression and therapeutic targeting.

Expression Levels of Matrix Metalloproteinase-9 and P-Element Induced Wimpy Testis Like-2 in Prostate Cancer: A Case-Control Study. *M. Dianatpour[1,2], N. Pouyanfar[1], A. Amin Sharifi[3], A. Monabbati[4].* 1) Medical Genetics, Shiraz university of medical sciences, Shiraz, Fars, Iran; 2) Transgenic technology research center, Shiraz university of medical sciences, Shiraz, Iran; 3) Urology, Shiraz university of medical sciences, Shiraz, Fars, Iran; 4) Pathology, Shiraz university of medical sciences, Shiraz, Fars, Iran.

Prostate cancer is the second most prevalent cancer in human. Also this is the most common malignancy and the sixth important cause of death in men worldwide. The most routine diagnostic test for prostate cancer is PSA test which is associated with some limitations like too many false positive results. This study intends to investigate the role of matrix metalloproteinase-9 (*MMP9*) and P-element induced wimpy testis like-2 (*PIWIL2*) expression levels as different biomarkers in prostate cancer biopsy specimens. Seventy formalin-fixed paraffin embedded samples (35 normal and 35 cancerous cases) were selected. Expression levels of *PIWIL2* and *MMP9* genes were evaluated, using Real-time PCR. *MMP9* and *PIWIL2* expression levels in cancerous tissues were significantly higher than the adjacent normal tissues (P< 0. 05). The survival analysis showed a significant correlation between expression level of *PIWIL2* and survival rate (P<0. 05), but such correlation was not observed in case of *MMP9* (P>0. 05). Higher levels of *MMP9* and *PIWIL2* expression were strongly related to Gleason score and age, using Pearson's correlation coefficient test, however, this kind of association was not evident between PSA and expression levels in the genes of interest. The expression level of *PIWIL2* had a significant correlation with metastasis rate, but this relationship was not seen about *MMP9* expression level. Our results confirmed the validity of *PIWIL2* expression as a valuable prognostic biomarker for early diagnosis of prostate cancer.

L-1 activity and expression in Normal esophagus, Barrett's esophagus, esophageal adenoarcinoma, and Esophageal Squamous cell carcinoma. *T. T. Doucet[1,2], N. Rodić[3], R. Sharma[3], I. Darbari[1], G. Abril[1], J. T. Choi[1], J. Y. Ahn[1], Y. Cheng[4], R. A. Anders[3], K. H. Burns[1,3], S. J. Meltzer[4], H. H. Kazazian Jr.[1].* 1) Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD. 21205 USA; 2) Pre-doctoral training program in Human Genetics, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205, USA; 3) Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland, United States of America Baltimore, MD 21287; 4) Division of Gastroenterology and Hepatology, Department of Medicine and Department of Oncology, Johns Hopkins University, Baltimore, Maryland 21205.

Because retrotransposition has been observed in many gastrointestinal epithelial cancer types, we focused on L1 mobilization as a source of instability in cancer. We hypothesized that L1 retrotransposition is active in esophageal squamous cell carcinoma (ESCC), esophageal adenocarcinoma (EAC), and EAC's precursor Barrett's esophagus (BE). To test our hypothesis, we evaluated 5 patients with benign BE, 5 patients with BE and concomitant esophageal adenocarcinoma (EAC), 10 additional patients with EAC, and 9 patients with ESCC to determine the level of L1 activity in these diseases. Following L1-seq, we confirmed 160 somatic insertions by PCR in 17 of 29 individuals. We observed clonal amplification of several insertions which appeared to originate in normal esophagus (NE) or BE and were later clonally expanded in BE, in EAC, or in ESCC. Additionally, we observed evidence of clonality within the EAC cases: specifically, 22 of 25 EAC-only insertions were present identically in distinct regions available from the same tumor, suggesting they occurred in the founding tumor cell of these lesions. Our data show that somatic retrotransposition occurs early in many patients with BE and EAC, and indicate that early events occurring in histologically normal esophageal cells may be clonally expanded in esophageal adenocarcinogenesis. Additionally, we evaluated L1 ORF1 protein expression in 9 of the carcinoma cases for which formalin-fixed paraffin embedded tissue was available. Using immunohistochemistry, we detected expression of ORF1p in all tumors evaluated. Interestingly, we also observed dim ORF1p expression in the normal esophagus of all 4 patients for whom additional blocks of normal esophagus containing squamous epithelium was available. To determine if ORF1p expression is a hallmark of unaffected tissues, we obtained both skin and esophageal biopsies from two unaffected individuals. In both biopsies, ORF1p expression was evident in the squamous cell epithelium. ORF1p may be expressed in many normal epithelial tissues which could account for the high incidence of somatic retrotransposition events in epithelial cancers. Thus, our data show that L1 is weakly expressed in normal esophagus and retrotransposition can occur in normal tissue during the development of esophageal adenocarcinoma. Due to the pervasive activity of retrotransposons in epithelial cancer, it is likely somatic insertions play a role in tumorigenesis.

Caveolin-1: A Potential Biomarker of Aggressive Triple-Negative Breast Cancer in African American Women. *J. Getz[1,2], D. Teoh[1,2], S. Nasser[1], C. Legendre[1], W. Tembe[1], V. Yellapantula[1], M. E. Ahearn[1], C. Gomez[3], M. Jorda[3], S. M. Wong[1], M. Pegram[4], J. Carpten[1], L. Baumbach-Reardon[1].* 1) Translational Genomics Research Inst. , Phoenix, AZ; 2) Arizona State University. , Phoenix, AZ; 3) University of Miami Medical School, Miami, FL; 4) Stanford University School of Medicine, Stanford, CA.

In the U. S. , breast cancer (BC) incidence between African American (AA) and Caucasian (CA) women are similar, however, AA women have a significantly higher mortality rate. In addition, AA women often present with tumors at a younger age, with a higher grade and at a later stage and are more likely to be diagnosed with the highly aggressive triple-negative breast cancer (TNBC) subtype. Even within the TNBC subtype, AA women have a worse clinical outcome compared to CA. Although multiple socio-economic and lifestyle factors may contribute to these observed health disparities, it is essential that the molecular characteristics and underlying biological differences between CA and AA TNBC are identified. In this study, gene expression profiling was performed on archived FFPE samples, obtained from CA and AA women diagnosed with early stage TNBC. Initial analysis revealed a pattern of differential expression in the AA cohort compared to CA. Further molecular characterization of the data showed that the AA cohort segregated into 3-TNBC molecular subtypes; Basal-like (BL2), Immunomodulatory (IM) and Mesenchymal (M). Gene expression analyses resulted in 190 differentially expressed genes between the AA and CA cohorts. Pathway enrichment analysis identified Cytoskeletal Remodeling, Cell Adhesion, WNT, Tight Junctions, and Immune Response in the AA TNBC-Cohort and significantly upregulated genes associated with the Wnt/β-catenin pathway. These results were validated using qRTPCR on an independent cohort of FFPE samples from AA and CA women with early stage TNBC, and identified Caveolin-1 (CAV1) as being signficantly expressed in the AA-TNBC cohort. Furthermore, CAV1 was shown to be highly expressed in a cell line panel of TNBC, in particular, those of the mesenchymal and basal-like molecular subtype. Finally, a loss of function study by siRNA revealed that silencing of CAV1 resulted in a significant decrease in proliferation in each of the TNBC cell lines. These observations suggest that CAV1 expression may contribute to the more aggressive phenotype observed in AA women diagnosed with TNBC.

Chromosomal imbalances detected by array CGH from thirty-one Chinese non-smoker adenocarcinomas of the lung. *Y. Gu[1,2], L. Peng[1], X. Wang[2], W. Li[2], S. Li[2], S. Hua[1].* 1) Department of Reparatory and Critical Care Medicine, The First Hospital of Jilin University, Chang Chun City, Ji Lin Province, P. R. China; 2) Department of Pediatrics, College of Medicine, The University of Oklahoma Heath Sciences Center, Oklahoma City, OK 73104, US.

Smoking tobacco is the number one risk factor for lung cancer. However, people who never smoked can also develop lung cancer. It is unclear whether chromosomal changes in these two groups of patients with smoking or non-smoking history have the same or different genetic profile at the cytogenetic level. In this pilot study, we have collected 31 tumor samples from patients diagnosed with lung adenocarcinoma in clinical phase I-IIa who claimed they had never smoked before. They were 23 female patients with a mean age of 57. 4 years old and 8 male patients with a mean age of 62. 4 years old. Samples of DNA were isolated from the tumor tissues and aCGH was performed using Agilent's array platform Sureprint 2x400K. Approximately 81% of the samples showed a gain of whole chromosome 5 or partial duplication of the short arm of chromosome 5 and 77% of the samples showed a gain of whole chromosome 7 or a duplication of short arm of chromosome 7. Duplication of the long arm of chromosome 8 (61%), deletion of the short arm of chromosome 8 (52%), deletion of the short arm of chromosome 9 (41%), duplication of the long arm of chromosome 14 (48%) and duplication of short arm of 16 (48%) were also detected. Compared to common deleted or duplicated regions of adenocarcinoma of the lung published previously, these findings indeed had unique patterns. Whether chromosomal imbalances found in our cohort of patient samples were contributed by the fact that our samples were from non-smoker adenocarcinomas of the lung or not, more patients were needed to draw a definitive conclusion.

2655W

The landscape of microsatellite instability in cancer exomes. *R. J. Hause[1], E. H. Turner[2], M. Beightol[2], C. C. Pritchard[2], J. Shendure[1], S. J. Salipante[2].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Laboratory Medicine, University of Washington, Seattle, WA.

Microsatellites, 2-5 base pair repetitive sequences present throughout the human genome, can abnormally shorten or lengthen because of defects in the DNA mismatch repair (MMR) system, resulting in a "microsatellite instability" (MSI) phenotype. MSI is a key prognostic and diagnostic tumor phenotype that has been well studied by conventional methods. However, both the genomic landscape of MSI events and differences in MSI among cancer types remain poorly illuminated. We here present a comprehensive analysis of the landscape of MSI in cancer exomes. We catalogued MSI events at over 500,000 incidentally sequenced microsatellite loci across 4,224 cancer exomes spanning 18 different cancer types from The Cancer Genome Atlas. We constructed a global classifier for MSI that achieved 93. 75% sensitivity and 98. 5% specificity compared to gold-standard MSI calls based on the revised Bethesda guidelines. We observed that MSI-low (MSI-L) samples did not display significant differences from MS-stable (MSS) samples in the number of MSI events and support discontinuation of the use of MSI-L as a distinct classification. Comparative examination of MSI revealed both cancer-specific and core loci associated with global MSI, such as a frameshift mutation in an 8-bp polyadenine tract in exon 10 of the tumor suppressor *ACVR2A* observed in 56. 6% of MSI-high (MSI-H) cancers. Lastly, we investigated the relationships between MSI and mutations in MMR genes, gene regulatory features, and clinical covariates. Our results provide a comprehensive view of MSI in cancer exomes, highlighting both conserved and cancer-specific MSI properties and identifying candidate genes underlying predisposition to global MSI. Future work will attempt to functionally validate these candidates as causally influencing global MSI.

Cell-free urinary microRNA quantification as non-invasive biomarker in patients with bladder urothelial carcinoma. *A. Horinek[1,2], M. Korabecna[1,2], A. Brisuda[2], S. Pospisilova[1], E. Pazourkova[1,3], V. Soukup[4], J. Hrbacek[2], O. Capoun[4], I. Svobodova[1], J. Mares[5], T. Hanus[4], M. Babjuk[2].* 1) Institute of Biology and Medical Genetics, 1st Faculty of Medicine, Charles University and General Faculty Hospital, Prague 2, Czech Republic; 2) Department of Urology, 2nd Faculty of Medicine, Charles University and University Hospital Motol in Prague, Czech Republic; 3) Department of Nephrology, 1st Faculty of Medicine, Charles University and General Faculty Hospital in Prague, Czech Republic; 4) Department of Urology, 1st Faculty of Medicine, Charles University and General Faculty Hospital in Prague, Czech Republic; 5) Department of Biology and Medical Genetics, Charles University in Prague, 2nd Faculty of Medicine, Czech Republic.

Background: Bladder carcinoma is one of the most common urooncological diseases. It is the sixth oncological disease and it makes 4% of newly diagnosed oncological illnesses in the Czech Republic. The early noninvasive detection contributes to decreased mortality rate in this disease. **Aim:**MicroRNAs (miRNAs) are small non-coding RNA molecules that function in the regulation of gene expression. The aim of the study was to detect candidate miRNAs in urine whose expression could reflect the onset and progression of bladdder cancer and that may be used as a potential diagnostic marker for early noninvasive diagnostics and for prediction of the severity of bladder cancer, as well. **Patients and methods:**Urine samples were collected in the period 10/2013 – 4/2015 and 61 samples were included in this study (15 healthy controls and 46 patients in different stages of bladder cancer (pTa - pT4)). The samples with positive culture were not included. In the first part of our study 381 miRNAs from urine were analyzed on TaqMan Human MicroRNA Array A (TLDA) by Real-time PCR method. In the second part TaqMan MicroRNA Assays of selected miRNAs from the TLDA platform were used to confirm the results. Relative quantification and statistical analyses were performed with Expression Suite v1. 0. 3 and with qBase+ v2. 4. Relative quantification was calculated using 3 reference genes (miR-191, miR-28-3p, miR-200b). Expressions of miRNAs were compared between the patients and controls using the Mann-Whitney test. **Results:**In the first part we identified 58 miRNAs whose expression was significantly different ($p<0.05$) between controls and patients. According the results of both methods we found miRNAs with statistically significant differences: 9 with $p<0.01$ (let-7c, miR-125b, miR-204, miR-425, miR-532-3p, miR-99a, miR-16, miR-30b and miR-93) and 1 with $p<0.05$ (miR-199a-3p). Others were not confirmed in the second part. 6 miRNAs (let-7c, miR-125b, miR-204, miR-532-3p, miR-99a, miR-30b) were 4-10 times more expressed in controls than in patients and 4 were 2-4 more expressed in patients (miR-425 miR-16 miR-93, 199a-3p). **Conclusion:**It has been demonstrated that the expression of six candidate miRNAs with significant differences in expression in urine of patients and controls could be promising diagnostic and prognostic markers for noninvasive diagnostics of bladder cancer. **Acknowledgements:**Supported by the Internal Grant Agency of the Ministry of Health of the Czech Republic no. NT12417.

Using Rare Mutation Analysis Using Digital PCR on QuantStudio® 3D to Validate Ion AmliSeq™ Next Generation Sequencing for Cancer Research. *M. Laig[1], A. Justino[2], R. Petraroli[1], L. Lac[1], D. Linh Vo[1], K. Varma[1], J. C. Machado[2], J. L. Costa[2].* 1) Thermo Fisher Scientific, South San Francisco, CA; 2) IPATIMUP, Porto, Portugal.

Introduction: Next generation sequencing (NGS) is becoming an increasingly important analysis tool in cancer research. In this study, we set out to confirm its sensitivity and accuracy detecting low frequency mutations using rare mutation analysis by digital PCR as an independent technology. **Methods:**Eleven cell free DNA samples isolated from plasma were typed using the Ion AmliSeq™ panel and the Ion Proton PGM. The samples were then analyzed by digital PCR in a blinded laboratory study to confirm the presence of the mutations detected. Samples represented a mixture of independent samples as well as the same sample taken from the same individual at different time points. Mutations were identified and quantified by digital PCR using Rare Mutation Assays (Applied Biosystems) for the following mutations: EGFR T790M (COSMIC ID 6240), L858R (COSMIC ID 6224), and exon 19 deletions E746_A750delELREA (COSMIC ID 6223) and L747_P753>S (COSMIC ID 12370), and KRAS mutations G12V (COSMIC ID 520) and G12D (COSMIC ID 521). Experiments were run according to the Rare Mutation Assays protocol. **Results:**Rare mutation analysis by digital PCR on QuantStudio® 3D confirmed the low mutation frequency detected by NGS. Both technologies showed matching results for all eleven samples tested at mutation rates below 1%. Both technologies also detected expected mutation rates based on the time points. **Conclusions:**We confirmed the sensitivity and accuracy of NGS for low frequency mutation detection. Rare mutation analysis by digital PCR on QuantStudio® 3D is an excellent application to validate NGS results for cancer research. For Research Use Only. Not for use in diagnostic procedures.

Targeted RNA Sequencing for simultaneous expression profiling and detection of gene rearrangements in FFPE biopsies. *K. Maddula, P. Roche, D. Thompson.* HTG Molecular, Tucson, AZ.

Recent developments in targeted cancer therapies have highlighted a need for quick, accurate gene mutation and rearrangement assays that work well with small biopsy specimens. Routine screening for rearrangements is complicated by the size of biopsy samples (fine needle aspirates or bronchoscopic biopsies) and the low prevalence of rearrangements. Ideally, fusion detection would be done in conjunction with routine pathology, using the same sample. We have developed HTG EdgeSeq chemistry and system, a coupling of nuclease protection with next generation sequencing (NGS) - mediated quantification. Library preparation occurs in two simple steps: nuclease protection, followed by limited PCR cycles to prepare libraries for NGS. No RNA extraction from FFPE is necessary. After sequencing, probe sequences are aligned to the sequencing reads, making data processing and fusion detection simple and very quick. To demonstrate utility of this assay for simultaneously detecting rearrangements and tumor subtyping markers, we are developing a HTG EdgeSeq lung fusion assay, a combination lung fusion and lung cancer subtyping assay. FISH is currently the gold-standard method for detecting ALK and RET rearrangements. We show here three examples from a small methods-comparison study. In the first two examples, the HTG EdgeSeq lung fusion assay and FISH assay both provided positive results (one sample is RET-positive, one ALK-positive). Interestingly, the third example failed two test attempts by an accredited ALK FISH testing lab due to poor sample quality; however, this sample tested positive for ALK rearrangement using the HTG EdgeSeq lung fusion assay. We confirmed the HTG EdgeSeq assay results by qPCR after isolating RNA from the FFPE block. This is significant because many clinical specimens do not contain enough tissue to test via qPCR, resulting in a meaningful ALK rearrangement potentially going undetected. In summary, the HTG EdgeSeq lung fusion assay is a promising technique for detecting gene rearrangements in small amounts of fixed tissue.

Genetic risk assessment for lung squamous cell carcinoma using exome sequencing in Korean men. *J. W. Park[1], E. P. Hong[1], Y. Kim[2], J. Jung[3], K. S. Park[4], K. Park[2], H. Kim[5].* 1) Dept Medical Genetics, Hallym Univ Coll Med, Chuncheon, Gangwon-Do, Republic of Korea; 2) Div Hematology, Samsung Medical Center, Seoul, Republic of Korea; 3) Syntekabio Inc, Seoul, Republic of Korea; 4) Dept Internal Medicine, Soul Natn'l Univ Coll Med, Seoul, Republic of Korea; 5) Dept Cell Biology, Ewha Womans Univ Coll Med, Seoul, Republic of Korea.

Lung squamous cell carcinoma (LSCC), the most common type of non-small cell lung cancer, is a leading cause of cancer deaths worldwide. Previous candidate gene and genome-wide association studies identified multiple single-nucleotide polymorphisms (SNPs) associated with lung cancer, each of which has a small to moderate effect. We performed an exome-wide association study to identify germline mutations by comparing100 Korean men diagnosed with LSCC to 131 age matched diabetic men without cancer. We developed LSCC risk prediction models composed of the genetic variants confirmed their functions by pathway analysis. Of 107,758 exonic variants, 158 nonsynonymous SNVs (nsSNVs) and seven insertions/deletions located in 102 candidate genes showed an exome-wide significance ($p < 4.6\times10\text{-}7$). A SNV (rs141472183, S209C) and a frameshift deletion (rs45576436) located in the genes, *HNRNPCL2* (OR=129, p=1. 4×10-41) and *HLA-A* (OR=191. 4, p=1. 4×10-35), showed the most significant association with LSCC. Our findings suggest that the genes, *HLA-A*, *MUC5B*, *TAS2R46*, and *TAS2R43,* play key roles in the primary tumor-cell growth of the epithelial surfaces and the dysfunctions of the pulmonary system. A genetic model composed of four nsSNVs and one deletion located in the genes that are associated with lung function showed 99. 9% predictabilityfor LSCC risk. Our findings will provide a foundation for future researches on early genetic diagnosis and risk prediction of LSCC susceptibility.

2660T

Cancer Genomic resources, opportunities and needs in the Latin American region. *S. Perdomo[1], J. Olivier[2], F. Vaca[3, 4].* 1) Instituto de Investigación en nutrición, Genética y metabolismo IINGM , Universidad El Bosque, Bogotá, Colombia; 2) Instituto de Ciencias Básicas y Medicina Experimental. Instituto Universitario Hospital Italiano de Buenos Aires Ciudad Autónoma de Buenos Aires, Argentina; 3) Facultad de Estudios Superiores Iztacala, Universidad Nacional Autónoma de México Tlalnepantla, Estado de México, Mexico; 4) Instituto Nacional de Cancerología, Estado de México, Mexico.

In 2012, approximately 1,005,255 new cancer cases and 550,164deaths from cancer occurred in both sexes in central and South American region, by 2025 and increment of nearly 30% of new cases and 35% of deaths from cancer are predicted. One of the priorities of cancer control within the region is to reduce avoidable deaths from cancer by improving early detection and personalized treatment. The development of cancer genomics and their integration to cancer care has shown a great improvement in cancer control worldwide; however, all these key advances have been mainly concentrated in highly developed nations and little is known about the capacities and needs of cancer genomics in the Latin-American (LA) context. In order to evaluate the capacity and development of cancer genomic applications in the LA we collected available information for all countries in central, South America and Cuba. Data reviewed included: number of cancer research institutions, number of NGS platforms, research groups working in cancer genetics, publications on cancer genetics for the last 10 years, educational programs on genomics and related health policies. In average 15 Research groups per country were registered as conducting cancer-genetics related projects. In the las 10 years, 206 publications on cancer genetics including reviews were led by (1st, 2nd or corresponding) authors affiliated to LA institutions and only publications in the last 2 years included cancer genomic analysis. Most publications related to breast and gastric cancer and hematological cancers were underrepresented in general. In the past 5 years physical resources have grown markedly by the acquisition of nearly 150 NGS platforms in 9 countries, the majority installed in medical related services and universities. Participation in large genomic consortia has only included two countries Mexico (as partner) and Brazil (as leading). Educational programs in genomics are scarce, almost exclusive of graduate programs and few are applied to cancer. Despite the recent advances in introducing cancer genomics knowledge and application in LA, the region lacks development of integrated genomic research projects, improved use of platforms dedicated to cancer, educational programs and health policies that might focus on the most frequent cancers and could impact cancer care.

Evaluation of four putative genetic risk factors affecting breast cancer susceptibility in patients with sporadic breast cancer. *M. Saeidnejad[1], A. Khorrami[2], E. Abedini[1], M. Mohaddes[2], M. Ziadi[2].* 1) Azad Islamic university of Tabriz, Tabriz, Iran; 2) Tabriz University of Medical Sciences.

Breast cancer is a complex multifactorial disease. Along with environmental factors genetic variations play a significant role in breast cancer Etiology. Single nucleotide polymorphisms (SNP) were highlighted as the key variations leading to genetic differences in breast cancer susceptibility between individuals. The methylene tetra hydro folate reductase enzyme (MTHFR), regarding its key role in DNA synthesis and DNA methylation, and hereditary hemochromatosis gene (HFE), coding iron-regulatory protein, have been associated with neoplastic disease development. The current study represents the analysis of A1298C, C677T (MTHFR) and H63D, C282Y (HFE) polymorphisms possible association with breast cancer risk in Iranian Azeri Turk women with sporadic breast cancer. A total of 80 cases and 100 controls participated in the study. Genotyping the markers in MTHFR gene were done using ARMS-PCR technique and in HFE gene using PCR-RFLP technique. The chi-square test with Yates' correction and Fisher's exact test were used for statistical analysis. Among the investigated polymorphisms, frequency of *HFE* H63D showed significant difference between patients and healthy volunteers (P = 0. 04), while allele and genotype distribution of A1298C, C677T and C282Y were similar in all groups. Our results suggest that *HFE* H63D mutation is associated with higher risk of sporadic breast cancer in studied population.

Contribution of molecular changes to Uveal Melanoma tumorigenesis in a Brazilian cohort. *H. Sarubi[1], F. Melo[1], E. Friedman[2], L. Rodrigues[3], M. Pedrosa[4], N. Amaral[5], A. Carmo[5], C. Gomes[5], R. Gomez[6], L. De Marco[1].* 1) Surgery, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) The Susanne Levy Gertner Oncogenetics Unit, Chaim Sheba Medical Center, Tel-Hashomer, Israel; 3) Department of Basic Sciences, Universidade Federal de Juiz de Fora, Brazil; 4) Department of Pathology, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 5) Department of Pathology, Biological Sciences Institute, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 6) Department of Oral Surgery and Pathology, School of Dentistry, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil.

Introduction: Uveal melanoma (UM) is the most common primary cancer of the eye in adults. Despite the availability of high effective treatments for eradicating the primary tumor, up to half of affected individuals later develop metastatic disease that is almost always fatal within a few months. The discovery of several common driver mutations has oppened the door to rational targeted therapies . BRCA2 has a predominant tumor suppressor function thought to be the repair of DNA double-strand breaks through homologous recombination. BRCA2 mutation carriers have elevated risk of breast and ovarian cancers and its mutation has also been implicated in uveal melanoma etiology, but the impact that molecular alterations in this gene have on uveal tumourigenesis is still unclear. The purpose of this study was to investigate BRCA2 contribution to the disease and to correlate these findings with clinical and histopathological parameters, such as P53 expression profile, since the tumour suppressor TP53 is frequently mutated in BRCA2 cancers and studies have shown a genetic interaction between them resulting in an increased constitutive DNA damage. **Methods:** 32 formalin-fixed paraffin-embedded tissues from enucleated eyes of UM patients were immunostained for BRCA2 and P53 and sequenced for Uveal Melanoma signature genes, such as GNA11, GNAQ and SF3B1. **Results:** Generally, immunostaining for p53 was weak (suggesting a lack of p53 mutations), but 05 of the 32 patients (15,62%) showed a markedly p53 positivity which has to be correlated with clinic and histopathologic parameters. Strong cytoplasmic staining was observed for BRCA2, which can be due to truncated forms of the protein, that do not translocate to the nucleus, and can be involved in the pathogenesis of the disease. **Conclusion:** Our data shows that despite BRCA2 and p53 are mutated infrequently in uveal melanoma, as shown in recent studies, their respective pathways may be functionally inactivated in the disease. Therefore, further studies are needed to investigate and help to define the real contribution of these pathways to tumorigenesis in Uveal Melanoma patients.

2663W

Mitochondrial DNA variation as a biomarker for the development of radiation-induced lung toxicity. *H. Smeets[1,2], A. Voets[1,2], C. Oberije[3], G. Nalbantov[3], A. Stassen[1], A. Hendrickx[1], K. Vandekasteele[5], K. Deruyck[5], H. Thierens[5], Y. Lievens[4], C. Herskind[6], P. Lambin[2,3].* 1) Dept Clin Genet, Maastricht UMC, Maastricht, Netherlands; 2) Maastricht University, GROW School for Oncology and Developmental Biology, Maastricht, The Netherlands; 3) MAASTRO Clinic, Data center, Maastricht, The Netherlands; 4) Ghent University Hospital, Radiotherapy, Ghent, Belgium; 5) Ghent University, Basic Medical Sciences, Ghent, Belgium; 6) Universitàtsmedizin Mannheim, Labor für Zelluläre und Molekulare Radioonkologie, Mannheim, Germany.

Purpose/Objective: Radiation-induced lung toxicity (RILT) varies significantly between patients at similar doses to the lung and can seriously affect the quality of life. The identification of prognostic biomarkers for radiation-induced toxicity is crucial for personalized RT: to select patients for proton therapy or dose escalation. We hypothesized variation in the mitochondrial genome (mtDNA) is a biomarker for RILT, since mitochondria and RT have several processes in common, among which reactive oxygen species (ROS) production. **Materials and Methods**: Blood DNA was isolated from 372 (training set, Maastricht) and 68 (test set, Ghent) lung cancer patients. After exclusion of patients that had surgery, had other tumors within 5 years prior to lung cancer, received a palliative dose or for which baseline dyspnea score was unknown, 277 and 53 patients were remaining for the training and test set respectively. Baseline dyspnea (at the start of RT) and maximal dyspnea 3-6 months after RT were scored according to the CTCAE version 3. 0 criteria. The endpoint of analysis was dyspnea grade>=2 after RT. Additionally, DNA was obtained from fibroblasts of 21 breast cancer patients for which the toxicity grade after radiotherapy was known (LENT/SOMA criteria). mtDNA was resequenced using mitochips and homoplasmic deviations from the revised Cambridge reference sequence were recorded. Variants were classified into 7 functional categories based on their theoretical effect on OXPHOS function. **Results**: Using the 7 functional categories as input features, logistic regression analysis corrected for baseline dyspnea score resulted in an AUC of 0. 78 for the training set, which was significantly better than the current international gold standard Mean Lung Dose (AUC 0. 57; $p < 0.001$). The AUC for the test set was 0. 66 but the power of the validation was limited due to the small sample size. Validation in a second external test set is ongoing. Additionally, using mtDNA variation data we were able to classify breast cancer patients in the correct toxicity group with 80% accuracy. **Conclusions**: Our data showed that mtDNA variation is a valuable biomarker for RILT. Furthermore, we have preliminary data in breast cancer patients that the predictive effect of mtDNA might be applicable to radiation toxicity in general.

2664T

Metastatic Signature Profiles in Triple Negative Breast Cancer. *K. Upadhyay[1], A. Pearlman[1], MT. Rahman[1], J. Loke[1], S. Fineberg[2], H. Ostrer[1].* 1) Pathology, Albert Einstein College of Medicine, Bronx, NY; 2) Pathology, Montefiore Medical Center, Bronx, NY.

Breast cancer is the most commonly diagnosed female cancer and the second leading cause of cancer deaths among women in the United States. Among the 3 clinical breast cancer subsets defined by immunohistochemistry, ER+ (65%-75%), HER2+ (15%-20%) and Triple Negative (TN 15%), TN have the highest rate of metastases. Previously, we developed a metastatic potential score (MPS) based on copy number alterations in a specific repertoire of 366 genes in metastatic prostate cancers and observed that this signature is predictive of metastastic risk in primary prostate cancers from surgical cohort (area under the receiever-operator charasteristic curve –AUC ~80%)(Pearlman et. al. , Journal of Probability and Statistics, vol. 2012, Article ID 873570, 19 pages, 2012). To examine the utility of the MPS in triple negaive breast cancer(TNBC), we performed array-CGH on 41 surgical specimen (28 metastatic-prone primaries - mBCs, 13 indolent primaries - iBCs) on Affymetirx Oncoscan V2 arrays. The median of MPS was lower for iBCs (0. 71) than mBCs (1. 00, p-value = 0. 01). A univariate logistic regression model of MPS predicted an odds ratio of 22. 59 (p-value = 0. 02) with an AUC of 75%. A univariate Cox regression model predicted a hazard ratio of 3. 8 (p-value = 0. 02) with Concordance-index 0. 63. This study demonstrates that like prostate cancer, TNBC is a disease of genomic instability, that amplification of a similar repertoire of genes is involved in disease progression, and that MPS is predictive of metastatic risk.

2665W

Association of Wnt signaling pathway gene variants in gallbladder cancer susceptibility, therapeutic response and survival. *A. Yadav[1], B. Mittal[1], A. Gupta[1], N. Rastogi[1], S. Agarwal[1], A. Kumar[1], V. Kumar[2].* 1) Sanjay Gandhi Post Graduate Institute of medical Sciences, Lucknow, India; 2) KGMC, Lucknow, India.

Background: Gallbladder cancer (GBC) is the most common malignancy of the biliary tract with adverse prognosis and poor survival. Wnt signals controls human development and homeostasis by cell-cell communication. Disregulations caused by germline genetic variants in Wnt pathway genes are cognate in development and expansion of cancers. This study analyzed association of Wnt signaling pathway genes (GLI-1, SFRP2, SFRP4, DKK2, DKK3, WISP3, APC, B-Catenin, AXIN-2) variants in GBC genetic predisposition, treatment outcomes and survival. **Materials and Methods:** The study included 610 GBC patients and 250 controls. Out of 610, 200 patients were followed-up for treatment response and survival. Toxicity grading was done in 200 patients (CTCAE V 3. 0) and tumor response (RECIST 1. 1) was recorded in 140 patients undergoing non-adjuvant chemotherapy (NACT). Genotyping was done by using PCR-RFLP, ARMS-PCR and Taqman assays. Statistical analysis was done by binary logistic regression, SNPstats, CART and GMDR. Survival was assessed by Kaplan Meier survival curve and multivariate Cox-proportional hazard model. **Results:** Single locus analysis showed statistically significant association of GLI-1 rs222826C/G [p-value=0. 001], SFRP4 rs1802073G/T [p-value= 0. 004], AXIN-2 rs4791171C/T [p-value= 0. 001], AXIN-2 rs2240308G/A [p-value=0. 003], B-catenin rs4135385A/G [p-value=0. 037], APC rs4595552 A/T [p-value=0. 021] with increased risk of GBC. Haplotypes of APC Trs459552Trs11954856 [p-value = 0. 0450] and AXIN-2 Trs4791171Ars2240308 [p-value = 0. 039] significantly associated with increased risk of GBC susceptibility. GMDR predicted GLI-1 rs2228226, APC rs11954856 [p-value=0. 0054] as significant model with GBC susceptibility. For treatment response and gastrointestinal toxicity GLI-1 rs2228226, AXIN-2 rs4791171 [p-value= 0. 0107, 0. 001] predicted as significant model. CART analysis represents APC rs4595552 (AT), APC rs4595552 (TT) higher risk genotype for GBC susceptibility and GLI-1 rs2228226 (GG), DKK3 rs3206824 (CC) with poor prognosis. Cox-proportional hazard model showed GLI-1 rs2228226 CG/GG genotype higher mortality and hazard ratio in post-operative and locally advanced GBC cases. **Conclusion:** GLI-1 rs2228226 emerged as major genetic variant in WNT signaling pathway influencing susceptibility, prognosis and survival in gallbladder cancer. Financial support from DBT, DST and CSIR, India.

2666T

Understanding Lung Adenocarcinoma Morphology and Prognosis by Integrating Omics and Histopathology. *K. Yu[1,2], D. L. Rubin[1], M. P. Snyder[2].* 1) Biomedical Informatics, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA.

Lung cancer causes more than 1. 4 million deaths per year worldwide, and adenocarcinoma accounts for 40% of lung cancer. For decades, histopathology evaluation has been the definitive diagnostic method for the disease. However, the molecular mechanisms underpinning histopathological patterns are not fully understood and prognosis prediction through histopathological sections is limited and subjective. In this study, we aimed to identify the transcriptomic and proteomic activities associated with histopathology grades and establish models for prognosis prediction. We analyzed transcriptomic and proteomic profiles of 480 lung adenocarcinoma patients from The Cancer Genome Atlas, and extracted histopathology annotations from their pathology reports. We divided the data into distinct training and test sets, built random forests models with training set data to predict the dichotomized histopathology grades (low grade versus moderate to high grade), and evaluated their areas under receiver operating characteristics curves (AUC) on the test set. We also built a least absolute shrinkage and selection operator (LASSO)-Cox proportional hazards model to predict survival outcomes. Enrichment analyses of the genes were conducted by querying the Database for Annotation, Visualization and Integrated Discovery (DAVID). Leveraging transcriptomic information, we successfully predicted histology grades of the tumor samples with AUC more than 0. 85 on the independent test set with 15 gene expression features. We identified important biological pathways enriched in the most predictive features, such as mitosis and ubiquitin-like proteins conjugation. Incorporating histopathology and omics variables, our model with three features classified patients into two distinct prognostic groups, with statistically significant difference in their survival time in the test set (P=0. 02). Gene ontology terms enriched in the survival-associated genes included extracellular region and cellular defense response. We identified the biological processes associated with pathology grades of lung adenocarcinoma, and accurately predicted patients' prognosis by omics and histopathology features. The analytical approaches described here reveal the underlying molecular mechanisms of cancer, and help predict prognosis. Our approaches can be applied to other types of tumors and will greatly contribute to establishing personalized cancer treatments.

2667W

Single gene (SG) vs. Multi-gene panel (MGP) testing for *TP53* germline mutations in Li Fraumeni syndrome (LFS). *H. Q. Rana[1], R. Gelman[1], J. Thompson[2], R. McFarland[2], H. LaDuca[2], E. Dalton[2], V. Speare[2], J. S. Dolinsky[2], E. Chao[2,3], J. E. Garber[1].* 1) Dana-Farber Cancer Institute, Boston, MA; 2) Ambry Genetics, Aliso Viejo, CA; 3) University of California, Irvine, Irvine CA.

Background:LFS is a rare highly penetrant hereditary cancer syndrome associated with pathogenic germline mutations in the*TP53*gene. Traditionally, testing of*TP53*has been limited to individuals and families who meet well-established criteria. With the advent of MGP tests,*TP53*analysis has expanded beyond these selected groups. **Methods:** *TP53*testing via SG and 8 different MGP by Ambry Genetics for 25,182 patients were collected. Retrospective review of personal and family cancer histories of those with a pathogenic or likely pathogenic*TP53*alteration (*TP53*+) was conducted, with solicitation of more complete family cancer histories ongoing. Cancer histories were examined to determine whether any National Comprehensive Cancer Network (NCCN) testing criteria were met including Classic criteria, Chompret criteria, and breast cancer (BC) diagnosis <36 years. **Results:**Of 25,182 individuals, 187 (0. 74%were *TP53*+; these results came from SG (118 of 2956, 3. 99%) and from MGP (69 of 22,226, 0. 31%). Of all those tested with adequate data, 95% having SG had a personal cancer history versus 82% of those having MGP. Among 102 *TP53*+ by SG providing adequate family history data, 73% (95% CI 63%-81%) met Classic or Chompret criteria for LFS, compared to 30% (95% CI 19%-47%) of 66 *TP53*+ by MGP (p=0. 0000001); adding in the cases meeting meeting the BC<age 36 criterion means 85% of those*TP53*+from SG and 53% of those*TP53*+on MGP met at least 1 of the 3 NCCN testing criteria. The personal BC<age 36 criteria was the only 1 of the 3 criteria met for 29% of 48*TP53*+on 4 MGP tests related to women's cancers versus 6% of 18*TP53*+on the other 4 MGP tests (p=0. 05). **Conclusion**: This is the largest cohort of*TP53*mutation carriers reported from one testing laboratory to date. MPG testing enables the identification of*TP53*mutations in individuals who would not otherwise have been tested by established LFS testing criteria. Further study is needed to determine whether patients and kindreds ascertained by SG versus MGP have truly different or similar LFS manifestations. Ultimately, these findings may alter testing criteria for *TP53* and counseling of those with a molecular diagnosis of LFS.

2668T

Biopsy-free comprehensive genomic profiling of over 5,000 cancer patients using a CLIA-certified commercial cell-free DNA next-generation sequencing test. *S. Mortimer[1], O. Zill[2], J. Vowles[1], R. Lopez[2], D. Delubac[6], K. Dilger[1], R. Mokhtari[2], W. Chen[2], S. Bakhtiari[2], C. Jackson[2], T. Vo[2], B. Kermani[2], K. Banks[3], R. Nagy[3], A. Baca[4], R. Lanman[3], H. Eltoukhy[5], A. Talasaz[5].* 1) Technology Development, Guardant Health Inc, Redwood City, CA; 2) Software and Informatics, Guardant Health Inc, Redwood City, CA; 3) Medical Affairs, Guardant Health Inc, Redwood City, CA; 4) Clinical Lab, Guardant Health Inc, Redwood City, CA; 5) Administration, Guardant Health Inc, Redwood City, CA; 6) Process Engineering, Guardant Health Inc, Redwood City, CA.

Analysis of cell-free circulating tumor DNA by next-generation sequencing (NGS) allows non-invasive real-time profiling of actionable genomic alterations. Current NGS cancer diagnostics based on tissue biopsies provide an incomplete picture of genomic alterations, particularly in metastatic cancers, due to tumor heterogeneity and continuous evolution of disease. Moreover, the widespread use of cell-free DNA (cfDNA) sequencing has been limited by frequent false positives present in standard NGS assays, especially given that the tumor-derived fraction of cfDNA is often below 1%. The Guardant360® test has been clinically validated to detect SNVs, indels, focal gene amplifications, and gene fusions in a 68-gene panel (138 kb), and was designed to include all NCCN-recommended genomic targets for matched therapies. Notably, this is the first cfDNA NGS assay to detect fusions without prior knowledge of both fusion partners. We demonstrate that our Digital SequencingTM methodology through the detection of single molecules achieves high sensitivity (>85%) and ultra-high specificity (>99. 99%). Variants identified in cfDNA with the Guardant360 test were verified by several outside CLIA-certified laboratories using various methodologies. Across 56 patients with a total of 86 variants (SNVs, CNVs, indels, and fusions), 90% of variants found in tissue were also detected in cfDNA. We present an analysis of cfDNA genomic alterations identified in over 5,000 cancer patients across more than 50 cancer types. 74% of patients were positive for at least one class of genetic variant, with a median of 3. 5 SNVs per patient, and median mutant allele fraction of 0. 4%. Of these patients, 15% had mutations indicating an approved therapy and 50% had mutations indicating an off-label therapy. On average we detect nearly one somatic variant of uncertain significance (VUS) per cancer patient. Although the test is optimized for late-stage/metastatic disease, it is also capable of earlier stage detection. We demonstrate detection of somatic SNVs, indels, and gene fusions in cfDNA at mutant allele fractions below 0. 05%. The present work shows the strong clinical impact of Guardant360 test for analysis of cfDNA, thereby allowing researchers and clinicians to comprehensively and non-invasively monitor the genomic profile of cancer throughout the body. Guardant360 technology empowers oncologists to make informed treatment decisions, especially when repeat tissue biopsy is not a feasible option.

Genomic variations in plasma cell free DNA differentiate early stage lung cancers from normal controls. *S. Xia[1,2], CC. Huang[3], M. Ie[1], RL. Dittmar[1], MJ. Du[1], TZ. Yuan[1], YC. Guo[1], Y. Wang[1], XX. Wang[3], S. Tsai[4], S. Suster[1], AC. Mackinnon[1], L. Wang[1].* 1) Department of Pathology and MCW Cancer Center, Medical College of Wisconsin, Milwaukee, WI 53226; 2) Department of Oncology, Tongji Hospital of Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China, 430030; 3) Department of Biostatistics, University of Wisconsin, Milwaukee, WI 53201; 4) Department of Surgery, Medical College of Wisconsin, Milwaukee, WI 53226.

Cell free tumor DNA (cfDNA) circulating in blood has a great potential as biomarker for cancer clinical management. The objective of this study is to evaluate if cfDNA in blood plasma is detectable in early stage lung cancer patients. We extracted cfDNAs and tumor tissue DNAs from 8 lung adenocarcinoma patients. We also extracted cfDNA from 8 normal controls. To evaluate copy number variations (CNV) and identify potential mutations, we performed low pass whole genome sequencing and targeted sequencing of 50 cancer genes. To accurately reflect the tumor-associated genomic abnormality burden in plasma, we developed a new scoring algorithm, Plasma Genomic Abnormality (PGA) score, by summarizing absolute log2 ratios in most variable genomic regions. We performed digital PCR and allele-specific PCR to validate mutations detected by targeted sequencing. The median yield of cfDNA in 400ul plasma was 4. 9ng (range 2. 25-26. 98ng) in patients and 2. 32ng (range 1. 30-2. 81ng) in controls (p=0. 003). The whole genome sequencing generated approximately 20 million mappable sequence reads per subject and 5303 read counts per 1Mb genomic region. Log2 ratio-based CNV analysis showed significant chromosomal abnormality in cancer tissue DNAs and subtle but detectable differences in cfDNAs between patients and controls. Genomic abnormality analysis showed that median PGA score was 9. 28 (7. 38-11. 08) in the 8 controls and 19. 50 (5. 89-64. 47) in the 8 patients (p=0. 01). Targeted deep sequencing in tumor tissues derived from the 8 patients identified 14 mutations involved in 12 different genes. The PCR-based assay confirmed 3 of 6 selected mutations in cfDNAs. These results demonstrated that the PGA score and cfDNA mutational analysis could be useful tool for the early detection of lung cancer. These blood-based genomic and genetic assays are noninvasive and may sensitively distinguish early stage disease when combined with other existing screening strategies.

Prevalence of *BRCA1* and *BRCA2* common mutations among Algerian patients with breast and/or ovarian cancer. *F. Cherbal[1], H. Gaceb[1], C. Mehemmai[1], R. Bakour[1], K. Boualga[2], H. Mahfouf[3].* 1) Unit of Genetics, LMCB, Faculty of Biological Sciences, USTHB, Algiers, Algeria; 2) Radiation Therapy Services, Anticancer Center of Blida, Blida, Algeria; 3) Public Hospital Academic Medical Oncology Services, School of Medicine, University of Algiers, Rouiba, Algeria.

Background: Breast cancer is currently the leading cause of cancer morbidity and mortality among Algerian women. The present work aimed to screen for the most common mutations in *BRCA1* and *BRCA2* genes in breast and/or ovarian cancer patients. To date, the common mutations in *BRCA1* and *BRCA2* genes screened in this study, have been previously detected in studies in Algerian patients with family history of breast and/or ovarian cancer. **Methods**: Patients were enrolled from 2011 to 2015 in several public hospitals covering most geographical areas of Algeria. Patients were selected on early age onset (< 50 years) and family history of breast and/or ovarian cancer. In addition, in this study, all women (age <50) with triple negative breast cancer (TNBC) were considered eligible. 192 breast and/ or ovarian cancer patients were screened for the common *BRCA1* mutations c. 83_84delTG and c. 798_799delTT. The *BRCA1* mutation c. 181T>G and the common *BRCA2* mutations c. 1310_1313delAAGA and c. 7235_7236insG have been screened in 96 breast and/or ovarian cancer. The approach used is based in PCR-direct sequencing. **Results**: The *BRCA1* mutation c. 83_84delTG detected previously in two unrelated Algerian breast cancer families has been identified here in three triple negative breast cancer patients, and in a patient with a bilateral ovarian cancer, respectively. This mutation has been detected with a frequency of 2% (4/192). The four patients had a strong hereditary breast and/ or ovarian cancer history. The rare unclassified variant c. 122A>G/p. His41Arg located in the Ring Finger of the *BRCA1* exon 3 has been detected here for the first time in young Algerian TNBC patient. Moreover, the pathogenic *BRCA1* mutation c. 181T>G/p. Cys61Gly located in exon 5, has been detected in a young bilateral breast cancer patient with a strong breast cancer family history. Interestingly, the *BRCA1* mutation c. 798_799delTT detected previously in 4 unrelated families from Algeria, has been identified here in a young triple negative breast cancer patient with a family history of prostate and breast cancer. The common *BRCA2* mutations c. 1310_1313delAAGA and c. 7235_7236insG have not been detected in this study. **Conclusions**: Based on our currents results, we recommend using the TNBC immunophenotype as criterion to screen for *BRCA1* germline mutations in patients with early onset breast cancer. Screening for common mutations in *BRCA* genes in Algerian population, may facilitate genetic counseling and testing.

2671W

Next-generation sequencing of the *BRCA1* and *BRCA2* genes for the genetic diagnostics of hereditary breast and/or ovarian cancer. *D. Trujillano.* Centogene AG, Berlin, Germany.

Genetic testing for hereditary breast and/or ovarian cancer (HBOC) mostly relies on laborious molecular tools that use Sanger sequencing to scan for mutations in the *BRCA1* and *BRCA2* genes. We have explored a more efficient strategy based on next-generation sequencing (NGS) of the *BRCA1* and *BRCA2* genes in 210 (HBOC) patients. We first validated this approach in a cohort of 115 samples with previously known *BRCA1* and *BRCA2* mutations and polymorphisms. Genomic DNA was amplified using the Ion AmpliSeq™ *BRCA1* and *BRCA2* panel. The DNA Libraries were pooled, barcoded and sequenced using an Ion Torrent PGM sequencer. The combination of robust bioinformatics tools allowed us to detect all previously known pathogenic mutations and polymorphisms in the 115 samples, without detecting spurious pathogenic calls. The assay achieved a sensitivity of 100% (95% CI: 99. 71% to 100%), with a specificity of detecting non-variant sites from the reference sequence of 99. 99% (95% CI: 99. 99% to 100%), a positive predictive value of 91. 17% (95% CI: 89. 72% to 92. 62%), and a negative predictive value of 100% (95% CI: 100% to 100%). We then used the same assay in a discovery cohort of 95 uncharacterized HBOC patients for *BRCA1* and *BRCA2*. In addition, we describe the allelic frequencies across 210 HBOC patients of 74 unique definitely and likely pathogenic, and uncertain *BRCA1* and *BRCA2* variants, some of them not previously annotated in the public databases. Targeted NGS is ready to substitute classical molecular methods to perform genetic testing on the *BRCA1* and *BRCA2* genes, and provides a greater opportunity for more comprehensive testing for at-risk patients.

2672T

Identification of a circulating miRNA signature for noninvasive detection of early colonic polyps through optimized miRNA-seq of blood plasma. *A. Hardigan[1,2], B. Roberts[1], M. Kirby[1], C. M. Wilcox[2], R. Myers[1].* 1) HudsonAlpha Institute for Biotechnology , Huntsville, AL; 2) University of Alabama at Birmingham, Birmingham, AL.

Colorectal cancer is the third most prevalent cause of cancer morbidity and mortality in the United States. Currently, screening for colorectal cancer involves receiving an annual colonoscopy for those over age 50 and even younger in at-risk populations. Although effective, colonoscopy screening is invasive and its associated costs represent a significant economic burden to the health care system. Development of a less invasive and highly sensitive molecular assay capable of detecting precancerous adenoma formation would be highly informative and provide not only a mechanism for early detection and treatment of colon cancer, but also reduce the personal and economic burden of unnecessary colonoscopies. The discovery of stable miRNA species in blood and other easily accessible human biological fluids has led to their investigation as potential biomarkers for a variety of diseases such as cancer, neurodegenerative disease, and cardiovascular disease. Next-generation sequencing (NGS) of small RNAs in these fluids is a powerful method for comprehensive identification and quantification of miRNAs species. However, due to methodological challenges related to the small size of miRNA species and their relatively low abundance in human plasma, the identification of reproducible and specific miRNA biomarkers has been difficult. Here, we have optimized miRNA-sequencing library generation from human plasma as well as developed statistical quality control metrics to ensure accuracy and reproducibility of the miRNA-seq libraries. In order to determine a circulating miRNA signature capable of distinguishing between patients with early, precancerous adenomas and those without polyps, we applied these optimized methods to generate miRNA libraries from plasma taken from over 200 patients who underwent colonoscopy screening. Through these analyses we identified a candidate panel of miRNAs that is capable of discriminating between adenoma-burdened and normal patients. The methodological improvements we have made and our candidate circulating miRNA signature provide a foundation for future advances in both colon cancer detection and treatment as well as the detection of other diseases by means of circulating miRNAs.

PIK3CA mutational analysis platform utilizing the Labcyte Echo® Liquid Handler to reduce cost, sample amount and increase throughput to broadly assess acquired mutational status. *J. Lesnick, L. Orren.* Labcyte Inc, Sunnyvale, CA.

The phosphoinositide-3 kinase (PI3K)/AKT signaling network is one of the two most commonly mutated pathways identified in human cancers and the most frequently mutated pathway in breast cancer. Somatic alterations including PIK3CA mutations are the most common genetic alteration of this pathway; 80% or more occur within the helical (E542K, E545K) and kinase (H1047R) domains of p110. Such mutations confer increased catalytic activity for the generation of the second messenger phosphatidylinositol (3,4,5)- triphosphate (PIP3) and downstream pathway activation to induce cell proliferation, survival and potential tumorigenesis. These mutations can also confer resistance to therapeutic intervention. Identifying acquired mutations, not present in normal patient tissue, in tumor derived material, including CTC's and DTC's, is important to diagnostic predisposition testing for cancer, prognosis and can ultimately inform targeted therapy. Utilizing the Labcyte Echo liquid handler, together with real-time PCR mutation analysis, we have demonstrated a highly efficient, low-cost assay platform to detect PIK3CA somatic mutations. The mutations identified include the helical E542K, E545K and kinase domain H1047R pathway activating mutations. The Echo 555 liquid handler was used to dispense sub-microliter volumes of reagents from the EntroGen PIK3CA real-time PCR mutation analysis kit for subsequent analysis on the Roche LightCycler® 480 real-time PCR instrument. The methods detailed here reduce the total volume of reaction from 30µL to 3µL resulting in a lower cost assay platform. The high analytical sensitivity, limit of detection, of the assay platform enables detection of mutant allelic frequency below 10% over wild-type background. These results were obtained following assay miniaturization that used significantly less input of precious, limited sample DNA. The use of the Echo system provides a highly efficient workflow that minimizes the risk of operator handling errors and faster reaction process time. The use of a high density 384-well reaction plate increases throughput further by 4-fold over the standard 96-well format. The Labcyte Echo liquid handler enables highly efficient, low cost, precise and accurate mutational analysis for PIK3CA mutation profiling. This fast, low-cost and robust method can identify mutations of importance toward predisposition testing of cancer, prognosis, targeted therapy as well as identification of inherited disease.

The upregulation mechanisms of leptin-induced ADAMTS-1, involved in angiogenesis. *K. O. Yaykasli[1], O. F. HATIPOGLU[2], M. DOGAN[3], Y. SAHIN[4], E. YAYKASLI[5], E. GUNDUZ[2].* 1) Department of Medical Biology, Kahramanmaras University Medical Faculty, Kahramanmaras, Turkey; 2) Department of Medical Genetics, Turgut Ozal University Medical Faculty, Ankara, Turkey; 3) Department of Medical Genetics, Duzce University Medical Faculty, Duzce, Turkey; 4) Department of Medical Genetics, Necip Fazil City Hospital, Kahramanmaras, Turkey; 5) Department of Medical Biology and Genetics, Duzce University Institute of Health Science, Duzce, Turkey.

Objective: ADAMTS-1 belonging a disintegrin and metalloproteinase with trombospondin motifs (ADAMTs) protease family. Besides the aggrecanolytic activity, ADAMTS-1 is involved in angiogenesis. Angiogenesis is a normal physiological process and described as a formation of new blood vessels. However, aberrant regulation of angiogenesis caused several pathological processes including cancer. Even, the etiology of cancer has been not understood yet, the obesity was assumed one of the main factors for several cancers like chondrosarcoma. Recently, a novel adipokine called leptin secreted from adipose tissue was identified. Then, leptin become target to develop new therapy against to obesity associated diseases like cancer. The aim of this study was to investigate the signaling pathways involved in ADAMTS-1 upregulation induced by leptin in human chondrocytes. **Material and Method:** Confluent human articular chondrocytes were cultured with serum-free medium for 24 hours. Then the cells were pretreated with SB203580, SP600125, PD98059, QNZ and LY294002 reagents for inhibition of p38, JNK, MEK1, NF-κB and PI3-kinase pathways respectively for 30 min. Subsequently, the cells were treated with leptin at 1000ng/mL for 48 h. At the end of the incubation, total RNA was extracted using TriPure reagent, and 2 µg of total RNA was reverse-transcribed. The ADAMTS-1, and β-actin genes expression were analyzed by real-time polymerase chain reaction. **Results and Conclusion:** The current study was investigated that leptin increased the ADAMTS-1 gene expression level by mitogen-activated protein kinases (MAPKs) signaling pathways. Vascular endothelial growth factor (VEGF) has angiogenic property, and leptin caused VEGF upregulation has been identified recently. Similarly, the upregulation of ADAMTS-1 gene expression level by leptin and VEGF was demonstrated. Even, the roles of ADAMTS-1 in angiogenesis are under debate, it was clarified that ADAMTS-1 involved in angiogenesis. So, ADAMTS-1 has pivotal importance for obesity related cancer like chondrosarcoma. In this study, the signaling pathways of ADAMTS-1 upregulation caused by leptin were investigated. The elucidation of these pathways may give new idea to develeop new approach for chondrosarcoma therapy. However, further studies are needed.

Couch[2].* 1) Department of Medicine, Division of Hematology-Oncology, University of Pennsylvania, Philadelphia, PA; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 3) Clinical Genetics Research Lab, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 4) Hereditary Cancer Program, British Columbia Cancer Agency, Vancouver, BC; 5) Department of Medical Oncology, Division of Clinical Cancer Genetics, City of Hope, Duarte, CA; 6) Department of Medicine Division of Translational Medicine and Genetics, University of Pennsylvania, PA; 7) Clinical Genetics Service, Department of Medicine, Memorial Sloan-Kettering Cancer Center, New York, NY; 8) IFOM, the FIRC Institute of Molecular Oncology, and Department of Preventive and Predictive Medicine, Fondazione IRCCS Istituto Nazionale dei Tumori, Milan, Italy; 9) Division of Oncology, Stanford University School of Medicine, Stanford, CA; 10) Center for Cancer Genetics and Prevention, Dana Farber Cancer Institute, Boston, MA; 11) National Institutes of Health, Bethesda, MD; 12) Beckman Research Institute of City of Hope, Duarte, CA.

BRCA1 and *BRCA2* (BRCA) testing is uninformative in approximately 80% of families with clinical features of inherited susceptibility to breast cancer. Early identification of the individuals at risk in *BRCAx* families may lead to enhanced screening and prevention strategies, and potentially improved overall survival, as has been seen for carriers of *BRCA1/2* mutations. A proportion of these families are likely explained by mutations in other high penetrance and moderate penetrance breast cancer susceptibility genes. We performed targeted panel sequencing in 2331 *BRCA1/2* negative individuals with high-risk familial breast cancer, defined as a proband and at least two first or second degree relatives with breast cancer under age 70 or an individual with both breast and ovarian cancer. Data were analyzed for identification of all variants in 11 known high and moderate penetrance breast cancer susceptibility genes (*CDH1, PTEN, STK11*, *ATM, BARD1, BRIP1, CHEK2, MRE11A, NBN, PALB2, RAD50*). Overall, pathogenic mutations were identified in 179 of the 2331 *BRCA1/2* negative individuals (7. 8%). The most commonly mutated breast cancer susceptibility gene was *CHEK2*, which accounted for 54% of the mutation carriers and was found in 4. 2% of individuals overall. Other more commonly identified moderate penetrance genes included *ATM* (13% of mutation carriers, 1. 0% of individuals overall) and *PALB2* (9% of mutation carriers, 0. 7% of individuals overall). Outside of *TP53* (reported in a separate abstract), high penetrance gene mutation carriers were exceedingly rare, with identification of one *CDH1* mutation carrier (0. 04% of individuals), two *PTEN* mutation carriers (0. 09%) and no *STK11* mutation carriers. Our data show that significant genetic heterogeneity exists in *BRCAx* families; however, the majority of the individuals tested do not have mutations by multiplex panel testing of the assayed genes. Large-scale collaborative efforts are required to attain sufficient power to understand how to appropriately apply these results clinically in cancer risk evaluation and to identify the genetic risk factors in negative families.

2676T

Using expression data to define patient specific predictors for survival outcomes in lung adenocarcinoma. *G. Cai[1], F. Xiao[2], C. Cheng[1], Y. Li[3], C. I. Amos[3], M. L. Whitfield[1].* 1) Department of Genetics, Geisel School of Medicine at Dartmouth, Hanover, NH; 2) Department of Biostatistics, Yale University School of Public Health, New Haven, CT; 3) Department of Biomedical Data Science, Dartmouth College, Hanover, NH.

Background: Disease prevalence and drug responses vary widely among populations because of heterogeneous genetic makeups. Tumor and paired tumor-adjacent normal tissues are often collected and measured to remove noise from this heterogeneity. Methods that take into account patient-specific factors such as tumor-normal pair and ethnicity are required in studying the transcriptome expression in cancer. Here, our objective was to develop a novel mixed model that would combine these variables in analyses of paired tumor-normal studies. **Methods:** A mixed effect linear model was designed to detect differential expression (DE) genes between tumor and normal tissues with random effects of patient and ethnicity. Further, we selected diagnosis and prognosis biomarkers using the L1 penalized regression technique. **Results:** The method we developed was applied in lung adenoma datasets. In both Caucasians and Asians, we found cell cycle checkpoint pathways were down-regulated in tumors, whereas metabolic-related pathways like *PPARG* pathway and acetate metabolism pathways differed between two ethnic groups. We also demonstrated the potential for disease and prognosis prediction by gene expression markers. We identified a 10-gene biomarker panel for both diagnosis and prognosis of lung cancer, which are applicable for both Caucasian and Asian lung adenoma patients. Compared to low risk groups, high risk groups showed significantly shorter overall survival time (HR=2. 70, *p*-value=1. 37E-06 when training algorithm using data from Caucasian patients; HR=3. 25, *p*-value=0. 002 when testing the prediction performance using data from Asian patients). **Conclusions:** We developed a novel statistical method that can detect DE genes between tumor and normal tissues with random effects of patient and ethnicity. These results provide a valid strategy and basis for minimally identifying biomarkers from high-throughput transcriptome profiling data for other tumor types or different diseases.

Deubiquitinating enzyme Usp15 Regulates cell cycle progression by deubiquitination of spliceosomal protein. *T. DAS[1,2], JK. Park[1], JY. Park[1], E. Kim[1], YS. Yoo[1], Eunice. Kim[1], EJ. Song[1,2].* 1) Korea Institute of Science and Technology, seoul, Seoul, South Korea, South Korea; 2) University of Science & Technology (UST), Daejon, Korea.

Splicing of pre-mRNA is catalyzed by dynamic splicing machineries, spliceosome. Reversible post-translational modifications such as ubiquitination contribute the spliceosome dynamics for efficient pre-mRNA splicing, but little is known about the underlying mechanism. Here, we showed that Prp31, a component of the U4 snRNP, is modified with K63-linked ubiquitin chains by Prp19 complex and is deubiquitinated by Usp15 and Sart3 which translocates Usp15 from cytoplasm to nucleus thereby mediate to target for its substrate. Ubiquitination and deubiquitination status of Prp31 regulates its affinity to U5 snRNP component, Prp8. It regulates catalytic activity of spliceosome for efficient splicing by stabilization of U4/U6. U5 tri-snRNP. In addition, depletion of Usp15 interferes with the proper mRNA splicing of cell cycle related genes, for example Bub1. Usp15 regulate spliceosomal activity by inhibiting the modification of spliceosomal proteins with ubiquitin chains. Loss of Usp15 interferes with the accumulation of correctly spliced mRNAs. Therefore, our findings indicate that Usp15 is involved in cell cycle progression by regulating the modification of spliceosomal proteins.

Down-regulation of *hTERT* in glioblastoma cell lines using siRNA. *G. K Chetan, Ch. Lavanya, M. K Sibin, M. M Srinivas Bharath, Bhat. I Dhananjaya, K. V. L Narasinga Rao.* National Institute of Mental Health and Neurosciences, Bangalore, Karnataka, India.

Purpose: Glioblastoma accounts for more than half of all malignant glioma cases that are associated with high morbidity and mortality. Presence of increased telomerase activity is a common feature of all cancers. *hTERT* gene expression increases with the grade of glioma and it is considered as a good candidate for the targeted therapy. Both RNA and catalytic subunits are targeted for blocking the activity of *hTERT*. Artificial transcription factors, drugs, antisense oligonucleotides coupled with radiation have been used to regulate *hTERT* with varied success rate. The present study shows the effective down-regulation of telomerase activity using RNA interference approach in glioblastoma cell lines. **Methods:** We used Grade IV LN-18 glioblastoma cell line for this study. siRNA1 was used to target exon4 and siRNA2 was used to target exon3. Level of expression of *hTERT* mRNA was detected by qRT-PCR. MTT assay was performed to determine cell viability after transfection at different time intervals. Expression of *hTERT* protein was determined by western blotting. One-way ANOVA was performed to compare the mean values of control, *hTERT* siRNA treated and negative siRNA treated groups. p<0. 05 was considered statistically significant for all the tests. **Results:** The *hTERT* was transiently transfected in to LN-18 cell line. We compared the results of *hTERT* specific siRNA treated groups with control and scrambled siRNA. We observed a significant decrease in the percentage of cell viability in LN-18 cell line transfected with siRNA1 (P<0. 01) and siRNA2 (P<0. 05) as detected by MTT assay. We also observed that, siRNA1 is more effective than siRNA2 with more than 50% inhibition of cell proliferation in all time points. The level of *hTERT* mRNA expression with siRNA1and siRNA2 treated group was ~ 60%and ~ 40%respectively with a P<0. 05. The level of *hTERT* protein was significantly lower in siRNA1 compared to siRNA2 groups. The siRNA1 against *hTERT* showed increased suppression of *hTERT* at mRNA and protein levels than siRNA 2. We conclude that, choosing the right siRNA for effective *hTERT* down regulation is important and siRNA approach is a promising technique, which can be used in animal models and Humans as a therapeutic target.

The role of periostin in regulating of early tumorgenesis in oral squamous cell lines carcinomas. *G. E-H. Gawish[1, 3], H. A Al Omer[2, 3].* 1) Medical Genetics, College of Medicine, Al Imam Muhammad Ibn Saud University, riyadh, Saudi Arabia; 2) Prince Abdulrahman Advanced Dental Institute (PAADI), Ministry of Defense and Aviation, Riyadh, Saudi Arabia; 3) Oral Biological Medical Science, University of British Columbia, Canada.

Oral squamous cell carcinomas (OSCCs) are the most frequent malignancy of the oral cavity. Tissue microarray analysis of OSCC found the upregulation of *POSTN* gene (periostin, osteoblast specific factor) expression in OSCC compared with normal tissues. It was reported that periostin contributes to malignancies mainly by preventing apoptosis and promoting angiogenesis, invasion, and metastasis. The roles of periostin in regulating cell proliferation and in genomic instability of cancer cells during tumorigenesis still require further investigation. The aims of this study was to indicate the oncogenic activity effect of periostin in OSCC, contribution of periostin in promoted OSCC proliferation and calculate the DNA index of ploidy and anploidy channels. SCC4, SCC9, SCC15, and SCC25 were transfected with periostin. For unbiased, siRNA and transfected Ca9-22 cells were used. Expression of periostin was analyzed then cells were stained by annexin V for apoptosis detection and PI for proliferation and DNA ploidy then stained cells were analyzed using FACScaliber. This study found that the oral squamous cell carcinoma cell lines transfected with periostin, exhibited significantly increased proliferation, compared with non-transfected. Periostin-overexpressing cells stained with annexin V and PI showed significantly ($p<0.05$) and ($p<0.005$) respectively. We have recorded that the number of hyperdiploid passages was 33% and 67% were diploid. Hyperdiploid passages with DNA index ≥ 1.16 and ≤ 1.6 were12 passages and hyperdiploid with DNA index >1.6 (11passages). We conclude that periostin play an important role in the tumorigenesis of OSCC by deregulation of the cell cycle, escaping from apoptosis, and the potential for unlimited replication. It encourages genetic alterations by enhancing chromosomal instabilities.

Molecular cytogenetic characterization of the malignant primitive neuroectodermal tumor cell line SK-PN-DW. *N. Du[1,2], W. Bao[1], K. Zhang[1], X. Lu[2], H. Pang[2], X. Wang[2], Y. Gu[2,3], G. Liu[2,4], J. Lu[2,5], Y. Kim[2], Y. Ren[2,6], F. Wang[1], S. Li[2].* 1) Department of Infectious Diseases, the First Hospital of Jilin University, Changchun, Jilin, P. R. China; 2) Department of Pediatrics, University of Oklahoma Health Sciences Center, Oklahoma city, OK; 3) Department of Pulmonology, the First Hospital of Jilin University, Changchun, Jilin, P. R. China; 4) Department of Gastroenterology, the First Hospital of Jilin University, Changchun, Jilin, P. R. China; 5) Department of Hematology, the First Hospital of Jilin University, Changchun, Jilin, P. R. China; 6) Department of Hematology, The First Affiliated Hospital of China Medical University, Shenyang, Liaoning, P. R. China.

Background: The SK-PN-DW cell line was established in 1979 and it is commercially available from the ATCC. This cell line has been used as an in vitro model in functional and therapeutic studies for malignant primitive neuroectodermal tumor (PNET). However, genetic alterations at the cytogenetic level have not been well established. **Results:** Utilizing a combination of multiple techniques (routine G-banded chromosome analysis, fluorescence in situ hybridization (FISH), and oligonucleotide array comparative genomic hybridization (array CGH) assays, we have successfully characterized all chromosomal changes of this cell line. The G-banded karyotype showed that the cell line had a modal number of chromosomes ranging from 40 to 41, all the cells had a loss of the Y chromosome and chromosomes of 11, 13, and 18. Some cells had a loss of chromosome 10. The cells analyzed also had chromosomal structural changes including an unbalanced translocation between chromosomes 1 and 7, the translocation between chromosomes 11 and 22 at breakpoints of 11q24 and 22q12 which is a classical translocation associated with Ewing sarcoma, a derivative chromosome due to the whole arm translocation between chromosomes 16 and 17 at likely breakpoints of 16p10 and 17q10, and possible rearrangement of the short arm of chromosome 18. A variable number of double minutes in each metaphase cell was also observed. The array CGH assay showed genomic-wide chromosomal imbalances in this cell line and precisely placed chromosomal breakpoints on unbalanced, rearranged chromosomes. This assay also disclosed subtle chromosomal changes as well as the chromosomal origin of the double minutes. The FISH assay, with multiple combinations of FISH probes, confirmed routine cytogenetic analysis and array CGH findings. **Conclusions:** Accurate determination of those genetic changes will provide guidance in making genotypic and phenotypic correlations and for establishing authenticity of the cell line when it is applied in biological studies.

Detection of Subtelomeric CNVs in Colorectal Cancer using MLPA. *M. Rocha[1,2], F. A. R Madia[2], E. A. Zanardo[2], T. V. M. Costa[2], A. T. Dias[2], F. Balsamo[1], S. D. F Borato[1], S. H. C. Horta[1], B. A. Bianco[1], D. M. Christofolini[1], C. P. Barbosa[1], J. Waisberg[1], L. D. Kulikowski[1,2].* 1) Laboratory of Genetic, Faculdade de Medicina do ABC (FMABC), Santo André-SP, Brazil; 2) Laboratory of Cytogenomic (Lim 3), Faculdade de Medicina da USP (FMUSP), São Paulo-SP, Brazil.

Colorectal cancer (CRC) is a health problem that is increasing in importance worldwide but its etiology is still poorly understood. Copy number variations (CNVs) are recognised as an alternative source of genetic instability that may influence cancer risk. In this sense we investigate CNVs in subtelomeric regions using MLPA technique (Multiplex ligation-dependent probe amplification) to better understand the genomic features associate to CRC. As a pilot study, 20 tissue samples were obtained by biopsy of 10 patients with CRC, being 10 neoplastic samples and 10 samples obtained from adjacent regions (10cm distant tumor tissue). The DNA was extracted using the QIAamp DNA Blood Midi Kit (QIAGEN, Valencia, California). Subsequently we performed MLPA (MRC-Holland®, Amsterdam, The Netherlands) with specific kits for the subtelomeric regions (P036 and P070). The results were analyzed using the software GeneMarker® (SoftGenetics, LLC, State College, PA - www. softgenetics. com). The results showed several different *indels*: deletions in *KDM5A*(12p), *TNFRS18* (1p), *CTDP1* (18q), *TRIML2(*4q*) IL-17RA*(22q), *MTA1*(14q), *GAS8* (16q) genomic regions; and duplications in *CHL1*(3p), *PSPC1*(13p*), SOX12*(20p), *SYBL1*(Xq), *CDC16*(13q), *PDCD6*(5p), *RABL2B* (22q) genomic regions. Structural variants could impact gene dosage and influence directly the number of functional copies of the gene that are available for transcription. We observed subtelomeric *indels* associated with cell migration and adhesion, transcriptional activation, cellular apoptosis and autoimmune diseases. Also the results showed that the cells are characterized by an unstable genome with heterogeneous and complex genomic abnormalities suggesting that “chromotripsis” could be a possible mechanism involved in these tumors. Moreover, modifications of subtelomeric genomic regions could play an important role in CRC predisposition and development.

Unusual revertant mosaicism in three siblings affected with Fanconi anemia group FA-G. *S. Chandrasekharappa[1], D. C. Kimble[1], F. Lach[2], J. Kennedy[2], A. Smogorzewska[2], A. D. Auerbach[2].* 1) Cancer Genetics and Comparative Genomics Branch, NHGRI/NIH, Bethesda, MD; 2) Laboratory of Genome Maintenance, The Rockefeller University, New York, NY.

Fanconi anemia (FA) is a genetically and phenotypically heterogeneous disorder characterized by congenital malformations, progressive bone marrow failure and predisposition to cancer. We describe here an unusual family followed by the International Fanconi Anemia Registry (IFAR) since 1989, with 4 of 11 siblings affected with FA. The index case (370_1) was diagnosed with FA around age 25, showing increasing pancytopenia after the birth of a child. She developed squamous cell carcinoma (SCC) of mouth and tongue in her mid-twenties, leading to death at age 39. She also had intra-ductal breast carcinoma at age 35 and SCC of the skin. A sister (370_2) had onset of pancytopenia at age 8, controlled with prednisone and later danizol. At age 37 she was diagnosed with invasive vulvar SCC with metastatic disease, and died soon thereafter. Sibling 370_3 had a matched sib BMT for MDS with complex cytogenetic abnormalities, and died at age 32 after a complicated post-transplant course. She had a history of multiple skin, cervical, perineal and perianal cancers and carcinomas-in-situ. An older brother (370_4) diagnosed at about age 10 with aplastic anemia was treated with prednisone, developed AML at age 18, and died in 1969 at age 19. DNA was not available from this sibling for genomic analysis. Sequencing of *FANCG* in lymphoblastoid cell lines from the 3 affected sisters indicated 3 different mechanisms accounting for reverse mosaicism (RM). The maternal variant c. 1158dupC in exon 10 was absent in the proband (370_1), likely from a gene conversion event correcting the mutant allele. The paternal alleles in each of 370_2 and 370_3 with inherited variant c. 1771dupC in exon 14 (p. L591PfsX14)(see http://www. rockefeller. edu/fanconi/) were found to be associated with *de novo* genomic variants c. 1729delC in exon 13 and c. 1761-1G>A in intron 13 respectively. cDNA analysis revealed, as predicted for 370_2, that the c. 1729delC results in correcting the defect caused by the inherited variant c. 1771dupC by restoring the reading frame except for altering amino acids encoding 577-589 from QTKGSHEDALWSL to KLRGHMKMLCGLS. Similarly, the *de novo* intronic variant c. 1761-1G>A in 370_3 causes c. 1761delG in the cDNA, resulting in only changing amino acids 587-589, from WSL to CLS. Three distinct alterations appear to be accounting for RM in the three affected siblings. The extent of RM, and the nature of the altered protein products might influence the phenotypic heterogeneity in FA.

The G2 micronucleus assay in lymphocytes shows increased radiosensitivity in in healthy BRCA1 mutation carriers. *K. BM. Claes[1], A. Baert[1-2], J. Depuydt[2], T. Van Maerken[1], B. Poppe[1], M. Van Heetvelde[1], K. De Leeneer[1], A. Vral[2].* 1) Center for Medical Genetics, Ghent University Hospital, Gent, Oost-Vlaandere, Belgium; 2) Department of Basic Medical Sciences, Ghent University Gent, Oost-Vlaanderen, Belgium.

The risk of breast cancer increases drastically in individuals carrying a germline *BRCA1* mutation. It is therefore crucial to subject individuals carrying a mutation to an intensified screening to detect possible tumours in an early stage. The general approach is to use mammography screening, complemented with MRI and/or echography. The screening typically starts at young age, resulting in a relatively high cumulative dose of ionizing radiation received during subsequent mammography screening. The exposure to ionizing radiation of *BRCA1* mutation carriers is contra intuitive since BRCA1 is active in the DNA damage response pathway. Moreover, BRCA1 is important in the initiation of homologous recombination and the G2/M checkpoint. In this study, radiosensitivity was determined in healthy *BRCA1* mutation carriers by means of the G2 micronucleus assay. We applied the assay on blood samples of carriers and non-carriers. We determined the radiosensitive phenotype using a robust grading system (grade 0-3) based on 4 parameters that investigate DNA repair as well as G2 arrest capacity. The robustness of this approach was demonstrated by a high reproducibility of the results obtained on samples taken at different time points from both carriers and non-carriers. Our analyses clearly show that healthy germline *BRCA1* mutation carriers are more radiosensitive compared to healthy non-carriers and we found that 39% of *BRCA1* mutation carriers had a radiosensitive grade of 2 or 3. These high grades were never observed in the non-carriers. Prospective studies are required to determine if these results may impact approaches for screening, e. g. avoiding mammography screening at young age in individuals demonstrating a high grade of radiosensitivity. In the current patient cohort, only patients with truncating mutations have been analysed. Further studies are ongoing to evaluate if a radiosensitive phenotype is also seen in carriers of pathogenic missense mutations. .

Identification of new target genes in microsatellite unstable colorectal cancer by exome sequencing. *J. Kondelin[1,2], E. Pitkänen[1,2], A. E. Gylfe[1,2], K. Palin[1,2], H. Ristolainen[1,2], R. Katainen[1,2], E. Kaasinen[1,2], M. Taipale[2,3], J. Taipale[2,3], L. Renkonen-Sinisalo[4], H. Järvinen[4], J. Böhm[5], JP. Mecklin[6], P. Vahteristo[1,2], S. Tuupanen[1,2], L. A. Aaltonen[1,2].* 1) Department of Medical and Clinical Genetics, University of Helsinki, Helsinki, Helsinki, Finland; 2) Research Programs Unit, Genome-Scale Biology Research Program, University of Helsinki, Helsinki, Finland; 3) Science for Life Center, Department of Biosciences and Nutrition, Huddinge, Sweden; 4) Department of Surgery, Helsinki University Central Hospital, Hospital District of Helsinki and Uusimaa, Helsinki, Finland; 5) Department of Pathology, Jyväskylä Central Hospital, University of Eastern Finland, Jyväskylä, Finland; 6) Department of Surgery, Jyväskylä Central Hospital, University of Eastern Finland, Jyväskylä, Finland.

Approximately 15% of colorectal cancers (CRCs) display microsatellite instability (MSI) caused by defective cellular mismatch repair. Most MSI CRCs are sporadic and result from biallelic inactivation of the *MLH1* gene, most often due to hypermethylation of its promoter. Cells displaying MSI accumulate a high number of mutations throughout the genome, especially in short repeat areas, microsatellites. These mutations typically lead to a premature stop codon resulting in a truncated protein product that may inactivate the gene, a mechanism known typical of tumor suppressor genes. To date, several genes have been proposed as MSI target genes based on high mutation frequency in targeted searches of microsatellites. New sequencing technologies, however, enable genome-wide investigation of mutations in human cancers. This has in turn led to identification of a vast amount of mutations in cancer, most of which are passenger mutations that do not confer selective growth advantage. The challenge is therefore to distinguish true driver genes from passengers. The high number of mutations in MSI tumors augments this challenge. The aim of this study is to identify new target genes in MSI CRC that function as true drivers in this tumor type. In this study, 24 sporadic MSI CRCs and their corresponding normal samples were exome sequenced to identify changes of somatic origin. An analysis and visualization program developed in our group, “RikuRator” (unpublished), was utilized along with a script to estimate the accurate somatic mutation frequency of each coding mononucleotide repeat. A statistical model based on exome sequencing data was developed that takes into account the background mutation frequency of microsatellites depending on the repeat length and nucleotide context. The most mutated repeats from the top 73 genes are validated by MiSeq-sequencing in a set of additional MSI CRCs. Functional studies will be carried out to further investigate the pathogenic effect of the new target genes identified. The systematic screening of mutations in microsatellites will improve our understanding on the mutation profile of these tumors. With our approach that takes into account the background mutation frequency of microsatellites, we aim to identify true driver genes in MSI CRC. A detailed understanding of the molecular background of this tumor type is important for the development of more efficient screening methods and personalized treatments for patients with MSI CRC.

Integrated landscape of molecular alterations in Uveal Melanoma. *H. Anbunathan[1], A. M. Bowcock[1], J. W. Harbour[3], R. Rabadan[2], R. D. Melamed[2].* 1) Imperial College London, London, LONDON, United Kingdom; 2) Columbia University, New York, USA; 3) Bascom Palmer Eye Institute, Miami, USA.

Uveal melanoma (UM) is the second most common form of melanoma and the most common primary cancer of the eye in adults. Tumors arise from neural-derived melanocytes of the uveal tract of the eye leading to tumors of the iris, ciliary body and choroid. Approximately 50% of tumors metastasize within 10 years, most commonly to the liver. Tumors can be subdivided into groups on the basis of gene expression differences that correspond to those low metastatic risk (class 1 tumors) and high metastatic risk (class 2 tumors). Class 2 tumors are frequently associated with monosomy 3. We previously used exome sequencing to identify driver mutations in *BAP1* gene in the metastasizing class 2 tumors with monosomy 3 and recurrent mutations in *SF3B1* in the class 1 tumors with less metastatic competency. *EIF1AX* mutations have also been identified in the low-grade class 1 tumors. We have now completed exome sequencing of 40 UM samples, 23 matched normal DNAs, 2 metastases, and 6 UM cell lines. In the case of one tumor we were able to exome sequence three independent segments and one metastasis which provided information about tumor evolution. We have also performed RNA-Sequencing on 22 UMs, and analysed 14 UM/normal pairs for CNVs by interrogating the Illumina OmniArray. UMs harbored an average of 79 somatic mutations, including 47 nonsynonymous mutations. Chromosomal copy number profile reveal 1q gain, monosomy 3, 6p gain, 6q loss, 8q gain and 9p loss which is consistent with previous findings. We also observed changes in chr11 and chr13 in 5 class 1 tumors. Gene fusions were identified with RNA-Seq data using more than one fusion detection tool (Defuse, Chimerascan and Tophat). These included *NAIP-OCLN*, *AZGP1-GJC3* (validated with RT-PCR), and *CHIA-TMEM101* fusions. The six cell lines harboured an average of 950 mutations per sample including 540 nonsynonymous mutations. Cell lines harboured known mutations in *SF3B1* and *EIF1AX* but none contained *BAP1* mutations. We found an average of 40 mutations in the two tumor metastases. However, there were no shared altered genetic drivers in the metastases other than those seen in the primary tumors. This suggests that for uveal melanoma, pathogenic mutations in *BAP1*, *EIF1AX* and *SF3B1* still are the best predictors for tumour progression. .

Somatic and genomic mutation spectrum of unilateral Vestibular Schwannoma (VS). *R. Birkenhager, S. Arndt, W. Maier, A. Aschendorff, R. Laszig.* Department of Otorhinolaryngology and Head and Neck Surgery, University Medical Center Freiburg.

A vestibular schwannoma (VS) (acoustic neuroma) is a benign tumors originated from schwann cells (SC) of the vestibular nerve and located in the cerebellopontine angle or the inner auditory canal. The tumor results from an over proliferation of SC; these cells wrap themselves around nerve fibres, often causing gradual hearing loss, tinnitus and dizziness. It can also affect with the facial nerve causing paralysis by compression. Early detection of the tumor is sometimes difficult, because the symptoms may be subtle and may not appear in the beginning. There are two types of VS: Bilateral and unilateral. Until now there is only one single gene known for bilateral VS, that leads to neurofibromatosis type 2 (NF2). Unilateral VS account for approximately 8 % of all cranial tumors. The exact cause of unilateral VS is unknown, most occur spontaneously. Our study group consists of 144 patients (from 139 independent families) of which 23 have a bilateral VS (NF2), 119 unilateral VS and 2 with an initial suspicion of VS. All patients were clinically clearly defined. Genetically we performed a mutation analysis on the NF2 gene at the genomic and tumor level. So far we identified different missense/nonsense and splice mutations in NF2 gene, on the genomic level and in some cases exclusively in tumor cells, which all lead to a loss of function of the gene product Merlin and the appearance of VS. In addition to somatic changes and mutations there are possible indications of a genomic predisposition to unilateral vestibular schwannoma.

Comprehensive genomic characterization of three spatially and temporally distinct tumors from different organs in a single patient exhibiting both BRCA2 and VHL germline mutations. *S. M. Boyle[1], M. J. Clark[1], T. H. Ho[2], M. L. Stanton[2], E. P. Castle[2], A. S. Parker[3], R. Alla[1], E. Helman[1], S. Luo[1], M. Snyder[4], J. West[1], R. Chen[1].* 1) Personalis, Menlo Park, CA; 2) Mayo Clinic, Inc. , Scottsdale, AZ; 3) Mayo Clinic, Inc. , Jacksonville, FL; 4) Department of Genetics, Stanford university, Stanford, Ca.

Inherited genetic mutations have been strongly associated with heightened risk for a broad range of cancer subtypes. Over the last two decades, large efforts have focused on recognizing cancer driver genes and better understanding their role in cancer progression, resulting in identification and characterization of important drivers, such as BRCA1, BRCA2, , PTEN, and VHL. In very rare cases, a single individual has germline mutations in more than one of these cancer driver genes. To profile multiple tumor progression when two susceptibility gene mutations are detected, we applied next generation sequencing to analyze and characterize the development of three distinct tumors in a 54-year-old female with germline mutations in both BRCA2 and VHL. BRCA2 is well known for its role in breast, ovarian,, and skin cancers. Damaging germline mutations in VHL are rare (1/36,000 individuals) and cause Von Hippel-Lindau, a rare autosomal dominant disorder that predisposes to a range of distinct cancers, including renal cell carcinoma (RCC), hemangioblastomas. To our knowledge, extensive genetic profiling has not been performed on a patient with both BRCA2 and VHL mutations. Over the course of 5 years, this patient was diagnosed with pheochromocytoma, RCC, and basal cell skin cancer. Each of the tumors was identified more than one year apart, was treated, and is currently under active treatment for RCC. Using the ACE Extended Cancer Panel, a targeted enrichment sequencing platform including over 1,300 cancer genes and 200 miRNAs, we sequenced each neoplastic site as well as adjacent normal tissues. Both the DNA and RNA were sequenced to high depth, and small variants, gene expression, copy number alterations, and gene fusions were assessed. Additionally, by sequencing both DNA and RNA, we evaluated allele specific expression and verified copy number changes affecting gene expression. This is the first study to investigate the progression of multiple tumors arising from dual BRCA2/VHL germline mutations in a single patient. In addition to identifying the impact of inherited BRCA2 and VHL mutations in each tumor, we extensively characterized driver mutations in all tumors, identifying private mutations in each. We discuss how each contributes to overall cancer progression and demonstrate the ways in which an integrated RNA/DNA approach with a cancer focused augmented enrichment panel enables a greater understanding of the genetics of cancer in a particular case.

2688T

Down regulation of TGFB3 plays a critical role in chordoma formation. *W. Chen[1], L. Wang[2], Q. Hu[1], Z. Wu[2], J. Zhang[2], C. Zeng[1].* 1) Laboratory of Genomic and Precision Medicine, Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) Department Neurosurgery, Beijing Tian Tan Hospital, Capital Medical University, Beijing, China.

Chordoma is rare malignant tumor, arising from notochordal remnants and occurs along the spine. Study on chordoma is challenging owning to its low prevalence and lack of normal controls. Although the expression of T gene was seen as a diagnostic marker, its direct effect to tumor genesis remains unclear and thus far no other gene is consistently reported to be involved in chordoma development. To identify the important pathway in the formation of chordoma, we conducted miRNA and mRNA sequencing in two chordoma tissues and two fetal notochords, which were seen as normal control tissue of chordoma. We found the differentially expressed mRNA-miRNA pairs were enriched in TGFB pathway. And the chordoma up-regulated miR-29b-3p and its down-regulated target gene TGFB3 were further validated in additional 8 chordoma tissues and 8 notochords. There is a significant negative correlation between the expression of TGFB3 and miR-29 in chordoma samples (r2=0. 87). Lacking of such a correlation in notochords suggests the down-regulation of TGFB3 in chordoma were mainly caused by up-regulation of miR-29. We further compared the copy number of miR-29 gene loci between chordoma tissues and their paired blood samples. Among the 8 chordoma patients, 5 had somatic copy number gain at miR-29b1 and/or miR-29b2 loci. In addition, in seven chordoma samples with enough blood controls, somatic copy number loss of TGFB3 were observed in 4/7 samples. To verify the interruption of TGFB3 in chordoma formation, we knocked down TGFB3 on zebrafish eggs by morpholino approach. As the zebrafish lavas developed to 48 hours, about a half of them showed curved shape phenotype. Chordoma like phenotype in zebrafish notochords was then identified by H&E staining and immunohistochemistry. Our findings demonstrate that down-regulation of TGFB3 directly causes chordoma formation and TGFB3 or miR-29 may act as a plausible drug target for chordoma treatment.

2689W

Genomic alterations in *BCL2L1* and *DLC1* contribute to drug sensitivity in gastric cancer. *S. Y. Cho[1], H. Park[1,2], H. Kim[2], D. C. Na[1], J. Y. Han[1], J. Chae[3], C. Park[3], O. K. Park[3], K. Min[1], J. Kang[1], B. Choi[4], J. Min[4], Y. S. Suh[5], S. H. Kong[5], H. J. Lee[4,5], E. Liu[2], J. I. Kim[3], S. Kim[6], H. K. Yang[4,5], C. Lee[2].* 1) Department of Life Science, Ewha Womans University, Seoul, Korea; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 3) Department of Biomedical Sciences, Seoul National University College of Medicine, Seoul, Korea; 4) Cancer Research Institute, Seoul National University College of Medicine, Seoul, Korea; 5) Department of Surgery, Seoul National University College of Medicine, Seoul, Korea; 6) Department of Molecular Medicine and Biopharmaceutical Sciences, Seoul National University, Seoul, Korea.

Gastric cancer (GC) is the third leading cause of cancer-related deaths worldwide. Recent high-throughput analyses of genomic alterations reveal several driver genes and altered pathways in GC. However, therapeutic applications from genomic data are limited, largely due to the lack of druggable molecular targets and preclinical models for drug selection. To investigate therapeutic targets for GC, we performed whole exome sequencing and array Comparative Genomic Hybridization (aCGH) of DNA from 103 GC patients. Pathway analysis showed recurrent alterations in the Wnt signaling (*APC, CTNNB1* and *DLC1*), the ErbB signaling (*ERBB2, PIK3CA* and *KRAS*) and the p53 signaling/apoptosis (*TP53* and *BCL2L1*) pathways. Notably, in 18% of GC cases (19/103), amplification of *BCL2L1* was observed and subsequently a BCL2L1 inhibitor was shown to markedly decrease cell viability in cell lines and in similarly altered patient-derived GC xenografts, especially when combined with other chemotherapeutic agents. In 11% of cases (6/55), mutations in *DLC1* were found and also shown to confer a growth advantage for these cells via activation of Rho-ROCK signaling, rendering these cells more susceptible to a ROCK inhibitor. Taken together, our study implicates *BCL2L1* and *DLC1* as potential druggable targets for a subset of GC cases.

2690T

Flying Blind: Building a Cancer Genomic Standard. *M. Clark, E. Helman, S. Boyle, R. Alla, S. Luo, D. Church, N. Leng, S. Kirk, P. Sripakdeevong, A. Huang, J. West, R. Chen.* Personalis, Inc. , Menlo Park, CA.

Cancer genomes are a hodgepodge of mutational types, including small variants as well as more complex structural changes, directed by strong selection pressures to enhance oncogenesis, or simple genomic instability. Tumor heterogeneity is common, such thatcancer genomes are not a single entity, but rather a population of genomes with varied mutations. Tumor samples range from solid tumors to liquid biopsies, and are often contaminated with adjacent normal tissue. Moreover, cancer samples are treated with formalin and embedded in paraffin for archival purposes, causing additional genomic variations. Much attention has been paid to recent efforts to define gold standard human genomes, but thus far they lack many features that are characteristic of cancer genomes. No single cancer sample contains all of these various features, and any given cancer sample is very limited in quantity. There are some single-sample cancer reference standards, including the Horizon Quantitative Multiplex, an engineered FFPE cell line mix with variants at allele frequencies (AFs) from 1. 0 to 41. 5%. Sequencing this cell line, we detected 18/18 SNVs and 4/4 indels. While samples of this type have limited utility, there is a clear need for samples containing the full spectrum of mutation types and frequences. Therefore, we made a collection of 28 cancer cell lines to generate a cancer genome standard set including 817 known SNVs, 62 small indels, 21 deletions, 23 amplifications, and 14 gene fusions. We simulated tumor heterogeneity by mixing the cell lines at various ratios, generating variant allele frequencies down to 1% and emulated reduced purity by mixing cell lines with paired normals at ratios down to 10%. These experiments required sequencing over 140 samples and mixes. Using an augmented oncome panel (targeting >1,500 cancer genes), these multiplexes enabled us to interrogate substantial quantities of variants. We detected 16136/16146 SNVs at 5% AF, 639/646 indels at 10% AF, 29/30 CNAs at 20% purity, and 14/14 gene fusions using this panel. These high variant counts enabled us to establish tighter confidence intervals and validate this oncome platform for detection of all major cancer variant types. .

Genetic profile of tumorigenesis in Brazilian NSCLC patients. *P. GP. Couto[1], F. M. MELO[1], R. GUIMARAES[2], S. D. PENA[2], A. VILHENA[1], E. FRIEDMAN[3], L. BASTOS-RODRIGUES[4], L. DE MARCO[1].* 1) Departments of Surgery, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 2) Departments of Biochemistry, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil; 3) The Susanne Levy Gertner Oncogenetics Unit, Chaim Sheba Medical Center, Tel-Hashomer, Israel; 4) Department of Basic Sciences, Universidade Federal de Juiz de Fora, Brazil.

Introduction: Lung cancer is the most common type of neoplasm and the leading cause of cancer-related deaths worldwide. To improve the survival rate of lung cancer patients, a better understanding of tumor biology is required to help the development of new therapeutic strategies. Over the past decade, it has become evident that subsets of NSCLC can be further defined at the molecular level by recurrent 'driver' mutations that occur in multiple oncogenes including *AKT1, ALK, BRAF, EGFR, HER2, KRAS, MEK1, MET, NRAS and PIK3CA*. Next-generation sequencing technologies have revolutionized cancer genomics research by providing an unbiased and comprehensive method to detect genome abnormalities. **Materials and methods**: Our study analyzed seven samples each from smokers and non-smokers Brazilian patients with lung adenocarcinoma through whole exome sequencing. Samples were subjected to whole exome capturing and sequencing using the Roche NimbleGen V2 chip and the Illumina HiSeq2000 sequencing platform. The generated files were analyzed separately using *Ingenuity® Variant AnalysisTM* and *Mendel, MD* softwares. Variant calling of both samples resulted in 102,933 single nucleotide variations (SNVs) being 13,837 registered as novel variants. **Conclusion**: Our data shows that genes other than those that have already been published are present in Brazilian patients. Therefore, further studies are needed to investigate molecular alterations in tumor-related genes and help define a genetic profile of tumorigenesis in Brazilian NSCLC patients.

2692T

Breast cancer mutations are enriched in ERVK elements. *D. Ebrahimi[1,2,3], G. J. Starrett[1,2,3], N. A. Temiz[1,2,3], R. S. Harris[1,2,3].* 1) Biochemistry, Molecular Biology and Biophysics, University of Minnesota, Minneapolis, MN 55455 USA; 2) Masonic Cancer Center, University of Minnesota, Minneapolis, MN 55455 USA; 3) Institute for Molecular Virology, University of Minnesota, Minneapolis, MN 55455 USA.

Nearly half of the human genome is composed of repetitive elements including DNA transposons and two main classes of retrotransposons. Human cells use several mechanisms including silencing by CpG methylation and inhibition by APOBEC3 editing enzymes to repress the activity of these endogenous elements (1). Both of these mechanisms can lead to C-to-T mutations through deamination of methylcytosine and cytosine bases respectively, however in different sequence contexts. Methylation drives mutation within CpG motifs and editing by all APOBEC3 enzymes except one occurs mainly within TpC (2). Recent studies have shown that C-to-T mutations within the contexts of CpG and TpC are also dominant in many cancers including breast carcinoma (3, 4). These observations suggest that the mechanisms responsible for inhibiting endogenous elements may also play a role in inducing cancer mutations. Importantly a large number of cancer mutations occur in non-genic regions composed of mainly endogenous elements. However studies of cancer mutations are mostly limited to exonic regions. Here we quantify the distribution of mutations in whole genome breast cancers to investigate whether certain mutations, in particular CpG methylation and APOBEC3 signatures are enriched within the endogenous element sequences of cancer genomes. An enrichment would suggest a link between the repression of endogenous elements and cancer mutations. Our analyses of 21 whole breast cancer genome sequences indicate that all elements are susceptible to 'spontaneous' mutagenesis but somatic mutations are enriched in ERVK elements. The most enriched mutations were C-to-T within CpG motifs suggesting a link between the methylation of these elements and their mutation in breast cancer. C-to-T mutation within the APOBEC3 preferred target TpC was not enriched in the endogenous retroviral sequences. These results suggest that a retrotransposon methyl-maintenance mechanism may be deregulated in some breast cancers. 1. N. Zamudio, D. How deep does intra-tumor genetic heterogeneity run in breast cancer? Identifying multiple different mutations in a single gene (intra-gene heterogeneity) within individual breast cancer tumors. *B. Gottlieb[1,2,3], F. Babrzadeh[5], K. Klein[1], C. Alvarado[1], C. Wang[5], B. Gharizadeh[5], M. Basik[2,4], L. K. Beitel[1,3,4], M. Trifiro[1,2,3,4].* 1) Lady Davis Inst Med Res, Montreal, QC, Canada; 2) Segal Cancer Center, Jewish General Hospital, Montreal, QC, Canada; 3) Dept Human Genetics, McGill University, Montreal, QC, Canada; 4) Dept Medicine, McGill University, Montreal, QC, Canada; 5) Stanford Genome Technology Center, Stanford University, Palo Alto, CA.

Recent studies that have revealed the degree and complexity of intra-tumor genetic heterogeneity within breast cancer tumors and between single tumor cells have been limited to identifying genetic alterations in different genes, but have yet to investigate the degree of genetic heterogeneity within the same gene (intra-gene heterogeneity, IGH). While next generation sequencing (NGS) has technically made this feasible, there are a number of issues that must be resolved before we can actually do so. In particular, present sequence analysis algorithms are designed so that they effectively ignore IGH, as there is the assumption that IGH is very unlikely to occur. Thus, most NGS analysis tools use filters and other techniques such as specific sequence alignment tools whose design has resulted in the reduced possibility of finding IGH in tumor tissues. To resolve this issue, we have developed a new approach to sequencing and sequence analysis that has allowed us to examine IGH within the androgen receptor gene (*AR*), even while removing sequence variance due to sequence or sequence analysis errors. The examination of a number of breast cancer tumors using this approach has revealed the presence of IGH within the *AR.* Initial data indicate that the vast majority of *AR* mutations in the breast cancer tumors exist only in minority forms, we believe these would have been totally missed using traditional sequencing and sequencing analysis tools. In light of the recent attention being paid to *AR* mutations, particularly in triple negative breast tumors, identification of minority *AR* mutations in breast cancer tissues could be important in considering treatment options. Furthermore, the inability to identify estrogen receptor mutations in most breast cancer patients, may be because they exist as minority variants within breast cancer tissues, Indeed, the presence of IGH could explain how both carcinogenesis and resistance to chemotherapy can be associated with rapidly occurring mutations in both tumor suppressor and oncogenes. It could also explain their significance in cancer ontology and treatment.

Complementing NGS panel sequencing by high rersolution custom array CGH increases the mutation detection rate in hereditary breast and ovarian cancer. *K. Hackmann[1], K. Kast[2], P. Wimberger[2], E. Schrock[1], A. Rump[1].* 1) Institut fuer Klinische Genetik, Medizinische Fakultaet Carl Gustav Carus, TU Dresden, Dresden, Sachsen, Germany; 2) Klinik und Poliklinik fuer Frauenheilkunde, Medizinische Fakultaet Carl Gustav Carus, TU Dresden.

As a diagnostic routine we perform next generation sequencing (NGS) and apply Illumina's TruSight Cancer panel to identify mutations that are causative for familial cancer predisposition in hereditary breast and ovarian cancers (HBOC). In order to also conduct a thorough detection of deletions and duplications we designed a customized array that covers all 94 genes that are present on the TruSight Cancer panel. In 11 families and 15 persons out of 232 individuals we detected copy number variants that were causative for tumor predisposition and affected the 10 genes that are recommended for diagnostic analysis by the German Consortium for Hereditary Breast and Ovarian Cancer . In addition to previously reported variants we found unreported deletions in *ATM*, *RAD51C* and an intragenic duplication in *BRCA2*. Besides adding about 5% to the total detection rate in HBOC cases, precise knowledge of the breakpoint positions makes it possible to carry out PCR for subsequent predictive testing of family members or segregation analysis. Generally, we can recapitulate copy number changes from NGS data to a certain degree. But in genomic areas with low read coverage we are not confident that NGS coverage analysis is sufficiently reliable. This may change with an increasing number of cases and appropriate software.

2695W

Somatic mutation detection in urological cancers from liquid biopsies. *C. Ionescu-Zanetti[1], R. Brobey[2], K. Rosenblatt[3], M. Dehghani[3], M. Schwartz[1], R. Amato[2].* 1) Research and Development, Fluxion Biosciences, South San Francisco, CA; 2) University of Texas Health Science Center at Houston; 3) Research and Development, CompanionDx.

Purpose: Next generation sequencing (NGS) of blood-derived nucleic acids is an emerging paradigm for determining the mutational status of cancer patients over time. Both circulating tumor cells (CTC) and cell-free circulating DNA have been proposed as possible sample types for extracting tumor DNA. Here, we present data from a CTC enrichment modality that results in tumor cell purities in excess of 10% followed by a high sensitivity NGS data analysis workflow. This study is aimed at urological cancers (kidney, prostate) that historically have not performed well for CTC analysis. **Methods:** Urological cancer blood samples were enriched for CTCs using immunomagnetic separation in a microfluidic chamber. CTCs were lysed and amplified, followed by DNA purification. Targeted libraries were sequenced and data was analyzed using a customized variant pipeline based on standard alignment tools and functional interpretation. Matched blood samples were enumerated to determine the CTC load (CK+, CD45-, nucleated cells). **Results:**Multisite analytical validation data, based on spiking of cells into whole blood, demonstrated a detection limit down to 10 cells from a blood draw with a false positive rate of below 0. 1 calls per sample. Clinical data from two different urological cancer pilot studies (prostate and kidney) demonstrated the detection of somatic variants for a majority of samples with significant overlap between detected mutations and known somatic mutation sites. We detected common mutations (i. e. TP53, PTEN and APC genes) that are similar to the population distribution of mutation rates in tissue biopsies. Over 90% of samples tested had CTCs above the detection limit (10 tumor cells). **Conclusions:** This assay makes possible the detection of somatic variants from urological cancer patients without the need for a tissue biopsy.

Case analysis of advanced cancers with Watson Genomic Analytics. *T. Koyama[1], S. Jones[2], F. Utro[1], Y. Ma[2], K. Rhrissorakrai[1], Y. Shen[2], B. Carmeli[3], M. Jones[2], Z. Waks[3], E. Plesance[2], R. Norel[1], R. Moore[2], E. Bilal[1], A. Mungal[2], K. Beaty[1], J. Schein[2], V. Michelini[4], M. Marra[2], A. Royyuru[1], J. Laskin[2].* 1) IBM Research, Yorktown Heights, NY; 2) British Columbia Cancer Agency, Vancouver, British Columbia, Canada; 3) IBM Research, Haifa, Israel; 4) IBM Watson, New York, NY.

The personalized onco-genomics project (POG) at British Columbia Cancer Agency (BCCA) aims to use paired tumour/normal whole genome and transcriptome sequence information from a cancer patient to inform treatment options. The analysis and interpretation of this large and complex data set is difficult to complete within a clinically relevant timeframe. As whole genome sequencing becomes more readily available there is a need to scale-up these interpretive processes but maintain a high degree of evidence and data integrity. This project compares the output of the human curated literature review and data analysis methods employed at the BCCA with that of Watson Genomic Analytics (WGA), a novel IBM Watson solution. The POG project has biopsied, sequenced and analyzed over 100 metastaticcancers since 2012. Each case has whole genome and transcriptome sequencing andthe data is mined to identify somatic mutations or disrupted signaling cascadesthat might be functionally critical for understanding driver events within anindividual's cancer or useful for rationalizing treatment planning. Anonymized data from 29 cases was input into WGA which readsmutation, copy number and gene expression files. It performs a molecularprofile analysis to identify possible driver events, followed by a pathway analysis to find possible pharmaceutical interventions including phase 3 candidates. Pathways, off-target pharmacological effects, and pharmacogenomics/biomarker information are augmented with relationshipsdiscovered by natural language processing from millions of PubMed abstracts and full text biomedical journals. Theoutput of WGA consists of a list of drug candidates with rationales and scoresalong with literature evidence that supports their consideration. The results were compared to the human curated reports produced by the POG team. In all 29 instances of retrospective analysis, WGA finds actionable insightsand identifies potential drugs for consideration along with visualization for molecular profile analysis and pathways. The automated generation ofthese insights is achieved by WGA in minutes. With increasing adoption of molecular targeted therapies, there is a strongneed to continuously update the relationships between genomic alterations,cancer biology and drugs. This is a task that requires extensive and time consuming review of latestscientific literature. WGA may allow for more efficient androbust way of performing the analysis in precision medicine.

Highly Sensitive and Cost-Effective Detection of *BRCA1* and *BRCA2* Cancer Variants in FFPE Samples Using Multiplicom's MASTR Technology & Single Molecule, Real-Time (SMRT®) Sequencing. *S. Kujawa[1], A. Sethuraman[1], P. Baybayan[1], J. Del Favero[2].* 1) Pacific Biosciences, Menlo Park, CA; 2) Multiplicom N. V. , Niel, Belgium.

Specific mutations in *BRCA1* and *BRCA2* have been shown to be associated with several types of cancers. Molecular profiling of cancer samples requires assays capable of detecting the entire spectrum of variants. Next-Generation Sequencing (NGS) has been a powerful tool for researchers to better understand cancer genetics. Single Molecule, Real-Time (SMRT) sequencing offers several advantages, including sensitive detection of variants and long read lengths capable of spanning entire protein coding regions. We examined the detection sensitivity of SMRT sequencing in combination with the BRCA MASTR Dx kit from Multiplicom, amplifying all coding exons of *BRCA1* and *BRCA2* covered by 181 overlapping amplicons ranging in size between 120 bp and 230 bp. FFPE derived DNA samples were multiplex PCR amplified followed by a second round of PCR amplification enabling sample multiplexing by adding a unique set of 16-bp PacBio barcodes to either end of each amplicon. The resulting amplicons were further purified, concentrations normalized, and mixtures made prior to sequencing. SMRTbell™ libraries were constructed and sequenced using standard Pacific Biosciences® P6-C4 chemistry and protocols. With a 90-minute movie collection protocol, the average polymerase read lengths were approximately 8,000 bp across samples, with 5% of reads longer than 20,000 bp. For coverage and variant detection analysis, we sequenced a number of sample combinations, from 1 sample per SMRT Cell up to several samples per SMRT Cell. With 4 samples multiplexed in a single SMRT Cell, we obtained enough circular consensus sequencing (CCS) coverage of all 181 amplicons for efficient downstream variant analysis. Using either a reference-based approach or a *de novo* approach for variant analysis, we accurately and reliably detected all the expected variants for the samples in the mix. The random error profile, long read lengths, and high accuracy CCS reads make it possible to call variants from as few as 10 molecules. While SMRT sequencing can identify cancer mutations with high accuracy, the associated low cost of consumables and fast turnaround time make this an ideal platform for clinical research applications.

2698T

Clinical validation of a droplet PCR-based targeted gene panel for the detection of somatic variants in solid tumors. *L. Liang[1], F. B. Patel[1], Q. Tan[1], H. Gaspard[1], W. M. Hussain[1], A. I. Brooks[1], J. A. Tischfield[1], A. Sahota[1,2].* 1) Department of Genetics, Rutgers University, Piscataway, NJ; 2) Department of Pathology and Lab Medicine, Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ.

Introduction: Next generation sequencing enables the sensitive detection of sequence variants in multiple genes from small amounts of tumor tissue. The resulting mutational profile may serve multiple purposes, including personalized patient care, enrollment in clinical trials, or basic research into the molecular heterogeneity of cancer. Here, we describe the clinical validation of the ThunderBolts (TB) Cancer Panel from RainDance Technologies for the detection of sequence variants in DNA from FFPE tissue from a variety of solid tumors. This panel targets 230 amplicons spanning 50 genes. Many of the targeted mutations are in hotspot regions and therapies are available for a subset of the molecular pathways involving these mutations. **Methods:** DNA was extracted from FFPE tissue and a minimum of 10 ng DNA in a total volume of 40 µl was analyzed using the TB panel. The reaction mixture was subjected to picoliter-volume droplet formation and the droplets then amplified by PCR. The amplified products were purified and a second round of PCR was carried out to add barcoding sequences. Following further purification, PCR products from up to 16 samples were pooled and sequenced on the Illumina MiSeq. Nucleotide sequence data were analyzed using MiSeq Reporter and associated software. **Results:** We analyzed DNA from 59 FFPE samples (51 tumor and 8 normal adjacent tissue) and three well-characterized human cell lines. For the FFPE samples, the average read per sample was 2. 1x106, with an average read of 10,083 per amplicon and over 99% of the amplicons had a read depth greater than 1,000. The assay was highly reproducible, both for cell line and FFPE DNA. Based on analysis of cell line DNA, the analytical sensitivity and specificity was 98. 6 and 100%, respectively. The Life Technologies Ion AmpliSeq Cancer Hotspot Panel v2 was used to confirm, in 27/59 of the FFPE samples, the sequence variants identified by the TB panel. Sequence variants down to 5% could be readily detected using cell line mixtures and this was confirmed in clinical samples. **Conclusions:** The TB panel eliminates the need for traditional library preparation and it has additional advantages over other targeted panels, including the ability to amplify degraded DNA and precise detection of low-prevalence somatic mutations based on single molecule PCR. The assay is highly reproducible and we have validated it for use in the clinical laboratory for the detection of sequence variants in solid tumors.

***Cis*-regulatory drivers in colorectal cancer.** *H. Ongen[1], C. L. Andersen[2], J. B. Bramsen[2], P. G. Ferreira[1], T. F. Orntoft[2], E. T. Dermitzakis[1].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, 1211 Geneva, Switzerland; 2) Department of Molecular Medicine, Aarhus University Hospital, Aarhus, Denmark.

The cis-regulatory effects have been shown to be important in colorectal cancer (CRC) development (Ongen H et al. , *Nature*, 2004). To better characterise the impact of the regulatory effects on CRC tumorigenesis, we conducted an RNA-sequencing experiment on 300 matched tumour and adjacent normal colon mucosa samples from CRC patients, which are also germline genotyped. On average there are 529 significant allele-specific expression (ASE) signals (FDR = 1%) per sample. Utilizing the changes in ASE in matched pairs of samples we discover 261 Genes with Allelic Dysregulation (GADs – or genes with cis regulatory driver mutations), enriched for TCGA PANCANCER drivers. We also correlated genotypes and gene expression to identify expression quantitative trait loci (eQTLs) and find 7114 and 2462 cis-eQTLs in normals and tumours, respectively. We estimate that 10% of the tumour cis-eQTLs are exclusive to CRC. Importantly tumour specific cis-eQTL genes also accumulate more cancer somatic mutations when compared to the shared cis-eQTL genes, raising the possibility that some of them may be germline-derived cancer regulatory drivers. We have investigated the trans effects on gene expression, and preliminary results show the there are 9 and 7 trans-eQTLs, in normal and tumour respectively, which are shared between the cell types. Furthermore we are assessing the trans effects of cis-eQTLs in order to increase our power in detecting regulatory variants that may act in trans. We are also using ASE differences in matched samples and the correlation of these differences with clinical characteristics to discover a cascade of regulatory changes that happen in tumorigenesis. In conjunction with this approach we are also assessing whether eQTL effects correlate with tumour progression. Furthermore we are investigating if ASE differences classify CRC samples into subtypes and whether these correlate with CRC phenotypes. We are also extending our analysis for finding GADs to un-matched normal and tumour samples, which will facilitate discovery of putative somatic regulatory drivers in un-matched cohorts. Moreover, the GADs are being assessed for their driver potential by comparing the expression levels in tumour vs. normal samples. Collectively the integration of genome and the transcriptome reveals a substantial number of putative somatic and germline cis-regulatory drivers.

Gene polymorphisms vis-a vis susceptibility to breast cancer and benign breast disease: A case-control study from Jammu region of J&K State, India. *R. K. Panjaliya[1], R Sharma[2], J Kour[3], S Bhardwaj[4], T Ajad[5], P Kumar[1, 6].* 1) Human Genetics Research cum Counselling Centre, University of Jammu, Jammu, J & K, India; 2) Human Genetics Research cum Counselling Centre, University of Jammu, Jammu, J & K, India; 3) Human Genetics Research cum Counselling Centre, University of Jammu, Jammu, J & K, India; 4) Department of Pathology, Govt. Medical College, Jammu, J&K; 5) Department of Surgery, Govt. Medical College Jammu, J&K; 6) Department of Zoology, University of Jammu, J&K.

Breast cancer is the most common cause of death in women all over the world. It is the most frequent cancer of both developed and developing regions. In India, breast cancer is the second most common cancer in females after cervical cancer and accounts for 22. 2% of all new cases diagnosed and 17. 2% of all cancer deaths in women. Molecular epidemiological studies have revealed the association of different gene polymorphisms with breast cancer risk. In the study under report, gene polymorphisms namely MTHFR C677T, ESR- PvuII, ESR -XbaI, CYPI-AI-Msp I, ACE I/D, GSTMI and GSTT1 have been genotyped in a total of 316 females including 60 confirmed patients of sporadic breast cancer, 105 benign breast disease and 150 age matched healthy females from Jammu region of J&K state. Polymerase chain reaction (PCR) was used to determine the genotypes in case of ACE I/D, multiplex PCR for GSTMI and GSTTI and PCR-RFLP method for remaining polymorphisms. Besides, modifiable and non-modifiable risk factors were also considered for the gene-environment interaction study and gene-gene interaction was also performed by using MDR analysis. Out of these polymorphisms GSTMI null genotype showed a significant association with the risk of breast cancer. T allele of MTHFR C677T polymorphism also conferred increased risk for breast cancer with significant p value. All other polymorphisms showed a lack of association with risk of breast cancer and benign breast disease as well. The small sample size is limitation of the present research work which seeks a study on large sample size that we intend to do.

2701W

Whole exome sequencing and copy-number variation analysis of 20 neurofibromatosis type 2-associated spinal and cranial meningiomas. *A. Pemov[1], R. Dewan[2], N. F. Hansen[3], S. Chandrasekharappa[3], J. C. Mullikin[3], A. R. Asthagiri[4], D. R. Stewart[1], NIH Intramural Sequencing Center, Comparative Sequencing Program.* 1) NIH/NCI, Bethesda, MD; 2) University of Maryland School of Medicine, Class of 2017, Baltimore, MD; 3) NIH/NHGRI, Bethesda, MD; 4) Department of Neurosurgery, University of Virginia School of Medicine, Charlottesville, VA.

Recent studies in high-throughput sequencing of genomes of sporadic meningiomas have revealed that inactivation of *NF2* is the most frequent genetic event in the tumors and is mutually exclusive with mutations occurring in genes such as *TRAF7, KLF4, AKT1* and *SMO*. It is accepted that somatic inactivation of the second copy of the *NF2* gene is associated with tumor initiation in patients with NF2, however little is known about what other genes or pathways are involved in the tumor formation and progression in patients with this disorder. To investigate this question we performed whole exome sequencing (WES) (Illumina Hi-Seq 2500 platform, 96 Mb SeqCap EZ Exome + UTR Library, NimbleGen) and SNP-array analysis (HumanOmniExpressExome-8, v1. 2 arrays, Illumina) of 20 spinal and cranial meningioma samples from seven NF2 patients. We identified 4 nonsense germline *NF2* mutations, a splice site mutation and an intronic mutation near the acceptor splice site (-9 bp) in six patients. SNP-array analysis revealed a large deletion in chromosome 22 containing the *NF2* gene in all but one meningioma sample. The second most frequent chromosomal aberration was a deletion within chromosome 1p (2 tumors) followed by the entire chromosome X deletion and complex rearrangements in chromosome 17q. The remaining samples exhibited the genomic architecture of a normal diploid cell. Next, we investigated the somatic mutation burden in the genomes of the tumors. We identified ~20 point substitutions and small indels in 20 tumor samples. Most of the mutations were observed only once. We identified a few mutations that were common among multiple samples, however none of these mutations were shared among the samples originating from different patients. Validation of these mutations by an orthogonal sequencing technology is pending. In conclusion, our genomic study revealed that somatic inactivation of *NF2* is the most frequent and the only recurrent genetic event in NF2-associated meningiomas. Large LOH events such as large deletions in chromosome 22 are by far the most prevalent mechanism of the second hit. Large LOH events elsewhere in the genome, especially on chromosome 1, could represent a common path of tumor progression toward a more advanced stage. Somatic single nucleotide substitutions and small indels are relatively rare in these tumors and understanding the role of these types of mutations in NF2-associated meningioma tumorigenesis will require further studies.

2702T

Driver gene mutations and fusion genes in patients with sezary syndrome. *A. Prasad[1], R. Rabionet[1], L. Zapata[1], A. Puig[1], Y. S. Trujillo[1], A. M. Puiggros Metje[2], B. Espinet[2], F. Gallardo[2], R. M. Pujol[2], X. Estivill[1].* 1) Bioinformatics and Genomics, Centre for Genomic Regulation (CRG), Barcelona, Barcelona, Spain; 2) Laboratorio de Citogenetica Molecular, Servicio de Patologia, Hospital del Mar, Barcelona, Spain.

Sezary syndrome is one of the most common types of cutaneous T-cell lymphoma and is characterized by extensive red, itchy rashes all over the body. The prevalence of Sezary syndrome is around 0. 3 cases per 100,000 people. The genetic etiology of the disease is poorly understood with chromosomal abnormalities and mutations in some genes shown to be involved in the disease. The goal of our study is to understand the genetic basis of the disease by looking for driver gene mutations and fusion genes in a matched tumor and normal pair of 17 Sezary cases. We have undertaken a whole-exome, RNA and small RNA sequencing approach. We have identified somatic point mutations in genes including *TP53*, *ITPR1*, *DSC1*, *PLCG1*, *CARD11*, *GLI3* and some of these genes are mutated in more than one individual. We have observed several somatic copy number variations including a recurrent deletion on 17p (~15 Mb) in six of our cases. Furthermore, we have discovered several fusion RNAs. Of particular interest are the ones involving *RASA2* and *BCR* genes due to their relevance in a variety of human cancer types. In addition, we see specific profiles of deregulation of microRNAs in our cases. Currently, we are correlating the clinical phenotype of patients with somatic mutation spectrum, fusion RNAs, RNA and microRNA expression profiling to better understand the disease pathogenesis.

2703W

Microfluidic Single Cell Exome-seq and RNA-seq analysis of Tumor Composition. *I. Ragoussis[1], P. Savage[3], C. Batchu[2], Y-C. Wang[1], T. Ravil[1], D. Badescu[1], E. Iacucci[1], L. Letourneau[1], A. Monast[3], N. Bertos[3], A. Omeroglou[4], M. Park[3].* 1) McGill University & Genome Quebec Innovation Centr, McGill University, Montreal, Quebecc, Canada; 2) Fluidigm Corporation,7000 Shoreline Boulevard, Suite #100 South South San Francisco, CA 94080 United States; 3) The Rosalind and Morris Goodman Cancer Research Centre, McGill University, Montreal, Quebec, Canada; 4) Department of Pathology, McGill University, Montreal, Quebec, Canada;.

Human breast tumors have been shown to exhibit extensive inter- and intra-tumor heterogeneity. While recent advances in genomic technologies have allowed us to deconvolute this heterogeneity, few studies have addressed the functional consequences of diversity within tumor populations. Here, we identified an index case for which we have derived a patient-derived xenograft (PDX) as a renewable tissue source to identify subpopulations and perform functional assays. On pathology, the tumor was an invasive ductal carcinoma which was hormone receptor-negative, HER2-positive (IHC 2+, FISH average HER2/CEP17 2. 4), though the FISH signal was noted to be heterogeneous. On gene expression profiling of bulk samples, the primary tumor and PDX were classified as basal-like. We performed single cell RNA and exome sequencing of the PDX to identify population structure. Using a single sample predictor of breast cancer subtype, we have identified single basal-like, HER2-enriched and normal-like cells co-existing within the PDX tumor. Genes differentially expressed between these subpopulations are involved in proliferation and differentiation. Functional studies distinguishing these subpopulations are ongoing. Microfluidic whole genome amplification followed by whole exome capture of 81 singe cells showed high and homogeneous target enrichment with >75% of reads mapping uniquely on target. Variant calling using GATK and Samtools revealed founder mutations in key genes as BRCA1 and TP53, as well as subclonal mutations that are being investigated further. Loss of heterozygocity was observed in 16 TCGA cancer driver genes and novel mutations 7 cancer driver genes. These findings may be important in understanding the functional consequences of intra-tumor heterogeneity with respect to clinically important phenotypes such as invasion, metastasis and drug-resistance.

2704T

***Helicobacter* DNA integrations in the gastric cancer genome.** *K. M. Robinson[1], N. Kumar[1], J. Torres[2], J. C. Dunning Hotopp[1,3,4].* 1) Institute for Genome Sciences, University of Maryland School of Medicine, Baltimore, MD, USA; 2) Unidad de Investigación en Enfermedades Infecciosas, UMAE Pediatría, IMSS, México City, DF, México; 3) Department of Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD, USA; 4) Greenebaum Cancer Center, University of Maryland School of Medicine, Baltimore, MD, USA.

There are 10 times more bacterial cells in the human body than human cells, and various bacteria are known to influence carcinogenesis. *Helicobacter pylori* is considered a carcinogen by the World Health Organization due to its ability to promote carcinogenesis in gastric tissue. While viral DNA integrations in the human genome have been shown to promote carcinogenesis, bacterial DNA integrations (BDI) into the human genome are rarely investigated. Our previous analysis of publicly available sequencing data from the Cancer Genome Atlas showed BDIs from *Pseudomonas* spp. rRNA into proto-oncogenes of gastric cancer samples in the 5'-UTR of four proto-oncogenes as well as in *Ig* (the immunoglobulin gene). However, our inability to obtain the materials required to validate our findings in these samples left us with many unanswered questions. Therefore, we sought to sequence a different cohort of patients in order to identify BDIs in gastric tumors using transcriptome sequencing data with further sequencing and analysis of whole genome and whole exome sequencing for BDI positive samples. Using our previously published BWA-based pipeline, we have identified putative BDIs from *Helicobacter pylori* rRNA into numerous genes in one tumor sample as well as in its adjacent matched sample, including BDIs in the *Ig* locus. Validation of these results is ongoing and will be presented. Following validation, tests examining the carcinogenic potential of these insertions can be conducted. Given these results, more consideration should be given to bacterial DNA integrations into the human genome when bacterial associations with diseases are suspected.

Somatic mutation load and risk of colorectal cancer: NGS-study of a large panel of healthy and diseased individuals. *N. T. Rodchenko[1], M. P. Salomon[1,2], P. Marjoram[2], S. V. Nuzhdin[1].* 1) Molecular and Computational Biology, University of Southern California, Los Angeles, CA; 2) Division of Biostatistics, Department of Preventive Medicine, Los Angeles, CA.

DNA mutations are the source of evolution, but also a hindrance to organism survival. There is selection to reduce the germline mutation rate, that is known to occur at a rate of 10^{-10} to 10^{-8} changes per nucleotide per generation among higher eukaryotes. However, the somatic mutation (SM) rate is under a lesser selection constraint as the soma is disposable. From selection assay experiments it appears that SMs arise one or two orders of magnitude more rapidly than germline variants. Mutations, ranging from single base substitutions to large genome rearrangements, gradually accumulate in cells as the organism ages with an intensity dependent on the cells' exposure to damage, level of mis-functioning of repair genes and the speed of tissue proliferation. There are many outcomes of accumulation of SMs, with age being a major determinant of risk of human cancer and other diseases. A study of a large number of case and control samples from accessible healthy tissues, such as blood, is required to understand whether overall rate of SMs and presence of particular hot spot mutations can be indicative of a higher risk of the disease.

In this work we examined the abundance of single-nucleotide somatic mutations (SNSMs) in blood samples of two large panels: (1) individuals with known colorectal cancer (CRC) diagnosis and (2) healthy subjects (~3700 samples in total). We used targeted genomic sequencing data for regions spanning CRC-associated GWAS peaks (~5. 5 Mbp per sample) and developed a pipeline to call SNSMs in a conservative way using a subset of bi-allelic genomic positions sequenced at a depth of at least 100x. We used available phenotypic data (age, sex, ethnicity and medical records of the individuals) to examine associations between elevated SM rates and phenotypic parameters.

Results show association between the number of SNSM's and age, sex and ethnicity of the individuals, as well as significant differences between colon cancer patients and healthy individuals with respect to proportions of transitions and transversions in coding regions . Follow-up mutation annotation shows the presence of SNSMs that have been found to be functional in this group of cancers in previous studies and that are potential hot spots in the colorectal cancer cohort.

2706T

Enhanced error correction and increased sensitivity in variant calling in FFPE samples with cancer hot spot amplicon panels. *T. Singer, I. Khrebtukova, H. Zhang, A. Barr, L. Way, A. Wong, G. DeSantis, G. P. Schroth.* Genomic Applications, Illumina Inc. , San Diego, CA.

Low frequency variant calling in FFPE DNA is notoriously difficult due to high false positive error rate in those samples. We designed a palette of small amplicon cancer "hot spot" panels to perform targeted amplification of 50 oncogenes and tumor suppressor genes to investigate various error correction methods. The probe panels were designed by modifying the design pipeline of the TruSeq custom amplicon workflow to allow tiling designs of very small overlapping amplicons targeting both strands of DNA. Each panel represents a single tube assay and is comprised of ~300 amplicons with an average size of 110bp, targeting 1,917 Cosmic SNPs. A 100% coverage of target regions was achieved. The panels were designed in "mirror" fashion, to enable interrogation of opposite strands of DNA. In addition, panels were modified to include bar codes or UMIs ("unique molecular identifiers") to enable molecular counting. These amplicon panels are uniquely suited to enable investigation of low frequency somatic variant calling in degraded FFPE samples. We will present data testing various strategies to reduce false positive calls in Illumina dual strand sequencing data. A bioinformatics analysis pipeline was developed to reduce error rate, increase quality scores and enhance low frequency variant calling in next generation sequencing reads. A comparison of dual strand amplicon strategy, the use of replicate FFPE samples and benefits of UMIs will be presented.

2707W

Evaluation of single-molecule real-time long-read sequencing as a rapid-turnaround tool for validation of somatic mutations in cancer genomics. *A. Uzilov, L. Newman, I. Bourzgui, C. Lau, E. E. Schadt, R. P. Sebra, R. Chen.* Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

Background: Next-generation sequencing of tumor DNA is on the rise in research and in clinical diagnostics. Because tumor specimens are heterogeneous, limited, and may have low tumor content, clinical-grade accuracy is a challenge. Efficient validation by an orthogonal platform is needed. **Methods:** We assess targeted single-molecule real-time (SMRT) sequencing on the PacBio RSII platform as a high-coverage, long-read (>1000 nt) method to validate mutations found in lower-coverage, short-read (2x100 nt) whole-exome sequencing (WES) on Illumina HiSeq 2500. Actionable somatic mutation candidates (SNVs and indels) were identified from running WES on tumor/normal genomic DNA from cancer patients as part of a study on clinical actionability of cancer sequencing. Amplicons of size ~500 nt were made that included ~250 nt flanks around each WES-identified mutation. Each circularized amplicon molecule was read several times by a continuous long read; consensus reads were assembled, aligned, and analyzed using PacBio and in-house tools. **Results:** Normal/tumor DNA from five patients were sequenced using SMRT for validation (13 to 27 WES candidates selected per patient). 96-100% of the candidates were validated by SMRT sequencing. For one patient (27 candidates), a primary tumor (frozen, ~50% purity based on WES data) and a metastasis (FFPE, ~10% purity based on WES data) were available. Two mutations called as unique-to-primary from WES were found in the metastasis on SMRT (allelic fractions <2%, mean coverage 1993X of metastatis sample sequencing run), showing the tumors were more similar than would be inferred from WES alone (mean coverage 223X of metastatis sample sequencing run). Allelic fractions from SMRT and WES agreed that metastatic tumor was < 10% pure. Turnaround time per patient from submission of candidates and DNA to sequencing data can be as little as four days, needing 10-50ng of gDNA per candidate. **Conclusions:** SMRT sequencing is an effective method for validation of variants on a clinical timescale, resolving low-purity tumors that would be harder to interrogate with Sanger-based or qPCR assays. This can also be used for personalized, low-cost tracking of tumor genome evolution, e. g. regions identified from WES could be cheaply, rapidly re-sequenced on SMRT in recurrent and metastatic tumors to see how the cancer genome evolves during disease course.

Comprehensive characterization of the cancer genome by integrating targeted DNA and RNA sequencing. *P. Van Hummelen[1,3], R. Abo[1,3], S. Hunter[1,3], L. Lin[1,3], M. Ducar[1,2], A. Thorner[1,3], W. C. Hahn[1,3,4], M. L. Meyerson[1,3,4], E. P. Garcia[2], L. M. Sholl[2], L. E. MacConaill[1,2,3].* 1) Center for Cancer Genome Discovery, Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA; 2) Department of Pathology, Brigham & Women's Hospital, Boston, MA; 3) Department of Medical Oncology, Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA; 4) Broad Institute of MIT and Harvard, Cambridge, MA.

Genome variant analysis (DNA-seq) and transcriptome profiling by sequencing (RNA-seq) provide multiple levels of insight into the cancer genome. These approaches generate endpoints such as somatic mutations, rearrangements, copy number aberrations and expression analysis. Combining DNA and RNA-seq data will add functional confirmation by quantifying the expression level of the genomic variant or its effect on gene expression down stream of its pathway. Furthermore, chimeric transcripts that result from structural rearrangements in the genome can also be corroborated by detection and quantification at the RNA level. This poster will give an overview of our DNA&RNA targeted sequencing platform, including specific tools for rearrangement detection (Breakmer), copy number analysis (RobustCNV) and allele specific expression analysis. Our targeted DNA-seq pipeline has been established and translated to the clinical setting in 2013 as part of PROFILE, a collaboration between Dana-Farber Cancer Institute, Brigham and Women's Hospital and Boston Children's Hospital, to preemptively screen every admitted cancer patient for a targeted genome analysis of the tumor. For RNA-seq we have developed and characterized protocols and analysis procedures and compared three different RNA-seq strategies (whole-transcriptome, exome and targeted RNA-seq) investigating the implications of the choice of strategy on the downstream analysis and results. In addition, we show a proof of principle for verifying DNA variants by RNA-seq, including activating mutations in *EGFR* and loss of function variants in tumor suppressor genes such as *STK11* and *RB1*. Our protocols are made compatible with archival clinical tissues and amenable for clinical sequencing on a large scale.

2709W

Genomic alterations associated with clonal hematopoietic expansion and malignancies inferred in normal human blood samples. *M. Xie[1,2,3], M. Wendl[1,2,4], L. Ding[1,2,3,5].* 1) McDonnell Genome Institute, Washington University, Saint Louis, MO; 2) Department of Medicine, Washington University, Saint Louis, MO; 3) Department of Genetics, Washington University, Saint Louis, MO; 4) Department of Mathematics, Washington University, Saint Louis, MO; 5) Siteman Cancer Center, Washington University, Saint Louis, MO.

Blood cancer formation is a long-term clonal expansion process. It often takes a couple of decades for a patient to develop a clinically detectable tumor that is severe enough to be diagnosed or produce symptoms, so some early mutations are more likely to exist many years in patients who have no apparent disease symptoms. These mutations have the potential to confer advantages in self-renewal or proliferation, resulting in clonal expansion, and causing hematopoietic malignancies by cooperating with subsequent mutations. Therefore, identifying these early mutations and monitoring clonal expansions in normal individuals could facilitate development of prevention strategies to reduce the risk of progression to cancer. Here, we collected whole-exome sequencing data from 6,099 TCGA cancer patients who only have first-time primary cancers and have had no treatment with radiation and/or chemotherapy. To systematically detect the variants in blood samples, we applied three widely used softwares, VarScan (for SNV and indel detection), GATK (for SNV and indel detection), and Pindel (for indel detection). After false-positive filtering and variant allele fraction comparison, we identified 81 recurrently mutated genes with blood-specific somatic truncations that are present in blood sample (variant allele fraction > 10%) but not present or present only at very low levels in either the tumor samples or tumor-adjacent normal samples. As expected, *DNMT3A*, *ASXL1* and *TET2* are the top 3 most recurrently mutated genes. Besides, we also found *KDM6A*, *MLL3*, *PPM1D*, *PTPRN2* are also frequently mutated in normal individuals. To validate the functional impacts of these new identified genes or mutations on clonal hematological expansion, further analysis is still needed. This study will provide a comprehensive profiling of genes and variants that initiate clonal expansion. It will enable to shed light on understanding of mechanism underlying hematological malignances, and facilitate to develop new strategies for early detection and prevention of hematologic cancer.

Frequent alterations in cytoskeleton remodeling genes in primary and metastatic lung adenocarcinomas. *X. Zhao[1], K. Wu[1], X. Zhang[2], F. Li[1], D. Xiao[2], Y. Hou[1], S. Zhu[1], D. Liu[1], X. Ye[1], X. Xu[1], H. Yang[1], K. Kristiansen[4], J. Wang[1], N. Zhong[2], J. Wang[1], Q. Pan-Hammarström[3], J. He[2].* 1) Beijing Genomics Institute (BGI-shenzhen), Shenzhen, Guangdong, China; 2) The First Affiliated Hospital of Guangzhou Medical University, Guangzhou, China; 3) Karolinska Institutet, 14186, Stockholm, Sweden; 4) University of Copenhagen, Copenhagen 1599, Denmark.

Lung adenocarcinoma results in a high mortality globally. The landscape of genetic alterations in tumours derived from Asian patients is however largely uncharacterized. Here we present an integrated genomic and transcriptomic analysis of 244 primary lung adenocarcinomas and 35 corresponding lymph node metastases from Chinese patients, of which 60% were at an advanced disease stage. A total of twelve significantly mutated genes were identified, including two novel mutation targets, *RHPN2* and *GLI3*. *TP53* was the most commonly mutated gene and mutations in this gene were significantly enriched in tumours from patients harbouring metastases. Genes regulating cytoskeleton remodeling processes were frequently altered, especially in metastatic samples, of which the high expression level of IQGAP3 was identified as a marker for poor prognosis. Functional studies further demonstrated that IQGAP3 facilitates tumour cell invasion. Our study represents the first large-scale sequencing effort on lung adenocarcinoma in Asian patients and provides a comprehensive mutational landscape for both primary and metastatic tumors. Our findings thus form a basis for future personalized medical care and may also shed light on the molecular pathogenesis of metastatic lung adenocarcinoma.

Mutation spectra of *BRCA* genes in Iranian women with early onset breast cancer, 15 years experiences. *V. R. Yassaee[1,2], Z. Soltani[1], Z. Ravesh[1], F. Hashemi-Gorgi[1], S. M Poorhosseini[1,2], R. Anbiaee[3], A. Joulaee[4].* 1) Genomic Resreach Center, Shahid Beheshti University of Medical Sciences, Tehran, IRAN; 2) Dept. of Medical Genetics. Faculty of Medicine Shahid Beheshti University of Medical Sciences Tehran, IRAN; 3) Dept. of Radiotherapy & Oncology, Imam Hossein hospital, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran; 4) Dept. of Surgery, Mahdieh, Women's hospital, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Breast cancer is the most common cancer in Iran. In the recent years an upward trend (10%) has been observed in the Iranian population. Early detection by molecular approaches may reduce breast cancer morbidity and mortality. We consulted 3781 women diagnosed with early onset breast cancer during the past 15 years (1999-2014). To establish a data set for *BRCA* gene alterations in at risk Iranian families, two hundred and fifty three women who met the criteria were selected. A total number of 46 alterations including 17 variants with unknown clinical significance (37%), 19 Missense mutations (41%), 8 Indels (17%) and 3 large rearrangement sequences (6%) were identified. Further scanning of affected families revealed that 48% of healthy relatives harbor identical causative mutations. This is the first report of comprehensive *BRCA* analysis in Iranian women with early onset breast cancer. Our findings provide valuable molecular data supporting physicians as well as patients for the best decision making on disease management.

iCAGES: integrated CAncer GEnome Score for comprehensively prioritizing cancer driver genes in personal genomes. *C. Dong[1], H. Yang[1], Z. He[3], X. Liu[2], K. Wang[1].* 1) Keck School of Medicine, University of Southern California, Los Angeles, CA, 90089, USA; 2) Division of Epidemiology, Human Genetics and Environmental Sciences, The University of Texas Health Science Center at Houston, Houston, TX, 77030, USA; 3) Department of Computer Science, New York University, New York, NY 10012, USA.

All cancers arise as a result of the acquisition of somatic mutations that drive the disease progression. Even though a number of computational tools have been developed to identify driver genes for a specific cancer from a group of cancer samples, it remains a challenge to identify driver mutations/genes for an individual patient and design drug therapies. To tackle this challenge, we developed iCAGES (integrated CAncer GEnome Score), a novel statistical framework to rapidly analyze patient-specific cancer genomic data, prioritize personalized cancer driver events and predict personalized therapies. iCAGES includes three consecutive layers: the first layer utilizes machine learning models and integrates contributions from coding, non-coding and structural variations to infer driver variants. The second layer identifies driver genes for different cancer subtypes, using information from the first layer and integrating prior biological knowledge on gene-gene and gene-phenotype networks. The third layer prioritizes personalized drug treatment, by classifying potential driver genes into different categories and querying drug-gene databases. Compared to currently available tools, iCAGES achieves better performance by correctly classifying point coding driver mutations (AUC=0. 97, 95% CI: 0. 97-0. 97, significantly better than the second best tool with P=0. 01) and genes (AUC=0. 93, 95% CI: 0. 93-0. 94, significantly better than MutSigCV with P<1X10-15). We also illustrated two examples where iCAGES correctly nominated two targeted drugs for two advanced cancer patients with exceptional response, based on their somatic mutation profiles. iCAGES leverages personal genomic information and prior biological knowledge, effectively identifies cancer driver genes and predicts treatment strategies. iCAGES is available at http://icages. usc. edu.

Sensitive Mutation Detection By Sequencing Circulating Cell-Free DNA. *N. Fang, R. Tolun, K. Keitz, C. Baron.* QIAGEN, Hilden, Germany.

Circulating DNA, the cell-free DNA (cfDNA) found in serum or plasma, has become a powerful tool in non-invasive prenatal testing (NIPT), as well as in cancer liquid biopsy. In cancer testing, it has been shown that the quantity and integrity, as well as the mutation content of the cfDNA in cancer patients differ from that in healthy controls. Therefore, cfDNA may serve as a biomarker for cancer diagnosis, prognosis, and stratification. High-throughput sequence analysis of the cfDNA using next generation sequencing (NGS) technologies provides a highly sensitive and specific method in detecting and characterizing somatic mutations in cancer samples. However, the cfDNA concentration in serum or plasma is normally very low, which makes sequencing library construction challenging. Here, we describe an optimized library construction protocol that combines high-efficiency adaptor ligation and unbiased library amplification to deliver a sequencing library with high yield and complexity from as little as 1 ng cfDNA. The sequencing library can be used in combination with target enrichment for sensitive and reliable mutation detection in cfDNA samples.

2714T

Low cost, broad panel (100kb) liquid biopsy with reduced DNA sequencing by depletion of wild-type sequence. *A. Marziali[1,2], J. Pel[1], M. Despotovic[1], P. Davies[1], L. Gelinas[1], D. Broemeling[1].* 1) Boreal Genomics, Vancouver, BC, Canada; 2) University of British Columbia, Vancouver, BC, Canada.

The most significant barrier to widespread clinical deployment of a highly sensitive circulating tumor DNA (ctDNA) assay (liquid biopsy) is the high cost of the assay compared to potential reimbursement. Assay cost is currently dominated by the large amount of DNA sequencing required to achieve coverage of a broad gene panel, and by the high read depth required for high clinical sensitivity. The common practice of attaching unique molecular barcodes to ctDNA fragments for the purpose of error reduction further increases the sequencing requirements, making liquid biopsy commercialization in many clinical applications impractical. Since the majority of sequencing reads are wasted re-sequencing wild-type cell free DNA (cfDNA) fragments, a powerful solution to this challenge is to somehow separate mutant cfDNA from wild-type cfDNA so that only relevant tumor molecules are sequenced. Given that in many clinical cases ctDNA represents only 0. 1% – 0. 01% of the total cfDNA, this approach has the potential to reduce required sequencing by 1,000 – 10,000 fold. While we have previously demonstrated such separation for specific mutations, the larger challenge is to achieve this separation and enrichment of ctDNA without any prior knowledge of the mutation site or sequence, and over a broad set of relevant genes. We present a new version of our electrophoretic enrichment technology that can deplete a sample of wild-type genomic DNA prior to sequencing without *a priori* knowledge of the mutation sequence or location, and over large regions of the genome, in the range of 100kb or more. By narrowing the sample to contain primarily mutant ctDNA, both the sequencing cost and false positive sequencing errors are greatly reduced. We present a methodology used to deplete wild-type sequence over large genomic regions, as well as data from clinical samples. The addition of wild-type DNA depletion to NGS assays enables lower cost, high sensitivity, and high specificity liquid biopsy tests to be developed, enabling commercialization in applications with limited reimbursement, potentially including early cancer detection.

Detection of somatic mosaicism in children with suspected DICER 1 syndrome using high sensitivity sequening with molecular tag-containing Haloplex [HS]. *L. de Kock[1,2], Y. C. Wang[3], B. Rivera Polo[1,2], D. Badescu[3], T. Revil[3], E. Weber[4], N. Sabbaghian[2], M. Wu[1,2], C. Sandoval[5], S. M. J. Hopman[6], J. H. M. Merks[6], A. van Hagen[7], D. A. Plager[8], A. Ramasubramanian[8], C. Cher[9], N. Hamel[4], D. Bouron-Dal Soglio[10], J. R. Priest[11], I. Ragoussis[3], W. D. Foulkes[1,2,4,12].* 1) Department of Human Genetics, McGill University, Montréal, Québec H3A 0G4, Canada; 2) Lady Davis Institute, Segal Cancer Centre, Jewish General Hospital, Montréal, Québec H3T 1E2, Canada; 3) McGill University and Genome Quebec Innovation Centre & Department of Human Genetics, McGill University, Montréal, Québec H3A 0G4, Canada; 4) Department of Medical Genetics, Research Institute of the McGill University Health Centre, Montréal, Québec H3H 2R9, Canada; 5) Department of Pediatrics, New York Medical College and Maria Fareri Children's Hospital, Valhalla, New York 10595, USA; 6) Department of Pediatric Oncology, Emma Children's Hospital, Academic Medical Center, 1105 AZ Amsterdam Zuidoost, The Netherlands; 7) Department of Clinical Genetics, VU University Medical Center, 1081 HZ Amsterdam, The Netherlands; 8) Glick Eye Institute, Indiana University School of Medicine, Indianapolis, Indiana 46202, USA; 9) Agilent Technologies; 10) Department of Pathology, CHU-Sainte Justine and University of Montreal, Montréal, Québec H3T 1C4, Canada; 11) Minneapolis, Minnesota 55414, USA; 12) Program in Cancer Genetics, Department of Oncology and Human Genetics, McGill University, Montréal, Québec H2W 1S6, Canada.

DICER1 is a protein critical for the processing of mature microRNAs and germ-line mutations in the *DICER1* gene cause a rare cancer syndrome, the DICER1 Syndrome, or the pleuropulmonary blastoma (PPB) familial tumor and dysplasia syndrome (PPB FTDS). The syndrome is characterized by PPB along with other rare childhood sarcomas and dysplasias. Four children who presented with multiple primary tumors associated with the DICER1 syndrome were each found to carry a specific *DICER1* "hotspot" RNase IIIb mutation in multiple tumor biopsies from different sites. However, the mutations were not detected in the patients' germ-line using conventional technology, leading to the suspicion of somatic mosaicism. We investigated and characterized the suspected mosaic origin of the *DICER1* RNase IIIb mutations by deep sequencing of multiple tissues: Both tumor and normal tissues from the four patients were deep sequenced. An in-house, custom made *DICER1* Fluidigm Access array (which selectively captures all protein coding regions and intron-exon boundaries of *DICER1*) and a novel, commercially unavailable Haloplex array (which captured a 250kb region including *DICER1*) were used prior to next generation sequencing on the Illumina HiSeq at high coverage (>10,000x). Using the molecular tag technology, the relative abundance of the previously-identified mutations was assessed between tumor and non-tumor samples from the respective patients with the aim of confirming or refuting the hypothesis of a mosaic origin. By applying the Haloplex HS to multiple tissues from each patient, we have identified low-frequency mutations (at 0. 24%) and we have been successful in testing somatic tissues. In conclusion, we have confirmed the hypothesis that *DICER1* RNase IIIb mosaicism is the cause of the rare DICER1-associated tumors in these children. The Haloplex HS provided the sensitivity required to generate and analyze deep coverage data and accurately detect rare low-frequency mosaic mutations.

Reconstructing clonal evolutionary process among copy number variants in tumor. *A. Tai[1], W. Hsieh[1], C. Peng[2].* 1) Institute of Statistics, National Tsing Hua University, Hsinchu, Taiwan, R. O. C; 2) Departments of Resource Center for Clinical Research, Chang Gung Memorial Hospital, Taoyuan, Taiwan, R. O. C.

Clonal evolution of cancer is a complex issue and needs to be reconstructed with the following three important parts. The first part is to clearly measure the variants such as single nucleotide variants and structure variants. Subclones can then be identified according to the proportion of presence of those variants. The final step is to restore the order of their emergence with a tree structure. Recently, many studies investigated the cancer-clone evolution by analyzing the sequencing data. They are mostly built on single nucleotide variants with some correction from the copy number effects. The potential evolutionary sequence of copy number variants has not been touched yet. In this study, we propose a method based on Poisson distribution to integrate the above three issues specifically for copy number variants with sequencing data. This method first determines the copy number states by a Poisson mixture model. With the copy number variants detected, the second step is to predict the evolutionary relationship between each pair of copy number variant locus with a likelihood-based approach. The likelihood function is constructed to distinguish the following three potential relations: being present at the same subclone, being present at subclones descended from each other, or being present at subclones with farther/independent relationship. This strategy can cluster the locus into their emerged subclones and at the same time build the evolutionary relationship among subclones. We will demonstrate the accuracy of the relationship assignment through simulations under different scenarios.

2717W

Successful detection of 40 COSMIC hotspot mutations at allelic frequency below 0. 5%. *A. Mongan, R. Chien, D. Brinza, K. Bramlett, F. Hyland.* Thermo Fisher Scientific, South San Francisco, CA.

Research has shown that circulating cell free DNA (ctDNA) is informative of tumor load and tumor evolution in both solid and hematological cancer. Detecting mutations in these ctDNA holds the promise for an accurate and non-invasive approach to assess minimum residual disease as well as treatment response in the future. However, as ctDNA makes up only a small fraction of cell free DNA recovered from the plasma, traditional methods of targeted sequencing often face a poor signal-to-noise ratio that can not be overcome with deep coverage. Here we present a novel research method that is capable of detecting ultra-rare mutations at allelic frequency below 0. 5%. This approach leverages target multiplexing capabilities of the Ion AmpliSeq™ technology with some important modifications to the sample preparation procedures. The new protocol requires as little as 20 ng of input DNA and offers a sample-to-answer turn-around time under 24 hours. To support the analysis of this new approach, we have further developed a novel Bayesian statistics that models the propagation of potential artifacts introduced during amplification and sampling effects during sequencing to differentiate false positives (variants observed in sequencing data that were not present in input DNA) from true mutations that were present at very low levels in the original sample. We successfully applied this new method to detect spike-in mutant DNA in both cell line (Coriel GM23485) and cfDNA samples. Specifically, we demonstrated the detection of 40 COSMIC genomic aberrations found in frequently mutated genes including EGFR, ALK, PIK3CA, KRAS, NRAS, MET, PTEN, KIT, ATM, RB1, TP53 and others. At hotspot locations of 40,000x coverage, the method achieved 90% sensitivity and 100% specificity with no false positive results. In summary, we are reporting, for the first time, a novel research method that is capable of detecting ultra-rare mutations at allelic frequency below 0. 5% using the Ion Torrent™ platform.

2718T

The transcriptional landscape and mutational profile of follicular thyroid neoplasm. *H. Cho[1,4], SK. Yoo[1,6], HG. Jee[2], SJ. Kim[3], S. Lee[1], JY. Shin[1], YJ. Park[1,5], KE. Lee[1,3], JS. Seo[1,4,6].* 1) Genomic Medicine Institute (GMI), Medical Research Center, Seoul National University, Seoul, Korea; 2) Research Institute, National Medical Center, Seoul, Korea; 3) Department of Surgery, Seoul National University Hospital & College of Medicine, Seoul, Korea; 4) Department of Biomedical Sciences, Seoul National University Graduate School, Seoul, Korea; 5) Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea; 6) Interdisciplinary Program in Bioinformatics, Seoul National University, Seoul, Republic of Korea.

Follicular thyroid carcinoma accounts for 10% of the thyroid neoplasm, and similar cytological feature of follicular thyroid carcinoma (FTC) and follicular thyroid adenoma (FA) is huge diagnostic challenge in clinics. We performed RNA sequencing (RNA-seq) for 32 FTC and 19 paired-normal tissues, 25 FA and 18 paired-normal tissues. We then additionally analyzed 82 papillary thyroid carcinoma (PTC), 53 follicular variant papillary thyroid carcinoma (fvPTC). Driver mutations in 83% of follicular thyroid neoplasms (FTN) were discovered, and 41% follicular thyroid neoplasms harbored RAS (KRAS, NRAS, and HRAS) mutations. Furthermore, DICER1 and EIF1AX are second most common drivers, which accounts for 6% of FTN, respectively. Unlike previous reports PAX8-PPARG fusion gene was detected in only one case in FTC (0. 01%) which represents ethnic difference and no other fusion driver was detected. Moreover, chromosome 22q deletion was more recurrent in RAS driven neoplasms (chi-square test p = 2. 701e-41). Principal component analysis of gene expression and three gene expression based on the scoring systems represented all of thyroid neoplasms; they are grouped by BRAF-like, RAS-like regardless of cytological classification. In addition, we discovered some FTNs show up-regulatited TCA cycle and other metabolic pathways. Also they represented oncocytic variant feature (Fisher's exact test p = 6. 214e-08). In the present study, we successfully extended transcriptomic landscape of thyroid neoplasm and figured out dominant role of driving genetic alterations in follicular and papillary thyroid neoplasms.

2719W

Haplotyping and structural variant detection from whole exome sequencing of 1ng of cancer cell line DNA. *K. M. Giorda, M. Schnall-Levin, S. Kyriazopoulou-Panagiotopoulou, G. X. Y. Zheng, P. Marks, P. Mudivarti, H. Ordonez.* 10X Genomics, Pleasanton, CA.

Structural changes, and particularly gene fusions, are known driving mutations in many cancers. In many cases they have also proven to be effective drug targets. However, sample input mass is often limited (<50 ng) and detecting fusions is a challenge with existing short-read sequencing technologies, particularly when using exon target enrichment approaches to achieve the ultra-deep coverage required to sensitively detect important mutations in heterogeneous cancer samples. The new GemCode system was used to obtain high-depth whole exome sequencing data from 1ng of cancer cell line DNA. The GemCode Platform massively partitions and barcodes DNA, producing sequencing-ready libraries with >100,000 specific barcodes. Custom algorithms use this barcode information to map reads back to original long molecules of DNA, creating Linked-Reads that span many 10's to 100s of kilobases. Since GemCode barcodes are incorporated during library construction, targeted whole exome libraries retain long-range information used for haplotype phasing and structural variant detection including gene fusions. Haplotype phasing of GemCode whole exome samples produced N50 phase blocks >125 kb, with more than 95% of genes shorter than 100kb fully phased. Variant calling from duplicate removed high depth sequencing (≥160X) starting from 1ng input achieved sensitivity and precision comparable to ligation-based libraries using 200ng of DNA. Linked-Read information was used to detect structural variants in cancer cell lines. We detected EML4/ALK and ALK/PTPN3 fusions in the lung cancer cell line NCI-H2228, an NPM1/ALK fusion in the lymphoma cell line SU-DHL-1 and SLC26A/PRKAR2A fusion in the triple negative breast cancer cell line HCC38. Furthermore a complex genome rearrangement known as chromoplexy was uncovered in the VCaP prostate cancer cell line. The closed quartet chromosome-shuffling event includes TMPRSS2/ERG fusion that is found in half of prostate cancers. In summary, comprehensive tumor profiling includes phasing and structural variant detection from precious samples. We employed the 10X Genomics platform to generate highly complex libraries for gene phasing and fusion detection while simultaneously following intricate chromosome rearrangements including chromoplexy from just 1ng of DNA.

2720T

The Genomic Landscape of Allelic Imbalance in the Normal-Appearing Airway Field of Cancerization. *H. Kadara[1], Y. A. Jakubek[1], W. Lang[1], S. Vattathil[1], M. Garcia[1], L. Huang[1], W. Lu[1], C. Chow[1], Z. Weber[2], G. E. Davies[1], C. Behrens[1], N. Kalhor[1], C. Moran[1], J. Fujimoto[1], R. J. Mehran[1], J. Fowler[1], E. A. Ehli[2], I. I. Wistuba[1], P. Scheet[1].* 1) MD Anderson Cancer Center, Houston, TX; 2) Avera Inst. For Human Genetics, Sioux Falls, SD.

The phenomenon of field cancerization has been observed in various cancers, including those of the lung. We have recently demonstrated that "normal" airway cells carry expression profiles that are often characteristic of the adjacent tumor. A better understanding of mechanisms driving these field changes may provide important biological insights into lung tumorigenesis. Loss-of-heterozygosity (LOH) and other forms of acquired chromosomal alterations (allelic imbalance; AI) have an established role in oncogenesis. However, the relationship between AI and field cancerization has not been studied comprehensively across the genome. Here we address this void by interrogating a rich collection of normal airways from non-small cell lung cancer (NSCLC) patients. We applied Illumina 1M SNP arrays to characterize whole genome copy number alterations in 435 samples from 45 early-stage NSCLC patients [31 adenocarcinomas (ADCs), 14 squamous cell carcinomas (SCCs)]. Each patient set comprised samples from the primary tumor and adjacent airways paired with blood cells and/or uninvolved normal lung tissue. A subset of these included brushings from large mainstem bronchi and from the nasal cavities as well as multi-region tumor biopsies for intra-tumoral analysis. To characterize the field in airways at a genome-wide scale, we applied a haplotype-based computational program, hapLOH, to profile AI events (loss, gain, copy neutral LOH) in a paired mode contrasting signals in the blood or normal lung. We detected 247 AI events in airways of 21 of 45 patients. Of the 21 patients, 19 had events in the adjacent airway, 3 had events in the large airway, and no events were observed in nasal brushings, indicating a pronounced AI field gradient. We detected AI in the airways of ~30% of ADCs regardless of smoking status (2 of 7 non-smokers, 8 of 24 smokers), and 79% (11 of 14) of SCCs, clearly indicating squamous histology as a greater predictor of genomic field effects ($P < 0.01$). The most frequently observed airway alterations were in 9p and 9q, affecting 13 smoker patients. Finally, we note that AI events were present in the airways of 4/5 (80%) of patients with recurrence and only in 17/40 (43%) patients without recurrence, signaling a prognostic value in studying the field in NSCLC. Although preliminary, our findings suggest that chromosomal aberrations are common in the airway field of cancerization and can provide insights into the biology of lung cancer pathogenesis.

2721W

Towards understanding the genomic architecture of cancer genomes. *E. T. Lam[1], A. Hastie[1], M. Imielinski[2], C. Zhong Zhang[2], J. Wala[2], Z. Džakula[1], H. Cao[1].* 1) BioNano Genomics, Inc. , San Diego, CA; 2) Broad Institute of Harvard and MIT, Center for Biomedical Informatics, Cambridge, MA.

Understanding the genetic architecture of cancer requires whole-genome and integrative approaches. Cancers often feature genomic alterations that range from single-base changes to large-scale structural rearrangements. Having a complete catalogue of mutations in cancer is crucial for identifying key drivers and providing accurate diagnosis, prognosis, and targeted therapy. Next-generation sequencing (NGS) platforms have limited power to decipher large, complex rearrangements frequently observed in cancer. Genome mapping represents a complementary technology that provides critical long-range structural information. It involves high-throughput analysis of single molecules spanning hundreds of kilobases in NanoChannels. Long-range information is preserved and direct interrogation of complex structural variants made possible. Therefore, leveraging the strengths of these complementary platforms would give a comprehensive view of a cancer genome. Here, we present our analysis of well-studied cell lines as well as fresh patient tumor samples (multiple myeloma and prostate cancer). We constructed complete *de novo* genome map assemblies with N50 lengths of more than 1 Mb. We derived multi-sample normalized copy number profiles of matched tumor-control pairs based on genome mapping data. We observed that tumor samples had highly variable copy number profiles, corresponding to focal and chromosome-scale changes. Copy number breakpoints were shown indicative of translocation events. We also present a pipeline to integrate NGS and genome mapping data to validate and refine translocation calls. Genome mapping data helped bridge and phase neighboring translocation events. Finally, we present a computational approach to identify translocations by clustering single molecules with abnormal alignment to the reference and by performing local assemblies of these molecules. Overall, integrating NGS and genome mapping data provides a comprehensive view of a cancer genome.

Direct Structural Variation Analysis of FFPE Samples Using Long Mate Pair NGS Libraries. *D. Mead[1], D. Smith[2], S. Monsma[1], M. Lodes[1].* 1) Lucigen, Middleton, WI; 2) Mayo Clinic, Rochester, MN.

The vast majority of cancer biopsy samples are routinely formalin fixed and embedded in paraffin (FFPE) in order to preserve the morphological features of suspected tumor samples. While FFPE samples are valuable for archiving histological data, the formalin treatment is detrimental to nucleic acids, resulting in fragmentation, oxidation, deamination, and protein-DNA crosslinks. Although methods for PCR amplification and exome capture from FFPE samples have been successfully developed and validated, little long-span information is available to aid the study of structural variation (SV) in cancer samples. SV analysis would benefit greatly from construction of mate pair libraries from FFPE samples, but such studies have not been described, and this capability has been declared unachievable. In spite of these challenges, we have developed methods to construct mate pair libraries from genomic DNA extracted from FFPE samples. The purpose of this study is to measure the efficiency of coverage and ability to uncover SV from FFPE samples using a new NGS tool for direct mate pair library construction and analysis. Results from normal and cancer samples indicate feasibility of 2-3 kb mate pair libraries, for example a library constructed from FFPE prostate tissue exhibited a mean mate pair distance of 1,690 +/- 720 bp, and a library constructed from FFPE kidney exhibited a mate pair distance of 2,068 +/- 840 bp. The ability to query these samples for structural variations could unleash a new era in cancer diagnostics and enable detection of.

2723W

Genomic alterations profile in triple negative breast tumors with loss of BRCA1 nuclear expression. *T. Tapia[1], A. Aravena[2], C. Alvarez[1], V. Cornejo[4], W. Fernández[4], M. Camus[5], A. Maass[2,3], P. Carvallo[1].* 1) Departamento de Biologia Celular y Molecular, Pontificia Universidad Catolica de Chile, Santiago, Santiago, Chile; 2) Centro de Modelamiento Matemático, Universidad de Chile, Santiago, Chile; 3) Departamento de Ingeniería, Universidad de Chile, Santiago, Chile; 4) Unidad de Anatomía Patológica, Hospital San Borja Arriarán, Santiago, Chile; 5) Centro de Cáncer, Pontificia Universidad Católica de Chile, Santiago, Chile.

Triple-negative breast cancer (TNBC), defined by the absence of expression of estrogen and progesterone receptors and epidermal growth factor receptor 2 (HER2), represent an aggressive group of tumors lacking directed therapy. TNBC tumors are frequently observed in women carrying a germline mutation in the *BRCA1* and in approximately 30% of non-carrier women with loss of expression of BRCA1 in tumors, suggesting that loss of function of BRCA1 could be relevant in TNBC tumor development and/or progression. A knowledge of the genes involved in this type of cancer may have relevance for treatment. Also, identifying regions affected by copy number alterations may help to detect genes in molecular or signaling pathways that could be potential treatment targets. We studied 48 TNBC by immunohistochemistry for cytokeratins 5 and 14, EGFR and BRCA1. Using array-CGH we characterized common gains and losses between tumors. Analysis of BRCA1 by immunohistochemistry revealed different patterns of expression and localization of this protein in TNBC tumors. We identified 31% of tumors with absent or reduced nuclear expression of BRCA1. This group was mainly comprised of TNBC/Basal-like tumors. Considering all TNBC tumors, array-CGH analysis revealed common gains (5q15. 33, 20q13. 33, 21q22. 3) and losses (6p11. 2, 9q33. 1, 11q22. 3). Clustering of TNBC tumors separated two main groups, one of which correlates with the mislocalization of BRCA1. Moreover, we found copy number alterations significantly different among subgroups of tumors with different expression/localization of BRCA1. These results suggest that loss of BRCA1 expression or its mislocalization is relevant for tumor progression. Analysis of the genes contained in these regions revealed specific biological processes and signaling pathways. Specifically, in TNBC/Basal-like tumors with absent/low nuclear expression of BRCA1 we identified genes related to epithelial cell differentiation and RAS protein transduction, suggesting that this signaling pathways may be relevant in the progression of BRCA1 deficient tumors. Our results suggest that TNBC/Basal-like tumors with loss of BRCA1 nuclear expression may be selected for personalized treatment with PARP inhibitors and DNA-damaging agents such as platinum. Identifying somatic copy number alterations for cervical cancer in the Latino population. *C. Xu[1], A Joseph[1], J Ordonez[2], L Palmer[3], C Camarillo[2], A Torabi[5].* 1) Department of Pediatrics, Texas Tech University Health Sciences Center, El Paso, TX; 2) Departments of Biomedical Sciences, Paul L. Foster School of Medicine, Texas Tech University Health Science Center, El Paso, TX, USA; 3) University of Texas at El Paso, TX, USA; 4) Departments of Medical Education, Paul L. Foster School of Medicine, Texas Tech University Health Science Center, El Paso, TX, USA; 5) Departments of Pathology, Paul L. Foster School of Medicine, Texas Tech University Health Science Center, El Paso, TX, USA.

Cervical cancer affects millions of Americans. The rate for the Latino population is approximately twice that for non-Latinas. However, the etiologies of cervical cancer are still not fully understood. Recent advances in genome studies have led to the discovery of one important type of variation, copy number alterations (CNAs), with high throughput technology. A number of somatic mutations, including TP53, PIK3CA, PTEN, STK11 and KRAS and several CNAs in the pathogenesis of cervical carcinomas were suggested in the non-Latino populations. Therefore, to identify somatic mutation events in the Latino population, we conducted a pilot study of genome wide copy number alteration analysis using 2. 5 million markers in four diagnostic groups: healthy normal tissue (N=2), low grade dysplasia (N=4), high grade dysplasia (N=5), and invasive carcinoma (SCC, N=5). The source of the DNA was derived from these tissues and CNA was detected with used Illumina HumanOmni2. 5-8 BeadChip Kit follow by statistical and bioinformatics analyses using the PennCNV and cnvPetition since the use of multiple algorithms has been shown to increase the reliability of observations with different degrees of confidence. A total of 83 CANs (8. 4% insertions and 91. 5% deletions) over 100 kb was identified in only low grade dysplasia, high grade dysplasia and SCC. Recurrent CNAs included 1q21. 2 (2 SCC, 592 – 330 kb deletions), 3p21. 31 (3 high grade dysplasia, 3 SCC where RBM6, tumor suppressor gene located, 219-3379 kb deletions), 17q21. 2 (2 low grade dysplasia, >1215 kb deletions, where BRCA1, tumor suppressor gene located), 19p13. 2 (high grade dysplasia, SCC, >650 kb deletions), and 9q34. 12 (high grade dysplasia and SCC, ~ 242 kb deletion and insertion, where ABL1, oncogene located). Moreover, difference sizes of deletions were also discovered in 16p13. 3 (5 SCC and 4 high grade dysplasia) close to the location of CREBBP, tumor suppressor gene. This is first report of CNAs identified as known (tumor suppressor or oncogene) and as novel loci for cervical cancer in the Latino population. We are aware of the major limitation of the study, a small sample size. Thus, currently we are confirming the findings with more sample and analyzing our data using public available data of normal tissue (N=40) as references. However, additional studies with a large sample are needed to confirm the current findings.

2725W

Racial differences in molecular cytogenetic abnormalities in consecutive black and white patients with multiple myeloma. *Y. S. Zou[1, 4], Y. Huang[2], Z. Feng[2], S. Chan[3], I. Lee[4], Z. Singh[4], M. R. Baer[5], A. Z. Badros[5].* 1) Clinical Cytogenetics Lab, University of Maryland School of Medicine, Baltimore, MD; 2) Department of Mathematics and Statistics, University of Maryland, Baltimore County, MD; 3) Department of Human Genetics and Genomic Medicine; 4) Department of Pathology; 5) Department of Medicine and Greenebaum Cancer Center, University of Maryland School of Medicine, Baltimore, MD.

Background:Multiple myeloma (MM) is a clonal plasma cell malignancy with disparities in prevalence and incidence betweenblacks andwhites. Although a few studies have reported differences in molecular cytogenetic abnormalities betweenblacks and whiteswith MM, no study has been performed inconsecutiveblack and white patients with MM, which can avoid the bias from differences due to chromosome culture conditions, fluorescence*in situ* hybridization (FISH) methods/probes used in different centers, etc. We sought to define the prevalence of cytogenomic alterations in consecutive patients with MM using integration of chromosome and interphase FISH in CD138-positive cells. **Methods**:-Consecutive patients seen at the University of Maryland Greenebaum Cancer Centerwere diagnosed with MM by clinical and hematopathology criteria. Routine chromosome analyses andFISH were performed. CD138 cells were isolated from bone marrow samples and analyzed by FISH for eight cytogenetic subtypes (monosomy 13/del(13q), monosomy 17/del(17p), gain of 1q, t(11;14), t(4;14), t(14;16), IGH rearrangements, and other abnormalities by FISH). IGH rearrangements included t(11;14), t(4;14), t(14;16) and other IGH rearrangements. **Results**:From July 2013 to January 2015, 180 consecutive patients with MM were studied, of whom 85 were the black (mean age = 58. 3) and 95 were the white (mean age = 62. 2). White patients were older than black patients (p=0. 007) and included a higher proportion of males (p=0. 01). With regard to racialdifferencesin molecular cytogenetic abnormalities, black patients had significantly lower frequencies of -17/17p- (7. 1% versus 20. 4%; p=0. 01) and -13/13q- (28. 6% versus 43. 0%; p=0. 047) than whites. Black patients also had a trend toward lower frequencies of IGH rearrangements, t(14;16) and abnormal karyotypes than white patients (0. 05<p<0. 10). Within age groups of < 60 and ≥ 60 years, black patients had significantly lower frequencies of the -17/17p- abnormality than whites (p=0. 0037), and had lower frequencies in abnormalities of -13/13q- and IGH than white patients (0. 05<p<0. 06). Within race groups, younger patients showed significantly higher frequencies of the -17/17p- abnormality than older patients (p=0. 02). **Conclusions**:To the best of ourknowledge, this is the first molecular cytogenetic study of consecutive black and white patients with MM. This study showed significant differences in cytogenomic profiles between black and white patients with MM.

2726T

Genetic Hotspots of Glioma Progression by Array CGH: A Systematic Review. *C. J. DeGraffenreid, T. Dickyi, B. Vo, S. Romee, J. Gu, V. Hopwood, M. Zhao.* Cytogenetics, University of Texas MD Anderson Cancer Center School of Health Professions, Houston, TX.

Glioma is a common form of primary brain tumor that arises from the three principle types of glial cells and is categorized into low grade (grade I and II) and high grade (grade III and IV). The use of whole genome array and sequencing technology has revealed that chromosomal copy number variations (CNVs) are commonly seen in glioma, and increase in frequency with tumor progression. Survival is very poor once glioma has progressed to high-grade form, and therefore it is important to establish which copy number aberrations harbor genes that lead to glioma tumor progression. The purpose of this study was to determine which chromosome segments show significantly increased chromosomal copy number variations in the progression from low to high-grade glioma. We hypothesized that chromosomal regions that contain cell cycle regulator genes would show significantly increased aberrations between low and high grade glioma tumors, including chromosome 7p (*EGFR* gene), 9p (*p16* gene), 10q (*PTEN* gene), and 17p (*p53* gene). A systematic review was performed by searching PubMed, Scopus, and Cinahl using keywords glioma, array CGH, sequencing, and whole genome. Data involving CNV in glioma found using array and sequencing technology of the whole genome was extracted. Our result showed significant increases in copy number variation between low and high-grade glioma. Chromosomes showing an increase in aberration gain frequency include 1q (39% increase), 7p(17%), 9p(12%), and 10q(15%) and those showing an increase in aberration loss frequency include 9p(30%), 10q(18%), 17p(26%), 17q(13%), and 22q(10%). Increased gains and losses of chromosome segments in high-grade glioma was found to be consistent with our hypothesis, as those regions where cell cycle regulator genes are located were increasingly gained or lost in high grade glioma as compared to low grade. Other regions found to show increased aberration possibly contain other mutated genes involved in tumor grade advancement. More research is needed to identify the specific genes on the regions showing aberration that could be affecting tumor growth and progression.

Hepatitis C Virus and Schistosomiasis as A Causative Factor for hTERT Amplification in Hepatocellular Carcinoma. *O. M. Eid, N. A. Helmy, W. Ezzat, I. Fadel, M. M. Eid.* National Research Centre - Egypt, Giza, Egypt.

Background Telomere abnormalities appear to play a role in carcinogenesis. hTERT is the catalytic component of the telomerase complex. It is regulates telomerase activity in cancers such as hepatocellular carcinoma (HCC). Amplification of the hTERT gene have been detected in about 21% of HCC. HCC occurs frequently in patients with chronic viral hepatitis or liver cirrhosis. Hepatitis B virus (HBV) or hepatitis C virus (HCV) induce HCC. The schistosomal parasite plays a role in the development of HCC through modify the course of hepatitis C accelerating progression to hepatitis C-associated fibrosis and thus quicker progression to HCC. **Objectives and methods**Evaluation of hTERT amplification in HCC in association with HCV and schistosomiasis. Fifteen surgically resected HCC (Grade two) and fourteen cirrhotic resected liver were examined using FISH technique. **Results** Amplification of hTERT gene were found in 80% (21/15) of HCC which is much higher than the previously reported data. Eight samples were HCV and schistosomiasis positive, 4 were HCV positive, 2 were schistosomiasis positive and one was HCV and schistosomiasis negative. Amplification of the hTERT gene was not observed in cirrhotic tissues except two cases which is probably due to extension of adjacent HCC. **Conclusions**From our results, the coexistence of HCV and/or schistosomiasis with hTERT amplification, we can conclude that the HCV and schistosomiasis may play an important role in upregulation of this gene. Consequently, this may lead to the development of HCC rather than just a marker for cancer development. However this conclusion might need further investigation.

2728T

Translocation t(5;16)(q32;p13) and trisomy 8 in a patient with Acute Eosinophilic Myelomonocytic Leukemia. *X. Montenegro[1], R. Céspedes[2], Y. Llimpe[1,3], A. Arias[1].* 1) Equipo Funcional de Genética y Biología Molecular, Instituto Nacional de Enfermedades Neoplásicas, Lima, Perú; 2) Universidad Nacional Federico Villarreal (UNFV), Facultad de Ciencias Naturales y Matemáticas. Lima-Perú; 3) Universidad Nacional Mayor de San Marcos (UNMSM), Facultad de Medicina. Lima-Perú.

Acute eosinophilic myelomonocytic leukemia (AML-M4Eo) is considered an entity with unique cytogenetic, morphologic and prognostic qualities. AML-M4Eo presents at a young median age, with organomegaly and high peripheral white blood cell count, and usually has a good response to chemoterapy although relapses in central nervous system are common. Bone marrow morphology is characterized by blast cells, monocytic cells and eosinophills showing positivity for chloroacetate esterase (CAE) and peroxidase. AML-M4Eo is frequently associated with inv(16)(p13q22) or the variant t(16;16) which involves the genes: *CBFB* at 16q22, that codes for beta subunit of a heterodimeric core-binding transcription factor belonging to the PEBP2/CBF transcription factor family (CBFb) and the gene *MYH11* at 16p13 that codes for smooth muscle myosin belonging to the myosin heavy chain family (SMMHC), generating a chimeric protein CBFβ-SMMHC, that blocks myeloid cell differentiation. We report the case of a one year old female patient, that presented with pallor skin, fever, hepatosplenomegaly and lymphadenopathy. A Peripheral blood study showed hemoglobin 10,1 g/dL, leukocytes 15,7x109/L, lymphocytes 20%, monocytes 17%, neutrophils 13%, blasts 50% and platelets 48x109/L. Bone marrow aspirate was hypercellular and heterogeneous with 23% of blasts, Neutrophils and their precursors, monocytes and their precursors each comprise more than 20% of bone marrow cells. The eosinophils count was elevated (10%) and showed prominent basophilic-staining granules. Bone marrow cytochemical studies revealed CAE and peroxidase positive. Flow cytometry demonstrated mature monocytes positive for CD14, CD64, CD4; polyclonal lymphocytes T CD/CD8 ratio of 1,18 and inmature non granular myeloid population (9,39%) positive for CD45, CD34, CD13, CD33, CD15, HLA, DR, CD117, MPO, CD71, CD19. Bone marrow cytogenetics revealed 47,XX,t(5;16)(q32;p13),+8. She was diagnosed with AML-M4Eo and received chemotherapy treatment but died ten months after diagnosis. The translocation t(5;16)(q32;p13) is not very common. It affects the genes *PDGFRB* on chromosome 5 and *NDE1* at chromosome 16. It is important to note that the genes *MYH11* and *NDE1* overlap and are transcribed in opposite ways, therefore *NDE1* is altered in more than 90% of cases with inv(16)(p13q22). In our case, t(5;16) is present with trisomy 8 in the same clone, even though t(5;16)(q32;p13) may be a variant from t(16;16), the prognosis is uncertain.

2729W

Sensitive cancer fusion detection and discovery in FFPE samples by RNA-Seq. *L. C. Watson, S. M. Gross, A. M. Mai, F. Schlesinger, I. Khrebtukova, G. DeSantis, G. P. Schroth.* 5200 Illumina Way, San Diego, CA 92122.

Gene fusion detection in cancer samples can provide tumor-specific information for cancer research, clinical diagnosis and targeted treatment. Common fusion detection methods such as qPCR and FISH are restricted to known fusion junctions and limited in the number of genes that can be detected in parallel. In contrast, RNA sequencing is a powerful approach for simultaneous discovery of all possible fusion junctions in a single reaction. But, the sequencing depth required for sensitive detection of fusions from whole-transcriptome libraries can be cost-prohibitive. Here we describe a cancer-specific capture-based approach for fusion detection by RNA sequencing that requires only a fraction of the sequencing depth of whole-transcriptome methods. We designed oligo probes that densely target coding regions of over 200 clinically relevant gene fusions and cancer-associated genes. This oligo panel was used to capture cancer-specific fusions from total RNA-Seq libraries. We used commonly studied cancer cell lines including MCF-7, K562, PC-3, LnCAP, A431 and Universal Human Reference RNA (UHRR) to compare the sensitivity of fusion detection across three RNA-Seq library prep methods: (1) cancer panel library capture (2) whole-transcriptome library capture and (3) PolyA selection. We show that probes targeting individual exons can robustly capture well-characterized cancer gene fusions such as *BCR-ABL* and *BCAS4-BCAS3,* as well as translocations where fusion junctions are unknown. Furthermore, these comparisons demonstrate the enhanced sequencing efficiency of the targeted cancer panel, while maintaining highly accurate quantitation of gene expression. We show that selective enrichment of RNA-Seq libraries with cancer-specific capture probes enables high-resolution mapping of genomic rearrangements in patient cancer samples, even those derived from FFPE, facilitating sequencing studies that were not previously possible.

2730T

A complex variant of t(7;12) with loss of RB1 locus in a case of Acute Erythroblastic Leukemia. *A. Yenamandra, A. Hollis, T. Leftwich, D. Head.* Pathology, Microbiology and Immunology, Vanderbilt University Medical Center, Nashville, TN.

Recurrent and cryptic rearrangements of t(7;12) involving the ETV6 locus at chromosome 12p13 have been identified in children of age two years or younger with various types of leukemia. Heterogeneityin the breakpoints of chromosome 7 ranging from 7q32 to 7q36 have been reported in myeloid disorders. We report here a case of Acute Erythroblastic Leukemia with a variant translocation involving three chromosomes, t(5;12;7), with additional loss of the RB1 locus on 13q. Sequential cytogenetics and metaphase FISH were performed to identify the partner chromosomes with the ETV6 locus rearrangement. A two- year old male with fatigue, bruising, petechiae and fever presented for evaluation of normocytic anemia and thrombocytopenia in February, 2014. His initial bone marrow (BM) biopsy was packed, with a predominance of erythroids and a large percentage of immature forms. Flow cytometry was positive for CD33, CD7, CD36 and CD71, consistent with erythroid differentiation of immature cells. The diagnosis was FLT3-, NPM1-, and KIT17 D816V- AML. Cytogenetics revealed seventeen of the twenty cells analyzed had 46,XY,t(5;12;7)(p15. 1;p13;q32),del(13)(q12q14)[17]/46,XY[3], with deletion at 5p15. 1 and 12p13 of der(5) and der(12) respectively, along with a deletion of 13q12q14 involving the RB1 locus. The patient entered remission with induction chemotherapy, received consolidation chemotherapy, and at most recent follow up 16 months after initial diagnosis bone marrow studies were negative for leukemia by morphology and cytogenetics. The variant translocation described here has not been previously reported. The putative disrupted gene in this translocation at 7q32 is unknown, but this breakpoint appears to have a better prognosis than translocations involving the 7q36 locus, as most patients with the 7q36 breakpoint have had a poor outcome. In summary, we present a case with a novel rearrangement involving the important hematopoietic regulatory gene ETV6 in a case of pediatric primary AML. References:

Transformation of 5q- Syndrome to Chronic Myelogenous Leukemia with a Novel Complex BCR/ABL1 Translocation with Rapid Transformation to Acute Myelogenous Leukemia: An Update. *A. Zaslav[1], B. Burke[1], M. Schuster[2], S. Itwaru[2], B. Jalilizeinali[2], T. Mercado[1], E. Knorr[1], D. Tully[1], T. Ahmed[1].* 1) Pathology - Cytogenetics Lab, Stony Brook Medicine - SUNY Stony Brook, Stony Brook, NY; 2) Medicine, Stony Brook Medicine-SUNY Stony Brook, Stony Brook, N. Y.

We report a case of a 72 year old female who initially presented in August, 2010 with Myelodysplastic Syndrome (MDS). G-banded chromosome analysis of bone marrow (BM) revealed a deletion of part of the long arm of chromosome 5 (i. e. del(5)(q12q33), in 11/20 metaphase cells confirmed by FISH. A diagnosis of MDS with isolated 5q deletion was made. In June 2014 she was found to have increased blasts on BM. Cytogenetic and FISH analysis of BM revealed the del(5q) in 1. 5% of nuclei, and a complex BCR/ABL1 translocation [i. e. , 45,XX,t(9;15;22)(q34;p10;q11. 2),-22] in 20/20 metaphase cells and in 10/10 metaphase FISH. In July 2014 G-banding and FISH evaluation of unstimulated blood (UB) revealed the presence of blasts, the complex translocation and clonal evolution. An additional der(15)t(9;15;22)(q34;p10;q11. 2) in 5/20 metaphases was observed. The del(5) was not present in this analysis. In November of 2014 BM the revealed the same clones as July 2014 and the del(5) in metaphase (5%) and FISH (0. 5%) analyses. In April 2015 UB nuclear FISH revealed the del(5) (0. 5%) and a variant BCR/ABL1 translocation in 3% and three copies of ABL1 in 16% of the nuclei. All FISH studies were performed using the LSI5q EGR1/D5S23 (5q31,5p15. 2) and the LSI BCR/ABL DC DF (9q34,22q11. 2) (Abbott, Des Plaines, IL) probes on nuclei and/or metaphase spreads. Molecular testing demonstrated a p210 BCR/ABL1 transcript. Flow cytometry revealed 18% blasts. These results indicated that the patients' MDS transformed to chronic myelogenous leukemia (CML) with rapid transformation into acute myelogenous leukemia (AML). The patient was placed on the tyrosine kinase inhibitor Tasigna and was in stable condition. However, as clonal evolution occurred, she is being readied for transplant. Transformation from MDS to CML has rarely been reported. To our knowledge transformation with this complex translocation has never been described. This case illustrated the importance of careful monitoring to definitively determine the nature of this disease and course of patient treatment.

2732T

Multi-omics analysis defines core genomic alterations in pheochromocytomas and paragangliomas. *N. Burnichon[1,2,3], LJ. Castro-Vega[1,2], E. Letouze[4], A. Buffet[1,2,3], PF. Plouin[1,2,5,8], J. Bertherat[2,6,7,8], L. Amar[1,2,5], A. De Reynies[4], J. Favier[1,2], AP. Gimenez-Roqueplo[1,2,3,8].* 1) INSERM, UMR970, Paris-Cardiovascular Research Center, PARIS, France; 2) Paris Descartes University, Sorbonne Paris Cité, Faculté de Médecine, PARIS, France; 3) Department of Genetics, Assistance Publique-Hôpitaux de Paris, Hôpital Européen Georges Pompidou, PARIS, France; 4) Programme Cartes d'Identité des Tumeurs, Ligue Nationale Contre Le Cancer, PARIS, France; 5) Hypertension Unit, Assistance Publique-Hôpitaux de Paris, Hôpital Européen Georges Pompidou, PARIS, France; 6) INSERM, U1016, Institut Cochin, PARIS, France; 7) Department of Endocrinology, Assistance Publique-Hôpitaux de Paris, Hôpital Cochin, PARIS, France; 8) Rare Adrenal Cancer Network COMETE, PARIS, France.

Pheochromocytomas and paragangliomas (PCCs/PGLs) are rare neural crest tumors derived from chromaffin cells in adrenal medulla or extra-adrenal sympathetic paraganglia, respectively. PCCs/PGLs are characterized by a remarkable genetic heterogeneity with at least 12 identified susceptibility genes comprising two oncogenes (*RET* and *HIF2A*) and ten tumor suppressor genes (*NF1, VHL, SDHA, SDHB, SDHC, SDHD, SDHAF2, FH, TMEM127* and *MAX*). PCCs/PGLs present a high degree of heritability with up to 40% of affected patients carrying a germline mutation in one of these genes. Moreover, loss-of-function mutations in *NF1* and *VHL*, as well as activating mutations in *RET, HIF2A* and *HRAS,* have been reported at the somatic level in about 30% of these tumors. Here we report the first integrated genomic examination of a collection of 202 PCC/PGL. Whole-exome sequencing, single-nucleotide polymorphism (SNP) array, as well as mRNA, miRNA and DNA methylation profiling were performed aiming to characterize the major genomic alterations underlying PCCs/PGLs. SNP array analysis reveals distinct copy-number patterns associated with genetic background. Whole-exome sequencing shows a low mutation rate of 0. 3 mutations per megabase, with few recurrent somatic mutations in common cancer genes not previously specifically associated with PCC/PGL including *TP53*, *CDKN2A* and *MET*. DNA methylation arrays and miRNA sequencing identify DNA methylation changes and miRNA expression clusters strongly associated with messenger RNA expression profiling. Overexpression of the miRNA cluster 182/96/183 is specific in *SDHB*-mutated tumors and induces malignant traits, whereas silencing of the imprinted DLK1-MEG3 miRNA cluster appears as a potential driver in a subgroup of sporadic tumors. Altogether, the complete genomic landscape of PCC/PGL is mainly driven by distinct germline and/or somatic mutations in susceptibility genes and reveals different molecular entities, characterized by a set of unique genomic alterations. In the near future, omics-based tests should be developed to offer access to a precise molecular classification of PCCs/PGLs. The knowledge of specific genomic alterations should guide the choice of targeted therapy for malignant cases. Therefore, our findings pave the way towards omics-based clinical management and personalized medicine for patients with PCCs/PGLs.

Leukemia is an hematological malignancy characterized by an high etiologic, risk and response heterogeneity among subsets of patients. To improve the diagnosis and prognosis it's thus crucial to develop tools able to identify and discriminate different types of leukemia. Within the project "Next Generation Sequencing platform for targeted Personalized Therapy of Leukemia" (NGS-PTL; FP7 european grant) we are involved in the setup of a bioinformatic pipeline for the identification of biomarkers for different types of leukemia from the analysis of Next Generation Sequencing (NGS) data. The pipeline setup is based on the identification of somatic mutations in control-tumor pairs coupled with statistical and functional analysis aimed to identify genes carrying potential driver mutations. Somatic mutations identification step was setup with a combined approach that integrates GATK software for calling of Indels and MuTect for calling of SNPs which allowed to achieve a 89% validation rate. Different strategies can be employed to detect putative genes carrying driver mutations based for example on the not-random distribution of driver mutations in the genome or on the predicted effect of mutations. To maximize the sensitivity of the detection of drivers to be used as candidate leukemia biomarkers we choose to employ a combined approach of three complementary statistical methods. The first method identifies genes significantly enriched in somatic mutations (MutSigCV), the second is based on mutation clustering on protein domains (OncodriveClust) while the third identifies genes accumulating putative driver mutations with high functional impact (OncodriveFM). Finally candidate driver genes detected by one or more methods are mapped on a functional network to identify driver genes perturbing the same metabolic pathway or functional module. Using the method setup we analyzed the sequencing data generated from cohorts of patients affected by 2 different leukemia types (AML,ALL) detecting 41 putative biomarkers which will be used as a base to build diagnostic kits. Using the method setup we analyzed the sequencing data generated from cohorts of patients affected by 4 different leukemia types (AML,ALL,CLL,ET) detecting 47 putative biomarkers which will be used as a base to build diagnostic kits.

Identification of Two Families with Li Fraumeni Syndrome on Multi-Gene Panel Testing. *C. Csuy[1], JM. McDonald[2].* 1) Novant Health Presbyterian Medical Center, Charlotte, NC; 2) Novant Health Gynecologic Oncology.

Li Fraumeni Syndrome (LFS) was thought to be a rare disorder affecting approximately 1 in 20,000 individuals. LFS has typically been defined to include very young onset breast cancer, adrenocortical tumors, sarcomas, leukemias and lymphomas. It is thought that 50% of patients have cancer by the age of 30 and 90% of patients will develop cancer by the age of 60. In the past year, two patients presented to our clinic that were not classic presentations for LFS however were found to have *TP53* mutations. Both patients were identified utilizing pan-cancer panel testing. The first patient presented because of a personal history of bilateral breast cancer at the age of 46. She documented that her sister was diagnosed with colon cancer at the age of 21. Her father was diagnosed with colon cancer at the age of 45 and her paternal grandmother was diagnosed with breast cancer at the age of 50 and colon cancer in her eighties. Her mother was diagnosed with bladder cancer at the age of 60. A maternal aunt (a maternal half-sister of her mother) was diagnosed with breast cancer in her forties and a maternal great-aunt was diagnosed with breast cancer under the age of 50. The *TP53* mutation was identified ("c. 97-2_99dup). The other patient was unaffected at the age of 42. Her father passed away from an unknown primary at the age of 49. A paternal aunt was diagnosed with breast cancer at the age of 40 and a paternal uncle was diagnosed with prostate cancer at the age of 50. A paternal first cousin was diagnosed with breast cancer in her forties. Her paternal grandfather was diagnosed with colon cancer and passed away at the age of 49. Her mother was adopted but the patient documented that her maternal grandmother was diagnosed with breast cancer in her fifties. The *TP53* mutation "p. R267W" was identified. Neither of these patients were classic in their presentation for LFS however, their results have drastically changed their medical management and follow up. Panels have changed how genetic testing has been offered in the clinical setting and will continue to help clarify syndromes and the prevalence of these conditions.

≤Evaluation of *IGK* and *IGL* Molecular Gene Rearrangements According to the BIOMED-2 Protocol for Clinical Diagnosis of Hodgkin Lymphoma≥. *S. Ghorbian[1], I. Jahanzad[2], G. R Javadi[3], E Sakhinia[4].* 1) Department of Molecular Biology, Ahar Branch, Islamic Azad University, Ahar, Ira, Ahar, Iran; 2) Department of Pathology, Imam Khomeini Hospital Complex, Medical Sciences / University of Tehran, Tehran, Iran; 3) Department of Biology, Science and Research Branch, Islamic Azad University, Tehran, Iran; 4) Department of Medical Genetics, School of Medicine, Tabriz University of Medical Sciences, Tabriz, Iran.

Molecular clonality of light chains (*IGK* and *IGL*) gene rearrangements assessed by applying BIOMED-2 protocols in Hodgkin's Lymphoma (HL) cases. We evaluated an protocol in HL cases, which has been suggested previously as an gold standard method for molecular clonality analysis on formalin fixed, paraffin-embedded (FFPE) tissue in Non-Hodgkin Lymphoma (NHL) patients, especially. We recruited 50 consecutive FFPE tissue of HL samples to evaluate *IGK* and *IGL* clonality gene rearrangements using BIOMED-2 method. Our finding revealed a total of 94% (47/50) positive clonality, which consisted of 70% (35/50) for *IGK* and 44% (22/50) for *IGL*. In three of cases, clonality was no detected in any of the immunoglobulin gene segments. Analysis of clonality gene rearrangements in *IGK* and *IGL* genes using BIOMED-2 protocols, could be implemented as a valuable method for increase sensitivity (94%) and accuracy of HL diagnosis similarly to NHL by clonality detection.

BRCA1/2 Mutation Status Is an Independent Factor of Improved Survival for Advanced Stage Ovarian Cancer. *R. Janavicius[1, 2], V. Rudaitis[1], T. Žvirblis[1], L. Griškevičius[1].* 1) VUH Santariskiu Clinics, Santariskiu st. 2, Vilnius, Lithuania; 2) State Research Institute Innovative Medicine Centre, Vilnius, Lithuania.

The aim of this study was to evaluate BRCA1 and BRCA2 mutation impact on prognosis of advanced-stage (III-IV) ovarian cancer patients after standard treatment. Methods: A total of 521 patients with advanced-stage (primary) epithelial ovarian cancer (EOC) were identified from a clinical database during year 1998-2013 and enrolled in a prospective, single-center study. All cases with available germline DNA (n=297) were screened for BRCA1 and BRCA2 gene mutations using combination of methods (HRM, Sanger/Next Generation Sequencing, MLPA); a total of 155 mutation carriers were identified. Progression-free survival (PFS) and overall survival (OS) was assessed between BRCA1/2 mutation carriers and BRCA1/2 wild-type patients. To reduce survivorship bias, analysis was limited for cases with BRCA testing performed <36 month from the diagnosis. Various clinical risk factors for PFS and OS were assessed by univariate and multivariate Cox regression analysis with stepwise model selection process. Results: Older age (hazard ratio [HR], 1. 032; 95% confidence interval [CI], 1. 010-1. 055; P=0. 0047), nonoptimal cytoreduction (HR, 3. 170; 95% CI, 1. 986-5. 060; P=0. 0001), and BRCA1/2 wild type (HR, 1. 625 [1. 003-2. 632]; P=0. 0486) were significantly associated with shorter PFS in multivariate Cox regression analysis. Nonoptimal cytoreduction (HR, 2. 684; 95% CI, 1. 264-5. 701; P=0. 0102) and BRCA1/2 wild type (HR = 1,612 (95% CI 1,16 - 2,23; P=0. 0002) were statistically significant risk factors for shorter OS. The overall 5-year survival for the hereditary case patients was better than that of the nonhereditary patients, however after that time no survival advantage was apparent. The carriers of Baltic founder BRCA1 c. 4035delA mutation had worse survival than other BRCA1 carriers (p=0,014) till 4 years. Conclusions: Advanced ovarian cancer patients harboring BRCA1/2 mutation treated with debulking surgery and platinum-based adjuvant chemotherapy have a longer PFS and OS not longer than 5-years. Available data suggest that*BRCA1* c. 4035delA mutation may be associated with poor survival.

Gene expresion analysis of *TNF-α, 5-LOX* and *iNOS* in tumoral and normal adjacent tissue of sporadic colorectal cancer patients. *U. Santana-Bejarano[1,2], L. Bobadilla-Morales[1,2], B. González-Quezada[1,2], V. Maciel Gutierrez[3], M. Centeno-Flores[3], J. Corona-Rivera[1], H. Pimentel-Gutiérrez[1,2], C. Ortega-de la Torre[1,2], A. Corona-Rivera[1,2].* 1) Laboratorio de CitoGenética, Genotoxicidad y Biomonitoreo, Instituto de Genética Humana “Enrique Corona”, Centro Universitario de Ciencias de la Salud, Universidad de Guadalajara, Sierra Mojada 950, Col. Independencia, c. p. 44340. Guadalajara, Jal; 2) Unidad de CitoGenética, Servicio de Hematología y Oncología Pediátrica . Hospital Civil de Guadalajara. “Dr. Juan I. Menchaca”. Salvador de Quevedo y Zubieta No. 750. Guadalajara, Jalisco, MX; 3) Servicio de Colon y Recto del Hospital Civil de Guadalajara “Dr. Juan I. Menchaca”. Salvador de Quevedo y Zubieta No. 750. Guadalajara, Jalisco, MX.

Colorectal cancer (CRC) is one of the most frequent malignant diseases caused by accumulation of genetic changes. *TNF-α, iNOS* and *5-LOX* are complementary genes to critic cancer alterations, their function is associated with the control between tumor cells and their environment. It’s thought that their cooperation is essential to complete tumor development. To analyze the expression of *TNF-α, iNOS* and *5-LOX* genes in tumor tissue we compared to normal adjacent tissue from the same patient with sporadic CRC in different tumor stages. The patients were classified into 2 groups: advanced stages (III and IV, n = 20) and early stages (I and II, n = 7). Tumor and normal adjacent tissue were collected and underwent to RNA extraction. Starting concentration of 1 µg of RNA was used to synthesize cDNA. QRT-PCR was performed for *TNF-α, iNOS* and *5-LOX genes*, the assay were validated using the constitutive genes *GUS, ABL* and *ACTB*. The results were analyzed by comparative CT method (χCT). The use of *GUS* and *ACTB* to validate expression assays in CRC was confirmed and also the use of *ABL* aims to validate similar studies. Genetic overexpression in tumor tissue compared to normal adjacent tissue from the same patient befall in the 3 genes, at the same time gradually increasing gene expression was also observed comparing advanced stages with early stages in all of them. In both groups, overexpression of *TNF-α* was observed in tumor tissue compared to normal adjacent tissue in 100% of cases. According to our results, we suggest that *TNF-α, iNOS* and *5-LOX* genes exhibit overexpression in tumor tissue compared to adjacent normal tissue, it could be due to the importance of their activity in biological processes during the establishment of CRC and that the association of overexpression with increasing tumor stage is due to their increasing actions during CRC development.

Clinical multiplex genetic testing using a standardized panel approach in a population-based hereditary cancer clinic. *K. A. Schrader[1,2,3], T. R. Docking[1,3], I. Bosdet[1], S. Young[1], T. Tucker[1], S. van den Berg[2], M. He[1], Z. Lohn[1], J. Nuk[1], M. Taylor[1], J. Scott[1], A. Mindlin[1], C. Portigal-Todd[1], C. Cremin[1], M. J. Asrat[1], K. Turner[1], J. Sawkins[1], J. Thompson[1], HCP. clinical team[1], L. Armstrong[2], B. McGillivray[2], R. Moore[1], A. Mungall[1], L. A. Swanson[1], L. P. Yang[1], J. Slind[1], M. Balasundaram[1], J. Schein[1], G. Mitchell[1], A. Karsan[1,2].* 1) Hereditary Cancer Program, Michael Smith Genome Sciences Centre, Department of Pathology & Laboratory Medicine, Department of Molecular Oncology, BC Cancer Agency, Vancouver, BC, Canada; 2) Department of Medical Genetics and Department of Pathology and Laboratory Medicine, University of British Columbia, Vancouver, Canada; 3) equal contributions.

The BC Cancer Agency's Hereditary Cancer Program (HCP), is the primary provider of cancer geneticsservices to families and individuals across British Columbia (BC) and the Yukon. Services include genetic counselling (GC) and testing and cancer risk management advice in high-risk families. A pilot study at the HCP showed economic feasibility for conducting multiplex genetic testing of a 14-gene panel. The pilot study of 90 patients including 2 positive controls, revealed expected genetic diagnoses in 4 patients (4%), an unexpected diagnosis in 1 patient (1%), and variants of uncertain significance (VUS) in 36 patients (40%). The remaining 49 patients (54%) had no presumed pathogenic variants or VUS. These results highlight the possibility of unexpected diagnoses even in small panel testing and the significant number of VUS. Since October 2014, clinical implementation of panel testing for eligible HCP patients has replaced single gene testing for associated genes. This has expedited diagnoses and has avoided costly iterative single gene testing, although it has presented challenges necessitating alterations in GC. GC for panel testing must now highlight to patients issues related to simultaneously testing multiple genes, most of which are not predicted to contribute to the patient's clinical and/or family history. Genes in this panel were chosen to represent those that confer increased cancer risk for breast, ovarian and colorectal cancers, but can be applied to phenotypically diverse conditions. The most common indication for testing is for hereditary breast and ovarian cancer (85%) followed by Lynch syndrome (14%). The other less common hereditary cancer susceptibilities account for 1% of patients tested. While there are multiple benefits to panel testing, it is clear there are scenarios that result in potential complexities in GC, such as a higher rate of VUS, the identification of variants in which risk is only associated with specific ethnic groups, and the identification of presumed pathogenic variants associated with susceptibility to cancer types not present in the person or family history. The challenge for GC is to present sufficient information within the limited appointment time to ensure informed consent, without overwhelming patients with information unrelated to their presenting history. We will present our experience to date regarding panel testing implementation of affected individuals with a clinical suspicion for hereditary cancer.

Shipman[1,2].* 1) University of Cambridge, Cambridge, Cambridgeshire, UK; 2) East Anglian Medical Genetics Service, Cambridge University Hospitals NHS Foundation Trust, UK; 3) PHG Foundation, Cambridge, UK; 4) Cambridge Cancer Trials Centre, Cambridge University Hospitals NHS Foundation Trust, UK; 5) Clinical Oncology, Peterborough and Stamford Hospitals NHS Foundation Trust, UK; 6) Cancer Services, The Ipswich Hospital NHS Trust, Ipswich, UK; 7) Clinical Cancer Services, Hinchingbrooke Health Care NHS Trust, Huntingdon, UK; 8) Cancer Research Team, Norfolk & Norwich University Hospitals NHS Foundation Trust, Norwich, UK; 9) Department of Oncology, The Queen Elizabeth Hospital King's Lynn NHS Foundation Trust, Kings Lynn, UK; 10) Cancer Services, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK; 11) Department of Obstetrics and Gynaecology, Norfolk and Norwich University Hospitals NHS Foundation Trust, Norwich, UK; 12) Department of Primary Care and Public Health, University of Cambridge, Cambridge, UK; 13) Department of Psychology, University of Chester, Chester, UK; 14) Cancer Research UK Cambridge Institute, Cambridge, UK.

Background: Genetic testing for germline mutations in BRCA1/2 has been available for many years, but until recently technical complexity and cost has limited testing access to high-risk cases. The advent of targeted therapies for BRCA1/2 mutation carriers necessitates new service delivery models for genetic testing. The Genetic Testing in Epithelial Ovarian Cancer (GTEOC) Study explores the feasibility and acceptability of offering genetic testing to all women recently diagnosed with EOC. **Methods:** From 1st July 2013 to 30th June 2015 women newly diagnosed with EOC were recruited though 6 sites in East Anglia, UK, which has an outbred population of 2. 5m with no BRCA1/2 founder mutations. Eligibility was irrespective of patient age and family history of cancer. Consent for genetic testing was obtained by the research team after participants reviewed the study information sheet. BRCA1/2 testing was done by NGS and MLPA. The psychosocial arm of the study utilised quantitative questionnaires (Depression Anxiety and Stress Scale, DASS, Impact of Event Scale, IES) and qualitative interviews subjected to Interpretive Phenomenological Analysis. **Results:** 208 women have been recruited and testing completed in 186. The mean age at diagnosis was 65 years (range 30-90). 13 mutations were detected (9 in BRCA1, 4 in BRCA2) giving a yield of 7%. The mutation yield is 10. 5% in unselected women <70 (11/105) and 2. 5% in unselected women 70+ (2/81). Testing only those with a positive family history (1o or 2o) increases the mutation yield to 13% in women <70 (9/70), but 15% of mutations in this age group will be missed. Preliminary analysis of the first 81 completed questionnaire responses showed that IES and DASS scores in response to genetic testing were significantly lower than equivalent scores of IES and DASS in response to cancer diagnosis ($p<.$ 001). Correlation tests revealed that whilst older age is a protective factor against any traumatic impacts of genetic testing (as measured by the IES, $p<.$ 05), no significant correlation exists between age and distress outcomes. **Conclusion:** The mutation yield in an unselected cohort of women diagnosed with EOC from a heterogeneous population with no founder mutations is 7% in all ages and 10. 5% in women under 70. Population-based genetic testing appears to be acceptable to patients and is less resource-intensive than standard practice where all patients have a full assessment by the genetics team prior to testing.

2740T

Desmoid tumor as a presenting symptom of FAP in a 54 year old man with a disease causing mutation in APC and family history of FAP. *C. Vinkler[1], K. I. Dayan[2], D. Lev[1], A. Singer[4], R. Brener[3].* 1) Inst Med Gen, Wolfson Med Ctr, Holon, Israel; 2) Inst Oncology, Wolfson Med Ctr. Holon, Israel; 3) Dpt of Surgery, Wolfson Med Ctr. Holon, Israel; 4) Medical Genetic Unit, Barzilai Medical Center, Ashkelon Israel.

Sporadic desmoid tumors is estimated at 1 to 2 per million whereas more than 15% of patients suffering from familial adenomatous polyposis (FAP) develop such extraintestinal tumors. FAP is a colon cancer susceptibility syndrome in which hundreds to thousands of colonic polyps develop. Typically beginning at the 2nd decade of life. By age 35 years, 95% of individuals with FAP have polyps. Different phenotypes ofFAP have been described and some genotype-phenotype correlations have been raised, associated with different sites of germline mutations in the adenomatous polyposis coli (APC) gene. We report on a 53-year-old male presenting first with intestinal obstruction. Colonoscopy revealed two small adenomatous polyps in the colon. Gastroscopy demonstrated more than 200 polyps located in the fundal part of the stomach. CT showed a large abdominal mass . A large tumor of the peritoneum was removed by surgery and was later diagnosed as desmoid tumor. The pedigree revealed other relatives with adenomatous polyposis. They werepreviously diagnosed as FAP mostlyduring their 3rd-4rddecade of life. In those relatives the disease manifested with polyposis of the colon requiring preventive surgery or colorectal cancer with death at an early age. The probandhadnormal colonoscopies and was asymptomatic until a short time before he was admitted to the hospital. DNA sequencingin the proband showed a frameshift mutationin exon 8 c. 896_897delCT(het); p. Ser299Cysfs*27; rs397515735. Desmoid tumor at an older age, with no GI manifestation is rarely reported as a presenting symptom of FAP. This unusual presentation demonstrates the variability in expression of this mutation. It may be postulated thatdifference in genetic background along with environmental factors may be involved in modifying the phenotypic expression in this case.

2741W

A comparative analysis of the mutaome profile of 10 frequently mutated genes in newly diagnosed and refractory and relapsed acute myeloid leukemia. *Y. Zhang, F. Wang, X. Chen, J. C. Fang, W. Teng, X. P. Han, M. Y. Wang, H. Wang, C. R. Tong, H. X. Liu.* Molecular Medical Laboratory, Ludaopei Hematology and Oncology Center, Beijing, China.

Objective To investigate the mutaome profiling of 10 frequently mutated genes in newly diagnosed and refractory and relapsed acute myeloid leukemia (AML) patients. **Methods** 125 newly diagnosed AML patients and 148 refractory and relapsed AML were enrolled, in which the median age is 24 and 26 respectively. Mutations of 10 frequently mutated genes were detected by Sanger sequencing in bone marrow samples, including kinase gens FLT3 and KIT, transcription factor genes CEBPA, NPM1 and PHF6, as well as epigenetic regulation genes ASXL1, DNMT3A, TET2, IDH1 and IDH2. **Results** (1) Mutations of the 10 genes were detected in 70. 40% of newly diagnosed AML and 62. 16% of refractory and relapsed AML. CEBPA (25. 58%), NPM1 (13. 95%) and FLT3-ITD (13. 18%) were the most frequently mutated three genes in newly diagnosed AML, and that were FLT3-ITD (19. 59%), KIT (12. 84%) and CEBPA (11. 49%) in refractory and relapsed AML. Concurrent mutations of more than one gene is statistically significant higher in newly diagnosed AML (28. 00% vs 10. 14%, P<0. 01). Mutations of CEBPA in newly diagnosed AML is also higher (25. 60% vs11. 49%, P<0. 05). (2) We observed consistent rules in the occurrence of gene mutation in two groups. KIT mutations usually occurred alone, while IDH1 and IDH2 often mutated accompanied with other genes. The kinase genes FLT3 and KIT were mutually exclusive. 80% among patients who carried more than one gene were accompanied with transcription factor gene mutation. Transcription factor genes mutated accompanied with kinase genes and/or epigenetic regulation genes is the most common mutated combination. (3) When analyzed the two groups according to age of ≤35 and >35, refractory and relapsed AML patients who were in the group of ≤35years carry more mutations of single gene (60. 19% vs 31. 11%, P<0. 05), in which KIT and FLT3-ITD account for 49. 21%. While patients in the group of >35years carry more mutations of more than one gene(20. 00% vs 6. 80%,P<0. 05). Moreover, the mutation of NPM1 were higher in>35 yearsin both groups (28. 13% vs 9. 68%, 20. 00% vs 2. 91%, P<0. 05). **Conclusions** The results showed that there were certain rules in the mutaome profiling of AML patients, which was related to the function classification of genes and age. So analysis of the mutaome profiling comprehensively is contribute to investigate its role in the development of AML as some genes affected clinical prognosis alone while some required coordinated with other genes.

2742T

Alternative genetic treatment technique for Leukemia. *S. Rashmi.* BIOTECHNOLOGY, AMITY UNIVERSITY, NOIDA, India.

The widely used chemotherapy for the hematological malignancy acquired genetic disease has transformed the disease from fatal to chronic. The development of Trypsin- inhibitor drug imatinib targeting the Philadelphia chromosome was considered as a boon in the treatment of chronic myeloid leukemia. But the question lies, is inhibition of *BCR-ABL* activity really helping in the complete eradication of the stem cell? There is a unanimous agreement that the stem cell survival don't depend on the presence or absence of the chimeric gene activity. Imatinib, a lifelong taken drug, inhibits the kinase activity exhibited by the *BCR-ABL* fusion gene without affecting the Leukemia stem cell survival. These stem cells with the help of cytokines survive and proliferate. Such cells have the potential to revert back. Out of the 95% patients responding to the medicine most of them are detected by RT-PCR with the presence of *BCR-ABL* transcripts. While the others with no such detection experiences recurrence on discontinuing the drug which proves the potential of the stem cells surviving on cytokines to develop cancer. Scientists are engaged in studying the mechanism behind the imatinib inhibition and persistence of *BCR-ABL* gene so as to come up with more cost efficient, with lesser side effects and secondary complications, and restrains the survival of the root cause that are the stem cells. It has been observed in literature that the RNA-binding protein Musashi2 (*MSI2*) plays a significant role in the self renewal programming of the leukemic stem cell by maintaining efficient translation of *Hoxa9*, *Myc*, and *Ikzf2* mRNAs. However, reduction of the colony formation, decrement in proliferation, and increment of apoptosis can be done by the depletion of MLL targeting the *Ikzf2* in leukemia stem cell. MSI can act as a potential therapeutic target for myeloid leukemia.

2743W

Hereditary Leiomyomatosis and Renal Cell Cancer (HLRCC): A 10-year retrospective chart review of Eastern Ontario referrals. *P. T. Bhola, C. Gilpin, G. E. Graham.* Regional Genetics Program, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Hereditary leiomyomatosis and renal cell cancer (HLRCC) is caused by autosomal dominant germline mutations in the fumarate hydratase (*FH*) gene. It is characterized by cutaneous leiomyomas, uterine fibroids and early onset renal malignancies that are typically of a type 2 papillary histology and aggressive. Estimates of renal cancer development in HLRCC are approximated at 15%. The rate of positive genetic testing with more than one cutaneous leiomyoma is 90-100%. Using a retrospective chart review, we sought to characterize the population of patients referred to the Regional Genetics Program at the Children's Hospital of Eastern Ontario for HLRCC from 2004-2014 and compare our experience with that described in the literature. Fifty-six patients, including 10 families, were seen for this indication from 2004-2014. Most of the referring providers were from primary care (family history of HLRCC) and dermatology (personal history of cutaneous leiomyoma(s)). Less common reasons for referral included papillary renal cell carcinoma (RCC) and a family history of fumarase deficiency. Fifty-four of the 56 patients (96%) pursued *FH* testing for HLRCC. Forty (74%) were positive for a clearly pathogenic mutation or likely pathogenic variant. The average age at presentation of the positive test population was 37. 8 years; 17 were male and 23 were female. Three patients presented with papillary RCC at an average age of 25. 7 years; all were the probands in their families and all were *FH* mutation positive. Of the positive test population, 20 patients were referred for a positive family history; when evaluated in our clinic, 3 had suspected cutaneous leiomyomas on exam. Of the new probands referred for cutaneous leiomyoma(s), 16 of 17 pursued genetic testing and 13 (81%) were positive for a clearly pathogenic mutation or likely pathogenic *FH* variant. Of the 3 mutation-negative probands referred for cutaneous leiomyoma(s), 2 had only a single leiomyoma but 1 had several leiomyomas, uterine fibroids and a family history of RCC. Our HLRCC population is similar to those described. Our patients with RCC were younger at diagnosis than the average age in the literature but all were the presenting probands in their families. Our experience confirms reports that multiple cutaneous leiomyomas and papillary RCCs are sensitive markers of HLRCC, suggesting a need to target dermatologists, oncologists and urologists for awareness-raising initiatives.

2744T

***APC* mosaicism in a young woman with juvenile fibromatosis.** *E. Grindedal[1], O-J. Norum[2], T. Berg[3], T. Hølmebakk[4], K. Aaberg[3], S. Steigen[3,5], AT. Stormorken[1].* 1) Section for Inherited Cancer, Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 2) Section for Orthopaedic Oncology, Department of Orthopaedic Surgery, Oslo University Hospital, Oslo, Norway; 3) Department of Clinical Pathology, University Hospital of North Norway, Tromsø, Norway; 4) Department of Abdominal and Pediatric Surgery, The Norwegian Radium Hospital, Oslo University Hospital, Oslo, Norway; 5) Department of Medical Biology- Tumor Biology Resarch Group, Faculty of Health Sciences, UiT The Arctic University of Norway, Tromsø, Norway.

Background: Familial adenomatosis polyposis (FAP) is caused by germline *APC* mutations. The classic form is characterized by hundreds to thousands of adenomas in the colorectum and early onset colorectal cancer (CRC) if left untreated. FAP is also associated with numerous extra-colonic manifestations. It is often referred to as Gardner syndrome when observed in combination with osteomas and soft tissue tumours (epidermoid cysts, fibromas and desmoid tumours). Somatic mosaicism has been reported in a few sporadic cases of polyposis, but may be an underestimated cause of the disease. This case report presents the detection of a mosaic *APC* mutation in a young woman with juvenile fibromatosis. **Clinical presentation:** Our patient had been diagnosed with juvenile fibromatosis as a child following removal of several subcutanous soft tissue tumours and epidermoid cysts throughout childhood. At 26 years she was referred to the Sarcoma group at the Norwegian Radium Hospital with a large soft tissue lesion in her left thigh, described histologically as inactive fibromatosis. A subcutanous soft tissue tumour was detected in her right buttock, histologically described as fibrous tissue but not fibromatosis. Based on her medical history, Gardner syndrome was suggested and upper and lower endoscopic examinations performed. Fifty adenomas were detected in her colon and 50 to 70 fundic gland polyps and adenomas in her stomach. Sanger sequencing of DNA from peripheral blood indicated presence of a pathogenic mutation c. 4348C>T (p. Arg1450*) in the *APC* gene. The signal representing the mutation was very weak, indicating somatic mosaicism. DNA was extracted from cells of her normal colonic mucosa and from adenoma tissue. The mutation was present at apparent heterozygous levels in both. There was no history of polyps or CRC in her family, and it was confirmed that she is a *de novo* carrier. The mutation is situated in the area of the *APC* gene associated with desmoid development. Based on her high risk of CRC, her present desmoid and risk of future desmoids, prophylactic proctocolectomy was recommended over colectomy with ileorectal anastomosis. Oesophagogastrosduodenocopies will be performed annually. **Conclusion:** Our case illustrates that a history of soft tissue tumours, and not just polyposis, may be an indication for *APC* genetic testing, and that *APC* mosaicism may be the cause of single cases of polyposis but also of the extra-colonic features of FAP.

2745W

Phenotypic delineation and bioinformatic detection of the pathogenic variant 5083DEL19 in *BRCA1* in two brazilian patients. *R. M. Minillo, P. M. Oliveira, C. L. Clozato, R. S. Francisco, M. C. Cervato, N. H. Muto, F. T. Lima, R. Sitnik, J. R. R Pinho, C. L. P. Mangueira.* Molecular Genetics, Albert Einstein Israelite Hospital, São Paulo, Brazil.

Introduction: Prevalence of pathogenic variants associated with the Hereditary Breast and Ovarian Cancer Syndrome varies according to different ethnicities and geographical regions. Next generation sequencing (NGS) is highly used for detecting these variants, although some of them are tricky to detect, either because of their chromosomal location and/or differences in the algorithms and parameters applied in the commercially available variant calling softwares (VCS) that integrate the bioinformatics pipelines (BP). One of these variants, c. 4964_4982del19 (5083del19), in *BRCA1*, is a founder mutation of South Italy (Calabria), associated with breast tumor that lack hormonal receptors expression, high levels of proliferation markers and ovarian serous adenocarcinoma. It was identified in two Brazilian patients with personal history of breast and/or ovarian cancer. **Objective:** To clinically describe the variant 5083del19 in *BRCA1* detected by NGS in two unrelated Brazilian patients. **Methods:** Review of medical records and BP used for the detection of the variant. **Results:** Patient 1 had triple negative breast carcinoma (with ductal infiltration) at age 50, skin cancer at age 55, ovarian serous adenocarcinoma at age 57 and rectal cancer at age 61. Her family is from South Italy; her mother had breast cancer at age 38, just like one niece of the maternal grandmother and one niece of the paternal grandfather. Patient 2 had ovarian serous adenocarcinoma ate age 40. Her family is from Minas Gerais (a southeastern Brazilian state); three aunts and two paternal cousins had cancer among ages 40 and 50. There is no information on anatomic pathology of the relatives' tumors. Both patients presented the same pathogenic variant, which was identified in each patient separately. We found that this variant is neglected when the default parameters of the VCS are applied, which makes it necessary to customize specific filters in the softwares for its correct identification. **Conclusion:** The patients herein described presented typical tumors associated with the 5083del19 in *BRCA1*. At least one of them quotes Italian ancestry, and also had rectal cancer. The high prevalence of this variant in individuals of Italian ancestry makes it epidemiologically relevant in Brazil, since there are about 17 million Italian-descendent individuals in Southeastern Brazil. We recommend that this variant should be manually screened by BP in *BRCA1* e *BRCA2* NGS panels.

Neuroendocrine tumors of the lower gastrointestinal tract in hereditary colon cancer syndromes. *C. Pedley, A. Blanco, M. Myers.* University of California, San Francisco , San Francisco, CA.

Neuroendocrine tumors are relatively rare; in 2004 the estimated incidence was 5. 25/100,000. In addition to being rare in the general population, neuroendocrine tumors of the lower gastrointestinal (GI) tract have not traditionally been associated with hereditary gastrointestinal cancer syndromes. However, with the arrival of next generation sequencing panels, the spectrum of reported cancers within each syndrome is growing, and there are documented case reports of neuroendocrine tumors of the lower GI tract arising in Lynch syndrome [MIM 120435] and Familial Adenomatous Polyposis (FAP [MIM 175100]). Six patients seen in the University of California, San Francisco (UCSF) Cancer Genetics and Prevention Program will be presented, each diagnosed with pathology confirmed neuroendocrine tumors of the lower GI tract and molecularly confirmed mutations in either *APC* [MIM 611731], *MLH1* [MIM 120436], *MSH2* [MIM 609309], *MSH6* [MIM 600678], *CHEK2* [MIM 604373] or *MUTYH* [MIM 604933], the latter two being homozygous mutations. Neuroendocrine tumors of the lower GI tract, while rare, are seen in inherited gastrointestinal cancer syndromes. Patients presenting with neuroendocrine tumors and other features to suggest an inherited syndrome, such as age of diagnosis and personal and/or family history of cancer should be referred for genetic counseling and genetic testing. Genetic testing with a next generation sequencing panel should be considered due to the occurrence of neuroendocrine tumors of the lower GI tract in several different inherited cancer syndromes.

2747W

Double heterozygosity for *BRCA1* and *BRCA2* pathogenic variants in a French metastatic breast cancer patient. *A. Vilalta[2], E. Curtit[1], G. Meynard[1], C. Villanueva[1], L. Mansi[1], M. Chaix[1], J. Kuo[2], M. Villa[2], J. Neidich[2], A. Tomar[2], A. Arianpour[2], P. Lebahar[2], X. Pivot[1].* 1) Service Oncologie Médicale, CHRU Besançon - IRFC , 3 Boulevard A. Fleming 25030 BESANCON Cédex; 2) Pathway Genomics Corporation, 4755 Nexus Center Drive, San Diego, CA 92121.

Double heterozygosity is an extremely rare occurrence in hereditary breast and ovarian cancer syndrome (HBOC) where two pathogenic variants, one in *BRCA1* and one in *BRCA2*, are found in an individual. To date, only a few case reports and case series have been reported in the literature (1-3). Furthermore, little is known about the clinical characteristics, family history, and tumor histology in these patients. In this study, we utilized targeted gene testing with next-generation sequencing (NGS) technology in an metastatic breast cancer patient from France. We evaluated germline variants using Pathway Genomics' BRCATrue NGS test, which analyzes variants in all exons and exon flanking regions in both *BRCA1* and *BRCA2* genes. All variant calls were determined after alignment and mapping to the GRCh37/hg19 reference genome. Variant calls were confirmed by Sanger sequencing. In this patient, a c. 1016dupA (p. V340GfsX6) frameshift variant was found in *BRCA1* along with a c. 6814delA (p. R2272EfsX8) frameshift variant in *BRCA2*. Both frameshift variants are predicted to truncate the BRCA proteins. The *BRCA1* c. 1016dupA variant is considered a Norwegian founder mutation but has also been observed in individuals of other ancestries (4-7). The *BRCA2* c. 6814delA (p. R2272Efs*8) pathogenic variant, also known as 7042delA, is predicted to truncate the BRCA2 protein and has been identified in individuals with a personal or family history of breast and/or ovarian cancer (8,9). To the best of our knowledge, the combination of these two pathogenic variants in an individual has not been previously reported. In a clinical diagnostic setting, the possibility of double heterozygosity of pathogenic variants in more than one susceptibility gene should be considered, especially in patients with early-onset metastatic cancers. Furthermore, genetic testing and genetic counseling should also be indicated for high-risk family members. meta1. (2012) *Breast cancer research and treatment* **134**, 1229-12392. The changing landscape of hereditary cancer testing: Lessons learned from 1703 patients seen at an NCI designated cancer center. *G. L. Wiesner[1,2], S. Lewis[1,2], J. Holt[1,3], R. H. Morgan[1], D. A. Riddle[1], S. W. Trump[1], K. McReynolds[1,2].* 1) Vanderbilt-Ingram Cancer Center, Vanderbilt Univ, Nashville, TN. , USA; 2) Department of Medicine, Vanderbilt Univ, Nashville, TN, USA; 3) Department of Biomedical Informatics, Vanderbilt Univ, Nashville, TN, USA.

Intro: Next generation sequencing (NGS) multi-gene panels were introduced in 2012 for genetic testing of patients at risk for hereditary cancer. These tests are controversial due to the lack of clinical guidelines related to rare genes on the panel and the possibility of a VUS result. It is also possible that more at risk patients will be identified with pathogenic mutations compared to usual testing protocols. Methods: We tested this hypothesis by examining the outcomes of genetic test reports from 1703 patients seen in the Hereditary Cancer Program at Vanderbilt-Ingram Cancer Center from July 2012 through Dec 2014. The tests were tabulated by type of test (single site, single genes such as BRCA1/2, or NGS panel), type of provider, and date of test. Results: Most of the 1703 patients were female (88%) and were seen for an indication of a personal history of breast cancer (38%) or a family history of breast cancer (72%) regardless of cancer history. The group was predominately white non-Hispanic (77%). Genetic tests were submitted on 1145 patients (67%), with 186 having a single site (16%), 346 (30%) single gene, and 613 (54%) multi-gene panel tests. 180 (16%) patients were identified with a pathogenic mutation, a VUS (239; 21%) or both (23; 2%). 70 (34%) pathogenic mutations were identified by multi-gene panels, 47 (23%) by single gene tests, and 86 (46%) by single site tests. There was no difference in the overall rate of pathogenic mutations identified by panel (11. 4%) compared to single gene tests (13. 6%). However, when the comparison was restricted to 497 tested women with breast cancer, 13 of the 189 (7%) tested with Sanger BRCA1/2 had pathogenic mutations compared to 40 mutations found in 308 (13%) with multi-gene testing (P=0. 035). There was a significant difference between MD or NP providers (67%) compared to genetic counselors (57%) in preference for multi-gene panels compared to single gene tests (P=0. 002). Over the 30-month study period, the proportion of panel tests sent increased markedly (P=0. 0001). Conclusion: The testing paradigm has shifted from testing a small number of genes to a larger multi-gene sets, with the potential to identify a greater number of pathogenic mutations, at least in patients with breast cancer. We also found clear differences in ordering practices by type of provider. Future studies should examine whether the clinical indication, cancer diagnosis, and patient desires are important factors guiding the choice of test.

2749W

Genetic counseling and analysis plan in Von Hippel-Lindau syndrome and pheochromocytoma. *W. Smaoui[1], A. Bahloul[1], H. Fourati[1], K. Chaker[1], O. Kaabi[2], R. Louati[2], MN. Mhiri[1], NB. Abdelmoula[2].* 1) Dep Urology, HB Univ Hospital, Sfax, Tunisia; 2) Lab Histology, Univ Medicine, Sfax, Tunisia.

Pheochromocytomas (PCCs) are rare catecholamine-secreting tumors that usually arise within the medulla of the adrenal gland or the sympathetic ganglia. The hormone imbalance affects the cardiovascular system leading to hypertension and other metabolic processes. PCCs are genetically determined in approximatelyone thirdofpatients by germline/somatic mutations in 11 known susceptibility geneslike RET,VHL, NF1, HIF2A and SDH. PCC treatment involves treatment of hypertension and surgical removal of the tumor. When PCC is the presenting tumor of syndromic forms, diagnosis may be difficult or missed, as often the first symptoms are labile hypertension that can be confused for other diagnoses. We report two Tunisian female patients who were surgically treated for pheochromocytoma associated to renal lesions. Case Report 1 was a 50-year-old woman who presented multiple cerebellar hemangioblastomas, cervical spinal cord and recurrent retinal angiomas. She was surgically treated for left clear cell renal cell carcinoma (ccRCC) and one year after for right PCC. She had also multiple pancreatic cysts and an ovarian cyst. Case Report 2 was a 39-year-old woman who underwent surgery for right PCC. At the same time clinical management showed bilateral polycystic kidneys as well as an ovarian cyst. Skin lesions and a positive family history with a spectrum of clinical phenotypes, evoking familial von Hippel–Lindau (VHL) disease were recorded for our two patients. As VHL (MIM 193300) is an autosomal dominant disorder caused by heterozygous mutations in the VHLtumor suppressor gene at 3p25. 3 linked tomTOR pathway, a genetic screening forVHLgene germline mutation detection was proposedat genetic counseling. Regarding phenotype presentation with PCC classed as VHL type 2B, VHL R167Q will be our first genetic analysis purpose, even though no therapeutic approach is available to target it. In fact, this missense mutation is the most common VHL point mutation in hereditary VHL disease. It is also a representative type 2B mutation that predispose to a high risk of ccRCC and finally it has been found in sporadic PCCs.

Examining severity of cancer history in patients with pathogenic variants in *ATM*. *J. Abernethy, E. Rosenthal, J. Kidd, P. Vail, S. Manley.* Myriad Genetic Laboratories, Inc. , Salt Lake City, UT.

Background: We tested the hypothesis that different types of pathogenic variants (PVs), particularly missense versus truncating variants, confer different levels of cancer risk in *ATM* carriers and their families. **Methods:** Patients ascertained for suspected hereditary cancer risk were tested with a clinical 25-gene hereditary cancer panel between September 20, 2013 and March 13, 2015. Clinical history data for those with PVs in *ATM* was obtained via healthcare provider report on the test request forms. 23 patients with PVs in more than one gene were excluded from the cohort. Variants classified as Deleterious or Suspected Deleterious by our laboratory were regarded as pathogenic. Many *ATM* missense variants are classified as pathogenic based on their contribution to the recessive condition Ataxia-Telangiectasia (A-T). **Results:** Of 59 female patients with a missense pathogenic variant in *ATM,* 17 (28. 8%) had a personal diagnosis of breast cancer at or before age 50. Of 310 female patients with a truncating variant in *ATM*, 86 (27. 7%) had a personal history of early onset breast cancer. Of 60 patients (males and females) with a missense variant in *ATM*, 32 (53. 3%) had a high-risk family history (3 or more diagnoses in the family, including the patient where applicable, of breast and/or pancreatic cancer). Of 316 patients with a truncating variant in *ATM*, 138 (43. 7%) had a high-risk family history. **Discussion:** This study identified no evidence for a significant difference in cancer risks associated globally with pathogenic missense compared to truncating variants, although wecannot rule out higher or lower penetrance associated with individual variants. As additional families are identified, these findings can be confirmed and the relative cancer risks associated with individual *ATM* variants can be further characterized.

Renal manifestations of TSC and early onset of hypertension: About two Tunisian familial cases. *N. Abdelmoula[1], W. Smaoui[2], K. Chaker[2], O. Kaabi[1], H. Fourati[2], MN. Mhiri[2].* 1) Lab Histology, Univ Medicine, Sfax, Tunisia; 2) Dep Urology, Univ HB Hospital, Sfax, Tunisia.

Renal manifestations of tuberous sclerosis complex (TSC) include angiomyolipomas, simple cysts, polycystic kidney disease, and renal-cell carcinoma. These lesions likely arise in infancy or early childhood, increasing in size and number with age. After neurologic complications, renal involvement is the second most common cause of morbidity and mortality in TSC. The most common renal lesions are angiomyolipomas found in 80% of TSC patients and renal cysts found in 17% of children and 47% of adults. Renal cysts are frequently multiple and bilateral. Polycystic kidney disease may also occur and is a more severe lesion with innumerable cysts that enlarge, replacing renal parenchyma, and causing renal insufficiency and hypertension typically at an early age. Here, we describe two Tunisian patients in whom TSC diagnosis was confirmed at the clinical level for both and molecularly for one of them. The first case was a 36-year-old man and harbored multiples bilateral renal cysts with two right angiomyolipomas rapidly transformed into renal cell carcinoma (RCC). In fact, surgical resection of five tumors with a very large one in the central regionleaded to phenotypic characterization of two central lesions as a Grawitz tumor and three peripheral ones as angiomyolipomas. Familial germinal small TSC1 deletion at codons 213-214 of exon 5 of the gene was confirmed in this patient. The second patient was a 25-year-old woman harboring at the renal level, bilateral multiples angiomyolipomas leading to total left kidney nephrectomy. Immunohistochemical analysis of renal tumors showed typical perivascular epithelioid cell phenotype. These two patients presented an early onset hypertension. High blood pressure in STC is generally related to renal cysts. We suggest through our observations that hypertension may be associated directly to angiomyolipomas genetic evolution and mTOR signaling dysregulation. In fact, relationships between hypertension, cardiac hypertrophy, Angiotensin II as well as dysregulation of signaling pathways and structural remodeling of vessel walls in angiomyolipomas were studied in animal models and needed confirmation and delineation in TSCs positive patients. .

Bilateral, multifocal renal tumors diagnosed as Birt-Hogg-Dubé syndrome confirmed by genetic analysis. *S. Park, S. Park, E. Kang, H. Cheong, D. Kim, K. Oh, Y. Kim, K. Joo, H. Lee.* Seoul National University Hospital, Seoul, South Korea.

Introduction: Birt-Hogg-Dubé syndrome (BHD) is an autosomal dominant disorder characterized by skin fibrofolliculomas, pulmonary cysts and spontaneous pneumothorax, and renal cancers. The syndrome is caused by germline mutations of the *FLCN* gene located in *17p11. 2* encoding folliculin. The risk of renal cancer is seven times higher in BHD patients. Bilateral, multifocal and chromophobe renal cell carcinoma is characteristic of renal cancers in BHD. Among about 110 pathogenic mutations reported in BHD, only twenty six of them have been associated with renal cancer. In this study, we described a case of 50-year-old woman with chromophobe renal cell carcinoma who had c. 1557delT mutation in the *FLCN* gene which is novel in BHD-associated renal cancer. **Case report:** A 50-year-old-woman presented with flank pain. A CT scan of abdomen showed multifocal tumors in both kidneys. To differentiate the origin of the tumors, a chest CT and a whole body PET-CT were carried out, although there was no other lesion except a few lentiform cysts at basal lungs. Histologic evaluation through a needle biopsy revealed that the mass was chromophobe type renal cell carcinoma. The patient underwent partial nephrectomy. Given multifocal distribution of the renal cell carcinoma, we suspected an inherited form of kidney cancer. Although she denied any specific familial history, the cystic change of both lungs and chromophobe renal cell carcinoma pointed towards the possibility of BHD. DNA sequencing of the entire *FLCN* gene identified a heterozygous c. 1557delT mutation in exon 14 [p. Phe(TTT)519Leu(TTA) fs*18]. **Discussion:**Once multifocal renal masses are diagnosed as renal cell carcinoma, histologic subtype, family history and other clinical features should be considered to recognize familial renal cancer syndromes. Multifocal chromophobe renal cell carcinoma should prompt genetic test for BHD even in a patient without typical skin lesion. In our patient, c. 1557delT mutation was found out which has been first reported in BHD-associated renal cancers.

2753W

Cytosine Modification Signatures Distinguish Clinical Subtypes of Glioblastoma Stem Cells. *W. Zhang[1,2], T. Shi[3], Z. Zhang[1], C. Liu[4], C. Horbinski[5], S. Y. Cheng[2,3].* 1) Department of Preventive Medicine, Northwestern University , Chicago, IL; 2) The Robert H. Lurie Comprehensive Cancer Center; 3) The Ken & Ruth Davee Department of Neurology, Northwestern University, Chicago, IL; 4) Department of Bioengineering, University of Illinois, Chicago, IL; 5) Department of Neurological Surgery, Northwestern University, Chicago, IL.

Glioblastoma multiforme (GBM), the most malignant form of primary brain tumors, is diagnosed in over 18,000 new patients in the United States every year and kills ~13,000. Despite access to state-of-art modalities of therapy, GBM prognosis remains dismal. A major challenge for treating these patients is that GBM is in reality a heterogeneous group of neoplasms, wherein discrete subsets feature unique patterns of pathogenesis, cellular biology, and prognosis. Though specific molecular markers are of considerable value in clinical care, including mutations in IDH1/2 and 1p/19q, there is still a great deal of room for improvement in prognostic stratification and targeted therapeutics. In particular, aberrantly high tumor heterogeneity in intra- and inter tumors of high-grade glioma (HGG) is recognized by four clinically relevant GBM subtypes based on distinguished gene signatures. However, molecular signaling in glioma stem cells (GSCs) in individual HGG subtypes remains to be fully characterized. Given that alterations in DNA methylation, a type of cytosine modifications, have been associated with survival and response to treatments in GBM patients (e. g. , methylation of *MGMT* promoter and response to temozolomide), these epigenetic markers may have the potential to distinguish GBM subtypes. Specifically, our previous gene expression analysis distinguished two mutually exclusive GSC subtypes: proneural (PN) from mesenchymal (Mes) GSCs, and revealed a pronounced correlation with the corresponding PN or Mes HGGs. In this study, we profiled whole-genome cytosine modification levels of eight PN and four Mes GSCs using the Illumina 450K arrays. At a raw p value of 0. 005, we identified 171 differential CpGs in 172 genes between PN and Mes GSCs. A hierarchical clustering analysis based on these differential CpGs showed complete separation between PN and Mes GSCs. In addition, these differential CpG sites were enriched in canonical pathways and Gene Ontology biological processes such as “anti-apoptosis”. Notably, an enriched pathway - “proteoglycans in cancer”- is related to multiple oncogenic pathways in tumor cells, and promotes critical tumor-microenvironment interactions. In summary, cytosine modifications appear to play a critical role in determining the molecular characteristics of GSC heterogeneity, suggesting potential applications of methylomic markers to distinguish GBM subtypes for the ultimate goal of precision medicine in these patients.

2754T

Differential Expression of miR-139-5p as a Saliva Biomarker in Tongue Squamous Cell Carcinoma Patients. *M. B. Duz[1], O. F. KARATAS[2], E. GUZEL[1,5], N. F. TURGUT[3], M. YILMAZ[3], C. J. CREIGHTON[4], M. OZEN[1,5,6].* 1) Department of Medical Genetics, Cerrahpasa Medical School, Istanbul University , Istanbul, Turkey; 2) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 3) Department of Otorhinolaryngology, Cerrahpasa Medical School, Istanbul University, Istanbul, Turkey; 4) Department of Medicine and Dan L. Duncan Cancer Center Division of Biostatistics, Baylor College of Medicine, Houston, Texas, USA; 5) Biruni University, Department of Molecular Biology and Genetics, Topkapi, Istanbul, Turkey; 6) Department of Pathology & Immunology Baylor College of Medicine, Houston, TX, USA.

41% of all oral carcinomas have been found to localize at tongue, where they were characterized as being aggressive and having capacity to locally invade and relapse frequently. Despite considerable enhancements in cancer diagnosis and treatment techniques, tongue squamous cell carcinoma (TSCC) still remains to be one of the most common and lethal cancer types in the head and neck region. In this study, we aimed to identify a signature of saliva-specific microRNAs (miRNAs) expression in TSCC patients. To explore putative diagnostic biomarkers, we compared the miRNA profiles of saliva samples obtained from 4 TSCC patients and 4 healthy control individuals using Agilent miRNA microarray (V19). Three of the differentially expressed miRNAs were selected for further validation with quantitative reverse-transcription PCR (qRT-PCR) using saliva samples of 25 TSCC patients and 25 healthy control individuals. Microarray analysis demonstrated that 419 miRNA probes were deregulated in TSCC patients when compared to control group and qRT-PCR results validated the reduced expression of miR-139-5p in TSCC saliva. Further analysis of post-operative saliva samples of TSCC patients revealed that miR-139-5p level elevated to normal level after surgery, pointing its diagnostic and prognostic power. As a conclusion, we propose saliva as a feasible source in routine patient examination for early diagnosis of TSCC patients, and our results suggest saliva miR-139-5p as a novel potential diagnostic marker.

HDACi-induced differentiation of myelogenous leukemia results in targeted chromatin accessibility changes. *C. L. Frank[1,2], D. S. Hsu[2], G. E. Crawford[2,3].* 1) Department of Molecular Genetics and Microbiology, Duke University, Durham, NC; 2) Center for Genomic and Computational Biology, Duke University, Durham, NC; 3) Department of Pediatrics - Division of Medical Genetics, Durham, NC.

Small molecule inhibitors of histone deacetylases (HDACi) serve as potent anticancer agents for particular malignancies. The exact mechanism by how HDACi work is unclear, but there is evidence these compounds either directly promote apoptosis or sensitize cancer cells by cell cycle arrest and differentiation, facilitating synergistic combinations with other compounds. For over 25 years it has been known the myelogenous leukemia cell line K562 can be differentiated in vitro by exposure to HDACi. Despite this, the precise genomic and epigenomic changes these cells must undergo to assume an erythrocytic state remain poorly defined. To investigate chromatin-based changes responsible for anti-proliferative differentiation, we treated K562 cells for 72 hours with sub-lethal concentrations of the HDACi sodium butyrate or SAHA, and assessed global chromatin accessibility and expression changes by DNase-seq and RNA-seq. Despite the potential for global hyperacetylation, we identified several thousand specific regulatory elements (<10% of total DHS sites) that become significantly more or less accessible following treatment. These regulatory elements are enriched for non-promoter regions of the genome, nearby to genes that change expression with HDACi exposure, and contain abundant motifs for key hematopoietic lineage-defining transcription factors. We verified by ChIP-seq that the pioneer factor PU. 1 increases binding at opened hypersensitive sites and likely contributes to active enhancer formation at these sites. Increased binding does not appear to be a result of PU. 1 induction following treatment. Luciferase assays demonstrate HDACi-opened sites containing PU. 1 motifs are sufficient for the transcriptional response. Ongoing and future work will examine the necessity of factors like PU. 1 for HDACi-induced differentiation of myelogenous leukemia and other cancer cell types.

Distinctive expression profiles of lncRNAs and lncRNA-related miRNAs in glioma subtypes. *D. Glavac[1], A. Matjašič[1], E. Boštjančič[1], M. Popovič[1], B. Matos[2].* 1) Department of Molecular Genetics, Institute of Pathology, Faculty of Medicine, University of Ljubljana, Slovenia; 2) Department of Neurosurgery, University Clinical Center, Ljubljana, Slovenia.

Glioblastoma the most common and most aggressive diffuse glioma is associated with short survival and characterized by morphological, genetic and gene-expression heterogeneity including long non-coding RNAs (lncRNAs) and microRNAs (miRNAs) expression. Due to the heterogeneity, most tumours develop resistance to treatment and shortly recurrence. Our purpose was to investigate differential expression profiles of lncRNAs in glioma and their potential association with different glioma subtypes as well as association to their co-regulated or co-expressed miRNAs. We used the qPCR approach in order to determine differentially expressed lncRNAs using LncRNA array profiler. A subset of differentially expressed lncRNAs and their potentially related miRNAs was further analyzed with alternative qPCR approach on a bigger cohort of glioma samples. We found measurable differences of lncRNA expression in glioma samples compared to brain reference RNA. Our results show downregulation of *MEG3*, *JPX* and *RNCR3* and upregulation of *HOTAIR* and *ZFAS1* in all glioma subtypes. *7SL* was downregulated in astrocytoma, primary and secondary glioblastoma and upregulated in oligodendroglioma and oligoastrocytoma. We have also observed a correlation in expression of *miR-124a* and *RNCR3*, *miR-196a* and *HOTAIR*, *miR-770* and *MEG3*. In a subcohort of our patients with recurrent tumour our data showed statistically significant change in expression of several miRNA (miR-7, miR-9, miR-21, miR-26b, mirR-124a, miR-199a and let-7f) in recurrent tumour compared to the first biopsy. Expression levels in recurrent tumour significantly changed for miR-15b, let-7d and in let-7f comparing treatment with radiotherapy and chemotherapy and with radiotherapy alone. Our data suggest that in the patients with glioblastoma time to tumour recurrence is longer when using radiotherapy and chemotherapy after surgery and that expression of certain miRNAs change based on therapy used. Wehave demonstrated distinctive glioma subtype lncRNA and miRNA -related expression patterns, which may contribute to more objective diagnosis and developing new therapeutical approaches.

2757W

SFRP1 promoter hypermethylation in white blood cells is associated with sprodic breast cancer in Iranians women. *Y. Kiumarsi[1], M. Norouzinia[2], M. Hasanzad[3], A. Pooladi[4], G. Khakpoor[5], A. Dehghani fard[6], M. Ahmadvand[6].* 1) Islamic Azad University, Medical Tehran branch, Tehran, Iran,MSc; 2) Department of Medical Genetics, Tarbiat Modares University, Tehran, Iran,Associate Professor; 3) Department of Medical Genetics Islamic Azad University, Medical Tehran Branch, Tehran,Iran, Associate Professor; 4) Department of Medical Genetics, Tarbiat Modares University, Tehran, Iran, Ph. D student; 5) Department of Medical Genetics, Tehran University, Tehran, Iran, Ph. D student; 6) Department of Hematology, TarbiatModares University, Tehran, Iran, Ph. D student.

Breast cancer is leading cause of cancer death in women worldwide but early detection is corelated free survival. Changes in DNA methylation in peripheral blood could be associated with cancer at early stage. Peripheral white blood cell DNA contains epigenetic marks that can be used as potential biomarker in order to detecting individuals predisposing to malignancies including breast cancer. We examined the association between promoter hypermethylation level of SFRP1 and CDH1 genes ,which are antagonist in WNT signaling and cell-cell adhesion respectively, in peripheral blood leukocyte DNA and breast cancer among Iranian women**.** *SFRP1 and CDH1* promoter methylation was examined by MeDIP-Realtime qPCR in WBC from 30 breast cancer patients aged less than 40 years with newly diagnosed sprodic breast cancer, no history of any therapy and 30 matched controls from medical checkup examinees in Imam khomayni hospital. Out of 30 breast cancer patients, 16 (53. 3%) manifested various levels of SFRP1(p-value=0. 04) and 1 (3. 3%) showed CDH1(p-value>0. 05) methylation. However, no methylation was found in 30 controls. The present results suggest that the SFRP1 promoter methylation level of peripheral blood leukocyte DNA is low in patients with breast cancer and may be a potential biomarker for breast cancer risk but highly methylated CDH1 promoter may be related to metastasing tumours.

Selection of Allelic Expression in lung adenocarcinoma through Genome-wide Allelic Expression Imbalance Analysis. *X. Kong, J. Huang, Y. Zhou, M. Wang, P. Zhang, M. Jin, Z. Xing.* Molec Gen, Inst Hlth Sci, Shanghai, China.

For heterozygous genes, the expression levels of paternal and maternal alleles should be the same if they are in the same environment. However, multiple factors such as *cis*-action, epigenetic regulation, and mRNA processing, can affect individual gene expression, resulting in the expression variations of alleles. Allele expression imbalance (AEI), defined as the quantitative difference of the degree in gene expression between two alleles, is a widespread phenomenon in human genome. In recent studies, growing evidences have proved the connections between the AEI status of oncogenes and cancer.

By analyzing RNA and DNA sequencing data of cancer and adjacent paired normal tissues obtained from 57 The Cancer Genome Atlas (TCGA) samples and RNA sequencing from 72 South Korean lung adenocarcinoma patients, we discovered that the allelic expression was under selection. In normal tissues, genes with synonymous Single Nucleotide Variants (SNVs) occupied higher ratios in AEI than those with nonsynonymous SNVs and the specific-expression genes had higher AEI frequencies than common-expression genes, which had no differences in tumor tissues. We screened genes which had high AEI frequencies in tumor tissues and low in normal tissues and genes with low AEI frequencies in tumor tissues and high in normal tissues. GO annotation of these two groups showed that genes with high frequencies in tumor tissues were significantly enriched in protein biogenesis related functions, while the other group of genes were enriched in immune related functions. More importantly, we found that in normal tissues, more conservative sites had lower AEI frequencies. On the contrary, more conservative sites had higher AEI frequencies in tumor tissues.

We conjecture that AEI works as modulating abnormalities of single allele caused by mutations and the loss of allele expression selection may contribute to tumorigenesis.

Tumor DNA methylation profiling in African American men: A high-risk prostate cancer population. *R. Rubicz[1], S. Zhao[1,2], J. L. Wright[1,3], S. Kolb[1], B. Klotzle[4], M. Bibikova[4], D. Troyer[5], R. Lance[6], E. A. Ostrander[7], Z. Feng[8], J. -B. Fan[4], J. L. Stanford[1].* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Biostatistics and Computational Biology Branch, National Institute of Environmental Health Sciences, Research Triangle Park, NC; 3) Department of Urology, University of Washington School of Medicine, Seattle, WA; 4) Illumina, Inc. , San Diego, CA; 5) Departments of Pathology and Microbiology and Molecular Cell Biology, Eastern Virginia Medical School, Norfolk, VA; 6) Department of Urology, Eastern Virginia Medical School, Norfolk, VA; 7) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 8) Department of Biostatistics, University of Texas MD Anderson Cancer Center, Houston, TX.

Men of African ancestry have the highest incidence of prostate cancer world-wide, and they are at increased risk of dying from the disease compared to other populations. There are a number of factors that likely contribute to this health disparity, such as socioeconomic factors, access to healthcare, type of treatment, and biological factors including genetics and epigenetics. DNA methylation is a major epigenetic regulator of gene expression that has previously been associated with prostate cancer. Here we characterized DNA methylation profiles of 76 African American men with prostate cancer who had radical prostatectomy as primary treatment. Samples were from two institutions: Fred Hutchinson Cancer Research Center (n=44), where patients were enrolled in a population-based study; and Eastern Virginia Medical Center (n=32), which included samples from a highly selected group of patients with no evidence of recurrence or who had lethal prostate cancer. The Infinium HumanMethylation450 BeadChip array (Illumina) was used to determine methylation status for ~480,000 CpG sites in prostate cancer tissues. Age- and cohort-adjusted analyses based on comparisons of M-values (minfi, Bioconductor) showed that 18 CpGs had significant differences in methylation levels between men with vs without evidence of prostate cancer recurrence, and 5 CpGs were differentially methylated in men with lethal prostate cancer (FDR q≤0. 2). DNA methylation differences were also observed between men with local vs regional pathological stage (2 CpGs) and for men with a high composite aggressiveness score (1 CpG) that was based on recurrence status, Gleason score, and pathological stage. The recurrence-associated CpGs include CpGs in the transcription start sites of *NEUROG1* (previously associated with medulloblastoma and colorectal cancer) and *PRTFDC1* (a possible tumor-suppressor gene). These results indicate that differentially methylated sites may contribute to more aggressive tumor biology in African American prostate cancer cases.

Epigenome-wide profiling of DNA methylation in paired prostate cancer versus adjacent benign tissue. *J. L. Stanford[1,2], S. Zhao[3], C. Wong[1], M. Bibikova[4], B. Klotzle[4], M. Wu[1], E. A. Ostrander[5], J. Fan[4], Z. Feng[6], M. S. Geybels[1,7].* 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Epidemiology, School of Public Health, University of Washington, Seattle, WA; 3) National Institute of Environmental Health Sciences, Biostatistics & Computational Biology Branch, NC; 4) Illumina, Inc. , San Diego, CA; 5) Cancer Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 6) MD Anderson Cancer Center, Houston, TX; 7) Department of Epidemiology, GROW School for Oncology and Developmental Biology, Maastricht University, Maastricht, the Netherlands.

Aberrant DNA methylation may promote prostate carcinogenesis. We investigated epigenome-wide DNA methylation in prostate cancer compared to adjacent benign tissue to identify differentially methylated CpGs. The study included paired prostate cancer and adjacent benign tissue samples from 20 radical prostatectomy patients. Epigenetic profiling was done using the Infinium HumanMethylation450 BeadChip. Linear models that accounted for the paired study design and False Discovery Rate Q-values were used to evaluate differential CpG methylation. Differentially methylated regions (DMRs) were called using the Probe Lasso method. The top-ranked differentially methylated genes were analyzed in relation to mRNA expression in the same paired tissue samples. There were 2,040 differentially methylated CpGs in prostate cancer versus adjacent benign tissue (Q-value <0. 001), the majority of which were hypermethylated (n = 1,946). Twenty-seven hypermethylated CpGs had a mean methylation difference of at least 40% in prostate cancer versus benign tissue, which included 25 CpGs in 17 genes. Furthermore, for ten genes over 50% of promoter region CpGs were hypermethylated in prostate cancer. The top-ranked hypermethylated genes included three genes that were associated with both promoter hypermethylation and reduced gene expression: *SCGB3A1*, *HIF3A*, and *AOX1*. A secondary analysis of DMRs showed 20 hypermethylated regions (Q-value <0. 001), several of which were in or near genes of the *HLA* gene family on chromosome 6. This study of prostate cancer versus adjacent benign tissue identified many differentially methylated CpGs and regions in and outside gene promoter regions, whichmay potentially beused for the development of future methylation-based diagnostic tests or as therapeutic targets.

2761W

BCL2 : A Relevant Immunohistochemical Marker for Triple Negative Breast Cancer Patients. *S. Zubeda[1,2,4,5], M. Khaliq Mohiuddin[2], K. Prabhakar Rao[1,5], Q. Hasan[2,3,4].* 1) Department of Genetics, Osmania University, Hyderabad, Telengana, India; 2) Department of Genetics, Vasavi Medical and research centre, Hyderabad, Telengana, India; 3) Department of Genetics, Kamineni Hospital, Hyderabad, Telengana, India; 4) Department of Genetics, Hyderabad Science Society, Hyderabad, Telengana, India; 5) RAS life sciences, Hyderabad, Telengana, India.

Breast cancer is a heterogeneous disease at histopathological, clinical and molecular level. Currently, the outcome or treatment response in patients with breast cancer are based on tumour size, N-status, histological grade and hormonal receptor status (ER/PgR) and Her-2. However, these conventional clinico-pathological characteristics are of limited value. More accurate prognostication markers are needed to select patients, who are most likely to benefit from treatment. Dysregulation of normal programmed cell death mechanisms play an important role in the pathogenesis and progression of breast cancer. BCL2, an anti-apoptotic gene that appears to block a distal step in an evolutionarily conserved pathway plays a crucial role in apoptosis. In this study BCL2- P2 Promoter methylation is evaluated by Methylation Specific Restriction Assay in 300 FFPE breast tissue samples, which included 100 each of fibroadenoma, breast cancer and adjacent normal breast tissue. Immunohistochemical expression and RNA transcripts levels of Bcl-2 were assessedin all three types of tissue (i. e fibroadenoma, breast cancer and adjacent normal) by using Rabbit polyclonal antibody specific to Bcl-2 (*Abcam, USA* ,Catalogue # *ab59348*) and by RT PCR respectively. 65% of BC tumour samples showed hypomethylation where as only 35% showed the expected 312 bp band indicating methylation of the BCL2 gene. While 67 % of adjacent normal breast tissues and 41% of benign tumours showed methylation of the same region. An overall mean of Bcl2 expression in BC tumour sections was 1. 40 ±0. 87, which is two times [P = 0. 002] higher than the adjacent normal tissue sections that had a mean of 0. 7424 ±0. 63 . BCL2 expression showed statistically significant association with triple negative [ER-, PR-, Her-2 -] breast cancer tissues with a mean of 1. 84 ±0. 8 [P = 0. 0006] , whereas the mean of Bcl2 expression in triple positive is only 1. 1 ±0. 7 . BCL2 transcript levels were found to have 5 fold up regulation in malignant tumours compared to benign tumours. Hence two fold increased expression of BCL2 in BC tumour tissues when compared to adjacent normal tissues and statistically significant difference in its expression in triple negative BC indicates that it is a relevant immunohistochemical marker for triple negative breast cancer. **Acknowledgements**I thank *UGC MANF – AND - MUS - 4126* for providing me the financial assistance for carrying out the work..

2762T

Thyroid nodules and multinodular goiter associated with germline mutations in *DICER1*. *N. Khan[1], L. Doros[2], K-A. Schultz[3], G. Williams[4], A. Bauer[5], L. Dehner[6], Y. Messinger[3], D. A. Hill[2], D. R. Stewart[1].* 1) National Cancer Institute, Rockville, MD; 2) Children's National Medical Center, Washington, D. C; 3) Children's Hospitals and Clinics of Minnesota, Minneapolis, MN; 4) International PPB Registry, Minnesapolis, MN; 5) Children's Hospital of Philadelphia, Philadelphia. PA; 6) Washington University, St. Louis, MO.

DICER1-syndrome is a recently recognized pleiotropic tumor predisposition syndrome. Multiple case-reports and case-series suggest nodular thyroid hyperplasia, non-toxic multinodular goiter (MNG), and possibly thyroid cancer are features of *DICER1*-syndrome. We collected self-reported histories of MNG and thyroidectomies from 76 cases with *DICER1*-syndrome recruited for history non-thyroid *DICER1*-syndrome-associated tumors, and 52 of their unaffected family members, and prospectively evaluated the cohort at the Clinical Center of the National Institutes of Health. The risk of diagnosed MNG was higher in both women (P=0. 0003) and men (P=0. 011). Counting thyroid surgery as a censoring event, the actuarial (lifetime) risks of diagnosed MNG in women and men with *DICER1*-syndrome were 29% and 11% by age 20 years, respectively, compared to 0% in controls of either sex. By age 40 years, the risks in cases were 80% and 19% among females and males, respectively, compared to 27% and 0% among female and male controls, respectively. In total, 22 out of 26 adult women with *DICER1*-syndrome reported a history of either MNG or thyroid surgery, compared to 5 out of 17 women without mutations (P<0. 001). In women without a history of MNG or thyroid surgery, more thyroid lesions were detected in those with *DICER1*-syndrome than in women without *DICER1*-syndrome. Similarly, a greater proportion of men with *DICER1*-syndrome reported a history of either MNG or thyroid surgery (p<0. 05), and more lesions were detected in cases (median:4; range:0-9) than were detected in controls (median:0; range:0-4) (P<0. 001). We used generalized estimating equations to test for differences in the size of lesions in cases (n=149) and controls (n=54). Lesions found in cases tended to be larger than those found in controls (P=0. 034). The composition of lesions (solid, cystic, partial cystic/solid, indeterminate) was not different between cases and controls. A total of 15 (10%) lesions in cases harbored calcifications compared to only one lesion (2%) in controls (P=0. 075). From 109 cases with 3,063 person-years of risk, three cases of thyroid cancer in the cohort yielded an observed/expected ratio of 15. 6 (95%CI: 3. 22-45. 6), though one case arose after administration of chemotherapy for PPB type II. We confirm in our cohort a high risk of diagnosed MNG, particularly in women and those between ages 15 and 25 years, and a modest increase in the risk of thyroid cancer.

Clinical Utility Evaluation of a Multiple-Gene Sequencing Assessment in Chinese Hereditary Breast Cancer. *X. Ye[1], X. Zhang[2], X. Wang[1], B. Xia[2], J. Xie[2], S. Zhu[1], J. Wang[1], D. Pang[2,3].* 1) BGI-Shenzhen, Shenzhen, Guang Dong, China; 2) Department of Breast Surgery, Harbin Medical University Cancer Hospital, China; 3) Translational Medicine Research and Cooperation Center of Northern China , Heilongjiang Academy of Medical Sciences, China.

Background Currently, dozens of susceptibility genes have been defined for cancer, including the most classic breast cancer susceptibility genes, BRCA1 and BRCA2, in hereditary breast cancer. Though several researches have proved the clinical utility of multiple-gene sequencing, instead of only BRCA1/2 test, in assessment of people with high hereditary cancer risk, little clinical approach is available. Especially, there is limited such research in China, which country counts for approximately one fifth of world population. Here, we use a multiple-gene sequencing assessment to identify the variations spectrum and evaluate the clinical utility of this assessment in Chinese cohort with high hereditary breast cancer risk. **Methodology/Principal finding:** Breast cancer patients, who meet the enrollment criteria of NCCN genetic or familial high-risk assessment guideline were informed and involved in this research. DNA was extracted from participants' blood. The coding regions of 115 genes, which are reported associated with the susceptibility or potential risk of 38 types of cancers were captured and sequenced using next generation sequencing platform. Single Nucleotide Polymorphism (SNP) and Insertion/deletion (Indel) variants were defined and analyzed. Pathogenic variants and potentially actionable results were informed to participants according to their willingness. Totally, 424 high-risk breast cancer patients participated in the research. From which, 89 patients harbored pathogenic germline variants, including 60 patients (14. 15%) carrying BRCA1, BRCA2 or PALB2 pathogenic variants, as well as 29 patients (6. 84%) carrying pathogenic variants in other genes. 250 VUS spots from 27 breast cancer susceptibility genes were identified in Chinese cohort and revealed a significantly different spectrum compared with Caucasian data. Additionally, 14 non-BRCA1/BRCA2/PALB2 gene pathogenic variant carriers and their relatives were followed and informed to recruit for further particular precancerous lesions screening. Positive precancerous lesion results have been observed in 3 families. **Conclusion** Overall, based on this research, we have revealed a comprehensive susceptibility variations spectrum and firstly evaluated clinical utility of a multiple-gene sequencing assessment in high hereditary breast cancer risk Chinese cohort.

Germline mutations in *RECQL* genes identified in high-risk breast cancer families. *F. Fostira[1], I. S. Vlachos[1,2], P. Apostolou[1], A. Vratimos[1], V. Mollaki[1], I. Konstanta[1], A. Vagena[1], M. Papamentzelopoulou[1], I. Konstantopoulou[1], D. Yannoukakos[1].* 1) Molecular Diagnostics Laboratory, National Centre for Scientific Research 'Demokritos', Athens, Greece; 2) DIANA-Lab, Department of Electrical & Computer Engineering, University of Thessaly Volos, Greece.

Even though extensive research has been performed in the field of breast cancer genetics using cutting-edge next generation sequencing (NGS) techniques, till date only a small number of candidate genes has been identified, most of which showing incomplete penetrance. Analysis of families with breast cancer aggregation and no mutations in the known breast cancer genes through exome sequencing has revealed a new promising gene: *RECQL1*. *RECQL1* is one of the five members in the RecQ helicases family, whichplay a critical role in DNA unwinding during DNA repair. Mutations in both alleles of *RECQL2, RECQL3* and *RECQL4* genes are known to cause Werner, Bloom and Rothmund-Thomson syndromes respectively, while a role in cancer susceptibility has been reported but remains unclear.

One hundred and ninety eight individuals (n=198) with early onset (<40 y) breast cancer, male breast cancer or having at least three breast and/or ovarian cancer cases within their family have been sequenced by NGS using the Illumina TruSight Cancer panel. It is a DNA capture-based targeted re-sequencing panel covering more than 1,700 coding exons of 94 cancer-related genes. All individuals have been previously tested negative for *BRCA1* & *BRCA2* mutations. All identified mutations have been validated with Sanger sequencing.

In total, four loss-of-function mutations were identified in RecQ family genes. Specifically, two mutations (c. 2205_2006insT & p. Q548X) have been identified in *RECQL3,* while one mutation has been detected in each of the*RECQL2* (p. R1406X) and *RECQL4* (c. 2300delG) genes. None of the mutations carriers had a detectable mutation in any other breast cancer predisposition gene including *BRCA1, BRCA2, CHEK2, PALB2, PTEN* and *TP53.*

Our findings suggest that genes within the RecQ family, other than *RECQL1,* can be potential breast cancer gene candidates. Further, large-scale genotyping will enable the determination of these genes' prevalence.

Whole exome sequencing enhances our understanding of pituitary adenoma. *K. Reddy[1], M. Korbonits[2], A. K. Madugundu[i], S. Sekhar[1], K. K. Mukerjee[3], A. Bhansali[3], P. Gupta[3], A. Rai[3], H. Gowda[1], R. K. Vashista[3], B. D. Radotra[3], A. Pandey[j], P. Datta[3].* 1) Institute of Bioinformatics, Bangalore, Karnataka, India; 2) Barts Health NHS Trust, London, UK; 3) PGIMER, Chandigarh, India.

Acromegaly(in adults)orgigantism(in child) isusually caused by a growth hormone-secreting pituitary adenoma. Apart from the well-known *GNAS* mutations, somatic sequence changes leading to somatotrophinoma tumorigenesis are unknown. We performed whole exome sequencing (WES) on DNA from 9 somatotrophinoma/paired peripheral blood sample and on 2 further somatotrophinoma samples (Illumina-HiSeq 2500)at an average read depth of 60X. We used a140 gene panel associated with acromegaly or pituitary adenomas to screen the exome. In a familial case of mother and daughter, the daughter had a NM_002072 (GNAQ):c. 286A>T(p. T96S) somatic variant in the adenoma but not in peripheral blood. In a second familial case of first cousins,one had somatic NM_001077488. 2(GNAS):c. 604C>T (p. Arg202Cys); the other cousin had a TSHoma and a somatic deletion disrupting a splice site previously-described as a pathogenic change in *MEN1.* A 3y patient had a heterozygote germline stop gain NM_003977. 2 (AIP):c. C241T(p. R81*) in *AIP*,which was hemizygous in the tumor sample. The tumor of a 7y patient had a novel low level somatic NM_001077490(-GNAS):c. 1639G>A(p. A547T) variant. A recurrent adenoma had a known pathogenic somatic substitution NM_020975. 4(RET):c. 2556C>G(p. I852M) (HGMD citationCM012799, RCV000021869), the paired blood or first tumor sample were not available for investigation. An acromegaly patient with Ph+ chronic myeloid leukemia (CML) had a pathogenic NM_020630(RET):c. 1118C>T(p. A373V) (HGMD citation CM065437) somatic *RET*variant. Three other cases had somatic*GNAS* variants: two were c. 604C>T and one was a novel variant NM_001077488(GNAS): c. 1120C>T(p. R374C). In conclusion, the majority of acromegaly samples (10/11, 90. 1%) harbored suspicious changes using WES. In our cohort, 54% (6/11) of adenomas had a *GNAS* somatic variant,of which 4/6 (67%) were the well described c. 604C>T variant. Interestingly, somatic *MEN1*, *GNAQ* and *RET* variants were also identified.

2766T

Challenges in disease gene identification in complex diseases: example from familial melanoma. *A. M. Goldstein[1], M. C. Fraser[1], H. Bennett[1], M. Rotunno[1], L. Burdett[1,2], A. Vogt[1,2], B. Hicks[1,2], K. Jones[1,2], S. J. Chanock[1], M. Yeager[1,2], X. R. Yang[1], M. A. Tucker[1], NCI DCEG Cancer Sequencing Working Group, NCI DCEG Cancer Genomics Research Laboratory.* 1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Bethesda, MD, USA; 2) Cancer Genomics Research Laboratory, Leidos Biomedical Research, Inc. , Frederick National Laboratory for Cancer Research, Frederick, MD, USA.

Although next generation sequencing (NGS) studies have resulted in the identification of a number of novel disease predisposition genes, disease gene discovery has been more limited for many cancers and other complex diseases. To investigate this issue further, we evaluated malignant melanoma patients from families with germline mutations in *CDKN2A/ARF*, *CDK4*, and *POT1* that are part of an ongoing single institution familial melanoma genetics study. Germline mutations in *CDKN2A*, the major known high-risk melanoma susceptibility gene, have been described in approximately 20% of familial melanoma kindreds. In contrast, germline mutations in *CDK4*, *ARF*, and *POT1*, occur in less than 1-2% of melanoma-prone families and are thus considered “rare” high-risk melanoma susceptibility genes. In our ongoing familial melanoma genetics study, we previously identified germline mutations in 28 melanoma-prone families including 23 in *CDKN2A*, 2 in *CDK4*, 1 in *POT1*, and 2 large deletions in *ARF*. Overall, 6% of melanoma patients (11/175) were sporadic, defined as not carrying their family’s high-risk melanoma-related mutation. Families with mutations in the rare melanoma predisposition genes (*CDK4*, *POT1*, and *ARF*) were significantly more likely to include sporadic patients (4/5) than families with *CDKN2A* mutations (4/23), p=0. 015. In addition, although early age at cancer diagnosis is a hallmark of genetic susceptibility, age at melanoma diagnosis in the sporadic patients (n=7) was below the United States median for 6 of the 8 families. Further, the sporadic patients in two families, both with mutations in rare melanoma predisposition genes, were among the youngest cases in their families with age at diagnosis six and fifteen years below the family median, respectively. Similarly, the sporadic patients were phenotypically indistinguishable from their mutation-carrying melanoma patient relatives. Therefore, selection of the youngest melanoma patient(s) for NGS or other types of genomic studies would have precluded disease gene identification in these families. Although based on a single genetics study at one institution, these findings illustrate some of the challenges in disease gene discovery in complex diseases. As investigators search for rarer disease predisposition genes, recognizing potential complexities of the diseases, studying multiple patients, and investigating larger numbers of families, most likely through collaborations, will be required.

2767W

Germline *BAP1* mutations misreported as somatic based on tumor-only testing. *M. H. Abdel-Rahman[1,2], K. Rai[2], C. M. Cebulla[1], R. Pilarski[2].* 1) Ophthalmology, The Ohio State University, Columbus, OH; 2) Division of Human Genetics, The Ohio State University, Columbus, OH.

Objective: There is an increasing interest in genomic-based management of tumors with several clinical laboratories offering molecular genetic testing of tumors using an extended panel of cancer genes as well as exome sequencing. Several of these laboratories utilize tumor tissue without matching germline DNA for their assessment. Results are based on in-house developed calling algorithms based on tumor cellularity and minor allele frequency (MAF) of the mutation. Here we present three patients reported with somatic mutations of *BAP1* in various tumors. Upon further assessment in our laboratory we determined these mutations to be germline heterozygous mutations. Methods: Germline *BAP1* mutations were evaluated by direct single-site sequencing of the reported somatic mutation in *BAP1* in germline DNA extracted from peripheral blood leukocytes. Cancer family histories of the patients were also collected. Results: Two of the mutations were reported by one laboratory while the third was reported by another laboratory. The three patients had strong personal and/or family histories suggestive of *BAP1*-Tumor Predisposition Syndrome. The tumor from the first patient was a metastatic adenocarcinoma of unknown origin; immunohistochemistry and imaging suggested a cholangiocarcinoma. Family history of pancreatic, ovarian, non-melanoma skin cancers, and mesothelioma was reported. The second patient presented with metastatic uveal melanoma with family history of uveal melanoma and a cancer of unknown origin. The third patient presented with personal history of invasive breast cancer and family history of mesothelioma, renal cell carcinoma, uveal melanoma, and several other cancers. Tumor tissue and germline DNA was tested in all three patients and heterozygous mutations were identified in both tumor and germline DNA in all cases. The somatic and germline mutation allelic ratios were similar in all cases (about 50:50). Conclusion: Sequencing of matching germline and tumor DNA is crucial for proper assessment of somatic versus germline mutation status. In patients with reported somatic mutation from laboratories carrying out tumor-only genomic testing, the possibility that a variant may be a germline mutation is warranted especially if personal and/or family history suggest hereditary cancer predisposition.

2768T

The association between RAD51 135G>C polymorphism and breast cancer risk. . *A. Mr. Alblihy.* Prince mohammad bin Naif medical centre, Riyadh, Saudi Arabia.

Breast cancer is the most frequent type of cancer diagnosed among women worldwide. Many dominantly inherited breast cancers result from mutations in the tumour suppressor genes *BRCA1* and *BRCA2* responsible for repairing DNA double strand breaks. A DNA double strand break (DSB) is the most dangerous type of DNA damage. *RAD51* located on chromosome 15q15. 1 and encodes for a protein plays a vital role in repairing DNA double strand breaks, particularly through a homologous recombination mechanism. A single nucleotide polymorphism in the 5' untranslated region of *RAD51*135G>C (rs1801320) has been identified to modify the risk of breast cancer among *BRCA1/2* mutation carriers. However, the results of studies that investigate the role of this polymorphism in the risk of breast cancer have been controversial. This report reviewed these studies in order to identify possible reasons for the discrepancies in results. It was found that there are many possible reasons could play roles in the inconclusive results. The effect of *RAD51* polymorphism on gene expression is still unclear. Thus, This report recommend to measure the gene expression in order to have a comprehensive understanding of the impact of this polymorphism in the *RAD51* function of homologous recombination (HR).

Genetics of Breast Cancer in a Highly Consanguineous Population, Challenges and lessons learned so far. *A. AlSaegh.* Genetics Department, Sultan Qaboos University, Sultanate of Oman.

Cancer genetics service was officially established in Sultanate of Oman in August 1st 2012 at the Genetics and Developmental Medicine Clinic in Sultan Qaboos University Hospital. Sultanate of Oman is situated in the southeast part of the Arabian Peninsula and it's characterized by high rate of consanguinity (52%) Individuals with moderate to high risk were referred mainly from the multidisciplinary breast clinic and other tertiary hospitals in the country. From August 2012 to May 2015, a total of 61 patients were referred, of which 36 individuals underwent molecular testing. 9/36 (25%) were found to haveBRCA mutations, 2/36(5. 6%) had PTEN mutations, 2/36 (5. 6%)had PMS2 mutations and 1/36 (2. 8%) had BRIP1 mutation . There were a number of challenges that were identified: lack of confirmatory dataon other affacted individuals of the family , concealing family history due to cultural believes, fear of stigma and some patients were treated outside the country . In addition, one major difficulty was selecting the right test when medical and pathological data was missing on other affacted members of the family. Conclusions: BRCA genes are to be considered in the Omani population. In some families, the predisposiposition to cancer was illustrating an autosomal recessive mode of inheritance, these families are to be approached differently toreveal their molecular etiology.

2770T

Next Generation Cancer Gene Testing in a Large HMO: the First 10 Months' Experience. *M. Alvarado[1], G. E. Tiller[1], J. Goff[1], R. Haque[2].* 1) Dept Genetics, Kaiser Permanente, Pasadena, CA; 2) Dept Research & Evaluation, Kaiser Permanente, Pasadena, CA.

Kaiser Permanente provides medical services to over 4 million members in southern California. Since July 2014, 1,343 patients (1,251 women and 92 men) who were referred to Genetics were tested via a multigene cancer panel, when the patient's clinical presentation and/or family history suggested the possibility of more than one cancer syndrome. Patient demographics: age 22-81 years; race/ethnicity: European 27%, Latino/Hispanic 25%, Asian 11%, African-American 7%, other 29%. The custom-designed panel included 20 cancer susceptibility genes: APC, ATM, BMPR1A, BRCA1, BRCA2, CDH1, CDKN2, CHEK2, EPCAM, MLH1, MSH2, MSH6, MUTYH, PALB2, PMS2, PTEN, SMAD4, STK11, TP53, and VHL. All tests were performed using NGS as well as CGH or MLPA. We identified 184 pathogenic/likely pathogenic mutations among 176 patients (13%) in the following genes: BRCA1 (42), BRCA2 (31), MUTYH (28; only one biallelic carrier), CHEK2 (22), ATM (18), PALB2 (13), MSH6 (6), TP53 (6), MSH2 (3), PMS2 (3), MLH1(2), CDKN2 (2) APC (2) VHL (2), and one mutation in each of the following genes: BMPR1, CDH1, and PTEN. Of the 176 patients with pathogenic mutations, 128 patients (73%) had both a personal and family history of cancer and/or polyps. Among the 176 patients with pathogenic mutations, 6 were found to carry more than one pathogenic mutation. No mutations were detected in 733 patients (55%); at least one variant of unknown clinical significance (VUS) was detected in 432 patients (32%); variants in ATM, APC, MSH6, BRCA2 and CHEK2 made up over 55% of all VUS detected. The overrepresentation of BRCA1 & 2 among all mutations identified (39%) likely reflected the significantly higher proportion of female patients referred to our department whose personal and/or family history included breast and/or ovarian cancer, compared to other cancer types. The identification of a significant percentage (37%) of dominant-acting gene mutations other than BRCA1 & 2 and those encoding MMR proteins provides further justification for offering a cancer gene panel to selected patients with a personal and/or family history of cancer. As more natural history data are compiled in patients with mutations in less well-characterized cancer genes, we anticipate a) expanding the scope of cancers associated with specific genes, b) encountering fewer VUS, and c) developing additional gene-specific surveillance protocols to enable early cancer detection in these high-risk patients and their family members.

Expression of A-kinase anchor protein 4 (AKAP4) in breast cancer. *S. Amini[1], E. Sakhinia[2], A. Abak[2].* 1) human genetic, tabriz university of medical science, tabriz, Iran; 2) biotechnology research center, tabriz, iran.

Introduction: Breast cancer is a common malignancy and a leading cause of cancer related death among woman. About 1. 3 million women are diagnosed with breast cancer each year over the world. A-Kinase anchor protein 4 (AKAP4) is a novel cancer testis antigen and it is a member of the AKAP family. AKAP4 is a part of protein kinase A super pathway. AKAPs are a group of proteins, which have function of binding to the regulatory subunit of protein kinase A. Early diagnosis contribute to improved survival rate and clinical outcome in breast cancer. AKAP4 gene are aberrant expressed by various malignancies but not by normal tissues with the exception of testis. The aim of this study was to investigate the association of AKAP4 with breast cancer and its relationship with the clinicopathological features of the patients. Materials and Methods: total RNA was isolated from 40 pairs of breast cancer tissues and adjacent non-cancerous tissues. CDNAs were synthesized. the expression level of AKAP4 gene was quantified by real time PCR. the correlation between the expression level of AKAP4 and clinicopathological features was studied. Results: AKAP4 was expressed in 87% (35/40) of breast cancer tissues but not in any of adjacent non cancerous tissues. and There was no significant relationship between AKAP4 mRNA expression and clinicopathological features of patients. Conclusions: This finding suggest that A-kinase anchor protein 4 can serve as a biomarker and novel prognostic indicator in breast cancer and may be a potential target for immunotherapy.

2772T

Systematic pan-cancer analysis of tumor purity. *D. Aran, M. Sirota, A. Butte.* UCSF, San Francisco, CA.

The tumor microenvironment describes the non-cancerous cells present in and around the tumor, including mainly immune cells, but also fibroblasts and cells that comprise supporting blood vessels. These non-cancer components of the tumor may play an important role in cancer biology. However, they also have a strong influence on the analysis of tumor samples by genomic approaches, and accordingly may alter the biological interpretation of the results of such analyses. Here we present a systematic analysis using different measurement modalities of tumor purity in more than 10,000 samples across 21 cancer types from The Cancer Genome Atlas (TCGA). We stratify patients according to clinical features to detect differences in purity levels, and demonstrate the confounding effect of tumor purity on correlating and clustering tumors with genomic data. Finally, using a differential expression method that accounts for tumor purity, we reveal an immunotherapy gene signature in several cancer types that cannot be detected by traditional differential expression analysis.

2773W

Large scale rare variation case-control studies. Comparing rare variation landscapes in uveal and cutaneous melanoma. *M. Artomov[1,4,6], I. Kim[2], A. Stratigos[3], M. Daly[1,4], H. Tsao[5].* 1) ATGU, Massachusetts General Hospital, Boston, MA; 2) Massachusetts Eye and Ear Infirm, Boston, MA; 3) Department of Dermatology, University of Athens Medical School, Athens, Greece; 4) Broad Institute, Cambridge, MA; 5) Department of Dermatology, Massachusetts General Hospital, Boston, MA; 6) Chemistry and Chemical Biology Department, Harvard University, Cambridge, MA.

Recent progress in sequencing data processing pipelines development allows creation of unprecedentedly large data sets. Here we report analysis involving almost 10000 full exome samples processed in a single batch using the most recent techniques for DNA variant calling. Ocular melanoma (OM) [OMIM 155720] is the most common primary intraocular cancer in adults. Unlike cutaneous melanoma (CM) [OMIM 155600], both environmental and genetic risk factors for OM are still largely unclear. It has long been recognized that OM and CM can co-exist in the same kindred though germline CDKN2A mutations, which occur in 10-40% of hereditary CM kindreds, account for a small fraction (<1%) of OM/CM families. Recently, a subset of hereditary OM families were found to harbor germline mutations in the BAP1 gene. Members of these BAP1 kindreds frequently develop CM, rather than OM, along with a host of other internal malignancies. These findings suggest that both ocular and cutaneous melanomas may share common risk pathways. Here we present our results of a large-scale rare variants association study. We assembled a full exome sequencing dataset of 400 cutaneous and ocular melanoma cases matched to 8000 non-cancer controls. We identified 19 loci that showed some evidence of association with OM risk though only BAP1 reached genome-wide significance. This analysis of an uncommon cancer phenotype (i. e. hereditary ocular melanoma) is important in establishing the dominance of BAP1 in the risk landscape of OM and in building a foundation for performing RVAS in the future. Literature reports that BAP1 protein is a member of highly cooperative BAP1 protein complex. Unlike in OM cases of CM do not show any enrichment of BAP1 mutations, however they show association signal for other members of BAP1 complex (ASXL1, ASXL2) allowing the discrimination between the two melanoma phenotypes based on the germline mutation landscape. As well this clarifies validity and value of rare variants association studies for various applications.

Report of two patients with unclassified variants in *BRCA2* gene. How to perform the genetic counseling? *M. D. F. Carvalho[1, 2,3, 4], K. M. Carvalho[1,2,3], E. D. F. Carvalho[1,2,3,4].* 1) Medical Genetics, Unichristus, Fortaleza, Ceara, Brazil; 2) Renorbio, Universidade Estadual do Ceará, Fortaleza, Ceara, Brazil; 3) Medical Genetics, Genpharma, Fortaleza, Ceara, Brazil; 4) Medical Genetics, APAE-CE, Fortaleza, Ceara, Brazil.

Hereditary breast and ovarian cancer syndrome, caused by a germline mutation in*BRCA1*or*BRCA2*, is characterized by an increased risk for breast, ovarian, prostatic and others cancers. An increased likelihood of a *BRCA1* or *BRCA2* mutation is suspected on the basis of certain personal and family history characteristics and various clinical criteria. The diagnosis is made by molecular genetic testing in an individual or family with a germline*BRCA1*or*BRCA2* mutation. DNA variants of uncertain significance (VUS) are common outcomes of clinical genetic testing for susceptibility to cancer. We report two patients with DNA VUS at *BRCA2* gene. Case 1 is a woman with a previous diagnosis of breast cancer before age 40. Her maternal grandmother and her father had breast and kidney cancer, respectively. The sequencing of the BRCA2 gene revealed the probably pathogenic heterozygous variant: c. 4804delA, not reported previously. This variant creates a frameshift in exon 11, resulting in a stop codon after 13 subsequent amino acids. There are no data in the literature regarding this particular variant, however, all frameshifts resulting in early stop codon in this exon are considered pathogenic causing loss of protein interaction domains. Case 2 is a woman without cancer diagnosis but with a family history of ovarian cancer in her mother and maternal haunt. She came to our ambulatory of medical genetics to perform genetic counseling. The sequencing of the BRCA2 gene revealed the heterozygous variant: c. A5096G, not reported previously. This is a rare variant with often less than 0. 1% of the population. Literature data are controversial as the role of variant in breast or ovarian cancer onset in people with personal or family history of breast cancer, it is not possible classifies it as pathogenic or benign. Bioinformatics analysis of this variant with pathogenicity prediction software and conservation show that the exchange occurred in the region not conserved among different species (low scores in PhyloP and GERP), and the SIFT and Polyphen 2 tools predict the exchange as not pathogenic. The LTR and Mutation Taster software ranked as neutral variant. Unclassified variants with unknown clinical significance in *BRCA1* and *BRCA2* genes pose a problem in genetic counseling, as their impact on risk of breast and ovarian cancer is still unclear. We encourage the development of international VUS-related guidelines for genetic counselors.

2775W

Characterization of Cycle-regulated genes in a cancer cell line by single cell genomics. *O. De la Cruz Cabrera[1], D. Mikkola[2,3], S. Edelheit[4], S. Markowitz[2,3].* 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH; 2) Department of Medicine, Case Western Reserve University and Case Medical Center, Cleveland, OH; 3) Case Comprehensive Cancer Center, Case Western Reserve University and Case Medical Center, Cleveland, OH; 4) Department of Genetics and Genome Science, Case Western Reserve University, Cleveland, OH.

We used single-cell RNA-seq data to characterize cycle-regulated genes in a rapidly dividing cancer cell line derived from an aggressive liver metastasis of a colon cancer. Integration of the static information from the 70 individual cells into dynamic information about the cell cycle was achieved by use of the CRESCA (Cycle-regulated Expression via Single Cell Analysis) method. Single cell sequencing of mRNA was performed using microfluidic capture and paired-end sequencing of barcoded libraries. CRESCA uses tools from manifold regression and statistical learning to estimate the position of the each cell along the cell cycle. These positions, called artificial time stamps, are then used as a synthetic time-course experiment to scan all genes for cyclical expression. This powerful combination of methodologies enables analysis of cell cycle gene expression in populations of actively dividing cells. In particular, it holds great promise in the genetic dissection of proliferation in cancer.

2776T

The power of next generation sequencing in the detection of breast and ovarian cancer susceptibility genes other than *BRCA*. *M. Eliade[1], J. Skrypski[2], A. Baurand[1,2], C. Jacquot[1,2], G. Bertolone[1], C. Loustalot[2], C. Coutant[2], F. Guy[2], P. Fumoleau[2], J. -B. Rivière[1], Y. Duffourd[1], F. Ghiringhelli[2], F. Végran[2], R. Boidot[2], S. Lizard[2], L. Faivre[1,2].* 1) CHU Dijon, Dijon, Cote d'Or, France; 2) Centre Georges-François Leclerc, Dijon, France.

Background : Most cases of breast and ovarian cancer susceptibility remains unexplained. Testing multiple genes in one go with next generation sequencing is then an asset with the recent discovery of new genes involved in breast and ovarian cancer susceptibility. Methods : We studied 457 patients originated from Burgundy (France) fulfilling the criteria for *BRCA1* and *2* testing using a next generation sequencing 25-gene panel including 17 genes of predisposition for breast and/or ovarian cancer (*ATM, BARD1, BRCA 1/ 2, BRIP1, CHEK2, PALB2, RAD51C, TP53, PTEN, RAD50, MRE11, MLH1, MSH2, MSH6, PMS2, STK11*). Results : A pathogenic *BRCA1/2* mutation was found in 8% (n=37) of patients. Besides, we found 39 deleterious or probably deleterious mutations in 13 different genes. The most frequently mutated genes were *CHEK2* (n=10 ; 2. 1 %), *ATM* (n=9 ; 2 %), and *PALB2* (n=4; 0. 9%). One patient had deleterious mutations in both *TP53* and *PALB2,* and another one had deleterious mutations in both *BRCA2* and *CHEK2.* The mutation could explain the phenotype in the majority of cases, but a pathogenic mutation was found in a different predisposing gene in 7 patients, and could be considered as incidental findings with the currently published spectrum of cancer locations. Conclusion : Besides *BRCA1/2* mutations, that remain the most frequent susceptibility genes for breast and ovarian cancer, gene panels remain a powerful tool for identifying the other less frequent susceptibility genes. The penetrance and spectrum of cancer associated to these other genes remain sometimes undefined, and further collaborative work is crucially needed to address this question. The possibility of double hits should led to careful genetic counseling.

2777W

Mosaic loss of chromosome Y (LOY) in peripheral blood is associated with smoking, shorter survival and increased risk of cancer in men. *L. A. Forsberg[1, 2], C. Rasi[1, 2], N. Malmqvist[1, 2, 3], H. Davies[1, 2], S. Pasupulati[1, 2], G. Pakalapati[1, 2], J. Sandgren[4], T. Diaz de Ståhl[4], A. Zaghlool[1, 2], V. Giedraitis[5], L. Lannfelt[5], J. Score[6], N. C. P. Cross[6], D. Absher[7], E. Tiensuu Janson[3], C. M. Lindgren[8, 9], A. P. Morris[8], E. Ingelsson[2, 3], L. Lind[3], J. P. Dumanski[1, 2].* 1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 4) Department of Oncology-Pathology, Cancer Center Karolinska, Karolinska Institutet, Stockholm, Sweden; 5) Department of Public Health and Caring Sciences, Uppsala University, Uppsala, Sweden; 6) Faculty of Medicine, University of Southampton, Southampton, UK; 7) HudsonAlpha Institute for Biotechnology, Huntsville, Alabama, USA; 8) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 9) Broad Institute of MIT and Harvard University, Cambridge, Massachusetts, USA.

We have shown that a male specific genetic risk factor, lifetime-acquired mosaic loss of chromosome Y (LOY) in non-cancerous blood cells, is associated with an increased risk of non-hematological tumors (Forsberg et al. 2014 Nature Genetics, PMID: 24777449). Analyzes performed in the Swedish ULSAM-cohort with >1100 participants analyzed on 2. 5M Illumina SNP-array indicated that LOY in peripheral blood could be associated with all-cause mortality (hazards ratio (HR) = 1. 91, 95% confidence interval (CI) = 1. 17–3. 13; 637 events) and non-hematological cancer mortality (HR = 3. 62, 95% CI = 1. 56–8. 41; 132 events). The median survival time after sampling in men affected with LOY was half, i. e. 5. 5 years shorter. The association of LOY with risk of all-cause mortality was validated in the independent PIVUS-cohort (HR = 3. 66, 95% CI = 1. 27–10. 54; 59 events). A frequent loss of the Y chromosome in the haematopoietic system was first described more than 50 years ago but its phenotypic consequences have been elusive. At least 15% of men above 70 years of age in our so far analyzed cohorts have LOY in a substantial degree of the blood cells. This discovery could help explain why males have a higher incidence and mortality from most sex-unspecific cancers. Smoking killed about 100 million people during the 20th century and is projected to kill one billion people during this century. We have recently shown (Dumanski et al. 2015 Science, PMID: 25477213), that having blood cells without a Y chromosome (LOY) is associated with smoking status using three independent cohorts (TwinGene: OR=4. 3, 95% CI =2. 8-6. 7; ULSAM: OR=2. 4, 95% CI=1. 6-3. 6; and PIVUS: OR=3. 5, 95% CI=1. 4-8. 4). A transient and dose-dependent mutagenic effect from smoking on LOY-status was observed. Lung cancer is the prime cause of cancer associated death in relation to smoking but it is less well appreciated that smoking also causes tumors outside the respiratory tract, which are predominant in men, and cumulatively roughly as common as lung cancer. The mutagenic effect from smoking on LOY could help explain why smoking seems a greater risk factor of cancer in smoking men compared to smoking women. It is well known that men have a shorter life expectancy compared to women in the entire word, but the underlying cause of this sex-difference was previously unknown. LOY in blood might help explain the shorter lives of men and could also become a new predictive biomarker of male carcinogenesis.

2778T

Germline PRKCD mutation linked to childhood EBV+ Hodgkin Lymphoma. *M. Ivanova[1], S. Lipinski[1], D. Loizou[2], R. Saadeh-Haddad[4], O. Alpan[2, 3], O. Goker-Alpan1[1, 2].* 1) Translation Medicine, Lysosomal & Rare disorders research treatment center, Fairfax, VA; 2) O and O Alpan, LLC, Fairfax, VA; 3) AmerImmune, Fairfax VA; 4) Medstar, Georgetown University Hospital, Washington, DC.

Hodgkin lymphoma (HL) comprises 6% of childhood cancers. While little is known about the molecular mechanisms, 40% of HL occurs after an infection by Epstein-Barr virus (EBV). It is suggested that B cells accumulate somatic mutations and DNA repair mechanism become nonfunctional. Chromosomal and genetic instability are typical features in the development of Hodgkin and Reed-Sternberg cells from B and, to a lesser extent, T cells. *Case report and results:* A five-year-old boy, born to non-consanguineous parents of Afghani descent, was evaluated for macrocephaly, developmental delay and hearing loss. At age 4, he was diagnosed with HL after the biopsy of a nasopharyngeal mass. He was (EBV+) and while he responded well to chemotherapy initially, he had recurrences in parallel with increasing EBV titers. Flow cytometric analysis of PBMCs showed the expansion of immature B (CD21 Dim 23. 7%) and absent memory B -CD20/CD27 cells(14, normal 22-134). B cells immunoglobulin expression were decreased, G (0. 5%) (normal 1. 4-12. 5%) and A (0. 3%) (1. 1-6. 0%), indicating a class switch defect. 98. 3% of B cells were CD5+ dim (normal average 1-9%). T helper cells showed slight lymphopenia (26%, normal 26-57%). The patient had normal NK and NKT populations (4. 6 and 3. 5%) (normal 3. 4-24% and 0. 6-8. 2%). Whole exome sequencing identified a homozygous **G3149D** variant of unknown significance in *PRKDC* (NM_006904. 6). EBV selectively inhibits CD5+ cells, and thus can stay latent by preventing apoptosis of the transformed cells. B cell impairments and CD5+ cell proliferation could be attributed to alterations in *PRKDC,* a DNA-dependent protein kinase catalytic subunit, acting as a molecular sensor for DNA damage, and a scaffold protein to deliver repair proteins to the site of DNA damage. While missense *PRKDC* mutations are associated with Severe Combined Immune Deficiency, with absent B and T cells, and additional dysmorphic features, CNS structural abnormalities, the somatic mutation G3149D is listed as a factor contributing to oncogenesis. GGC>GAC (c. 9446 G>A) in exon 68 leads to a replacement of glycine by aspartic acid, likely to impact the secondary protein structure and compromise the protein-protein binding ability by changing the polarity and charge. While *PRKDC* knockout models are used to study lymphoproliferative disorders and EBV infection, this is the first case in humans linking *PRKDC* to EBV associated *HL.* .

2779W

Non-random occurrence and early age of onset of diverse lymphoid cancers in families supports the existence of genetic risk factors for multiple lymphoid cancers. *S. Jones[1,2], J. Voong[3], R. Thomas[2], A. English[2], J. Schuetz[2], G. W. Slack[4], J. M. Connors[4], A. Brooks-Wilson[2,5].* 1) Medical Genetics, University of British Columbia, Vancouver, British Columbia, Canada; 2) Canada's Michael Smith Genome Sciences Centre, British Columbia Cancer Agency, Vancouver BC; 3) Department of Statistics and Actuarial Science, Simon Fraser University, Vancouver BC; 4) Centre for Lymphoid Cancers, BC Cancer Agency, Vancouver BC; 5) Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Vancouver BC.

Lymphoid cancers are a biologically diverse group of neoplasms, yet clustering of different lymphoproliferative disorders within families has been observed, suggesting the existence of shared genetic risk factors. We have established, in Metro Vancouver, British Columbia, Canada, a collection of 140 families with 2 or more members with lymphoid cancer. We hypothesized that lymphoid cancers arising in families as a result of genetic factors that predispose to multiple types of lymphoid cancers would have: 1) an earlier median age of onset, and 2) a different pattern of co-occurrence in families than that predicted based on population frequencies. The median age at diagnosis was 9, 9, 6 and 10 years earlier for Hodgkin lymphoma (HL), non-Hodgkin lymphoma (NHL), myeloma (MM) and chronic lymphocytic leukemia (CLL) cases in these families, respectively, than for SEER cases (Howlander et. al. , 2011, SEER cancer statistics review). This corresponds to the familial HL, NHL, MM and CLL cases being at the 32nd, 29th, 30th and 25th percentile for age of onset. We also observed earlier age of onset in later generations, a phenomenon referred to as anticipation. Apparent anticipation was seen in NHL ($P < 0.0001$), HD ($P < 0.0001$), CLL ($P < 0.0013$) and all lymphoid cancers together ($P < 0.0001$). Canadian population frequencies of HL, NHL, MM and CLL were used to derive expected frequencies for pairwise combinations of lymphoid cancer types. Observed pairwise frequencies in the families were compared to expected frequencies and significance of the difference determined by permutation. Familial co-occurrences differed from those expected based on population frequencies ($P < 0.0001$). The difference is accentuated in families with more affected members (2 cases, $P < 0.0001$; 3 cases, $P < 0.0001$; 4 or more cases, $P < 0.0001$). Non-random patterns of co-occurrence, and earlier age of onset of familial cases, underscore a difference between these familial cases versus population cases, which are mainly sporadic. These observations support the idea that lymphoid cancer families are not all collections of sporadic cases that arose in the same family by chance. These observations provide evidence for the existence of inherited genetic factors that significantly increase the risk of developing several types of lymphoid cancers, and justify the use of family-based genomic methods to identify lymphoid cancer susceptibility genes.

2780T

Feasibility of cascade screening in a randomly selected sample of families at risk for hereditary breast cancer from a statewide cancer registry. *M. C. Katapodi[1,2], D. Duquette[3], K. Mendelsohn-Victor[2], B. Anderson[3], J. J. Jang[2], L. L Northouse[2], S. Duffy[4], K. J. Milliron[5], D. Ronis[2], S. D. Merajver[5,6], N. K. Janz[7], S. J. Roberts[7].* 1) Institute of Nursing Science, University of Basel, Basel, Basel-Stadt, Switzerland; 2) University of Michigan School of Nursing, Ann Arbor, MI, USA; 3) Michigan Department of Health and Human Services, Lansing, MI, USA; 4) Ohio State University School of Nursing, Columbus, OH; 5) University of Michigan Comprehensive Cancer Center, Ann Arbor, MI; 6) University of Michigan School of Medicine, Ann Arbor, MI; 7) University of Michigan School of Public Health, Ann Arbor, MI.

Genetic counseling is recommended for women diagnosed with breast cancer at a young age and their close relatives. Cascade screening is a new public health intervention that promotes systematic familial testing amongrelatives of individuals with known mutations. In an effort to assess the feasibility of statewide cascade screening, we examined the willingness of young breast cancer survivors (YBCS) to invite their high-risk relatives in such a program. A randomized trial aiming to increase awareness of cancer genetics, identified a random sample of 3000 YBCS, diagnosed 25-45 years old, and stratified by race (Black/Other), through the Michigan Cancer Surveillance Program. YBCS' responses helped identify high-risk, unaffected, female relatives. A linear regression analysis, guided by the Theory of Planned Behavior, examined baseline demographic and clinical characteristics, access and attitudes towards healthcare services, family history, and family environment as predictors of the proportion of eligible relatives YBCS were willing to contact (number willing to contact/ number of all high-risk relatives). Responses from 859 eligible YBCS (33%) helped identify 1842 high-risk relatives. YBCS were willing to contact 1271 (69%) relatives. Response rate among invited relatives was 52%. The study recruited a final sample of n=431 eligible high-risk relatives with a mean age of 43±12 years old. Willingness to contact a greater number of relatives (b=26. 03), and higher perceived risk for another breast cancer (b=0. 82) were associated with contacting a greater proportion of relatives. Having a larger family (b=-18. 92) was negatively associated with the proportion of relatives contacted. Relatives were more likely to be invited in the study by the YBCS if they were living withing 50 miles distance. Most YBCS were willing to contact relatives for cascade screening, supporting the feasibility of this approach. Results suggest barriers and facilitators in disseminating information about hereditary breast/ovarian cancer among families. Recruitment from a statewide cancer registry helped target a large number of YBCS, with multiple "red flags" in their personal and family health history, and should be considered as a systematic approach for trials involving hereditary and familiar forms of common cancers.

Retaining familial cancer cases and families in a genetic research study on lung cancer. *D. Mandal[1], A. Bencaz[1], J. Chambliss[1], J. Thompson[1], J. E. Bailey-Wilson[2].* 1) Genetics, LSU Health Sciences Center, New Orleans, LA; 2) NHGRI/NIH, Baltimore, MD.

About 10% of lung cancer cases (22,000 cases per year in the U. S.) have at least one first-degree relative affected with lung cancer, and 25% of cases at least one first- or second-degree affected relative, indicating that family history is a significant risk factor. In order to identify susceptibility genes for lung cancer, a genetic research study was initiated in southern Louisiana in 1996. Families with 3 or more cases of lung cancer were enrolled for the genetic linkage study to identify rare variants with large effects. Affected individuals and unaffected relatives of individuals who were informative for genetic linkage analysis were recruited. In 2008, we also initiated recruiting familial cases with at least two cases of lung cancer in families to identify common variants with small effects. Recruitment for familial lung cancer study is challenging due to the poor prognosis once diagnosed. In addition, the family involvement required for linkage studies makes enrollment of complete families even more challenging. The objective of the present study is to report various retention strategies used in our research study that can be utilized in the retention of any familial cancer cases/families. Annual follow up phone calls and other communication methods were implemented to maintain retention of study subjects, since family health history status may change over the years and it is important to update any such information in genetic studies. To date, 2147 individuals with lung cancer have been interviewed and 742 of them reported having a family history of lung cancer. Of them, 19 high-risk families (3 or more affected cases per family) for the linkage study have been recruited. In addition, 147 familial cases (2 or more affected cases per family) have been recruited for the genome-wide association study. Identification of susceptibility genes for familial lung cancer is underway using whole genome linkage analysis, genome wide association studies and exome sequencing using next generation strategies in collaboration with GELCC (Genetic Epidemiology of Lung Cancer Consortium), which is the only familial lung cancer research group in the world. Retention strategies used to receive continuous participation of lung cancer cases/families will be discussed in detail.

2782T

A prospective study of mitochondrial DNA copy number and the risk of prostate cancer. *A. Moore[1], Q. Lan[1], J. N. Hofmann[1], C. S. Liu[2], W. L. Cheng[2], T. T. Lin[2], S. I. Berndt[1].* 1) National Cancer Institute, Bethesda, MD; 2) Vascular and Genomic Research Center, Changhua Christian Hospital, Taiwan.

Mitochondrial DNA (mtDNA) copy number may increase in response to DNA damage as a compensatory mechanism. Increased mtDNA copy number has been observed in prostate cancer (PCa) cells, suggesting a role in PCa development, but this association has not yet been investigated prospectively. We conducted a nested case-control study (793 cases and 790 controls) of men randomized to the screening arm of the Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial (PLCO) to evaluate the association between pre-diagnosis mtDNA copy number, measured in peripheral blood leukocytes, and the risk of PCa. We used logistic regression to estimate odds ratios (OR) and 95% confidence intervals (CI) and polytomous logistic regression to analyze differences in associations with non-aggressive (Stage I/II AND Gleason grade <8) and aggressive (Stage III/IV OR Gleason grade ≥8) PCa. Although mtDNA copy number was not significantly associated with PCa odds overall (per 1-unit increase on the natural log scale, OR = 1. 23, 95% CI 0. 97-1. 55, p = 0. 089), increasing mtDNA copy number was associated with an increased odds of non-aggressive PCa (OR = 1. 29, 95% CI = 1. 01-1. 65, p = 0. 044) but not aggressive PCa (OR = 1. 02, 95% CI = 0. 64-1. 63, p = 0. 933) compared to controls. We report that increasing mtDNA copy number is associated with an increased odds of non-aggressive PCa, suggesting that high leukocyte mtDNA copy number is a biomarker of risk associated with non-aggressive PCa development but not advanced PCa.

2783W

Exploring the regulatory roles of common variants associated with lung cancer subtypes. *T. O'Brien[1,2], P. Jia[2], Z. Zhao[2,3,4].* 1) Vanderbilt Genetics Institute, Vanderbilt University School of Medicine, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University School of Medicine, Nashville, TN; 3) Department of Psychiatry, Vanderbilt University School of Medicine, Nashville, TN; 4) Department of Cancer Biology, Vanderbilt University School of Medicine, Nashville, TN.

Lung cancer is classified into two main types: small cell lung cancer (SCLC) and non-small cell lung cancer (NSCLC). NSCLC has several subtypes, the two most common being lung adenocarcinoma (LUAD) and lung squamous cell carcinoma (LUSC). These three subtypes of lung cancer have distinct physiological, clinical, and genetic signatures. Previous research has identified common variants (i. e. SNPs) associated with lung cancer subtypes; however, these common variants are often located in the non-coding regions and their functional roles in each subtype remain largely unknown. We hypothesize that these non-coding SNPs function in common or distinct regulatory mechanisms for each subtype. Thus, we explored the potential regulatory roles for common variants found to be associated with each lung cancer subtype from genome-wide association studies (GWAS) of European samples. We first obtained the SNPs that are associated with each lung cancer subtype by $p < 10\text{-}5$. Then, we expanded this list to include all SNPs in linkage disequilibrium (LD) with $r2 > 0.8$ using the 1000 Genomes Project data. This expansion resulted in 1427, 1788, and 1059 SNPs for LUAD, LUSC, and SCLC, respectively. Next, we searched for enrichment of the lung cancer SNPs in expression quantitative trait loci (eQTLs) for lung and an additional eight tissues using the data from the Genotype-Tissue Expression (GTEx) Project. Although we found that several SNPs were eQTLs, there was no statistical enrichment compared to random SNPs selected from the GWAS platform. This lack of enrichment in eQTLs was confirmed in another lung tissue-specific eQTL dataset with a larger sample size. We further searched for regulatory enrichment using the data from five lung-related tissues and cell lines generated in the Roadmap Epigenomics Project. We found very distinct regulatory signatures that differed by lung cancer subtype and lung tissue/cell type, such as SNPs within enhancer regions in LUSC and SCLC in adult lung tissue, but not in LUAD. We also found similarities among subtypes such as the highest proportion of SNPs located in an active state identified by transcription signatures at the 3' and 5' end of genes (the "TxFlnk" class in Roadmap Epigenomics) in the A549 lung cancer cell line. These preliminary results suggest that genomic regions containing common variants found in three major subtypes of lung cancer may share both common and distinct regulatory chromatin states.

Correlation between BRAF and MLH1 hypermethylation testing in a Lynch syndrome universal screening program. *L. H. Rodgers[1], K. M. Shannon[1], A. J. Iafrate[2], G. Y. Lauwers[2], A. R. Mattia[2, 3], D. C. Chung[1].* 1) Center for Cancer Risk Assessment, Mass General Hospital, Boston, MA; 2) Department of Pathology, Mass General Hospital, Boston, MA; 3) Department of Pathology, North Shore Medical Center, Danvers, MA.

Universal MSI testing of all colorectal cancers is an effective strategy to detect new cases of Lynch syndrome (LS). Immunohistochemical (IHC) staining for the mismatch repair (MMR) genes MLH1, MSH2, MSH6 and PMS2 can be performed on all resected colorectal cancer specimens. The absence of one or more MMR proteins raises the suspicion of LS and further risk assessment is indicated. However, there is a significant subset of cases with MLH1 loss due to somatic MLH1 promoter hypermethylation. These cases are considered sporadic and do not require genetic evaluation. The presence of a BRAF mutation has been proposed as a surrogate marker for somatic MLH1 hypermethylation. We sought to determine the performance characteristics of BRAF mutation testing in comparison to MLH1 promoter hypermethylation testing in a large universal screening program established at our institution. In tumors in which MLH1 protein was absent by IHC, BRAF mutation analysis (V600E) and MLH1 promoter hypermethylation testing were both performed. Of the 1011 colorectal tumors that underwent IHC testing between January 2011 and December 2014, 148 (15%) exhibited loss of the MLH1 protein. 124 specimens were available for BRAF/MLH1 hypermethylation reflex testing. 84 (68%) were positive for MLH1 hypermethylation and a BRAF mutation and these were thus classified as sporadic tumors. Sixteen (13%) were negative for both the BRAF mutation and MLH1 hypermethylation and those individuals were invited for further genetic workup of suspected LS. The remaining 24 tumors (19%) exhibited discordant results: 23 samples did not exhibit the BRAF mutation but were MLH1 hypermethylated, while 1 exhibited the BRAF mutation but was not MLH1 hypermethylated. Although all of these 24 cases were invited in for additional risk assessment, only 9 (38%) participated in genetic counseling. The average age at diagnosis was 66 years (range 50-87), 0 met Amsterdam II criteria, and none had more than one LS associated tumor. 6/9 underwent germline genetic testing and no pathogenic mutations were identified. In conclusion, BRAF testing correlates with MLH1 hypermethylation results in 81% of colon cancer cases with MLH1 loss by IHC. Using BRAF testing as a sole strategy would result in excess referrals for genetic counseling and testing. No germline MLH1 mutations were identified in the group with discordant BRAF/MLH1 hypermethylation results but the rate of uptake for genetic counseling was low.

GSK3β is a pivotal regulator in cervical cancer development and a potential target of therapeutics. *A. Saeidian.* Department of Molecular and Human Genetics, Banaras Hindu University, Varanasi, Uttar Pradesh , India.

PI3K/AKT pathway is a crucial regulator for many cellular processes such as cell proliferation, cell survival, apoptosis, and cell cycle regulation and its deregulation leads to the growth of tumor. In this study, our objectives were to investigate the role of AKT1/GSK3b signaling in cell cycle regulation, especially the role of GSK3b, cyclin D1 and p27 in cervical cancer progression and we assessed the effect of drug SB216761 alone and in combination with MG132 on cervical cancer. Our western blots data showed the over expression of AKT1 and p-AKT1 (Thr-308) in both primary cervical tumor and in cervical cancer cell lines. Similarly, RT-PCR and western blotting results were indicative of the up-regulation of GSK3b at transcript level and the p-GSK3b (Ser-9) at protein level along with up-regulation of cyclin D1 protein that were suggestive of their critical role in cell cycle progression and cervical cancer development. Also, our results showed that the up regulation of GSK3b, cyclin D1 and inactivation of GSK3b through phosphorylation at Ser-9 via AKT1 signaling axis is important in cervical cancer development. Furthermore, our western blot analysis demonstrated the down-regulation of p27KIP1 and p-Cyclin D1 that leads to G1 progression of the cell cycle in cervical cancer. The treatment of cell lines such as SiHa, Hela, CaSKi, Me-180 in specific dose-and time-dependent manner with SB216761 alone and together with SB216763+MG132 induces GSK3b inactivation and also leads to rapid degradation of cyclin D1 through GSK3b as an important mediator in cervical cancer cell lines. Similarly, knockdown of GSK3b with siRNA resulted in the degradation of GSK3b and phospho-GSK3b (p-Thr-286). Inhibited GSK3b induced proteasomal degradation of cyclin D1 by reducing Thr286-phosphorylated cyclin D1 levels. FACS result also showed inhibited progression of cell cycle from G0/G1 phase to S phase in the presence of the particular dosage of MG132+SB2167663 which indicate the degradation of cyclin D1. Drug induced cyclin D1 ablation inhibits cancer cell proliferation and thus presents an important promising therapeutic strategy for treating and/or preventing cervical cancer.

Validation of copy number variations in hereditary prostate cancer families using Droplet Digital PCR. *K. Wood[1], R. Gambhira[2], E. Ledet[2], O. Sartor[2], D. Mandal[1].* 1) Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA; 2) Tulane Cancer Center, New Orleans, LA.

Prostate cancer (PCa) is the second leading cause of death in American men, and approximately 27,540 men will die from the disease in the US this year. Family history is one of the most prominent predictors of PCa risk, and approximately 10% of PCa cases are attributable to inheritable genetic factors. However, identifying PCa genetic susceptibility has been extremely difficult due to genetic heterogeneity. Genomic copy number variations (CNVs) have been detected in prostate tumors and several other cancers, but changes in copy number have not been studied extensively in germ-line DNAs from hereditary PCa (HPC) cases. In our preliminary study, we have identified CNVs in germline DNAs from 7 HPC families of European ancestry by using array comparative genomic hybridization (aCGH) technology. The regions identified were 2q22, 11q22, and 16q23, and these regions were found to be duplicated in all 7 of the HPC cases analyzed. In addition, a 68 kb duplication was observed at 2q14 in all 7 HPC cases of European ancestry, and this region was further identified by using linkage analysis in 4 of the 7 HPC families (heterogeneity LOD-score = 1. 94). The goal of the present study is to validate the CNVs identified by aCGH using other quantitative methods in our HPC families. Droplet Digital Polymerase Chain Reaction (ddPCR) provides absolute quantification of target DNA copies. This cutting edge technology can measure small fold differences in target DNA copy numbers. In the literature, the region 2q14 has been reported to harbor structural variations in prostate cancer tumors. We are validating the duplication observed within this region by performing ddPCR in the germline DNA samples from the HPC families. Each ddPCR reaction uses duplex TaqMan assay reagents for the target region and the reference gene. Analysis of ddPCR data will be conducted using QuantaSoft Analysis software (Bio-rad). The absolute quantification of copy number differences using ddPCR will provide fresh insight into HPC families. Validation of the variation in copy numbers and analysis of our results in HPC families using other affected and unaffected male family members will be presented.

Multi-gene panel testing in breast, ovarian, and pancreatic cancer cases: prevalence and unintended screening recommendations. *E. L. Young[1], D. W. Neklason[1,2], A. K. Snow[1], B. A. Thompson[1], M. A. Firpo[7], S. J. Mulvihill[7], T. L. Werner[8], R. Bell[1], K. R. Smith[5], A. Fraser[1], W. K. Kohlmann[1], L. A. Neumayer[6], L. A. Cannon-Albright[2,3], S. V. Tavtigian[1,4].* 1) Huntsman Cancer Institute, University of Utah; 2) Division of Genetic Epidemiology, Department of Medicine, University of Utah; 3) Research and Development Service, George E. Wahlen Department of Veterans Affairs Medical Center; 4) Department of Oncological Sciences, University of Utah School of Medicine; 5) Population Sciences, Huntsman Cancer Institute, University of Utah; 6) Department of Surgery and Arizona Cancer Center, University of Arizona, Tucson; 7) Department of Surgery, University of Utah School of Medicine; 8) Division of Oncology, Department of Medicine, University of Utah.

Multi-gene testing allows for the identification of variants from a list of genes in a single test. Multi-gene testing for hereditary breast and ovarian cancer (HBOC) is beneficial in instances where the suspected predisposition gene is ambiguous or when multiple variants are segregating in a pedigree. Results from multi-gene testing are used as rationale for increased screening or other preventive measures in individuals carrying pathogenic variants and their biological relatives. Consideration for HBOC germline testing is currently based predominately on family history criteria, which limits the availability of genetic testing of women with limited or unknown family histories. In an effort to expand the criterion for genetic testing, we examined the prevalence of medically actionable variants in breast (n=55), ovarian (n=25), and pancreatic (n=66) cancer cases, unselected for family history, with a custom 34-gene panel consisting of genes known or suspected to underlie familial cancer risk, including the pathways involved in DNA homologous recombination repair (HRR), mismatch repair (MMR), etc. We found that 12. 7% of our breast cancer cases, 36% of our ovarian cancer cases, and 13. 6% of our pancreatic cancer cases carried either a known pathogenic variant or a variant of uncertain significance (VUS) predicted to be deleterious based on priors found in publically available databases: InSIGHT for the MMR genes, or the HCI BRCA1/2 Prior Probabilities Database for BRCA1 and BRCA2. When such a database was not available, an in silico consensus prediction from CADD and Polyphen 2 was used. Of the pathogenic or predicted deleterious VUS findings, 72% occurred in genes with established screening recommendations. The combination of our ascertainment procedure and mutation screening results now put us in the position to use the Utah Population Database (UPDB), a comprehensive population-based resource linking genealogies with medical records, to ask whether the relatives of mutation-carrying ovarian cancer or pancreatic cancer cases are at increased risk of a screen detectable cancer. The answer to this question has important implications for the clinical utility of applying panel testing to a wide spectrum of incident cancer cases.

A new method to estimate clonal composition of solid tumors from whole whole-genome copy number profiles. *L. Wu[1], K. Sakai[2], K. Ueshima[3], M. Ukita[4], M. Mandai[4], M. Kudo[3], A. Roter[1], K. Nishio[2], J. Schmidt[1].* 1) Affymetrix Inc. , Santa Clara, CA; 2) Department of Genome Biology, Kinki University Faculty of Medicine; 3) Department of Gastroenterology and Hepatology, Kinki University Faculty of Medicine; 4) Department of Obstetrics and Gynecology, Kinki University Faculty of Medicine.

Background: Estimation of clonal composition or degree of heterogeneity in solid tumors is a challenging and important problem that has been linked to treatment choices and clinical outcome. The problem is particularly difficult because samples are typically admixtures of both aberrant tumor cells and normal tissue cells. We propose a novel method to estimate clonal composition in solid tumors from whole-genome copy number profiles obtained from OncoScan® FFPE Assay Kit from Affymetrix. Methods: Data from OncoScan FFPE Kit provides genome-wide segmentation, where each segment is associated with a Log2ratio (Log2R) (=Log2([observed signal]/[normal signal])) and B-allele frequency (BAF). Due to the admixture, Log2R is a function of the percentage of aberrant tumor cells (%AC) that contribute to the aberration and the true copy number (CN) in the cancer genome. The computation of BAF uses the notion of mA and TA (number of minor and total alleles at a heterozygous site, respectively). BAF of a segment is defined as mA/TA for the heterozygous sites within the segment (e. g. , for a segment with CN = 1, mA = 0, and TA = 1). Due to admixture, the interpretation of BAF values is more complicated as they too are a function of %AC. A key observation is that for fixed mA and %AC, Log2R is a linear function of log2(BAF), denoted by Log2B, and hence the (Log2B,Log2R) values of segments with same %AC and mA align in a straight line. Values corresponding to mA = 0 are of particular interest as they are sparse and well separated for different %AC. The (Log2B,Log2R) values of the segments of a cancer sample are clustered via an iterative clustering approach and mapped onto a 2D plot labeled with the theoretical (Log2B,Log2R) points and their associated mA and %AC values. Results: We processed more than 100 samples from a variety of cancer tissues and mapped them using this method. A significant number, including samples with hundreds of segments, clearly fall into 1–3 distinct %AC points, with each %AC corresponding to a distinct subclone. The method borrows many of the ideas brought forward by previous approaches, such as Genome Alternation Print (GAP) and Allele-Specific Copy Number Analysis of Tumors (ASCAT), but it provides two clear advances: 1) transparent and informative graphic presentation of clonality; 2) visual and analytical estimation of the clonality of a tumor sample.

2789W

Cost-effectiveness of routine screening for Lynch syndrome in endometrial cancer patients up to 70 years of age. *A. Goverde[1,2], M. C. W. Spaander[2], H. C. van Doorn[3], H. J. Dubbink[4], A. M. W. van den Ouweland[1], C. M. Tops[5], S. G. Kooi[6], J. de Waard[7], R. F. Hoedemaker[8], M. J. Bruno[2], R. M. W. Hofstra[1], E. W. de Bekker-Grob[9], W. N. M. Dinjens[4], E. W. Steyerberg[9], A. Wagner[1] on behalf of the LIMO study group.* 1) Dept. of Clinical Genetics, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 2) Dept. of Gastroenterology and Hepatology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 3) Dept. of Gynaecology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 4) Dept. of Pathology, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands; 5) Dept. of Clinical Genetics, Leiden University Medical Center, Leiden, Netherlands; 6) Dept. of Gynaecology, Albert Schweitzer Hospital, Dordrecht, Netherlands; 7) Dept. of Gynaecology, Sint Franciscus Gasthuis, Rotterdam, Netherlands; 8) Pathology laboratory Pathan, Rotterdam, Netherlands; 9) Dept. of Public Health, Erasmus MC, University Medical Center Rotterdam, Rotterdam, Netherlands.

Introduction Lynch syndrome (LS) is a hereditary cancer syndrome characterized by early onset of colorectal cancer (CRC), endometrial cancer (EC) and other cancers. Identifying LS carriers is important, since surveillance programs can reduce morbidity and mortality. Although routine screening for LS is recommended among CRC patients ≤70 years of age, guidelines for LS screening among EC patients remain ambiguous. We aimed to assess the cost-effectiveness of routine molecular screening for LS in EC patients ≤70 years of age. **Methods** Consecutive EC patients ≤70 years of age were routinely screened for LS by analysis of microsatellite instability, immunohistochemistry and *MLH1* hypermethylation, followed by germline mutation analysis if indicated. Life years gained (LYG) were based on the number of LS carriers detected among EC patients and their relatives. Total costs consisted of LS diagnostics and LS surveillance, including gynaecological surveillance and prophylactic surgery in relatives. We calculated the incremental cost-effectiveness ratios (ICERs) for LS screening among EC patients ≤70 years compared with those ≤50 years of age and compared with LS screening according to the revised Bethesda guidelines. **Results** Screening of 179 EC patients identified 7 LS carriers, only one of whom was ≤50 years of age. Genetic testing of relatives identified 27 LS carriers. In total, benefit from LS screening amounted to 26,5 LYG; 16,3 LYG for LS screening among EC patients ≤50 years and 10,2 LYG for screening EC patients 51-70 years of age. Total costs resulting from LS screening increased from kλ154 (λ8,125 per LS carrier detected) for screening among EC patients ≤50 years of age to kλ308 (λ9,073 per LS carrier detected) for screening among EC patients ≤70 years of age. The ICER for LS screening in EC patients ≤70 years compared with ≤50 years was λ15,056/LYG. The revised Bethesda guidelines identified 3/7 (43%) LS carriers among EC patients and 22/27 (81%) LS carriers among relatives. The ICER for routine LS screening in EC patients ≤70 years of age compared with the revised Bethesda guidelines was λ19,204/LYG. Both ICERs remained <λ25,000/LYG (<$30,000/LYG) in sensitivity analyses. **Conclusion** Routine screening for LS by analysis of microsatellite instability, immunohistochemistry and *MLH1* hypermethylation in EC patients ≤70 years is a cost-effective strategy compared with screening those ≤50 years of age and screening according to the revised Bethesda guidelines.

Genotype-phenotype analysis of Von Hippel Lindau syndrome in Korean families. *JS. Lee[1], JH. Lee[3], KE. Lee[2], JH. Kim[3], JM. Hong[1], EK. Ra[1], SH. Seo[1], MJ. Kim[1], SS. Park[1], MW. Seong[1].* 1) Departments of Laboratory Medicine,Seoul National University College of Medicine, Seoul, Korea; 2) Departments of Surgery, Seoul National University College of Medicine, Seoul, Korea; 3) Departments of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea.

Background: Von Hippel-Lindau(VHL) disease is a rare hereditary tumor syndrome, caused by *VHL* gene mutations and characterized by heterogeneous phenotypes: benign/malignant tumors of CNS, retina, kidney, adrenal gland and pancreas. The genotype-phenotype correlation has been studied in different ethnic groups. However, it has not been studied well in Korean population so far. The aim of this study is to evaluate Korean *VHL* mutation spectrum and genotype-phenotype correlations. **Methods:** 13 unrelated subects with *VHL* mutations were included. After *VHL* mutation was studied, clinical manifestations and family histories were consequently evaluated. **Results:** We identified 10 different *VHL* mutations. 2 frameshift mutations were novel: c. 592delC and c. 160_161delAT. Missense mutations were clustered in two domains(α in exon 1 and ß in exon 3). CNS hemangioblastoma(CHB)(n=10), Retinal hemangioblastoma(n=6), Renal cell carcinoma(n=5) and pheochromocytoma(n=2) were present in 13 subjects. Mild phenotypes were observed in possibly *de novo* patients(n=5)(*P*=0. 007). Our unique finding is that age specific risk for CHB is significantly higher in subjects carrying mutations within HIF-alpha binding site(*P*<0. 05). **Conclusions:** We report identified that HIF-a binding site mutations elevate the age-related risk of CHB. The results of this study also provide Korean VHL mutation spectrum and its correlation with phenotypes.

2791W

Majority of familial colorectal cancer unexplained by known cancer susceptibility genes. *B. A. Thompson[1], D. W Neklason[1,2], A. K. Snow[1], E. L Young[1], R. Bell[1], N. R. Sargent[1], W. K. Kohlmann[1], L. A. Cannon-Albright[2,3], S. V. Tavtigian[1,4].* 1) Huntsman Cancer Institute, Salt Lake City, UT; 2) Division of Genetic Epidemiology, Department of Internal Medicine, University of Utah, Salt Lake City, UT; 3) Research and Development Service, George E. Wahlen Department of Veterans Affairs Medical Center, Salt Lake City, UT; 4) Department of Oncological Sciences, University of Utah School of Medicine, Salt Lake City, UT.

It is estimated that ~30% of all colorectal cancer (CRC) cases diagnosed have a familial basis, ~5% of which are caused by high-risk germline mutations in *APC*, *MUTYH* and the DNA mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*). Identifying new genetic risk factors will likely contribute to our understanding of CRC susceptibility, initiation, and progression. Using germline DNA from 52 first or second-degree cousin target pairs from high-risk CRC families (n=101), we performed targeted capture sequencing with a 33-gene cancer susceptibility panel. The family collections from which the targets pairs are drawn had been sporadically screened for MMR gene mutations. We evaluated the germline alterations using multiple filters to categorize them as pathogenic, variants of uncertain significance (VUS), or likely benign. Likely pathogenic sequence variants were then tested for segregation in the families in which they were observed. There were 294 variants identified in the 33 genes, three of which are pathogenic mutations in high-risk genes. These included two *MSH2* truncating mutations: one found in both members of a cousin pair, while the other was found in a single case from a target pair. The third was a *BRCA2* frameshift mutation that segregated with breast cancer in a different branch of the family than that represented by the CRC target pair. Additionally, four monoallelic *MUTYH* mutation carriers and a case with the moderate risk *CHEK2* c. 1100delC variant were identified. There were 69 VUS, six of which were shared by a target pair (*BARD1*, *RAD50*, *PKHD1*, *PMS2*, *BRCA1*, *BRIP1*). In this screen of target cousin pairs with unexplained CRC, we identified two high-risk CRC, one high-risk breast cancer, and one moderate risk breast cancer susceptibility variants. Furthermore, at least two of the large CRC families in this study could have mutations in multiple genes contributing to cancer in different branches. Inactivating mutations in other known/novel cancer susceptibility genes may cause the CRC in the majority of these families.

TruSeq®FFPE DNA Library Prep, a reliable method for preparing high quality Illumina® Whole Genome Sequencing (WGS) libraries from challenging FFPE samples. *R. Sanches-Kuiper, S. MacArthur, A. Jackson, T. James, C. Haskins, H. Sansom, V. Smith.* Illumina Ltd, Chesterford Research Park, North Saffron Walden, Essex, United Kingdom.

Formalin-fixed, paraffin embedded (FFPE) samples are one of the most important sample types used in large scale Whole Genome Sequencing (WGS) studies, particularly those focused on cancer. Simple, flexible and reliable methods for the preparation of high quality WGS libraries from these samples are therefore required. Performing WGS studies using FFPE samples is challenging for a number of reasons: (i) DNA quality is highly variable, and challenging to predict based only on sample age and tissue type; (ii) DNA is often highly fragmented, limiting library yield, complexity and useful read-length; (iii) Chemically modified bases are prevalent, inhibiting library construction processes and producing false positives; (iv) Aggressive DNA extraction methods can result in coverage bias & alignment artifacts. The challenge is increased further because the quantity of FFPE DNA available is often limited, and because there is a requirement for libraries of high complexity to support deep sequencing to detect low-frequency somatic variants. Many methods currently used for the preparation of WGS libraries from FFPE samples fail to address the issues identified above and produce libraries with substantial compositional bias, artifacts which produce many false-positive variant calls and/or insufficient complexity to support deep sequencing. To enable routine use of FFPE DNA libraries in large-scale WGS studies we have developed an easy to use method, TruSeq® FFPE DNA Library Prep, that address the issues highlighted above. Here we show that TruSeq® FFPE DNA Library Prep enables reliable generation of high quality WGS libraries, supporting deep sequencing (>60x coverage) of tumor samples, from as little as 200ng of DNA. Sample quality is determined before the sample is committed using a qPCR-based QC assay. This enables DNA input to be adjusted for maximum assay performance and/or maximum preservation of scarce material. The method consists of several steps designed to maximize library complexity, minimize FFPE-specific artifacts and produce even coverage. Furthermore, we demonstrate that the method can be used to perform deep WGS of some tumor samples using as little as 20ng of input material. Genome wide analysis of copy number variation can be performed using as little as 1ng DNA. Additionally, when comparing TruSeq® FFPE DNA Library Prep with other commercially available protocols we found that it produces substantially fewer FFPE-specific false positive variant calls.

2793W

Using a Costello Syndrome cohort as a syndromic model to better understand embryonal rhabdomyosarcoma at the molecular, cytogenetic, and functional level. *K. M. Robbins[1,3], D. L. Stabley[1], J. Holbrook[1], R. Sahraoui[1,3], K. W. Gripp[2], K. Sol-Church[1].* 1) Center for Pediatric Research, Al duPont Hospital for Children Wilmington , DE; 2) Medical Genetics, Al duPont Hospital for Children, Wilmington, DE; 3) University of Delaware Biological Sciences, Newark, DE.

Costello Syndrome (CS) is a rare disorder, and patients have failure-to-thrive, coarse facial features, short stature, skeletal abnormalities, and a range of intellectual disabilities. CS is the result of heterozygous germline mutations in the proto-oncogene *HRAS*. CS patients have a predisposition for malignancies, specifically embryonal rhabdomyosarcoma (ERMS). We have one of the largest cohorts of Costello Syndrome patients in the world. Therefore, we have the unique opportunity to use this cohort as a syndromic model to study ERMS. ERMS is one of the most common pediatric soft-tissue malignancies in the general population. These sporadic ERMS tumors have rarely been associated with *HRAS* mutations, and instead are characterized by loss of heterozygosity (LOH) at 11p15. 5. We studied syndromic ERMS, in our unique cohort of CS patients, in addition to sporadic ERMS tumors and cell lines. We have ten ERMS tumors from seven unrelated CS patients. In addition, we have three sporadic ERMS cell lines and eight FFPE tumor samples. The goal of this study was to further characterize ERMS at the molecular, cytogenetic, and functional levels. First, we molecularly characterized the RAS mutation status in all ERMS through PCR and Sanger sequencing. Next, we cytogenetically characterized all ERMS using chromosome 11 microsatellite markers. Finally, we aimed to identify important signaling pathways involved in ERMS tumorigenesis. Differential gene expression analysis was performed using Affymetrix Human 1. 0 ST arrays. CS and sporadic ERMS arrays were normalized and compared to 6 CS patient derived fibroblast lines and 6 control fibroblast lines in order to identify ERMS specific genes. Real-time PCR and western blot analysis validated the ERMS specific genes/pathways. We discovered a higher frequency of RAS mutations in our sporadic ERMS cohort than previously reported. An unexpected novel finding was complete LOH of chromosome 11 due to uniparental disomy for the paternal allele within our syndromic and sporadic ERMS cohort. We determined ERMS specific genes contributing to tumorigenesis. This study demonstrated that using CS as a syndromic model for ERMS uncovered novel findings furthering our understanding of ERMS tumorigenesis. This knowledge will ultimately guide drug development and precision medicine based drug selection.

2794T

Variant of Unknown Significance Rates Vary by Ethnicity and Genes Analyzed. *L. Panos, J. Thompson, V. Speare, J. Dolinsky, K. Panchani, H. LaDuca.* Ambry Genetics, Aliso Viejo, CA.

As the uptake of multi-gene panel testing (MGPT) continues to increase worldwide, a primary concern of clinicians and patients is the possibility of variants of unknown significance (VUS). The VUS rate increases with expanding genomic content and ethnic diversity. We aim to define the likelihood of identifying a VUS on MGPT across five major ethnic groups: Caucasian, Ashkenazi Jewish, Asian, Hispanic, and African American. A retrospective review of over 40,000 patients undergoing MGPT for hereditary predisposition to cancer was performed at a single diagnostic laboratory. Ethnicity was indicated on test requisition forms. The rate of identifying one or more VUS was calculated for 10 different MGPTs ranging in size from 5-42 genes. Individuals with one or more VUS, including those who carried a pathogenic or likely pathogenic mutation were included. The number of individuals within each ethnic group varied from 1,873 Asians to 37,151 Caucasians. The likelihood of a VUS was consistently lowest for Caucasian and Ashkenazi Jewish individuals across all panels (Table 1). Asians showed the highest MGPT VUS rates on all panels except PancNext. The VUS rate for Lynch syndrome genes (*MLH1, MSH2, MSH6, PMS2, EPCAM*) across all panels was 6. 9% in Caucasians and 16. 4% in Asians. In *BRCA1* and *BRCA2*, the VUS rate for Asians was 5. 7%, while the VUS rate for Caucasians was 2. 1%. Our results demonstrate that VUS rates for MGPT vary based on the patient's ethnic background and the number of genes analyzed. The specific genes analyzed also play a role, as genes differ in size and some tolerate more variability than others. For example, BreastNext has higher overall VUS rates than RenalNext despite both panels containing 17 genes. Availability of population frequency data also contributes to VUS rate variation by ethnicity, although these gaps will continue to improve with the use of public population frequency databases such as the Exome Aggregation Consortium (ExAC).

Table 1: VUS Rates (%) by Ethnicity and MGPT

MGPT	# of Genes	Caucasian	African American	Ashkenazi Jewish	Asian	Hispanic
BRCAplus	5	4. 4	8. 9	2. 6	13. 7	8. 0

2795W

Phenotypic and molecular characterization of the SCA28 knockin mouse model harboring the *Afg3l2* p. M665R mutation. *C. Mancini[1], E. Hoxha[2,3], L. Iommarini[4], C. Cagnoli[1], E. Turco[5], F. Altruda[5], E. Giorgio[1], A. Brussino[1], S. Cavalieri[6], E. Di Gregorio[6], G. Gasparre[7], A. M. Porcelli[4], F. Tempia[2,3], A. Brusco[1,6].* 1) Department of Medical Sciences, University of Torino, Torino, Italy; 2) Neuroscience Intitute Cavalieri Ottolenghi; 3) Deptartment of Neuroscience, University of Torino (Italy); 4) Department of Pharmacy and Biotechnologies (FABIT), University of Bologna, Bologna, Italy; 5) Department of Molecular Biotechnology and Health Sciences, University of Torino, Torino, Italy; 6) Medical Genetics Unit, "Città della Salute e della Scienza" Hospital, Torino, Italy; 7) Department Medical and Surgical Sciences, Medical Genetics, University of Bologna, Bologna, Italy.

SpinoCerebellar Ataxia type 28 (SCA28, OMIM#610246) is one of the 41 known subtypes of autosomal dominant cerebellar ataxias (ADCA). SCA28 is caused by mutations in the*AFG3L2*gene, encoding for m-AAA metalloprotease (mitochondrial ATPases Associated with a variety of cellular Activities). Most data regarding SCA28 pathogenetic mechanism rely on yeast complementation experiments and on studies of*Afg3l2*-knockout heterozygous mice. Almost all known*AFG3L2*mutations are missense in exon 16, and their effect as haploinsufficiency or dominantnegative mechanism is debated. We generated a knockin (KI) mouse carrying the c. 1993A>G, p. M665R mutation (corresponding to the human p. M666R SCA28 mutation). Homozygous KI mice died perinatally; heterozygous KI mice showed a significant motor impairment in the beam balance test (P<0. 05) at 18 months. In the repeated Rotarod test their performance was indistinguishable from wildtype littermates. Morphological analysis revealed a preserved cytoarchitecture of cerebellar lobules, with unaltered thickness of the molecular and granular layers and a conserved number of Purkinje cells (PC). Electron microscopy showed moderate mitochondrial damage in PC. The spontaneous action potential firing of PC was significantly increased (P<0. 05), measured-*invitro*in cell-attached configuration. We evaluated mitochondrial morphology and function, studying both homo- and heterozygous Mouse Embryonic Fibroblasts (MEF). We showed an impairment in mitochondrial dynamics, detected as the complete loss of long OPA1 forms in homozygous KI MEF, with a fragmented mitochondrial network (MitoTracker Red staining). Homozygous KI MEF showed also a reduced uptake of the MitoTracker probe that might be suggestive of a decreased mitochondrial membrane potential. Bioenergetics analysis revealeda 25% reduction of Complex III activity in homozygous KI (P<0. 05), detected by spectrophotometric analysis of the respiratory chain. Homo-, heterozygous and wildtype MEF showed comparable citrate synthase activity, and the SDS–PAGE of complex subunits at steady-state level appeared normal: these data indicate that a compensatory event that increase the mitochondrial mass is unlikely. These results suggest that PC of SCA28-KI mice at 18 months display functional alterations associated with an initial mitochondrial damage, and that mutations hitting the peptidase M-41 domain negatively impact on m-AAA complex function, probably acting as hypomorphic.

2796T

***Rai1* haploinsufficient mice exhibit abnormal social behavior.** *K. Walz, C. Abad, N. Rao, I. C. Perez, J. I. Young.* Hussman Inst Human Genomics, Univ Miami, Miami, FL.

Smith-Magenis syndrome (SMS) is a genetic condition associated with a deletion of ~ 3. 7Mb in chromosome 17p11. 2. SMS is characterized by neurobehavioral abnormalities such as intellectual disability, developmental delay, sleep disturbance and self-injurious behaviors. Recently, SMS patients were reported to score within the autism spectrum range for social responsiveness and communication. Mutations in a single gene, the Retinoic Acid Induced 1 (*RAI1*), are found in ~30% of SMS patients. The objective of this study is to assess autistic features in the *Rai1*+/- mouse model in an attempt to determine whether *Rai1* is the dosage sensitive gene responsible for abnormal social interactions in SMS. We evaluated adult *Rai1*+/- mice (in a *C57BL/6-Tyrc-Brd* genetic background, *Rai1*+/- N=12; wildtype N=15) with a set of tests that inform on social behaviors: self-grooming in a novel environment (repetitive behavior), three chamber test (sociability and preference for social novelty), tube test (social behavior), and olfactory habituation/dishabituation (communication). All animal testing were approved by the IACUC at the Miller School of Medicine, UM. *Rai1*+/- mice displayed a significant increase in their preference for social novelty when compared to wildtype (p<0. 05). The tube test paradigm, confirmed the social behavior abnormalities of the *Rai1*+/- mice; when confronted to wildtype mice, they backed out of the tube significantly more times than expected by chance (83% of the times). No significant differences were observed between *Rai1*+/- and wild type mice in response to non-social or social odors, suggesting that the identification of social cues was not affected in the mutant mice. Repetitive behaviors were not augmented in the *Rai1*+/- mice. These data showing abnormal responses of the *Rai1*+/- mice in the three-chamber and tube tests suggest that Rai1 is involved in the regulation of a specific domain of social behavior.

2797F

Assessing Behavior and Anxiety in the *Dhcr7*$^{\Delta 3\text{-}5/T93M}$ mouse model of Smith-Lemli-Opitz Syndrome. *J. L. Cross, M. F Keil, F. D Porter.* NICHD, National Institutes of Health, Bethesda, MD.

Smith-Lemli-Opitz Syndrome (SLOS) is an autosomal recessive inborn error of cholesterol synthesis caused by mutation of the 7-dehydrocholesterol reductase (*DHCR7*) gene. This results in abnormal sterol levels; increased 7-dehydrocholesterol and typically decreased cholesterol. Although SLOS has a characteristic physical phenotype, with the most common finding being 2-3 toe syndactyly, there are also multiple behavioral abnormalities. These include cognitive deficits, anxiety, hyper-activity, sleep cycle disturbance, language impairment and autism spectrum behaviors. There are currently two main mouse models of SLOS; a homozygous null, *Dhcr7Δ3-5/Δ3-5*, and a model combining the null mutation and the common p. T93M missense mutation, *Dhcr7Δ3-5/T93M.* Unlike the null model, the hypomorphic *Dhcr7Δ3-5/T93M* mice can live to adulthood and are therefore suitable for behavioral studies. Two frequently used behavioral protocols, studying burrowing and nesting behavior, can be used to assess hippocampal function as it has been shown that hippocampal-lesioned mice engage in less burrowing and nest building than healthy controls. The burrowing test can additionally indicate anxiety as rodents exhibit defensive behavior by kicking the contents of the burrow to deflect intruders. In a pilot study, 3 to 5 month old *Dhcr7Δ3-5/T93M* mice were compared to age-matched controls for these two paradigms. It was observed that, on average, *Dhcr7Δ3-5/T93M* mice burrowed and engaged in less nest building than controls. Some variation was present but as only 75% of *Dhcr7Δ3-5/T93M* are found to have communicating hydrocephalus, structural analysis of the brain upon completion of the behavioral testing period may explain this variation. Future study will include use of the Elevated Plus Maze and Open Field protocols for further analysis of anxiety. These studies will provide insight into the mechanisms driving the behavioral phenotype in SLOS.

2798W

Mouse with substitution of type I collagen 3-hydroxylation site has altered ECM but does not recapitulate the bone dysplasia of types VII/VIII Osteogenesis Imperfecta. *J. C. Marini[1], N. Fratzl-Zelman[2], J. E. Perosky[3], A. Alimasa[3], R. Harris[3], P. S. Backlund[4], P. Roschger[2], K. Klaushofer[2], A. Forlino[5], K. M. Kozloff[3], W. A. Cabral[1].* 1) Bone and Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD; 2) Ludwig Boltzmann Institute of Osteology at Hanusch Hospital of WGKK and AUVA Trauma Centre Meidling, 1st Med. Dept. Hanusch Hospital, Vienna, Austria; 3) Orthopaedic Research Laboratories, Department of Orthopaedic Surgery, University of Michigan, Ann Arbor, MI; 4) Biomedical Mass Spectrometry Facility, NICHD, NIH, Bethesda, MD; 5) Department of Molecular Medicine, Biochemistry Unit, University of Pavia, Pavia, Italy.

Recessive types VII and VIII osteogenesis imperfecta (OI) are severe bone dysplasias caused by null mutations in the genes that encode prolyl 3-hydroxylase 1 (*P3H1*) or cartilage-associated protein (*CRTAP*), two mutually supportive components of the prolyl 3-hydroxylase (P3H) complex expressed in bone and cartilage. Individuals with types VII or VIII OI lack both the P3H complex components and post-translational hydroxylation of its collagen substrate at residue α1(I)P986. This primary modification defect leads to increased post-translational lysine hydroxylation of the type I collagen helix, consistent with delayed folding and loss of complex chaperone function. Several potential functions of the substrate modification have been proposed, including modulating collagen helical stability, fine-tuning the alignment of collagen monomers within fibrils, and regulating bone matrix mineralization. We therefore sought to clarify the role of the P986 substrate modification in bone dysplasia and collagen overmodification by generating a knock-in mouse model with an α1(I)P986A substitution that cannot be 3-hydroxylated. Exclusive expression of α1(I)A986 collagen in murine-derived tissues and cell transcripts and protein was confirmed by cDNA sequencing and mass spectrometry. Neither heterozygous (986P/A) nor homozygous (986A/A) mice recapitulate critical features of types VII and VIII OI. Mutant mice exhibited normal growth rates, femoral mechanical properties (stiffness, ultimate load, brittleness) and collagen folding kinetics. However, the P986A substitution affected collagen biochemistry, matrix organization and mineralization. Despite normal P3H complex levels in cell lysates, 986P/A and 986A/A osteoblast type I collagen was moderately overmodified on PAGE analysis. Dermal fibrils of 986A/A displayed decreased diameters and heterogeneity. Skeletal staining and radiographs revealed flared rib cages, delayed calvarial mineralization and kyphosis by 2 months in 986A/A pups. Interestingly, although femoral aBMD and TMD was reduced in 986A/A versus WT femora, bone matrix mineral density distribution assessed by qBEI was normal. Together, these data suggest that 3-hydroxylation of α1(I)P986 is important for regulating type I collagen modification, crosslinking and mineral organization in bone, but does not cause the severe bone pathology of collagen 3-hydroxylation defects, which likely result from absence of the ER complex and cartilage α1(II)P986 3-hydroxylation.

2799T

Defects of lipid synthesis underlie the age dependent demyelination caused by lamin B1 over expression. *Q. S. Padiath[1], H. Rolyan[1], Y. Tyurina[2], M. Hernandez[3], A. A. Amoscato[2], L. J. Sparvero[2], B. S. Nmezi[1], Y. Lu[4], M. R. H. Estécio[4], K. Lin[4], J. Chen[1], R. He[2], P. Gong[2], L. H. Rigatti[5], J. Dupree[6], H. Bayir[2], V. E. Kagan[2], P. Casaccia[3].* 1) Dept. of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Environmental and Occupational Health, University of Pittsburgh, Pittsburgh, PA; 3) Department of Neuroscience, The Icahn School of Medicine at Mount Sinai, New York, NY; 4) Department of Epigenetics and Molecular Carcinogenesis, The University of Texas MD Anderson Cancer Center, Houston, TX; 5) Division of Laboratory Animal Resources, University of Pittsburgh School of Medicine, Pittsburgh, PA; 6) Department of Anatomy and Neurobiology, Virginia Commonwealth University, Richmond, VA.

Lamin B1 is a component of the nuclear lamina and plays a critical role in maintaining nuclear architecture, regulating gene expression and modulating chromatin positioning. We have previously shown that *LMNB1* gene duplications cause Autosomal Dominant Leukodystrophy (ADLD), a fatal adult onset demyelinating disease. The mechanisms by which increased Lamin B1 levels cause ADLD are unclear. To address this, we studied a transgenic mouse model over-expressing Lamin B1. These mice showed severe age-dependent vacuolar degeneration of the spinal cord white matter together with secondary axonal damage and loss of neuronal cell bodies. Oligodendrocytes in the transgenic mice revealed alterations in histone modifications favoring a transcriptionally repressed state. Chromatin changes were accompanied by reduced expression of genes primarily involved in lipid synthesis pathways, many of which are known to play important roles in myelin regulation. Decreased lipogenic gene expression resulted in a significant reduction in multiple classes of lipids involved in myelin formation. Many of these gene expression changes and lipid alterations were observed even before the onset of the phenotype, suggesting a causal role. Our results have important implications for ADLD disease pathogenesis and establish, for the first time, a link between Lamin B1 and lipid synthesis in oligodendrocytes. They provide a mechanistic framework to explain the age dependence and white matter involvement of the disease phenotype and sheds light on a critical role for the nuclear lamina at the intersection of pathways involving aging,epigenetics,demeylination, and lipid metabolism.

2800F

Knockout CERKL gene causes retinal degeneration in zebrafish. *S. Yu, M. Liu.* Huazhong University of Science and Technology, Wuhan, China.

AbstractCERKL mutations are associated with severe retinal degeneration. Despite several CERKL knockout mice as well as CERKL knockdown zebrafish have been used to characterize the underlying mechanism in pathophysiology for this retinal disease, the function of CERKL remains unknown. In this study, we generated a CERKL knockout zebrafish model by TALEN technology. The targeted CERKL deletion resulted in progressive degeneration of both rod and cone photoreceptor outer segments (OS) and increased apoptosis of retinal cells, accompanying with oxidative damage. The electroretinogram assay for the CERKL-/- zebrafish showed that photoreceptor function was affected as early as 5-7 days before photoreceptor degeneration. Several key proteins involving in phototransduction cascade, including rhodopsin, GNAT1, PDE6B and GRK1, were found to decrease in various degrees in the CERKL-null fishes before the onset of photoreceptor degeneration. Collectively, our results showed that knockout of CERKL in zebrafish caused photoreceptor degeneration, with significant decreased expression of photoreceptor cascade proteins. These findings would help to understand the molecular pathogenesis of retinal degeneration caused by CERKL mutations.

2801W

A mouse modifier study using the Nphp10 (Sdccag8$^{Tn(sb-Tyr)2161B. CA1Cove}$) model to identify a modifier locus of ciliopathy-related phenotypes. *K. Weihbrecht[1,2], W. A. Goar[1,2], C. C. Searby[1,3], T. E. Scheetz[2], V. C. Sheffield[1,3], S. Seo[2].* 1) Department of Pediatrics, Univ. of Iowa; 2) Department of Ophthalmology, Univ. of Iowa; 3) Howard Hughes Medical Institute, Univ. of Iowa.

Serologically defined colon cancer antigen 8 (SDCCAG8), later defined as NPHP10, is a nephronophthisis-related ciliopathy gene, mutations in which cause Senior-Loken syndrome and Bardet Biedl syndrome. The mouse model, Sdccag8Tn(sb-Tyr)2161B. CA1COve, was generated by a Sleeping Beauty Transposon (SBT) insertion between exons 12 and 13 of Nphp10 leading to a deletion of Nphp10 exons 13-18 as well as exons 2-13 of the neighboring gene, Akt3. This mouse model was originally available on the FVB/NJ background and homozygous mutant mice (Nphp10 -/-) show a phenotype of death before P1 at 100% penetrance. Previous studies have shown that some genes show differential expression on different backgrounds and other studies have shown that background strain can have an effect on some phenotypes. For example, Bbs4 knockout animals are found at weaning near Mendelian ratios (25%) on a 129/SvEvTac background, but survival of knockouts on a FVB/NJ background is greatly decreased (5%). The purpose of this study was to determine if a modifier of Nphp10 -/- survival could be identified. Pure strain FVB/NJ Nphp10 +/- mice were crossed with 129/SvEvTac Nphp10 +/+ to generate Nphp10 heterozygotes on a 50% mixed background. These mice were then intercrossed and DNA was collected from Nphp10 -/- mice. Twenty samples were submitted to Jackson Lab for a custom 150 SNP panel: 10 survivors and 10 non-survivors. Chi-Square analysis with Bonferroni correction identified two SNPs of interest on chromosome 11: rs3023266 (p=0. 018) and rs3714172 (p=0. 030). The distance between these two SNPs is 15 Mb and contains hundreds of genes. However, multiple additional SNPs fall within this region that we were able to use to narrow the region of interest. We performed sequencing of these two SNPS plus SNPs falling between them on the original 20 samples plus an additional 26 survivors and 2 non-survivors (final ratio of 3:1 survivors to non-survivors) to determine if the region of interest could be narrowed. The addition of sequence data from these SNPs has narrowed our region of interest to 1. 2 Mb between rs3023266 and rs26968358, which contains ~30 genes of both known and unknown function. A few of these genes are of interest because of their role in cell death, such as tumor necrosis factor superfamily, member 13b (Tnfrsf13b) and ubiquitin specific peptidase 22 (Usp22). Further SNP analysis and additional crosses will allow us to determine a smaller region containing a specific modifier gene.

2802T

Interaction of *MAB21L2* with BMP signaling and *PAX6* in ocular development. *B. Deml[1,2], S. Muheisen[2], E. Semina[1,2].* 1) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI; 2) Pediatrics and Children's Research Institute, Children's Hospital of Wisconsin, Milwaukee, WI.

Coloboma is defined as the incomplete closure of the optic fissure and is often associated with additional ocular or systemic anomalies. Previously our lab identified a pathogenic variant, p. (Arg51Gly), in*MAB21L2*[MIM 604357]in a family with dominant ocular coloboma, microcornea, cataracts and skeletal dysplasia. To investigate this further, we created zebrafish*mab21l2*genetic lines carrying either a frameshift truncation (*mab21l2Q48Sfs*5*) or an in-frame deletion (*mab21l2R51_F52del*) allele and demonstrated the presence of variable severe ocular phenotypes in these mutants. Human*MAB21L*genes belong to the mab-21 family; first discovered in*C. elegans*, *mab-21* mutants display thinning of ray 6 and frequent fusion of rays 4 and 6. The molecular function of*MAB21L2*is unknown and its role in development is not well understood. Double mutant analysis in*C. elegans*indicates that *mab-21* is downstream of SMADs and is negatively regulated by BMPs, placing *mab-21* in the TGF-b/BMP signaling cascade. Additionally, *mab-18* (PAX6 [MIM 607108]ortholog) mutants demonstrate a phenotype that is highly similar to *mab-21C. elegans*mutants. Mutations in *PAX6*, considered a "master regulator" of eye development, *BMP4*[MIM 112262] and *BMP7*[MIM 112267]all cause ocular phenotypes, including coloboma. Taken together these data demonstrate the importance of the PAX6 pathway and TGF-b/BMP signaling cascade in ocular development and possible interaction of *MAB21L2*with them. To investigate these interactions, we crossed*mab21l2*mutants onto a destabilized eGFP (GFP) reporter line driven by Smad-mediated BMP signaling and a*pax6b*mutant line. In 24 hours post fertilization (hpf) wild type embryos, GFP expression is seen in the dorsal eye and lens. In both*mab21l2*mutants GFP levelsare reduced; additionally, GFP expression inhomozygous*mab21l2R51_F52del*embryos was found to be ectopically expressed in the posterior part of the eye. Mutants carrying double homozygous mutations in *mab21l2Q48Sfs*5*and*pax6b*demonstrated small eyes completely lacking the lens and ventral retina, which isa more pronounced phenotype in comparison tothe single mutants for either gene and thus suggests a synergistic effect for*mab21l2*and*pax6b*mutations in zebrafish. These findings reveal interaction of MAB21L2/mab21l2 with the TGF-b/BMP signaling cascade and PAX6/pax6 pathway during vertebrate eye development. Additional studies are underway to further define these relationships.

2803F

Ubiquitous expression of the Proteus mutation *Akt1* c. 49G>A, p. Glu17Lys causes embryonic lethality in mice. *M. J. Lindhurst[1], M. R. Yourick[1], C. Rivas[2], G. Elliott[2], J. Gomez-Rodriguez[2], L. Garrett[2], P. L. Schwartzberg[2], D. Bodine[3], L. G. Biesecker[1].* 1) MGMGB, NHGRI/NIH, Bethesda, MD; 2) GDRB, NHGRI/NIH, Bethesda, MD; 3) GMBB, NHGRI/NIH, Bethesda, MD.

Proteus syndrome is a rare disorder characterized by progressive, sporadic, segmental overgrowth that can affect any tissue in the body. Common manifestations include distorting bony overgrowth, cerebriform connective tissue nevi, epidermal nevi, dysregulated adipose tissue, and vascular malformations. It is clinically and molecularly distinct from other segmental overgrowth disorders and is caused in all patients evaluated to date, by the same c. 49G>A, p. E17K mosaic activating mutation in *AKT1*. This affirms the hypothesis of Happle (1986) who hypothesized that Proteus syndrome was due to a dominant mutation that would be lethal if present in the germ line. For many reasons, it is impossible to study the mechanism of lethality in humans. Therefore, we set out to test the Happle hypothesis using an inducible mouse model for the Proteus syndrome mutation. The conditional knock-in allele (*Akt1cond*) contains the c. 49G>A mutation and a STOP cassette inserted immediately upstream of the mutation and silences the allele until it is removed by Cre recombinase. To activate the mutation early in development, mice heterozygous for *Akt1cond* were crossed to mice expressing Cre using the β-actin promoter. No live born mutant (*Akt1mut*) offspring were identified (n=32). Timed matings were performed and embryos were harvested between E10. 5 and E17. 5 and assessed for appearance, heartbeat, and genotype. Before E14. 5, the phenotype of *Akt1mut* embryos ranged from normal with heartbeats to dead and being resorbed. By E14. 5, all *Akt1mut* embryos had a visible phenotype that included scattered hemorrhages throughout the embryo, fewer blood vessels and pale yolk sacs, although some of these embryos were still alive. Colony forming assays are being conducted to assess whether fetal livers from mutant E13. 5 embryos have similar numbers of myeloid progenitor cells and immunohistochemistry and perfusion studies are underway to examine the location, structure, and integrity of the embryonic vasculature. These experiments will contribute to our understanding why the mosaicism for the c. 49G>A mutation is rare in peripheral blood in humans with Proteus syndrome and test the Happle hypothesis. These data suggest that AKT1 plays a critical role in the development of the murine circulatory system.

2804W

Involvement of GTF2IRD1 in the control of facial skin features and patterning of Williams-Beuren Syndrome. *C. P. Canales[1], S. Corley[2], P. Carmona-Mora[1], F. Tomasetig[1], A. Beverdam[1], P. Kaur[3], I. Smyth[4], M. Wilkins[2], E. C. Hardeman[1], S. J. Palmer[1].* 1) Cellular and Genetic Medicine Unit, UNSW Australia, Kensington, Sydney, New South Wales, Australia; 2) School of Biotechnology and Biomolecular Sciences, the New South Wales Systems Biology Initiative, UNSW Australia, Sydney NSW, Australia; 3) Epithelial Stem Cell Biology Laboratory, Peter MacCallum Cancer Centre, Melbourne VIC, Australia; 4) Dept of Biochemistry and Molecular Biology, Monash University, Melbourne VIC, Australia.

GTF2IRD1 is an important transcriptional regulator located within the Williams-Beuren Syndrome (WBS) common microdeletion region in 7q11. 23, which involves up to 28 genes. Deletion of *GTF2IRD1*, discovered in our laboratory, and the evolutionary-related *GTF2I*, which encodes a protein (TFII-I) with overlapping functional properties, account for the major aspects of the WBS cognitive profile. Analysis of *Gtf2ird1* knockout mice recently allowed us to demonstrate that GTF2IRD1 has an important role in the auditory pathology of WBS. Genotype-phenotype correlations, drawn from patients carrying atypical deletions or duplications of the WBS critical region, have identified GTF2IRD1 and TFII-I as prime candidates for the cause of the distinctive WBS facial dysmorphology. By careful analysis of *Gtf2ird1* knockout mouse models, we have investigated the role of this transcriptional regulator in the control of epidermal proliferation and differentiation and its possible involvement in the causation of the physical WBS craniofacial features. Facial MRI analysis showed that the lack of *Gtf2ird1* produced striking similarities to aspects of the human disease, with soft tissue enlargement due to an extreme epidermal thickening in restricted regions of the face. However, CT imaging of this knockout model did not indicate any abnormalities of the skull. At the cellular level, keratinocyte proliferation was found to be augmented, keratinized epidermal layers were disorganized and the barrier function of the skin was compromised in the affected facial zones of *Gtf2ird1-/-* mice. Analysis of *Gtf2ird1* expression during development showed that transcripts from this gene are most abundant in regions of the skin where the phenotype is observed. In-depth RNA-Seq analyses of affected skin regions identified an abnormal FGF7 expression profile and associated molecular pathways. These data indicate that GTF2IRD1 is a crucial component of the transcriptional regulation machinery in specific regions of the skin and plays an important role in facial skin patterning, and keratinocyte proliferation and differentiation. Furthermore, these data also provide an insight into some of the molecular pathways involved in the craniofacial abnormalities of WBS.

2805T

Loss of function mutation of EGFR in compound heterozygous state causes severe skin defect, gastrointestinal dysfunction and electrolyte imbalance. *T. Yokoi[1,3], C. Hatano[1], Y. Tsurusaki[1], Y. Enomoto[1], T. Naruto[2], S. Hayashi[3], M. Kobayashi[3], H. Ida[3], K. Kurosawa[1].* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Kanagawa, Japan; 2) Department of Stress Science, Tokushima University Faculty of Medicine, Tokushima, Japan; 3) Department of Pediatrics, The Jikei University of School of Medicine, Tokyo, Japan.

<Background>Epidermal Growth Factor Receptor; EGFR is a receptor which recognizes EGF and is very important regulator for cell proliferation and differentiation. In this report we experienced a case which has compound heterozygous loss of function (LoF) mutations in *EGFR*. <Case report>He was born at 32 weeks' gestation, weighing 1089 g. He had defect of scalp hair and ventricular septal defect but no other morphological abnormality at birth. He had eczema, anhidrosis, hyperalgesia, milk allergy and electrolyte imbalance. He died from septic shock at day 134. <Method>Using the patient's DNA from peripheral blood, we performed Mendelian disorders related gene-based Next Generation Sequencing (NGS) (TruSight One, 4813 genes) on the Illumina Miseq. <Results> We identified two LoF mutations in *EGFR*; R98X/I365N. The pathogenicity of I365N is severely deleterious by ANNOVAR. Sanger sequencing demonstrated that each mutation was derived from each parent. <Discussion> Campbell et al. [2014] reported a male infant who had homozygous missense mutation of *EGFR* and had respiratory symptom add to cutaneous and digestive symptoms. The *EGFR* knock-out mice are not embryonic lethal but have the common phenotype in human as shown in the patients. These results suggest that EGFR is not necessarily essential for period of organogenesis, but is considered to be important for organs which has tissue-specific immune system, such as lung, digestive organs and skin after birth. NGS has been useful for detecting new pathogenic genes and new pathogenic variants in known genes. Further, rare complete knock-out in patients with characteristic and severe defect phenotype highlights the crucial roles of the genes in human development. NGS makes it possible to analyze unrecognizable function in known gene and establish new causes of diseases.

2806F

Lipoid Proteinosis (LP), a complex neuro-cutaneous disorder: Novel and recurrent mutations in the *ECM1* gene, and consequences of *Ecm1* knock-down in zebrafish. *L. Youssefian[1], H. Vahidnezhad[1,2,3], P. Mansouri[2], MA. Barzegar[4], M. Daneshpazhouh[2], H. R. Mahmoudi[2], R. Mobasher[2], S. Zeinali[3], Q. Li[1], J. Uitto[1].* 1) Thomas Jefferson University, Philadelphia, PA; 2) Tehran University of Medical Sciences, Tehran, Iran; 3) Pasteur Institute of Iran, Tehran, Iran; 4) Shahid Beheshti University of Medical Sciences, Tehran, Iran.

LP is a rare autosomal recessive disorder with cutaneous and neurologic manifestations. Specifically, the skin findings consist of infiltration of the skin with formation of verrucous plaques on the elbows and pearly eyelid papules. Neurologic manifestations include epilepsy and convulsions associated in most cases with mineralization of the brain. LP is caused by mutations in the *ECM1* gene which results in extensive phenotypic variability even in individuals with the same mutation. In this study, we have examined an Iranian cohort of 13 families comprised of 32 affected individuals with LP, all families being consanguineous. LP was diagnosed with characteristic mucocutaneous findings, and neurologic manifestations were present in half of the patients. Mutation analysis by sequencing of all 10 exons of *ECM1* in these families revealed homozygous loss-of-function mutations, 12 of them being nonsense mutations or small deletions resulting in frameshift of translation. Three of these mutations, c. 477delC, IVS3-2G>A, and p. W237R, were previously unreported. One missense mutation (p. W237R) was predicted to be pathogenic by informatics program (PolyPhen -2) and by conservation of W237 through evolution. Among the mutations, two of them, c. 507delT and c. 735delTG, were recurrent and were found independently in four separate families. Haplotype analysis with intragenic and flanking SNPs on chromosomal locus 1q21 identified a 2 Mb conserved region in families with c. 507delT, suggesting that this mutation is a result of founder effect, rather than being a hotspot mutation. The pathogenic role of *ECM1* mutations was confirmed in a zebrafish model using morpholino-mediated knock-down approach. A splice-site morpholino was designed at the exon 3/intron 3 junction of *Ecm1* to prevent pre-mRNA splicing, which decreased the corresponding mRNA levels by >95%. The knock-down induced a visible skin phenotype consisting of altered surface contour with micropapules and loss of microridges, noticeable at two days post-fertilization. Transmission electron microscopy of the morphants demonstrated apparent reduplication of basement membrane and accumulation of pinocytotic vesicles in the periphery of fibroblastic cells within the dermis, similar to findings seen in patients with LP. The knock-down phenotype was partially rescued with full-length human *ECM1a* mRNA. These results suggest zebrafish is a suitable model system to test the pathogenicity of missense mutations by mRNA rescue.

Zebrafish genetics and disease models: an emerging model for human disease. *S. A. Hutchinson, J. J. Dowling.* Genetics and Genome Biology, Hospital for Sick Chlidren, Toronto, Ontario, Canada.

The advance of next generation sequencing has resulted in the identification of many new disease associated gene mutations. However, validating the function of these variants, particularly in rare diseases, is still a challenge. Recent advances in targeted mutagenesis technology have led to the development of zebrafish models of human disease. Zebrafish have rapid early development, transparent embryos, and large clutch sizes making them suitable for high throughput drug screening and quick, *in vivo* testing of the consequences of newly identified gene mutations. Our goal is to use the expertise and infrastructure at the Hospital for Sick Children to establish a Zebrafish Genetics and Disease Models Facility, accessible to researchers worldwide, that provides all the services required to generate and analyze zebrafish models of human disease at the highest quality, most affordable prices and most efficient time frame. We provide targeted mutant generation and phenotype analysis services for a reasonable fee as part of our cost-recovery business plan. We are currently developing models for a diverse set of diseases including, but not limited to, inflammatory bowel disease, epilepsy, cardiac arrhythmia and congential myopathy. Zebrafish models of congenital myopathy led to both validation of human disease associated mutations, and the discovery of a novel potential therapeutic drug. For example, *CCDC78* was identified as a disease associated gene in a dominantly inherited congenital myopathy. Next, a zebrafish model of the disease resulted in fish with altered motor function and abnormal muscle ultrastructure that mirrored the human disease confirming *CCDC78* as a causative mutation1. Another example is the use of zebrafish dystrophin mutants, a gene known to be mutated Duchenne muscular dystrophy, in a non-biased drug screen looking for rescue of movement defects. A selective serotonin reuptake inhibitor called fluoexetine was identified as a potential therapeutic and the serotonin pathway as a target for further drug development2. The ability to accelerate the pipeline from identification of human mutations to drug discovery is a strength of the zebrafish model system. We provide access to this powerful model system by using our experience in zebrafish mutant generation, characterization and drug discovery to develop these models as a fee-for-service cost. Examples of our initial zebrafish mutants created to model and study human diseases will be presented.

Facilitating access to human disease models. *S. Rockwood, M. Sasner, The Genetic Resource Science Team.* The Jackson Laboratory, Bar Harbor, ME.

The mouse continues to be a widely used model organism, especially well-suited for the study of mammalian development and physiology, and more importantly, for elucidating details of disease mechanisms. Recent advances in genetic engineering have expanded the options available to researchers to precisely generate specific disease models. The Jackson Laboratory (JAX) Mouse Repository, as part of its mission, facilitates the access of these valuable mouse strains to the international biomedical research community. The JAX Mouse Repository has served as a centralized resource for the development, distribution, and cryopreservation of high health status mouse models for over 60 years. A wide selection of models are now available that have applications as hosts for cancer xenograft modeling, stem cell biology, and infectious disease research. Strains are increasingly specialized for specific purposes: *optimized* support of human and murine hematopoietic cell engraftment, *reduced* xenogeneic graft-versus-host disease response, engraftment of human hematopoietic stem cells *without* irradiation and immunological *tolerance* to firefly luciferase and enhanced green fluorescent protein. Mouse strains that recapitulate aspects of specific diseases and disorders, such as Alzheimer's Disease or Chordoma are available as are those that create conditions that facilitate disease states, such as increased oxidative stress. In response to the promising potential of CRISPR/Cas9 technology to be instrumental in the generation of novel mouse models of disease, a variety of Cas9-expressing lines are now available, including constitutive expressing and Cre-inducible models. Cas9 strains are available on multiple genetic backgrounds. In order to make the vast number of Repository models more accessible, we have recently developed a new search interface that facilitates queries by disease term as well as by keyword and strain, allele, and gene name or synonym. Donating a strain to the Jax Mouse Repository is an easy way to fulfill the NIH's requirements for sharing mice. Researchers wishing to have strains considered for inclusion in the Repository are encouraged to submit their strains at: www. jax. org/donate-a-mouse. This work is supported by NIH, The Howard Hughes Medical Institute, and several private charitable foundations.

Analysis of zebrafish orthologs of the human Peters Plus syndrome gene, *b3glcta* and *b3glctb*, using morpholino knockdown and TALEN-mediated genetic knockout assays. *E. R. Weh[1], N. Mlodik[1], S. Muheisen[1], E. V. Semina[1,2].* 1) Department of Pediatrics, Medical College of Wisconsin, Milwaukee, WI; 2) Department of Cell Biology, Neurobiology, and Anatomy, Medical College of Wisconsin, Milwaukee, WI.

Human *B3GLCT* deficiency results in a complex phenotype known as Peters Plus Syndrome (PPS). Patients with PPS display variable features, however three are almost invariably present: Peters anomaly (or other forms of anterior segment dysgenesis), short stature and brachydactyly. *B3GLCT* encodes for β-1,3-glucosyltransferase which is expressed throughout the developing embryo and adult tissues. Recently it was found that loss of B3GLCT disrupts a non-canonical ER quality control mechanism, however it is not known how loss of this apparently ubiquitously expressed enzyme can lead to tissue specific defects observed in patients with PPS. In this study we aimed to characterize the two zebrafish orthologs of *B3GLCT*, *b3glcta* and *b3glctb*, and to create a model of PPS using both morpholino (MO) mediated knockdown and TALEN genome editing. We identified the full coding region of both orthologs via 5' RACE and defined their expression patterns during embryonic development. Embryos were injected with two independent splice interrupting MOs for each ortholog and complete knockdown was confirmed using RT-PCR. The affected mRNA transcripts were predicted to encode a truncated protein product lacking the entire catalytic domain. We found a robust, repeatable phenotype correlating with the degree of knockdown of either transcript. Morphant embryos displayed shorter body length, disrupted craniofacial cartilage development, ocular defects and short, stubby fins; the phenotype associated with complete *b3glcta* deficiency was more severe than *b3glctb* deficiency. Following this, genetic knockout lines for both *b3glct* genes were generated using TALEN technology: for *b3gclta*, four frameshift mutations in exon 1 and a 1-bp deletion in exon 12 (c. 1013delG;p. (S338Ifs*9)) were generated; for *b3gcltb,* a 22-bp deletion in exon 12 (c. 1005_1026del22;p. (A336Cfs*2)) was created. The p. (S338Ifs*9) and p. (A336Cfs*2) mutations are expected to disrupt the required catalytic DXD residues located at positions 350-352 and 347-349 for b3gclta and b3gcltb, respectively. Contrary to MO data, both single and double homozygous *b3glcta:b3glctb* mutants showed no observable embryonic or adult phenotype. Our data indicate that, despite significant sequence conservation, the zebrafish orthologs of *B3GLCT* are not required for normal embryonic development. Additionally, the discrepancy between phenotypic effects produced by MO and genome editing approaches suggest caution in using MOs to model human disease.

2810W

A heterozygous mutation of *MOV10L1* in a pedigree of spermatogenic failure. *J. Lu[1], Y. Shao[1], J. Xiao[1], Q. Wang[1], X. Zhang[1], J. Zhang[1], C. Li[1], Z. Li[2], F. Zhang[1].* 1) Fudan university, ShangHai, China; 2) ShangHai General Hospital, ShangHai, China.

Piwi-interactive RNA (piRNA) is essential for silencing of transposon and genome integrity in the germline. Previous experimental evidence using mouse models has showed that the homozygous null mutations of piRNA biogenesis genes can result in spermatogenic defects and male infertility. However, the spermatogenic roles of piRNA biogenesis gene mutations have not been elucidated in human. Here we identified a heterozygous missense mutation in *MOV10L1*, a gene involved in piRNA biogenesis, in a pedigree of spermatogenic failure. It suggested that the inheritance pattern is autosomal dominant. The female carriers of this heterozygous *MOV10L1* mutation showed no defects in fertility. The knock-out (KO) mouse model has been generated using the CRISPR-Cas9 technology for further functional assays of this *MOV10L1* mutation.

2811T

A new mouse model of type 2 Gaucher disease. *A. Gonzalez[1], R. Grey[1], B. Berhe[1], E. I. Ginns[2], D. Ory[3], P. Elias[4], E. Sidransky[1], N. Tayebi[1].* 1) Molecular Neurogenetics section, MGB/ NHGRI, National Institutes of Health, Bethesda, MD; 2) Lysosomal Disorders Treatment and Research Program, Clinical Labs, University of Massachusetts Medical School, Worcester, MA 01545, USA; 3) Diabetic Cardiovascular Disease Center, Washington University School of Medicine, St. Louis, Missouri 63110, USA; 4) Dermatology Service, Department of Veterans Affairs Medical Center, and Department of Dermatology, University of California, San Francisco, CA USA.

Gaucher disease (GD) is a recessive lysosomal storage disorder caused by mutations in *GBA1*, the gene coding for the hydrolase glucocerebrosidase (GCase). GD is classically divided into three types based on the presence and progression of neurological symptoms. Type 1 GD is the non-neuronopathic form and presents with broad phenotypic heterogeneity. Types 2 and 3 GD are the less common acute and chronic neuronopathic forms, respectively. Type 2, the most severe form of GD, presents with symptoms either prenatally or during infancy, and patients usually die before the age of 3 years. In order to study the pathogenesis of neuronopathic type 2 GD we have generated a new mouse model by crossing two previously described mouse lines: the knock-in point mutation Leu444Pro (c. 1448T>G) and an effectively null *gba* allele created through the targeted disruption of mouse GCase (ϑMGC). A GCase null /Leu444Pro genotype is common among patients with type 2 GD. The Leu444Pro/ϑMGC mice were non-viable, dying within the first few hours after birth. GCase protein and enzymatic activity levels in different tissues from Leu444Pro/ϑMGC were similar to levels in homozygous null *gba* mice. However, Leu444Pro/ϑMGC mice do not show the lipid storage observed in the homozygous null *gba* mice, and thus the cause of death remains unknown. While brain LIMP-2 levels were unaltered in these mice, there is some evidence of enhanced neuroinflammation, shown by increased levels of one GFAP isoform in the brains from the Leu444Pro/ϑMGC mice compared to wild type controls. To identify factors contributing to the lethality of these mice, ultrastructural studies of skin are being performed and other indicators of neuroinflammation are being evaluated. These mice may offer a new model in which to study the pathogenesis of neuronopathic GD as well as other possible functions of GCase.

2812F

Modeling DPMS function in zebrafish to explore the interface of dystroglycanopathies and congenital disorders of glycosylation. *M. Manzini[1], D. von Alpen[1], H. Issa[1], H. Pond[1], C. Ardiccioni[2], O. Clarke[2], F. Mancia[2].* 1) Pharmacology and Physiology, George Washington University, Washington, DC; 2) Physiology and Cellular Biophysics, Columbia University, New York, NY.

Dolichol-phosphate mannose synthase (DPMS) catalyzes the synthesis of dolichol-P-mannose, an important donor substrate for multiple glycosylation processes in the endoplasmic reticulum. Autosomal recessive mutations in the DPMS subunits *DPM1*, *2* and *3* cause congenital disorder of glycosylation 1e (CDG1e), a complex disorder characterized by developmental delay, hypotonia, dysmorphisms, microcephaly and seizures. In some cases a muscle biopsy showing muscular dystrophy and loss of dystroglycan glycosylation has been observed, suggesting an overlap with dystroglycanopathies, the most severe forms of congenital muscular dystrophy. To better understand the function of DPMS we have used the crystal structure of GtrB, a bacterial homolog of DPMS, to map the residues mutated in humans. In addition, we have developed zebrafish models of *dpm1*, *2* and *3* loss-of-function, which recapitulate phenotypes found in humans such as developmental delay, microcephaly, muscle weakness and vascular abnormalities, providing a good vertebrate model for these disorders. We then performed structure-function studies in the zebrafish by injecting human mRNA carrying the human mutations to study how different mutations affect enzyme function. With this approach we found striking correlation between enzyme function and phenotype. We are now exploring how the muscle, the brain and other tissues are affected. In summary, we have developed a strategy combining structural biology and animal models to determine the catalytic mechanisms of DPMS and the function of human *DPM1, 2* and *3* mutations in order to study the role of these proteins in the pathogenesis of CDGs and dystroglycanopathies.

2813W

Functional characterization of deleterious alleles in the vitamin B12 receptor, *CD320*, in humans and mice. *D. J. Bernard[1], F. J. Pangilinan[1], J. Cheng[2], J. L. Mills[3], D. M. Kay[4], C. Horan[5], A. M. Molloy[6], L. C. Brody[1].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, NIH, Bethesda, MD; 2) Transgenic Mouse Core, National Human Genome Research Institute, NIH, Bethesda, MD; 3) Division of Intramural Public Health Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD; 4) New York State Department of Health, Division of Genetics, Albany, NY; 5) Institute of Molecular Medicine, Trinity Centre for Health Sciences, St. James's Hospital, Dublin, Ireland; 6) Department of Clinical Medicine, School of Medicine, Trinity College, Dublin, Ireland.

Inherited and acquired deficiencies of cobalamin (vitamin B12) can cause megaloblastic anemia (OMIM#261100) and serious neurologic disease. Low maternal levels of vitamin B12 increase the risk of pregnancy complicated by neural tube defects. Poor nutrition, malabsorption and genetic variation in the vitamin B12 transport and metabolic pathways can all produce cobalamin deficiency. Cobalamin is transported from the circulation into tissues via the vitamin B12 receptor, TCblR, encoded by the *CD320* gene. We hypothesized that variants in *CD320* would produce a metabolic picture consistent with cobalamin deficiency. Newborn screening programs measure C3 (propionylcarnitine) to detect a number of defects including cobalamin deficiency. We evaluated newborns with elevated and normal C3, testing for a 3bp deletion in *CD320* (c. 262_264delGAG, rs150384171, MAF ~0. 01) previously observed with transiently elevated levels of methylmalonic acid (MMA) in newborns (OMIM#606475). Significantly, 7 of 351 newborn cases with elevated C3 and none of 388 controls were found to be homozygous for this deletion ($p<6x10-6$). To evaluate the impact of *CD320* on cobalamin metabolism, we created *Cd320* null knockout mice. *Cd320* knockouts are healthy, viable and fertile. These mice present with a metabolic phenotype consistent with intracellular cobalamin deficiency: low tissue cobalamin and elevated plasma MMA and homocysteine. Of note, these animals resemble the biochemical abnormalities observed in humans with a compromised ability to absorb cobalamin. Dietary restriction of vitamin B12 in *Cd320* knockout mice produces infertility in females but not males. Experiments to determine the cause of the infertility indicate that although conception occurs, the embryos perish around the implantation stage. A complete absence of intracellular cobalamin is lethal. Ourresults with *Cd320* null animals maintained on diet containing ample vitamin B12 suggest that an alternative vitamin B12 transport mechanism exists in mice, and perhaps humans. The biochemical phenotype of *Cd320* null animals raised on vitamin B12 deficient chow is consistent with historical and epidemiological data suggesting that low vitamin B12 levels in humans are associated with infertility and developmental abnormalities. Genetic variation in the cobalamin receptor may play a role in health and disease throughout the life cycle.

2814T

Strategy for generating and characterizing a zebrafish model of spondylometaphyseal dysplasia with cone-rod dystrophy. *J. Jurgens, C. Woods, P. W. Hook, N. Sobreira, J. Hoover-Fong, A. S. McCallion, D. Valle.* Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD.

Spondylometaphyseal dysplasia with cone-rod dystrophy (SMD-CRD) is a rare, autosomal recessive disorder caused by partial or complete loss-of-function variants in the phosphatidylcholine biosynthesis gene *PCYT1A* [Hoover-Fong et al. , 2014; Yamamoto et al, 2014]. Clinical characteristics of SMD-CRD include progressive, early-onset degeneration of cone and rod photoreceptors as well as short stature, bowing of the long bones, metaphyseal flaring, rhizomelic shortening, platyspondyly, and scoliosis. The mechanisms underlying this phenotype are not well understood, in part because its molecular basis was recently identified and there are no existing animal models. Here we describe a strategy for generating and characterizing a zebrafish knockout model of SMD-CRD. We first analyzed mRNA expression patterns of the two zebrafish orthologs of *PCYT1A*, *pcyt1aa* and *pcyt1ab*, in fish embryos at 24, 48, and 72 hours post-fertilization (h. p. f.) by *in situ* hybridization. Both paralogs showed broad expression at 24 h. p. f. and acquired more anterior localization, including retinal expression, at the two later timepoints. Next, we targeted *pcyt1aa* and *pcyt1ab* for knockout using CRISPR/Cas9 genome editing. This system generates a double-stranded DNA break which is then repaired by nonhomologous end joining (NHEJ). Since NHEJ is an error-prone mechanism, it generates small insertions or deletions at the site of repair, often resulting in gene knockout. We exploited this system by microinjecting Cas9 RNA and guide RNAs directed against *pcyt1aa* and *pcyt1ab* into zebrafish embryos at the single-cell stage, resulting in fish mosaic for a heterozygous null allele in the corresponding paralog. These fish were then outcrossed to generate germline heterozygous knockouts for each of the two paralogs, which were screened by Surveyor assay followed by sequence verification. As in humans, the heterozygotes are asymptomatic. We are breeding these animals to generate individual and double homozygous knockouts for *pcyt1aa* and *pcyt1ab*, which we will examine for relevant phenotypes with tests including length measurement, bone and cartilage staining, optomotor response assays, and prey capture assays. We anticipate that these models will provide a resource for screening potential small molecule and/or nutritional therapies. We suggest that creating and characterizing a zebrafish model of SMD-CRD will facilitate greater understanding of this phenotype and perhaps other bone or retinal dysplasias.

2815F

Development of a zebrafish model for ATP7A-related motor neuron disease. *D. Martinelli[1], B. Feldman[2], L. Yi[1], V. Shram[3], S. G. Kaler[1].* 1) Section on Translational Neuroscience, Molecular Medicine Program, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD; 2) Zebrafish Core, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD; 3) Section on Cell Biology and Signal Transduction, Eunice Kennedy Shriver National Institute of Child Health and Human Development, NIH, Bethesda, MD.

Distal hereditary motor neuropathies comprise a heterogeneous group of diseases characterized by a length-dependent axonal neuropathy. The ATPase ATP7A regulates cellular copper homeostasis and is associated with Menkes disease, a severe pediatric neurocutaneous disorder. Recently, two novel *ATP7A* missense mutations (T994I and P1386S), have been implicated in a late-onset distal motor neuropathy without overt copper metabolic abnormalities or other clinical abnormalities. Understanding the precise functional role of ATP7A in the peripheral nervous system and the neurodegenerative effects of these two mutations remains elusive. *Danio rerio* (zebrafish) has emerged as a useful model of Menkes disease: a mutant harboring a mutation in the zebrafish homolog of ATP7A, *atp7avu69* (*calamity*), shows defects in pigmentation and hindbrain development, and early mortality (within 1 week). We are using *calamity* as a model system in which to study the effects of the human ATP7A motor neuropathy inducing alleles. We crossed *calamity*+/- heterozygotes with transgenic zebrafish that express green fluorescent protein (GFP) driven by a motor neuron-specific promoter, Hb9. This breeding scheme resulted in adult fish carrying one *atp7avu69* allele and one *Tg(Hb9-GFP)* allele. We crossed these double heterozygote fish (*Hb9-GFP*+/- /*calamity*+/-) to obtain *calamity*-/- mutants that selectively express GFP in motor neurons. Using time-lapse confocal imaging, we evaluated motor neuron development *in vivo* from 24 to 72 hours post fertilization (hpf). We observed motor neuron degeneration starting as early as 48 hpf in *calamity*, associated with progressive paralysis, as assessed by neurobehavioral testing (active motility; touch, light and sound sensitivity). Mutant embryos also showed disorganized motor neurons cell bodies and axonal distribution, and reduced GFP signal compared to wild type, suggesting an essential role of *atp7a* in normal zebrafish motor neuron development. We are currently exploiting this model system to dissect human disease mechanism(s) by microinjection of the P1386S and T994I human ATP7A RNAs into *calamity* embryos. We predict that these hypomorphic alleles will correct the early mortality and enable longer survival, allowing evaluation of the specific motor neuron degenerative effects of P1386S and T994I.

2816W

Differentially expressed striatal transcripts in the OVT73 ovine model of Huntington 's Disease. *R. G. Snell[1], S. J Reid[1], R. R Handley[1], R. Brauning[2], P. Maclean[3], S. Patassini[1], P. Tsai[4], H. J Waldvogel[1], J. F Gusella[5], M. E MacDonald[5], R. L. M Faull[1], H. D HDSCRG[6].* 1) Center for brain reserach University of Auckland, Auckland, Auckland, New Zealand; 2) AgResearch, Invermay Agricultural Centre, Mosgiel, New Zealand; 3) AgResearch, Ruakura Research Centre, Hamilton, New Zealand; 4) School of Biological Sciences, The University of Auckland, Auckland; 5) Center for Human Genetic Research, Massachusetts General Hospital, Harvard Medical School, Boston; 6) Huntington's Disease Sheep Collaborative Research Group.

We have made considerable progress in the characterisation of our Huntington's Disease, OVT73 transgenic sheep model and have identified time dependent progressive histopathological, behavioural and molecular changes. To progress beyond confirming that this model accurately represents the pre-symptomatic phase of HD we have undertaken a deep RNAseq experiment to identify transgene effects on transcription. RNA-seq data was collected from ribosomal depleted total RNA isolated from anterior striatum tissue of twelve 5-year old OVT73 sheep (6 transgenics, 6 controls). Specific differentially expressed transcripts in OVT73 were identified and 25 selected for further analysis. Nanostring nCounter quantification confirmed thirteen of these genes as differentially expressed in various sub-regions of the striatum. The validated transcripts will be presented; these include a urea transporter (SLC14A1) and a choline transporter (SLC5A7), both up-regulated in OVT73 striatum. The OVT73 line animals express the full length human huntingtin protein with 73 glutamine repeats[1]. We have shown there is reduced striatum levels of GABAA α1 receptor, cortical huntingtin aggregates [2] and an early circadian abnormality [3]. The sheep are healthy and visibly indistinguishable from control South Australian Merino. They present an opportunity to better understand and utilise the pre-symptomatic phase of Huntington's Disease. 1. Jacobsen, J. C. , et al. , *An ovine transgenic Huntington's disease model.* Hum Mol Genet, 2010. **19**(10): p. 1873-82. 2. HDSCRG, et al. , *Further Molecular Characterisation of the OVT73 Transgenic Sheep Model of Huntington's Disease Identifies Cortical Aggregates.* J Huntingtons Dis, 2013. **2**(3): p. 279-295. 3. 2817T

Functional dissection of *PITX2* in zebrafish. *K. Hendee[1,2], E. Sorokina[2], E. Semina[1,2].* 1) Cell Biology, Neurobiology and Anatomy, Medical College of Wisconsin, Milwaukee, WI; 2) Pediatrics and Children's Research Institute, Children's Hospital of Wisconsin, Milwaukee, WI.

Paired-like homeodomain 2 (*PITX2* [MIM 601542]) is a transcription factor that has been associated with Axenfeld-Rieger syndrome (ARS [MIM 180500]). The pathway by which *PITX2* causes the disease phenotype has yet to be elucidated. In order to identify the downstream targets of PITX2, we generated a zebrafish *pitx2* knockout line and performed comparative transcriptome analyses of wild-type and mutant tissues. TALEN-mediated genome editing produced an 8-bp deletion in the *pitx2* homeobox domain, resulting in a premature stop codon (c. 565_572del8 (p. (M64*)). The mutation is predicted to produce a truncated protein lacking a functional DNA-binding domain. Homozygous *pitx2M64** embryos display a severely underdeveloped anterior chamber beginning at 96 hours post fertilization (hpf); additionally, many embryos exhibit smaller eyes and craniofacial abnormalities, whereas heterozygous *pitx2M64**embryos appear phenotypically normal. Adult *pitx2M64** heterozygous fish were bred with a *Tg(-2. 6pitx2-CE4:GFP)* reporter line that expresses GFP under control of the *CE4* upstream regulatory element of *pitx2* in periocular mesenchyme*.* Head tissues from a mix of (*CE4:GFP):pitx2M64** heterozygous and homozygous embryos along with (*CE4:GFP)* control embryos were collected at 24 hpf, and GFP-positive and negative cell populations were isolated using fluorescence-activated cell sorting. RNA extracted from the collected cells was submitted for Affymetrix microarray analysis. Transcriptome comparison between mutant and control GFP-positive populations identified 96 significantly downregulated and 131 upregulated genes. The top targets of interest were notum pectinacetylesterase homolog 1b (Drosophila) (*notum1b*) and elastin microfibril interfacer 2a (*emilin2a*), both of which have human orthologues (MIM 609847 and MIM 608928, correspondingly). Downregulation of both *notum1b* and *emilin2a* transcripts in *pitx2* mutant tissues was independently confirmed by qPCR with transcript-specific primers. *In situ* hybridization analysis identified broad embryonic expression for both genes, with *emilin2a* showing some enrichment in the periocular mesenchyme. Further analysis is underway to explore developmental roles of *notum1b* and *emilin2a* and their functions in the *pitx2* pathway. Identifying downstream targets of *PITX2/pitx2* will allow for better understanding of mechanisms of normal ocular development and disease processes.

2818F

Postnatal excision of a Bardet-Biedl Syndrome gene results in leptin resistance, leading to obesity. *J. E. Garrison[1], Y. Hsu[1], D. Y. Nishimura[1], K. E. Bugge[1], C. C. Searby[1], V. C. Sheffield[1,2].* 1) Department of Pediatrics, University of Iowa, Iowa City, IA; 2) Howard Hughes Medical Institute.

Bardet-Biedl Syndrome (BBS) is a rare, autosomal recessive disorder that is commonly associated with obesity, retinitis pigmentosa, postaxial polydactyly, renal abnormalities, urogenital defects, and intellectual disability as well as increased susceptibility to hypertension, heart disease, and diabetes mellitus. Although BBS is rare in the general population, identifying the underlying molecular mechanisms of the disorders associated with this syndrome has garnered great interest due to the fact that components of the phenotype including obesity, hypertension and diabetes are common. Patients with BBS usually present with obesity (BMI >30), and have increased visceral fat and increased adiposity compared to BMI-matched controls. BBS mouse models consistently develop obesity. Previous data indicate that aspects of leptin signaling do not function optimally in congenital BBS congenital knockout mice, even when the mice have been calorie restricted to prevent obesity. This indicates that leptin resistance is intrinsic and primary to obesity. However, controversy remains as to whether leptin resistance is intrinsic or secondary to obesity. In order to understand the development of leptin resistance and obesity in BBS, we developed a conditional genetic model in which we can temporally eliminate expression of *Bbs8*, a component of the BBSome. As such, we can examine the role of BBS8 in the development or amelioration of phenotypes in adult mice and determine the critical time points for BBSome function in the pathophysiology of obesity. Using this system, we are able to achieve efficient removal of *Bbs8* in adult mice at the DNA and protein levels. Tamoxifen-induction of Cre recombinase leads to obesity within one to two months after treatment. Plasma leptin levels in treated mice are comparable to control littermates until the mice become obese, suggesting that plasma leptin levels rise in response to increased adiposity. Some mice in which *Bbs8*-excision has been induced are resistant to interperitoneal administration of leptin; these mice quickly become obese. Other treated mice are more leptin sensitive; these mice are much slower to develop obesity. We hypothesize that this difference results from can variable excision efficiency of *Bbs8* in the hypothalamus. Further understanding of the development and progression of leptin resistance in BBS will result in better management of BBS-related obesity and the accompanying phenotypes of diabetes and hypertension.

2819W

A Knock-out Mouse Model of CMAMMA (Acsf3 Deficiency) Displays Neurological Phenotype and Methylmalonic Acidemia. *M. W. Epping[1], C. X. Wang[1], I. Manoli[1], J. L. Fraser[1], J. Gomez-Rodriguez[2], G. Elliot[3], J. L. Sloan[1], V. Hoffmann[4], P. L. Schwartzberg[2], C. P. Venditti[1].* 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD; 2) Genetics Disease Research Branch, NHGRI, NIH, Bethesda, MD; 3) Embryonic Stem Cells and Transgenic Mouse Core, NHGRI, NIH, Bethesda, MD; 4) Office of Research Services, Division of Veterinary Resources, NIH, Bethesda, MD, 20892.

Combined malonic and methylmalonic aciduria (CMAMMA [MIM 614265]) is a rare, autosomal recessive metabolic disorder resulting from deficient activity of ACSF3, a mitochondrial acyl-CoA synthetase with high specificity for malonate and methylmalonate. ACSF3 may catalyze the first step in the mitochondrial *de novo* fatty acid synthesis pathway, which has recently been identified in mammals. The highly variable clinical phenotypes reported continue to generate debate about whether patients exhibit clinical symptoms beyond the biochemical perturbations. While the full spectrum of the clinical phenotype caused by ACSF3 deficiency remains to be fully defined, some patients have manifested adult-onset neurological disease. In order to define disease pathophysiology, a deletion allele that removed the first coding exon of *Acsf3* was generated using homologous recombination in B6/129 ES cells. *Acsf3*-/- mice were born in Mendelian proportions and exhibit normal survival. No immunoreactive Acsf3 was detected in the liver, kidney, or brain of *Acsf3*-/- mice. When reared on regular diet, *Acsf3*-/- mice displayed the same growth pattern and weight as their heterozygous and wild type littermates. Plasma methylmalonic acid concentrations in the mutants were significantly higher than wild type mice (p=0. 0008), ranging from 25. 40 to 63. 16 μM, with heterozygous mice also displaying slightly elevated levels (p=0. 0165). To help address whether patients with CMAMMA need dietary restriction, *Acsf3*-/-mice were fed a high protein diet. The mutants maintained weights comparable to wild type littermates following two and four months of high protein challenge but did not display significant elevations of plasma methylmalonic concentrations compared to mice maintained on a regular chow diet. Vitamin B12 responsiveness was also assayed in the mice with minimal or no change in methylmalonic acid levels after administration. *Acsf3*-/-adult mice exhibit a clinical neurological syndrome of abnormal motor planning, coordination, and gait, hindlimb drag, tail ruddering. On the accelerating rotarod, *Acsf3*-/-mice demonstrate significantly impaired performance (p=0. 03, n=12 per genotype), with gait anomalies as described above. Exploration of post-translational modifications in the mice are ongoing and will help to elucidate the role of Acsf3. This novel mouse model serves to advance our understanding of CMAMMA disease pathophysiology, as well as a platform for developing therapeutic approaches.

Phenotypic characterization of a zebrafish model of Smith-Lemli-Opitz syndrome. *C. V. M. Cluzeau[1], K. M. Tabor[2], E. Leff[1], J. Picache[1], K. Burkert[1], C. A. Wassif[1], B. Feldman[2], H. A. Burgess[2], F. D. Porter[1].* 1) Program in Developmental Endocrinology and Genetics, NICHD, NIH, Bethesda, MD; 2) Program in Genomics of Differentiation, NICHD, NIH, Bethesda, MD.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder with a broad phenotypic spectrum. It is characterized by multiple malformations, cognitive impairment and abnormal behavior including autistic traits. Mutations of the 7-dehydrocholesterol reductase (*DHCR7*) gene, encoding the penultimate enzyme in the cholesterol biosynthetic pathway, result in decreased cholesterol and accumulation of the precursor 7-dehydrocholesterol (7DHC). Major questions still remain as to the pathophysiological mechanisms, mainly the contribution of toxic effects due to 7-dehydrocholesterol accumulation versus the effect of cholesterol deficiency, and the contribution of potential developmental versus physiological defects to the neurological function. Several rodent models have proven useful for elucidating some aspects of this syndrome, but they have limitations. To gain additional insights into the pathophysiological mechanisms and produce a model allowing rapid *in vivo* drug screening, we generated a zebrafish model of SLOS using Transcription Activator-like Effector Nucleases to disrupt *dhcr7* gene. We showed that mutant fish present with the characteristic accumulation of 7DHC and decreased cholesterol in both liver and brain from 2 weeks of age, with variable severity depending on the specific mutation. We further characterized the phenotype of fish carrying a frameshift mutation (NM_201330:c. 371_387delinsAAAT). *dhcr7*-deficient fish growth is delayed from 3 weeks of age. Mutant fish have a decreased ability to breed compared to controls. The yolk from eggs produced by mutant females contains high levels of 7DHC. Compared to the progeny of heterozygous individuals, the mutant progeny of the mutant females (maternal zygotic, MZ fish) have high levels of 7DHC during their first week of life. Interestingly, these MZ mutant fish present an abnormal acoustic startle response at 1 week of age compared to control fish, with decreased responsiveness and altered movement kinematics for non-Mauthner escapes. Additionally, adult mutant fish demonstrate decreased anxiety in the novel tank diving test. We will pursue the characterization of the motor and cognitive functions as well as the social behavior of adult *dhcr7*-deficient fish. Future work will focus on the neuroanatomical characterization of *dhcr7*-deficient fish brain to identify the causes of the abnormal behavior in the mutant fish.

Motor-phenotypical characterization and neuronal analysis of a transgenic rat model for DYT1 dystonia focusing on age dependent and brain region specific pathological key features from date of birth to old age of rats. *V. Gaiser[1], L. Lotzer[1], T. Roenisch[1], B. Fabry[1], Q. Welniarz[2], M. Walter[1], J. Huebener[1], M. Schaller[3], O. Rieb[1], T. Ott[1], K. Grundmann-Hauser[1].* 1) Dept. of Medical Genetics and Applied Genomics, Tuebingen, Germany; 2) Institut de Biologie Paris Seine, Paris; 3) Department of Dermatology, University of Tuebingen, Tuebingen, Germany.

Background: DYT-1-dystonia is an inherited autosomal-dominant disease characterized by involuntary movements due to a dysfunction of the CNS and is mainly caused by a deletion (ΔGAG) in the Tor1A gene. The pathophysiological features of this mutation are still not well understood. To analyze the cellular mechanism underlying this disease a transgenic rat model harboring the full length human mutant and wild type TorsinA gene including promoter and regulatory elements was analyzed. **Methods:** We performed motor phenotypical characterization with as well as analysis of different brain regions by immunohistochemistry and electron microscopy. Brains of young (postnatal day 0–1 month), middle (2-8 months) and old aged rats (12-20 months) where analyzed to follow up the brain region specific and age dependent key features of pathology. **Results:** We were able to determine the onset of nuclear envelope alteration in hΔETorA transgenic rat brains. Interaction of TorsinA with INM (inner nuclear membrane) compartments can be seen especially during INM assembly as well as membrane bleb formation could be observed already at early stages. Furthermore, we found manifestation of the nuclear envelope disintegrity of middle aged transgenic rats increasing with age in different hΔETorA transgenic rat lines. Only selective neuronal populations of brain regions with specific expression patterns of Torsine A and B seem to be affected by this pathology. We have evidence that a cellular shift of TorsinA towards tips of neurites discovered in rats of higher age does not take place in brain regions with early onset of NE pathological key features like in cell subtypes of striatum. Motor phenotypical testing revealed impairment of hΔETorA transgenic rats in the performance of simple motor reflexes and in learning of new complex motor tasks at old age of rats. **Conclusions:** We suggest that the mutated TorsinA causes NE pathology at early postnatal stages with a progressive cellular subtype specific phenotype and negative influence of mutated TorsinA to a molecular transport mechanism. Thus it appears that alterations of neurites in hΔETorA transgenic rats with increased age and brain regions with crucial functions for movement control like striatum and cerebellum being affected, leads to motor disability and highlights the importance of this model system for pharmaceutical approaches.

2822W

Mouse Models of Human Disease: How mouse data provides mechanistic insight into disease etiology and developmental therapeutics. *C. L. Smith, S. M. Bello, J. T. Eppig, The Mouse Genome Informatics Staff.* Mouse Genome Informatics, The Jackson Laboratory, Bar Harbor, ME.

Large scale forward and reverse mouse mutagenesis projects, the vast history of published mouse genetics and genomics from laboratory research and the genome-wide phenotyping efforts of the International Mouse Phenotyping Consortium (IMPC) have yielded an immense amount of data aimed at creating translational mouse models of human disease. Mouse Genome Informatics (MGI, www. informatics. jax. org) provides these integrated mouse phenotype data sets to enable complete correlation of known mouse phenotypes with human clinical signs and symptoms. MGI catalogs all known published and submitted mouse mutant mutations with genotypes annotated to phenotype and OMIM disease model descriptions, and includes links to other supporting gene information including sequence, polymorphism, spatiotemporal expression, genomic location, biochemical function and process, sub-cellular topology, and mammalian gene homology. Standardization of nomenclature and application of bio-ontologies, including the Mammalian Phenotype (MP) Ontology, ensure that data are consistently annotated, making robust data mining possible. Exome sequence data from patients with diseases with unknown etiology have provided several hundred new candidate genes for many human diseases. In addition, comparison of gene, phenotype and genetic disease data provided by mouse models aids in the refinement of potential therapeutic targets. We will show examples of MGI phenotype and disease data queries and results utilizing comparative mouse data that assist in identifying novel gene mutations and variations that are causative for human disease. We will also provide examples in which the biochemical data generated from mouse models and available at MGI has been used to infer gene function of human disease genes and define the gene's role as a therapeutic target.

2823T

Genomic copy number alterations in non-syndromic hearing loss. *R. Mingroni-Netto[1], E. L. Freitas[1], D. T. Uehara[1], M. T. B. M. Auricchio[1], J. Oiticica[2], A. G. Silva[1], C. Rosenberg[1], A. C. Krepischi[1].* 1) Dept of Genetics and Evolutionary Biology, Institute of Bioscience, University of Sao Paulo, Sao Paulo, Brazil; 2) Dept. of Otorhinolaryngology, Medical School, University of Sao Paulo , Sao Paulo, Brazil.

Due to tremendous genetic heterogeneity, the identification of genes that are related to hearing impairment has been challenging. In the absence of a clear etiology for the phenotype, recurrence risk estimates are often based on family segregation, and may be imprecise. We investigated by oligonucleotide array-CGH 100 patients presenting non-syndromic deafness, with either autosomic recessive (n=50) or autosomic dominant (n=50) presumptive patterns of inheritance. Rare copy number variants (CNV) were detected in 12 probands; four of the detected CNVs comprised genes previously associated with hearing loss (*POU4F3*, *EYA1*, *USH2A*, *BCAP31*), and were considered as causative, stressing the contribution of genomic imbalances to non-syndromic deafness. In six cases, segregation of the CNVs in pedigrees excluded them as causative. In one case, segregation could not be investigated and in other, a point mutation probably explains the phenotype. The findings showed that the presumptive patterns of inheritance were incorrect in at least two cases, impacting genetic counseling. Additionally, we report the first duplication reciprocal to the rare *ABCD1*, *BCAP31*, and *SLC6A8* contiguos deletion syndrome; as most microduplication syndromes, the associated phenotype is much milder than the respective microdeletion and, in this case, restricted to hearing impairment.

2824F

Sporadic Hidradenitis Suppurativa (acne inversa) and acne conglobata are not associated with gamma-secretase gene mutations. *N. M. Saiyed[1], U. Ratnamala[2,3], N. K. Jain[3], D. Jhala[3], M. Raveendrababu[3], B. C. Gorijala[4], R. S. Rawal[5], T. Y. Mehta[6], S. Nair[7], N. K. Chandramohan[8], D. G. Saple[9], F. M. Al-Ali[10], L. I. Al-Otaibi[10], EAL. Mohamed[10], M. Naveed[11], S. R. Bakshi[1], S. K. Nath[12], U. Radhakrishna[13].* 1) Biotechnology, Institute of Science, Nirma University, Ahmedabad, Gujarat, India; 2) Department of Pharmacology, Creighton University, Omaha, NE, USA; 3) Human Cytogenetics, Department of Zoology, School of Sciences, Gujarat University Ahmedabad, India; 4) Oncology Department, Krishna Institute of Medical Sciences, Secunderabad, India; 5) Department of dermatovenereology, Vadilal Sarabhai Hospital, Smt. H Sheikh Sultan Bin Khalifa Al Nahyan Humanitarian & Scientific Foundation, Fairmont, Dubai, United Arab Emirates; 12) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 13) Department of Obstetrics and Gynecology, Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA.

Hidradenitis suppurativa (HS) also known as acne inversa (AI) (MIM 142690), is a chronic, inflammatory and painful skin condition, characterized by swollen or inflamed lesions in the apocrine gland-bearing areas of the body which include: the buttocks, thighs, scalp, neck, nipples, armpits, groin, and anogenital region. Occurrence of HS is generally isolated to single patients; however a familial history has been reported in 30–40 % of patients revealing an autosomal dominant form of inheritance of the disease. Genetic predisposition plays a key role in HS and recently some progress has been made in identifying mutations of *NCSTN*, *PSEN1* and *PSENEN* genes on 1q23. 3, 19q13. 12 and 14q24. 2, respectively. To date, 13 gamma-secretase gene mutations have been identified including two recently identified *NCSTN* gene mutations by our group, accounting for almost 75% of Asian and European HS families. In contrast, only 1 *PSEN1* and 6 *PSENEN* mutations have been reported, suggesting that *NCSTN* plays a significant role in HS development. Remarkably, all of the variants have been identified in patients with a family history of the disease; however no mutations have been reported in sporadic patients. Genomic DNA from 94 unrelated HS patients, 1 with acne conglobata and 100 healthy sex-age-matched subjects with the same ethnic background were analyzed. Direct sequence analysis of amplified PCR fragments for all regions covering the entire coding sequence and splice junctions of the genes *NCSTN, PSENEN, PSEN1* and *PSEN2* with an automated DNA Analyzer (3730xl; AB) revealed 2 nucleotide substitutions. Nucleotide variation (Ile69Lys) was the only substitution present in the coding region of the *PSENEN* gene in one HS patient. In conclusion, the present study demonstrates genetic heterogeneity in the HS disorder and suggests the involvement of novel genes. It also suggests that gamma-secretase gene mutations are not a common cause of sporadic patients with HS and or acne conglobate; otherwise, it is possible the disease is associated with variations in promoters.

2825W

UNIPARENTAL ORIGIN IN OCUOCUTANEOUS ALBINISM. *W. Cardenas, M. Lattig.* Biological Sciences, Centro de Investigación en Enfermedades Genéticas Humanas, Bogota, Colombia.

Oculocutaneous albinism (OCA) is a group of autosomal recessive disorders of the melanin biosynthesis pathway. OCA has been classified molecularly in seven different types OCA1 to OCA7. In previous results our group reported a high frequency of the p. G47D (rs61753180) mutation in the TYR gene (MIM*606933) in our colombian population with OCA1 disorder (MIM #203100). This mutation has been reported mainly in Israel and Puerto Rico populations and a migration pattern has been postulated for the p. G47D from Sephardic Jews that migrated to Marruecos, Canary Island and Puerto Rico. Our objective was to assess if the individuals with the p. G47D mutation in our country have a Jewish ancestry. We evaluated the mitochondrial DNA haplogroups and Y-STR haplogroups in nine individuals with the p. G47D mutation in the TYR gene. We amplified and sequence the D-loop of the mitochondrial DNA in all individuals and genotyped the Y-filer STR systems in five male individuals. We found that our entire sample belong to the Amerindian groups in the mitochondrial DNA, represented by the A, C, D and X haplogroups. We did not find any of the haplogroups reported for Jewish ancestry. However, we did find four different Y-STR haplogroups the R1a-M17, G2a, R1b1a-M269 and one African haplogroup. The possible origin of the R1a-M17 was in the Northeast Europe and in the Mediterranean. The G2a has been described in recent Caucasian and European individuals and was derived from Africa. To date the R1b1a is distributed in Western Europe and is the most common form in Europe closely associated with the diffusion of Indo-European language, but nothing was described with a Jewish origin. Our results show that our samples are in accordance with known history of migrations and admixing among European colonizers and Amerindian groups along the last three centuries. We could not find a direct relationship between Jewish haplogroups and the p. G47D mutation in our study sample. Nevertheless, this study is a first approach towards understanding the origin of the p. G47D mutation in the Colombian population. Key Words:Oculocutaneous albinism, ethnicity, mtDNA haplogroups, Y-STR haplogroups, Jewish.

Novel *FGF10* Mutation in Autosomal Dominant Aplasia of Lacrimal and Salivary Glands. *J. -W. Kim[1,3], F. Seymen[2], M. Koruyucu[2].* 1) Pediatric Dentistry, Seoul National University School of Dentistry, Seoul, South Korea; 2) Department of Pedodontics, Faculty of Dentistry Istanbul University, Istanbul, Turkey; 3) Department of Molecular Genetics & Dental Research Institute School of Dentistry, Seoul National University, Seoul, Korea.

Aplasia of lacrimal and salivary glands (ALSG) is a rare autosomal dominant inherited disease, characterized by aplasia, atresia or hypoplasia of the lacrimal and salivary systems with variable expressivity. The purpose of this study was to identify genetic etiology of an ALSG family. We recruited a Turkish family with ALSG and performed a mutational analysis, based on the candidate gene approach, to clarify the molecular genetic etiology. The candidate gene sequencing of the *FGF10* gene identified a novel heterozygous nonsense mutation (c. 237G>A, p. Trp79*) in the exon 1. The identified novel mutation would result in a haploinsufficiency of the FGF10, because of nonsense-mediated mRNA decay caused by a premature stop codon. This report further confirms that ALSG is caused by the haploinsufficiency of functional FGF10. This work was supported by grants by the National Research Foundation of Korea (NRF) grant funded by the Korea government (2014R1A2A1A11049931) and the Korea Science and Engineering Foundation (KOSEF) through the Biotechnology R&D program (2014020550).

Genome-wide linkage analysis of non-syndromic cleft lip with or without cleft palate in a large multigenerational Indian family. *U. Ratnamala[1], N. K. Jain[1], S. S. Chettiar[1], D. Jhala[1], S. Beiraghi[2], S. K. Nath[3], U. Radhakrishna[4].* 1) Department of Life sciences, University school of Sciences, Gujarat University, Ahmedabad, Gujarat, India; 2) Division of Pediatric Dentistry, University of Minnesota, Delaware Street SE, Minneapolis, MN 55455, USA; 3) Arthritis and Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, USA; 4) Department of Obstetrics and Gynaecology, Oakland University William Beaumont School of Medicine, Royal Oak, MI, USA.

Non-syndromic cleft lip with or without cleft palate (NSCL/P) is considered the most common severe craniofacial disorder having both an environmental and genetic origin. NSCL/P abnormalities are associated with increased morbidity and mortality in infancy, childhood, and adulthood. Nevertheless, the etiology of this disorder remains poorly defined. Earlier genetic studies by our group on NSCL/P has identified two loci on chromosome 13q33. 1-34 (Am J Hum Genet. 2006; 79(3):580-5) and a locus at 18q21. 1 (Am J Hum Genet. 2007; 81(1):180-8) in two large multiplex autosomal dominant NSCL/P families (UR17 and UR18). Also many susceptibility NSCL/P loci have been reported on different chromosomal regions. In an attempt to further characterize the causative factors of NSCL/P, a productive collaboration with clinicians and research scientists from India, Europe, Iran, other Middle Eastern countries and the USA has been established. This collaboration has resulted in the acquisition of samples from 50 multiplex NSCL/P families. We have recently conducted another genome-wide linkage analysis, usingOMNI-1S bead array Chips on a large multigenerational non-syndromic autosomal dominant, non-consanguineous Indian NSCL/P family (UR411) with 12 affected and 31 unaffected members. The study identified a NSCL/P susceptibility locus at 1q25-42 (non-parametric linkage [NPL] = 16. 61, p = 0. 0014). These results were also supported by multipoint parametric linkage analysis. A maximum multipoint LOD score of 3. 57 was detected assuming an autosomal dominant mode of inheritance with reduced penetrance. Haplotype analysis with informative crossovers enabled mapping of the NSCL/P locus to a region of χ22. 914 cM between single-nucleotide polymorphisms rs12064317and rs6668056. This genomic interval on 1q25-42 contains the known candidate gene IRF6. To our knowledge this is the first Indian NSCL/P family with a susceptibility locus mapping to chromosome 1q25-42 region. Mutation analysis of candidate genes is progressing.

2828W

Investigation into Clinical Significance of c-FLIP and Jun-B Expression in Psoriatic Patients. *N. Salleh[1], N. Shamsudin[2], H. Lai[1], R. Lai[1], I. Mustafa[1].* 1) Faculty of biomedical and Health Sciences, Universiti Selangor, Selangor Malaysia; 2) Department of Medicine, Faculty of Medicine and Health Sciences, Universiti Putra Malaysia, Selangor Malaysia.

Psoriasis is a chronic T cell-mediated inflammatory skin disease. Studies have shown that angiogenesis plays an important role in the pathogenesis of psoriasis. In the present study, we investigated the involvement of c-FLIP and Jun-B protein expression in the possible mechanisms of psoriasis. The hyperproliferation of keratinocytes observed in psoriasis prompted us to evaluate c-FLIP and Jun-B expression on biopsies collected from involved and uninvolved skin of 42 patients with active plaque-type psoriasis with respect to healthy skin. We analyzed the expression of C-FLIP and Jun-B at transcript and protein levels by quantitative RT-PCR and tissue microarray based immunohistochemistr. We demonstrated the expression of both genes c-FLIP and Jun-B in a hyperproliferative skin condition not related to neoplastic transformation. Interestingly, we observed that c-FLIP and Jun-B is not expressed in healthy skin, but it becomes detectable in non-lesional areas and it is even more expressed in lesional psoriatic skin. In addition, we found that Jun-B expression is correlated to the rate of keratinocyte proliferation and activation compared to c-FLIP. Hence, our observations indicate Jun-B as a new possible player, involved in the development and/or maintenance of the hyperproliferative state of psoriatic keratinocytes. Our study confirms distinct prognostic relevance of c-FLIP and Jun-B protein expression levels in the psoriasis patients and identifies an association of high Jun-B levels with elevated expression of Jun-B target genes and markers for infiltrating immune cells.

Development of refractive errors – what can we learn from retinal dystrophies? *V. J. M. Verhoeven[1,2,3], M. Hendriks[1,2,4], G. H. S. Buitendijk[1,2], J. R. Polling[1,5], M. A. Meester-Smoor[1], A. Hofman[2,6], M. Kamermans[7,8], L. I. van den Born[4], C. C. W. Klaver[1,2], RD5000 Consortium.* 1) Dept. Ophthalmology, Erasmus Medical Center, Rotterdam, The Netherlands; 2) Dept. Epidemiology, Erasmus Medical Center, Rotterdam, The Netherlands; 3) Dept. Clinical Genetics, Erasmus Medical Center, Rotterdam, The Netherlands; 4) The Eye Hospital, Rotterdam, The Netherlands; 5) University of Applied Sciences Utrecht, Faculty Eyecare, Utrecht, The Netherlands; 6) Netherlands Consortium for Healthy Ageing, Netherlands Genomics Initiative, The Hague, The Netherlands; 7) Netherlands Institute for Neuroscience, Amsterdam, the Netherlands; 8) Department of Neurogenetics, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands.

Purpose: Myopia (nearsightedness) is widely recognized as a multifactorial, complex genetic disorder. The global incidence of myopia is rising, and reaches epidemic proportions in some parts of the world. Previously, multiple loci for refractive phenotypes were identified. Still, it is unknown which retinal cells are involved in the retina-to-sclera signaling cascade causing myopia. Inherited retinal dystrophies (RD) are characterized by dysfunction of a single retinal cell type. We studied the association between affected cell type, causal gene and refractive error in RDs. **Methods:** We included patients with RD (N=302; RPE related, cone dominated (CD), rod dominated (RP), bipolar cell related dystrophies) from two ophthalmogenetic centers in the Netherlands. Distributions and mean spherical equivalent (SE) of each diagnosis and causal gene were calculated, and risks of myopia and hyperopia were evaluated using logistic regression. The population-based Rotterdam Study-III and ERF Study (N=5,550) served as a reference. **Results:** Bipolar cell dysfunctions were associated with the highest risk of SE (OR high myopia 239. 7; OR mild hyperopia 263. 2, both P<0. 0001; SE -6. 86 D [SD 6. 38]); followed by CD (OR high myopia 19. 5, P<0. 0001; OR high hyperopia 10. 7, P=0. 033; SE -3. 10 D [SD 4. 49]); RP (OR high myopia 10. 1, P<0. 0001; OR high hyperopia 9. 7, P=0. 001; SE -2. 27 D [SD 4. 65]); and RPE related dystrophies (OR low myopia 2. 7; P=0. 001; OR high hyperopia 5. 8; P=0. 025; SE -0. 10 D[SD 3. 09]). Mutations in *RPGR* (SE -7. 63 D [SD 3. 31]) and *CACNA1F* genes (SE -5. 33 D [SD 3. 10]) coincided with the highest degree of myopia; in *CABP4* (SE 4. 81 D [SD 0. 35]) with the highest degree of hyperopia. **Conclusions:** Refractive errors, in particular myopia, are common in RD. The bipolar synapse, and the inner and outer segments of the photoreceptor may serve as predilection sites for myopia development.

2830F

A Splicing Mutation in *VPS4B* Causes Dentin Dysplasia I. *F. Xiong[1], Q. Yang[1], D. Chen[2], C. X. Liu[1], Q. X. Yu[1], Y. H. Liu[1,3], J. Z. Liu[2], K. Y. Li[2], L. F. Zhao[4], Y. H. Ye[1], H. Zhou[2], L. L. Hu[1], Z. H. T[5], X. Shang[1], L. T. Zhang[5], X. F. Wei[1], D. N. Chen[1], W. J. Zhou[1], D. R. Li[6], W. Q. Zhang[4], X. M. Xu[1].* 1) Department of Medical Genetics, Southern Medical University, Guangzhou, Guangdong, China; 2) School of Stomatology, Zhengzhou University, Zhengzhou, China; 3) Department of Prenatal Diagnosis Center, Maternal and Child Health Hospital, Dongguan, China; 4) Department of Cell Biology, School of Basic Medical Sciences, Southern Medical University, Guangzhou, China; 5) Department of Stomatology, Nanfang Hospital, Southern Medical University, Guangzhou, China; 6) Department of Forensic Science, School of Basic Medical Sciences, Southern Medical University, Guangzhou, China.

Dentin dysplasia I (DDI) is a genetically heterogeneous autosomal-dominant disorder characterized by rootless teeth with abnormal pulpal morphology. Using a cohort of a large Chinese family with 13 normal members and 10 DDI patients, we mapped to a 9. 63 Mb candidate region for DDI on chromosome 18q21. 2-q21. 33. We then identified a mutation IVS7+46C>G which derived a novel donor splice site in intron 7 of the *VPS4B* gene with co-segregation of all 10 affected individuals in this family. The aberrant transcripts encompassing a newly inserts of 45-bp in size were detected in gingival cells from affected individuals. Protein structure prediction showed that a 15-amino acid insertion altered the ATP-binding cassette of VPS4B. The mutation resulted in significantly reduced expression of mRNA and protein by semiquantitative molecular analysis, and altered subcellular localization of VPS4B by confocal image analysis, indicating a loss of function of VPS4B. Using human gingival fibroblasts, the *VPS4B* gene was found to be as an upstream transducer linked to Wnt/beta-catenin signaling regulating odontogenesis. Furthermore, knock-down of *vps4b* in zebrafish recapitulated reduction of tooth size and absence of teeth similar to the tooth phenotype exhibited in DDI index cases, and the zebrafish mutant phenotype could be partially rescued by wild-type human *VPS4B* mRNA. We also observed that *vps4b* depletion in the zebrafish negatively regulates the expression of some major genes involved in odontogenesis. The study thus identifies the *VPS4B* as a disease-causing gene for DDI, which is one of the important contributors to tooth formation through the Wnt/beta-catenin signaling pathway.

2831W

Ehlers-Danlos syndrome, hypermobility type is linked to chromosome 8p22-8p21. 1 in an extended Belgian family. *P. J. Coucke, D. Syx, S. Symoens, W. Steyaert, A. De Paepe, F. Malfait.* Center for Medical Genetics Ghent, University Hospital Ghent, Ghent, O-VL, Belgium.

Joint hypermobility is a common finding in the general population with epidemiologic studies showing its presence in over 10% of Caucasians. In a subset of individuals however, it causes a range of clinical manifestations, mainly affecting the musculoskeletal system. Joint hypermobility often presents as a familial trait and is shared by several heritable connective tissue disorders, including the hypermobility subtype of the Ehlers-Danlos syndrome (EDS-HT) or benign joint hypermobility syndrome (BJHS). These hereditary conditions provide unique models for the study of the genetic basis of joint hypermobility. Nevertheless, these studies are largely hampered by the great variability in clinical presentation and the often vague mode of inheritance in many families. Here, we performed a genome-wide linkage scan in a unique three-generation family with an autosomal dominant EDS-HT phenotype, and identified a linkage interval on chromosome 8p22-8p21. 1, with a maximum two-point LOD score of 4. 73. Sequencing a number of interesting positional candidate genes such as *BMP1*, *LOXL2*, *CSGALNACT1* and *SLC39A14* revealed no disease causing mutation. Therefore, we applied the whole exome sequencing strategy in an attempt to unravel the underlying genetic cause within this candidate locus. This latter approach revealed the presence of a unique missense variant p. (His211Gln) in the *LZTS1* gene, encoding leucine zipper, putative tumor suppressor 1, in the candidate region. Although *LZTS1* itself was not linked to joint hyperlaxity, disruption of the *ProSAP2* gene, encoding a protein interacting with LZTS2 (LAPSER1) resulted in a syndrome with mild intellectual disability and joint laxity. Subsequent analysis of 230 EDS-HT/BJHS patients resulted in the identification of three additional rare *LZTS1* variants. This is the first reported genome-wide linkage analysis in an EDS-HT family, thereby providing an opportunity to identify a new disease gene for this condition.

2832T

Molecular diagnosis of F8 gene in sever hemophilia A in the Iranian population. *A. Ebrahimi[1,2], S. Mansouri derakhshan[1,2], M. r. Ranjouri[3], M. Shekari Khaniani[1,2].* 1) Genetics and Molecular Medicine, Tabriz university of medical science, Tabriz, Iran; 2) Hematology & Oncology Research Center, Tabriz University of Medical Sciences, Tabriz, Iran; 3) Medical Genetic Department, Faculty of Medicine, Zanjan university of medical science, Zanjan, Iran.

Background: Hemophilia A (HA) is an inherited X-linked disorder in blood coagulation cascade that caused by a variety of mutations in F8 gene. The most common mutation in sever HA is Intron 22&1 Inversion, exon deletion and point mutation in exon 14, respectively. **Objective:**This study aimed to detect these known DNA mutations in severe HA patients in Azeri Turkish population for the first time in North West of Iran. **Material and Methods:** Peripheral blood of 50 severe HA patients was collected and genotyped by Inverse-Shifting PCR (IS-PCR) method for intron 22 Inversion, long PCR for Intron 1 Inversion, multiplex–PCR for exon deletions and PCR- sequencing for exon 14 mutations. **Results:** Our study showed that 22 patients (44%) had Inversion 22, one individual (2%) had Intron 1 Inversion, no cases of exon deletions and one case presented mutation in exon 14 (2%). In this population, 52 % of patients don't carried mutations in the analyzed regions, but might have mutations in the other regions of gene. **Discussion:** We concluded that *F8* intron 22 inversion is causing mutation for nearly 50% in severe HA cases in Azeri Turkish population similar to other populations and IS-PCR a robust and rapid method for genetic analysis of sever HA patients in developing countries.

Exome sequencing identifies SPG3A and OTOF gene mutations in patients with Pure Hereditary Spastic Paraplegia. *S. Majid[1], D. Monies[1], S. Hagos[1], A. Qahtani[1], K. Ramzan[1], A. Abulaban[2], H. AlDossari[1], B. Meyer[1], S. Bohlega[2].* 1) Department of Genetics, KFSHRC, RIYADH; 2) Department of Neurosciences, KFSHRC, RIYADH.

Hereditary spastic paraplegias (HSP) comprises of clinically and genetically heterogeneous group of neurodegenerative diseases. SPG3A, a pure form of HSP which is characterized by progressive bilateral, mostly symmetric spasticity and weakness of legs, with diminished vibration sense caused by degeneration of the corticospinal tracts and dorsal columns. SPG3A encodes for protein called Atlastin (ATL1), a dynamin-related GTPase, which play a significant role in the assembly and functions of nuclear protein complexes. In this study, we describe a native Arabic consanguineous family comprising of four affected individuals where progressive spasticity started at age 2 to 8 years with no cognitive impairment or dysmorphic features. Two of the affected presented with severe dysarthria, disabling spasticity and they remained ambulatory until the third decade of life through multiple corrective surgeries. Using combined homozygosity and exome sequencing approaches, we identified two novel pathogenic mutations in ATL1 and OTOF gene that underlies HSP and hearing loss in this family respectively. The novel mutations were not detected in >600 ethnically matched normal chromosomes. By*in silico*analysis, OTOF mutation was predicted to damage protein structure or function. Most of the reported SPG3A cases are caused by heterozygous mutations in ATL1 gene. We have identified a homozygous non-sense mutation p. K330X in the ATL1 gene which is the causative gene for this rare autosomal recessive childhood HSP with complete penetrance for the mutation in the homozygous state. This study delineates the genetic spectrum spectrum of rare autosomal recessive form of Spastic Paraplegia 3A.

Informativeness of St14 VNTR marker for carrier detection and prenatal diagnosis of hemophilia A in Iranian families. *S. Mansouri derakhshan[1,2], A. Ebrahimi[1, 2], P. Aob[3], M. Shekari Khaniani[1,2].* 1) Department of Medical Genetics, School of Medicine, Tabriz university of medical science Tabriz, Iran; 2) Hematology & Oncology Research Center, Tabriz University of Medical Sciences, Tabriz, Iran; 3) Medical Genetic Department, Faculty of Medicine, Zanjan university of medical science, Zanjan, Iran.

Background: Due to the large size and hetrogenous mutations of F8 gene, direct mutation analysis is not practical. Therefore, indirect allele characterization using DNA markers linked to the *F8* locus appears to be more available approach for hemophilia A carrier detection. **Objective:** The aim of this study was to investigate the usefulness of an extragenic variable number of tandem repeat (VNTR) St14 (DXS52) on the human X-chromosome in linkage analysis to develop an informative and accurate carrier detection and prenatal diagnosis. **Material and Methods:**Hemophilia A patients, 104 male and female non-hemophiliac family members, and 35 potential female carriers were studied. They were sampled from North West of Iran (Azeri Turkish population). Molecular analysis for St14 marker was performed by long-distance Polymerase chain reaction (PCR) method. **Results:** 12 different alleles ranging from 700 to 1800 bp in size were observed. The most common allele corresponded to 1100 bp amplified fragment (18%) whereas the alleles with amplified fragment of 1700 bp (1. 6%) and 1800bp (1. 2%) were less prevalent among Iranian Azari Turkish population. Compared to Caucasians, this population showed a markedly higher occurrence of medium molecular weight fragments and a relatively low occurrence of high molecular weight fragments. **Discussion:**The observed heterozygosity among female subjects was 61% Linkage analysis using St14 marker in 35 suspected hemophilia A carriers revealed (9) 26% to be carrier. In consequence, St14 VNTR analysis by PCR should prove to be a useful tool in the genetic diagnosis of hemophilia A carriers and prenatal diagnosis in Azeri Turkish population. However, the use of other polymorphic markers such as *Bcl1*, *XbaI* and *HindIII*/RFLP and dinucleotide repeats (STR) in combination with VNTR St14 should raise the information of indirect markers for clinical diagnosis.

2835T

Oculocutaneous albinism in a boy with a complex phenotype, and homozygosity for an ancestral block on chromosome 11 bearing a double set of *TYR* mutations. *S. L. Everhart[1], N. Butala[2], W. R. Heymann[2], S. M. Manders[2], J. Chiang[3], A. Levin[4], R. E. Schnur[1].* 1) Division of Genetics, Department of Pediatrics, Cooper University Health Care, Camden, NJ; 2) Division of Dermatology, Department of Medicine, Cooper University Health Care, Cooper Medical School of Rowan University, Camden, NJ; 3) Casey Eye Institute, Oregon Health Sciences University, Portland, OR; 4) Wills Eye Hospital, Philadelphia, PA.

Oculocutaneous Albinism Type 1 (OCA1) is an autosomal recessive disorder due to mutations of tyrosinase (*TYR*) on chromosome 11q14. 3. OCA1A patients show nearly complete lack of pigmentation due to absence of tyrosinase activity; OCA1B patients, in contrast, have some residual TYR activity with milder pigmentary effects. We report a 10 year-old Hispanic (non-Puerto Rican) boy with features of OCA, including a complete absence of pigment. Non-OCA-related features include macrosomia, visceromegaly, history of pulmonary infections, easy bruising and learning disability. A distant relative on each side of the family was reported to have albinism. Chromosome microarray analysis detected a single, contiguous, 16. 15 Mb region of homozygosity on chromosome 11q13. 5-q14. 3 including the *TYR* locus [arr 11q13. 5q14. 3(76,447,458-92,594,422)x2 hmz], allowing us to target *TYR* as the likely etiology of his OCA. Subsequent *TYR* sequencing revealed homozygosity for a double set of variants, each previously individually reported to be pathogenic: p. R299H:c. 896G>A and L216M:c. 646T>A, consistent with our patient's OCA1A phenotype. Biparental inheritance of the double mutation set was confirmed. Thus, the single block of homozygosity likely represents very distant ancestral relatedness of the parents rather than segmental isodisomy. Interestingly, although the patient is homozygous for these two discrete missense changes, more distal SNPs within *TYR* are heterozygous, suggesting that an intragenic crossover event occurred at some point. In summary, our patient has OCA1A due to biparental transmission of a double set of *TYR* missense mutations that are carried on a larger ancestral homozygous block of chromosome 11. Our patient's "albinism-plus" phenotype may be the result of homozygosity for deleterious changes of other regional genes, although correlation of his non-albinism features with specific genes could not be made.

2836F

Hereditary motor and sensory neuropathy with proximal dominancy in the lower extremities, urinary disturbance, and paroxysmal dry cough maps to chromosome 1p13. 3-1q23. *S. Miura[1], S. Sano[1], K. Kosaka[2], R. Fujioka[3], H. Saitsu[4], T. Taniwaki[1], K. Yamamoto[5], H. Shibata[2].* 1) Department of Medicine, Kurume University School of Medicine, Kurume City, Fukuoka Prefecture, Japan; 2) Medical Institute of Bioregulation, Kyushu University, Fukuoka City, Fukuoka Prefecture, Japan; 3) Department of Food and Nutrition, Beppu University Junior College, Beppu City, Oita Prefecture, Japan; 4) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama City, Kanagawa Prefecture, Japan; 5) Department of Medical Chemistry, Kurume University School of Medicine, Kurume City, Fukuoka Prefecture, Japan.

We previously reported a clinically new type of autosomal dominant disorders of motor and sensory neuropathy with proximal dominancy in the lower extremities, urinary disturbance, and paroxysmal dry cough (Miura et al. J Neurol Sci 2008). The cardinal clinical features of the disease were as follows: i) slow progression; ii) muscular weakness with dominancy in the proximal portion of the lower limbs; iii) sensory involvement with dominancy in the lower limbs; iv) areflexia; v) fine postural tremor; vi) painful muscle cramping; vii) elevated serum creatine kinase level; viii) urinary disfunction; and ix) recurrent paroxysmal dry cough. To identify the causative mutation for the disease, we studied a Japanese pedigree with the disease consisted with 19 family members including 9 patients in five generations. On multipoint linkage analysis of the pedigree by randomly selected 1,752 cleaned SNPs with an average interval of 2 cM using GeneHunter implemented in easyLINKAGE package v5. 08, maximum LOD scores of > 2. 0 was obtained on 1p13. 3-q23 (LOD = 2. 24). The exome sequencing upon five patients and one healthy relative from the pedigree revealed 2526 patient-specific single nucleotide variants (SNVs). By the filtering processes using the information from the public SNP database and our linkage analysis, we identified 19 candidate SNVs in 14 genes. Moreover, we selected 3 candidate SNVs in 2 genes through validation by Sanger sequencing, confirming cosegregation, and genotyping 520 healthy Japanese individuals. Through the functional predictions of the cosegregated SNVs, we currently focus on one SNV located in *IQGAP3* which is associated with neurite outgrowth. The SNV possibly alters the splicing of *IQGAP3* and also located within a non-coding RNA which may affect the expression of IQGAP3. This study was approved by the Ethics Committees of Kurume University School of Medicine and Kyushu University, Faculty of Medicine.

2837W

Adult onset motor neuron disease predominant Triple 'A' syndrome in South India- ? due to a novel mutation. *D. Selvarajan[1], P. Jayapal[2], S. Krishnan[3], NJ. Elakatt[4].* 1) Internal Medicine, Vinayaka Mission's Medical College, , Karaikal, Pondicherry, India; 2) Internal Medicine, Madras Medical College, Chennai, Tamilnadu, India; 3) Internal Medicine, Presence Saint Francis Hospital, Evanston, Illinois; 4) Strand Centre for Genomics and Personalised testing, Bengaluru, Karnataka, India.

Triple A syndrome (Allgrove syndrome)is a rare autosomal recessive disease involving Chr. 12q13producing defective AAAS gene, encodes a protein, Aladin, which is a member of the WD-repeat family of regulatory proteins involved in normal development of nervous system. The protein consists of 546 amino acids and the gene is made up of 16 exons. Triple A syndromehas myriad of features mainly Addison's disease, Achalasia cardia and Alacrimia followed by peripheral neuropathy, Autonomic dysfunction, Microcephaly, Mental retardation, Ataxia ,etc. This is usually a childhood disease. We present a 20 year old adult female from South India who was born of second degree consanguity presented with dysphagia and severe small muscle wasting for the past three years and elsewhere diagnosed as motor neuron disease. But on further evaluation she revealed presense of Addison's disease and Type 11 Achalasia cardia and alacrimia and other above mentioned features. Mutation analysis was planned and using the Patient's DNA, Nextera technology was utilized in the enrichment of target sequences, which includes coding exons (>95%) and splice junctions of 550 genes. The generated library was subjected to next generation sequencing on the Illumina NGS platform (MiSeq). Variations were identified using the STRAND® NGS software and interpreted using StrandOmics. Of the 550 genes, 460 had >85% coverage at 20X. The patient harbored a novel homozygous variant (c. 545+2T>G) in the AAAS gene. The variant(NM_015665 c. 545+2T>G, chr12:53708533A>C)appears in the essential splice site region of intron 6. Online splice site prediction tools such as Alternative Splice Site Prediction and Berkeley Drosophila Genome Project have predicted the variant to disrupt the wild type splice site and favour an alternative splice site 19 nucleotide bases into intron 6. This causes the insertion of additional 19 nucleotide bases into the coding sequence. The online tool ORF finder has predicted that this variant could cause a frameshift and an eventual termination (p. Ser182ArgfsTer30) leading to a final peptide product of only 210 amino acids instead of the original 546. Her parents were tested to confirm heterozygosity (carriers) and younger brother had same disease with same homozygous mutation. Early diagnosis will lead to effective management by treating Addison's disease, Artificial tear drops and surgical correction of Achalasia cardia. Genetic counseling prevents further occurrences.

2838T

Novel Gene Discovery Using Whole Exome Sequencing and Linkage Analysis in a Large Family with Autosomal Dominant Ataxia. *S. Cho[1], M. Seong[1], H. Kim[2], S. Seo[1], S. Lee[1], J. Kim[1], B. Jeon[2], S. Park[1].* 1) Dept Laboratory Medicine, Seoul National Univ Hosp, Seoul, South Korea; 2) Departments of Laboratory Neurology, Seoul National Univ Hosp, Seoul, South Korea.

The autosomal dominant spinocerebellar ataxias (SCAs) represents a group of neurodegenerative diseases, characterized by a slowly progressive incoordination of gait. The genetic background of SCAs is heterogeneous, having 40 or more genetic subtypes. In addition, some SCAs are caused by sequence variants, but others by nucleotide repeat expansions. Here, we investigated genetic etiology using genomic approach in a large family with autosomal dominant spinocerebellar ataxia patients. We collected peripheral blood from 14 family members including 5 patients. Whole exome sequencing (WES) was done for 4 patients and 2 normal members. Sequence variants were called and filtered to find out pathogenic mutations located within coding regions and their flanking intronic regions. Also, we performed exome-wide linkage analysis using variants information discovered in WES to find out coding or non-coding nucleotide repeat expansion. Sanger sequencing and repeat-primed PCR were done for each repeat regions to reveal abnormal expansion. No sequence variant consistent with segregation pattern was identified in this family. However, we identified 10 genomic regions with highest LOD score. In these regions, there were 20 genes and 10 tri- to hexa-nucleotide repeat regions. Interestingly, *TGM6* (genetic cause of SCA30) and *NOP56* (SCA36) were included also. WES and exome-wide linkage analysis may be a useful tool to discover novel gene in genetically heterogeneous disease caused by different genetic mechanisms like autosomal dominant spinocerebellar ataxia.

The proteins encoded by *TELO2*, *TTI1*, and *TTI2* interact to form the TTT complex, a co-chaperone system for maturation of the phosphatidylinositol 3-kinase-related protein kinases (PIKKs). Here we report 6 individuals from 4 unrelated families with compound heterozygous mutations in *TELO2.* These individuals share overlapping features including global development delay, intellectual disability, dysmorphic facies, microcephaly, abnormal movements and abnormal auditory and visual function. WES of three affected individuals in Family 1 identified rare compound heterozygous missense variants in *TELO2,* C367F (c. 1100G>T) and D720V (c. 2159A>T). Subsequently, using GeneMatcher (www. genematcher. org), we identified affected individuals in 3 additional families all with compound heterozygous variants in *TELO2*. The proband in Family 2 is compound heterozygous for the C367F variant (found in Family 1) and the novel variant V766M (c. 2296G>A). The proband in Family 3 carries the P260L (c. 779C>T) and R609H (c. 1826G>A) variants and that in Family 4 is a compound heterozygote for the D720V (found in Family 1) and a complex allele, Q172X (c. 514C>T) with IVS16+1G>A, which encodes a markedly truncated protein from a transcript that is subject to nonsense mediated mRNA decay. All variants are rare and predicted to be damaging by Polyphen-2 and SIFT. TELO2, TTI1 and TTI2 protein levels were reduced to 34%, 27% and 15% of controls in lymphoblasts and fibroblasts from affected individuals in Family 1. Fibroblasts from the proband in Family 2 showed similar reductions. Despite this, PIKK functions were normal in ionizing irradiation, mitomycin C treatment, and telomere length assays in Families 1 and 2. Under stress conditions (17-AAG, treatment), TTT protein expression decreased more in Family 1 individuals' fibroblasts than in control fibroblasts (TELO2, TTI1, and TTI2 decreased by 11. 9%, 31. 6 %, and 20%, respectively). This further reduction in TTT proteins was associated with decreased ATM and DNA-PK levels in patients in Family 1 (34% and 56% of control fibroblasts, respectively). ATR and mTOR expression was not reduced under these conditions. This result indicates that with Hsp90 inhibition, the reduction of the TTT complex resulting from *TELO2* variants decreases abundance of some PIKK proteins. In summary, our results suggest that these *TELO2* missense variants result in loss-of-function, perturb TTT complex stability and cause a newly recognized autosomal recessive form of ID.

2840W

The Expanding Genetic and Phenotypic landscapes of Deafness Genes. *H. Azaiez[1], K. T. Booth[1], C. M. Sloan-Heggen[1], M. Beheshtian[2], H. Najmabadi[2], R. J. H Smith[1].* 1) Dept Otolaryngology, Univ Iowa, Iowa City, IA; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran.

The genetic, allelic and clinical heterogeneity associated with hereditary deafness are well established, with over 90 genes and 2000 mutations currently identified to cause non-syndromic hearing loss (NSHL) and a wide spectrum of phenotypic diversity in onset, severity, stability and audioprofiles. Less established although rapidly expanding, are genotype-phenotype relationships. This expansion directly correlates with the advancement in sequencing technologies. Here we expand the phenotypic spectrum associated with three genes; *PTPRQ*, *CEACAM16* and *COL11A1* using a combination of linkage analysis, custom-targeted genomic enrichment of all known deafness genes as well as whole exome sequencing in three large families. In an extended three-generation family with autosomal dominant (AD) non-syndromic post-lingual and progressive deafness, we have identified a novel nonsense mutation (p. W2122X) in *PTPRQ* gene that segregates with the disease phenotype. To date, pathogenic variants in *PTPRQ* have been exclusively associated with autosomal recessive (AR) NSHL that is congenital, severe to profound and progressive in nature. The mutation is located in the phosphatase domain and produces a protein that is lacking the last 6 amino acids. Given that many of the recessive mutations are loss of function, haploinsufficiency as the mechanism of action of the p. W2122X can be excluded. In a second consanguineous Iranian family segregating moderate to severe postlingual progressive ARNSHL we have identified a novel homozygous canonical splice-site mutation in the *CEACAM16* gene. Currently mutations in *CEACAM16* are only described in two families with ADNSHL. Interestingly all three families exhibit a similar phenotype suggesting that loss of function is the most probable mechanism of action of this novel variant. Finally, in a large 4- generation family of European descent with early-onset high frequency progressive ADNSHL, we have identified a novel canonical splice-site mutation in *COL11A1* segregating with the disease. Mutations in *COL11A1* have been previously linked to Stickler and Marshall Syndromes. High throughput next generation sequencing has already advanced our understanding of the molecular genetics of hearing loss, here we use it to expand the phenotypic landscape of deafness genes and shed light on their extraordinary pleiotropy.

Inner ear anomalies (IEAs) demonstrated with an imaging study have been reported in approximately 30% of the children with congenital hearing loss. While recent discoveries make molecular diagnosis accessible for a number of deaf individuals, recognized genetic causes of non-syndromic IEAs remain limited. In this work we present the results of whole exome sequencing (WES) in unrelated 68 families with non-syndromic IEAs. Sixty-four probands were simplex and four were multiplex with autosomal recessive inheritance. Agilent SureSelect Human All Exon 50 Mb kits and an Illumina Hiseq2000 instrument were used. Candidate variants were confirmed with Sanger sequencing and evaluated for co-segregation with IEAs in all available family members. We identified causative variants in 9 (13. 2%) families in the recognized IEA genes including *SLC26A4* (MIM 605646) (10. 29%), *FGF3* (MIM 164950) (1. 47%), and *CHD7* (MIM 608892) (1. 47%). While *CHD7* and *FGF3* mutations are known to cause CHARGE (MIM 214800) and LAMM syndromes (MIM 610706), respectively, affected children in this study were either non-syndromic or showed very subtle findings of these syndromes. In an additional family with two affected children we identified a mutation in *ROR1* (MIM 602336) as a novel gene for non-syndromic IEAs. Our data show that WES can be used to identify causative DNA variants in known and novel genes for IEAs and provide important insights into the etiology of deafness.

2842F

***PDZD7* and hearing loss: more than just a modifier.** *KT. Booth[1], H. Azaiez[1], K. Kahrizi[2], AC. Simpson[1], WTA. Tollefson[3], CM. Sloan[1], NC. Meyer[1], M. Babanejad[2], F. Ardalani[2], S. Arzhangi[2], MJ. Schnieders[3], RJH. Smith[1], H. Najmabadi[2].* 1) Molecular Otolaryngology and Renal Research Laboratories, Department of Otolaryngology - Head & Neck Surgery, University of Iowa, Iowa City, Iowa, 52242, USA; 2) Genetics Research Center, University of Social Welfare and Rehabilitation Sciences, Tehran, Iran; 3) Department of Biomedical Engineering, University of Iowa, Iowa City, IA 52242, USA.

Deafness, the most frequent sensory disorder, affects roughly 1 in 500 newborns and by the age of 80, half of all persons require amplification for meaningful communication. Over 90 genes are implicated in non-syndromic hearing loss, a testament to the extreme heterogeneity of this condition. By using targeted genomic enrichment with massively parallel sequencing (using OtoSCOPE®), it is possible to screen all known deafness-causing genes simultaneously. Herein we present four consanguineous families of Iranian origin segregating autosomal recessive non-syndromic hearing loss (ARNSHL). Audiological examination revealed bilateral moderate downsloping to severe hearing loss; ophthalmological examination was normal. Linkage analysis and homozygosity mapping identified segregation with the *DFNB57* locus in two families. OtoSCOPE® results identified five pathogenic variants in the *PDZD7* gene: two nonsense and three missense mutations. Variant segregation with the hearing loss was confirmed by Sanger sequencing in all families. The *PDZD7* gene encodes for the PDZ-domain- containing-7 protein (PDZD7). It is expressed in both the retina and cochlear hair cells, where it plays a vital role in the organization and anchoring of the USH2 protein complex. The two nonsense mutations are predicted to produce null alleles, while the missense mutations are predicted to alter conformational flexibility of specific protein domains. This report is the first to establish that pathogenic variants in *PDZD7* cause non-syndromic hearing loss and not Usher syndrome. These results in association with published data support an essential role for PDZD7 in normal auditory function.

2843W

Exome Sequencing for Deafness Genes: Reducing False Positives by Functional Analysis. *N. Danial-Farran[1], Z. Brownstein[2], A. Abu-Rayyan[3], M. Birkan[2], F. T. A. Martins[2], M. Khayat[1], M. Kanaan[3], S. Shalev[1], K. B. Avraham[2].* 1) Genetics Institute, Ha'Emek Medical Center, Afula, Israel and Rappaport Faculty of Medicine, Technion-Israel Institute of Technology, Haifa, Israel; 2) Department of Human Molecular Genetics and Biochemistry, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Hereditary Research Lab, Department of Life Sciences, Bethlehem University, Bethlehem, Palestine.

Since Next Generation Sequencing has become available as a strategy in genetic research and disease gene discovery, the number of reported causative variants has increased dramatically. Recent studies have shown that more than 25% of reported variants may be false positives, precluding them being the main contributing factors to disease. One of the main pitfalls in characterizing a new variant by computational prediction tools is its absence in sequencing databases or low minor allele frequency (MAF) scores. Our work focuses on identifying pathogenic variants causing hearing loss in the Middle Eastern population. Determining the etiology of hearing loss is crucial for clinical management, determining the prognosis of hearing loss and other abnormalities and assessing the recurrence rate in family members. The use of isolated populations, such as those of the Middle East, has had a strong influence on finding deafness genes worldwide, due to consanguinity and founder effects. We applied targeted gene capture, along with massively parallel sequencing (MPS), of 407 human genes and human orthologues of mouse deafness genes on unrelated families of Israeli Jewish and Palestinian Arab origin. MPS was analyzed using a combination of open-source tools, including Burrows-Wheeler Alignment (BWA) and variant calling with the GATK Genome Analysis Toolkit. We discovered variants that are candidates for deafness in our patients, including in mouse genes not previously associated with human deafness. Some variants predicted to be pathogenic appeared in healthy family members, demonstrating that caution must be taken with prediction tools. Functional analysis was performed on a subset of variants, including immunofluorescence to determine cellular localization. The c. 349C>T, p. (Leu117Phe) variant in SLC26A4 is associated with congenital profound deafness [MIM 600791] in our population. Based on population-scale data, it is predicted to be benign, but pathogenic by Polyphen2, SIFT, Mutation Taster and ConSurf. Our localization experiments of the wild-type and mutant proteins in transfected COS7 cells demonstrated that the mutant is retained in the endoplasmic reticulum, whereas the wild-type targets the plasma membrane, suggesting this variant is indeed pathogenic. The auditory system, through the use of cell and cochlear cultures and mouse models for human deafness, offers suitable avenues for functional analysis to link variants to pathogenicity.

2844T

Genetic variation in genes associated with autosomal recessive non-syndromic hearing impairment. *H. Kremer[1,2], J. Oostrik[1], A. Henkes[2], C. Gilissen[2], I. Feenstra[2], C. Zazo Seco[1], H. G. Yntema[2].* 1) Dept Otorhinolaryngology, Radboud University medical center, Nijmegen, The Netherlands; 2) Dept Human Genetics, Radboud University medical center, Nijmegen, The Netherlands.

Early onset hereditary hearing impairment is assumed to be inherited in an autosomal recessive pattern in the majority of the cases. Currently, more than 60 genes are known to be associated with this type of hearing impairment. Whole exome sequencing (WES) or targeted massive parallel sequencing of all known genes for autosomal recessive non-syndromic hearing impairment (arNSHI) are state-of-the-art strategies for genetic testing, with varying yields. Interpretation of genetic variation is a major challenge in genetic testing and currently, revised genetic diagnoses are to be reported to families that received a genetic diagnosis in the past (Shearer et al. Am J Hum Genet. 2014 95:445-53). To obtain insight in the genetic variation in the population of the Netherlands in 51 genes known to be associated with arNSHI, we have selected rare variants (MAF <1%) identified in WES of 3620 individuals. To assess the predicted outcome *CDH23* (MIM *605516) of nonsynonymous Single Nucleotide Variants (SNVs), the Condel score was determined which combines various prediction programs (e. g. SIFT, Polyphen2, MutationAssessor). A potential effect on splicing was predicted for SNVs from nucleotide +1 to +8 of splice donor sites and -8 to -1 of splice acceptor sites with Genesplicer, NetGene and NNSplice. The total number of predicted pathogenic variants in the 51 arNSHI genes was 1223, the majority of which were private variants. Seven variants in six genes had an allele frequency of 0. 5% or higher including mutations in *GJB2* (MIM *121011) and *MYO15A* (MIM *602666) and part of these were repeatedly detected in WES of patients with arNSHI. These variants are likely to be founder mutations or represent mutational hotspots. Predicted carrier frequencies of the 51 known genes for arNSHI varied between 4. 97% (*CDH23*) and 0. 04% (*SYNE4*; MIM *615535). The carrier frequency in *CDH23* already predicts an incidence of arNSHI of 2 in 1000 which is are higher than the reported incidence of arNSHI which is about 1 in 1875 based on an incidence of 1 in 750 for early onset hearing impairment with 40% of these cases based on autosomal recessive mutations. These findings demonstrate the importance of segregation analysis in genetic testing and the pitfalls in diagnostics of isolated cases. On the other hand, the high carrier frequency of (predicted) pathogenic variants raises the question whether these variants contribute to complex inheritance of hearing impairment with onset later in life.

Application of a targeted next-generation sequencing panel (OTO-NGS-Panel) in a cohort of Brazilian patients with hereditary hearing loss. *PZ. Ramos[1], L. Borreguero[2], M. Morin[2], L. Serrao-de-Castro[2], I. del Castillo[2], SM. da Silva-Costa[1], GM. de Carvalho[3], AM. Castilho[3], EL. Sartorato[1], MA. Moreno-Pelayo[2].* 1) CBMEG, University of Campinas (UNICAMP), Campinas, São Paulo, Brazil; 2) Genetics Department, Hospital Ramón y Cajal-IRYCIS, CIBERER-U728, Madrid, Spain; 3) ENT Department, Faculty of Medical Sciences, University of Campinas (UNICAMP), Campinas, São Paulo, Brazil.

Hearing loss is one of the most common sensory disorders in humans. Over 400 syndromes that include hearing loss have been described with at least 40 genes associated with the main types of syndromic hearing loss. Additionally, more than 80 genes and 140 loci have been identified for nonsyndromic hearing loss. Studies have shown that a single gene may be related to both syndromic and nonsyndromic hearing loss, or even associated with different patterns of inheritance, dominant or recessive. The identification of genetic variants can contribute to a better understanding of the molecular basis and the pathophysiological mechanisms involved in the different phenotypes of hereditary hearing loss, and can provide an accurate diagnosis, development of specific treatments and genetic counseling for patients and families. However, molecular diagnosis has been a challenge, mainly due to clinical and genetic heterogeneity of hearing loss. The application of new high-throughput technologies, such as next-generation sequencing, allows an optimization of genetic diagnosis and a comprehensive investigation of hereditary hearing loss. Therefore, the main goal of the present study was to elucidate the genetic etiology in a cohort of Brazilian patients with bilateral sensorineural hearing loss due to distinct inherited patterns using the OTO-NGS-panel, a targeted next-generation sequencing panel designed by the Genetic Department at the Hospital Ramón y Cajal, Madrid-Spain, and the Illumina MiSeq platform to simultaneously analyze 72 genes already known to be involved in hereditary hearing loss. In our pilot study we have screened 13 unrelated sporadic or familial cases and pathogenic mutations were identified in six out of 13 patients (approximately 50%). Nine mutations in five different genes were detected. The following genes were involved: *ACTG1* (MIM 604717) and *DFNA5* (MIM 608798), associated with autosomal dominant hearing loss and *CDH23* (MIM 601386), *MYO15A* (MIM 600316) and *OTOF* (MIM 601071), related to autosomal recessive hearing loss. We reported the identification of three novel mutations and the involvement of genes that had never been investigated before in Brazil. Our study confirms the usefulness of the OTO-NGS-panel for detecting the genetic etiology of hearing loss in a heterogeneous group of patients.

2846W

Whole Genome Sequencing Delineates Genetic Sub-Types of Neuromyelitis Optica. *K. Estrada[1,2,3], F. Zhao[2,3], C. Whelan[3], J. Flannick[3], C. Sun[1], T. Harris[1], B. Greenberg[4,5], J. Carulli[1], A. G. Day-Williams[1], D. MacArthur[2,3].* 1) Computational Biology and Genomics, Biogen, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston MA; 3) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA; 4) Department of Neurology and Neurotherapeutics; 5) Department of Pediatrics, University of Texas Southwestern Medical Center, Dallas, TX.

Neuromyelitis optica (NMO) is a rare autoimmune disorder of the central nervous system that affects the optic nerves and spinal cord with a prevalence of 1/100,000 in the USA. Auto-antibodies against Aquaporin 4 (AQP4) are found in about 70% of NMO patients (NMO-IgG+) yet no association to AQP4 has been identified in small genome-wide association studies (GWAS), but nominal associations to the HLA have been reported. We have performed the first whole-genome sequencing (WGS) analysis of NMO by deep sequencing (mean_DP>24X) 143 NMO patients and 658 population controls. We have performed joint variant calling yielding 42 million single-nucleotide variants (SNVs) and 6. 3 million insertions/deletions. After variant and sample quality control 29,092,408 variants were identified in 86 cases and 460 controls. In a single-variant association analysis of 9,357,936 variants with a MAF>0. 5%, we found at least two independent signals identified by the variants rs146828696 (OR=4. 8, P=4. 9x10-13) near the HLA-DRB5 gene and rs147131125 (OR=4. 5, P=6x10-9) near the HLA-DRB1 gene. In a stratified analysis by AQP4 auto-antibody status, both signals were significantly associated with NMO-IgG+, but only rs146828696 was associated in NMO-IgG- (OR=5. 6, P=3. 1x10-6). To further investigate the role of the HLA we imputed classical HLA alleles from the sequencing data. The HLA-DRB1:03*01 was the most significant imputed allele (OR=4. 5 P=6. 7x10-9) in the NMO-IgG+ and was not associated with NMO-IgG-. Both rs146828696 and rs147131125 remained associated after conditioning for HLA-DRB1:03*01. An imputed missense variant in HLA-DRB1 Arg74 carried by the HLA-DRB1:03*01 haplotype had the most significant association with NMO-IgG+ (OR=4. 2, P=6. 8x10-9). Gene-based analyses using only missense and/or loss-of-function variants with a MAF <1% did not show any gene with P<2. 5x10-6. Finally, we performed a CNV discovery and association analysis where we also identified a 3. 7kb deletion carried by HLA-DRB1:03*01 near the *C4* gene associated with NMO-IgG+ (OR=3. 7, P=7. 8x10-8). These genome-wide significant SNPs as well as 16 additional SNPs with P<1x10-5 are being replicated in 150 cases and 920 controls. Identification of the first genome-wide significant association in NMO is an important discovery in the field, and replicating differential genetic associations between NMO-IgG+ and NMO-IgG- would be a major advancement in the molecular understanding of the heterogeneity of the disease.

2847T

HA20: A novel autoinflammatory disease caused by haploinsufficiency of A20, encoded by *TNFAIP3* . *Q. Zhou[1], H. Y. Wang[1], M. Stoffels[1], Y. H. Park[1], M. Takeuchi[1], D. Yang[2], W. L. Tsai[3], Y. Zhang[4], E. Demirkaya[5], J. Lyons[4], X. M. Yu[4], H. Leavis[6], S. Ozen[7], M. Boehm[2], J. Milner[4], M. Gadina[3], J. J. Chae[1], D. L. Kastner[1], I. Aksentijevich[1].* 1) Inflammatory Disease Section, NHGRI, Bethesda, USA; 2) Laboratory of Cardiovascular Regenerative Medicine, NHLBI, Bethesda, USA; 3) Translational Immunology Section, NIAMS, Bethesda, USA; 4) Genetics and Pathogenesis of Allergy Section, NIAID, Bethesda, USA; 5) Institute of Health Sciences, R&D Center, Ankara, Turkey; 6) University Medical Center Utrecht, Utrecht, Netherlands; 7) Hacettepe University, Ankara, Turkey.

TNFAIP3/A20 protein functions as a potent negative regulator of the NFκB signaling pathway. Low-penetrance common variants of *TNFAIP3* have been associated with a number of autoimmune and inflammatory diseases. Biallelic somatic inactivating mutations in *TNFAIP3* have been described in B cell lymphomas. Here, we report 5 high penetrance dominantly inherited frameshift and nonsense *TNFAIP3* mutations in 11 patients from 5 unrelated families with early-onset systemic inflammation, arthralgia/arthritis, oral and genital ulcers, and ocular inflammation. The syndrome resembles Behcet's disease BDthat is typically considered a polygenic disease with onset in early adulthood. Targeted sequencing of *TNFAIP3* in Turkish and Japanese GWAS cohorts with BD identified one patient with a novel frameshift mutation. None of the mutations were reported in any public database. Expression of wild type (WT) A20 was reduced in patients' PBMCs and fibroblasts, while mutant proteins were not detectable. Over-expressed mutant proteins failed to suppress TNF-α-induced NFκB activity in transfected 293T cells in comparison to WT A20. Co-transfection with the WT A20 plasmid normalized the NFκB activity suggesting a haploinsufficiency mechanism of disease. Stimulated patients' cells showed increased phosphorylation of IKKα/β, increased degradation of IkBα, and increased nuclear translocation of p65. These data show strong evidence that mutant proteins cause enhanced signaling in the NF-κB pathway. Patients' cells displayed weak associations with the TNFR complex and a marked defect in the deubiquitination of target molecules RIP1, NEMO and TRAF6. This defect was partially rescued by co-transfection with a WT-A20 construct. Patients' cells had a sustained higher K63-ubiquitinaton level of NEMO and RIP1 and accumulated high-molecular weight Ub-aggregates. These results indicate that the reduced interaction of A20 with the TNFR signaling complex leads to inefficient deubiquitination of target proteins. Multiple experiments showed evidence for increased expression of NFκB target genes in patients' immune cells. Levels of IL-1β, TNF-α, IP-10, IL-17, and IL-9 were substantially increased in patients' serum and in the supernatants of stimulated PBMCs relative to healthy controls. Initial experience with agents targeting pro-inflammatory cytokines has been encouraging. This study provides the first example of the effects of high-penetrance loss-of-function mutations in *TNFAIP3* in humans.

Identification of uniparental isodisomy from sequencing data. *D. Bis[1], R. Schüle[2], P. Bauer[2], A. Söhn[2], T. Rattay[2], C. Saghira[1], L. Abreu[1], F. Tao[1], S. Züchner[1].* 1) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL; 2) Department of Neurodegenerative Disease, Hertie Institute for Clinical Brain Research and Center for Neurology, Tübingen, Germany.

Uniparental disomy (UPD) is the inheritance of two copies of a chromosomal region from one parent. The copied region can be an identical copy of one parental allele (isodisomy) or distinct alleles from the same parent (heterodisomy). Isodisomy can generate homozygosity for a deleterious recessive mutation, but without knowledge of the isodisomic event, the disease causing mutation is excluded from analysis since one parent would not carry the recessive allele. The extent of UPD as a cause of disease is still not fully understood. Only whole genome sequencing, and to some extent whole exome sequencing, allows for the routine detection of such events of nearly every size. We are systematically studying exomes and genomes of a sizable cohort (>100 families) of rare neurodegenerative diseases. Thus far, we have identified a case with Hereditary Spastic Paraplegia (SPG35) where a homozygous UPD spanned 80% of chromosome 16. Isodisomy was confirmed by excluding genomic deletions and genotyping polymorphic markers within the parents, and the homozygous disease-causing mutation was identified within this region. We will present the full evaluation of UPD in our cohort of rare Mendelian families, already excluded for candidate genes by whole exome sequencing. It is possible that the contribution of UPD has been significantly underestimated because of technical challenges to explore it in larger sample size.

Rare Variant Gene-Based Case-Control Burden Testing in a Mendelian Disease Framework Using Publically Available Control Data. *M. Lippincott[1], M. Guo[2], L. Plummer[1], J. Hirschhorn[2], W. Crowley[1].* 1) Reproductive Endocrine Unit, Massachusetts General Hospital, 55 Fruit Street, Boston, MA 02114; 2) Boston Children's Hospital, 3 Blackfan Circle, Boston, MA 02115.

Background: Isolated GnRH Deficiency (IGD) is characterized as failure to enter or progress through puberty. Over 30 mendelian loci have been identified which together account for only 1/3 of the disease cases. However, the majority of IGD cases are sporadic given the reproductive consequences of this disorder. We hypothesized that IGD cases would be enriched for rare deleterious variants in genes causing IGD compared to controls. Aim: To develop a gene-based burden testing model of WES data using publically available control data and to use this method to discover new genes in a rare disease model. Methods: Whole-exome sequencing was done on 148 non-Finnish European cases, which were enriched for IGD-causing variants in *PROKR2* (a positive control). The publically available Exome Aggregation Consortium (ExAC) WES data on non-Finnish Europeans was used for controls. Each data set was restricted to rare (MAF less than 0. 0001), putatively deleterious (nonsense, frameshift, essential splice, missense with CADD score >10) variants in areas of shared coverage with an average read depth of 10. These multiple variants were then collapsed by gene and the gene-based burden of variants was compared between cases and controls using Fisher's Exact Test. Results: Burden testing revealed genes known to cause IGD: *PROKR2* (9 variants in cases, p<1. 3E-9), *FGFR1* (9 variants in cases, p<1. 2E-8), and *KAL1* (5 variants in cases, p<1. 8E-5). All variants were confirmed by Sanger sequencing. In addition, 2 other genes had exome-wide significance p values (p<2. 5E-6) and are novel candidates for genes causing IGD. Conclusions: We report the ability to use publically available WES data to design rare variant case-control gene-based burden testing in a rare disease model. This rare variant burden testing was validated by its ability to recapitulate genes known to cause IGD. As a result, novel genes passing the burden testing are being evaluated for their possible role in IGD.

2850T

Identifying candidate mutations for rare birth defects through family trio-based exome sequencing. *T. Nicholas[1], D. Koboldt[1], D. Wegner[2], R. Fulton[1], B. Ozenberger[1], J. Wambach[2], D. Grange[2], R. Wilson[1,3], F. Cole[2].* 1) McDonnell Genome Institute , Washington University, St. Louis, MO; 2) Department of Pediatrics, Washington University, St. Louis, MO; 3) Department of Genetics, Washington University, St. Louis, MO.

Genomic information is increasingly relevant for clinical care, particularly with the availability of rapid, inexpensive tools for genome and exome sequencing. The McDonnell Genome Institute and the Department of Pediatrics at the Washington University School of Medicine have initiated a program to identify candidate pathogenic variants associated with rare birth defects. It is estimated that as many as 80% of such cases can be attributed to underlying genetic variation. Families recruited into the program are selected by a board of medical geneticists, clinicians, and genome scientists, based on phenotypic information, relevant clinical diagnostic studies, family history, and availability of appropriate informed consented samples. Our strategy for identifying candidate causal variants involves exome sequencing of the proband and immediate family members (parents and available siblings). The sequence data are aligned to the human reference sequence and assessed for variants, including both single nucleotide variants and indels, which are further annotated with gene and functional information. Candidate causal variants (*de novo* mutations and rare recessive or compound heterozygous variants) are reported and prioritized based on relevant segregation patterns, predicted functional consequences and population allele frequencies. This program provides a streamlined approach for combining clinical expertise with genomic methods to better identify causative genetic variants that can inform and aid the diagnosis and treatment of patients with rare birth defects, and reveal the genetic risk of family members. Here, we present the initial findings from exome sequencing of 8 families (28 samples total) with rare birth defects including congenital heart disease, congenital diaphragmatic hernia, genitourinary defects, sternal malformation, and neuromuscular disease.

The UK 100,000 Genomes Project. *K. Smith[1], J. Davies[1], A. Devereau[1], T. Fowler[1], T. Hubbard[1,2], E. McDonagh[1], M. Parker[1], A. Rendon[1], L. Riley[1], A. Rueda Martin[1], M. Ryten[1], E. Thomas[1], C. Turnbull[1], M. Caulfield[1], Genomics England.* 1) Genomics England, London, United Kingdom; 2) King's College London, London, United Kingdom.

The UK's 100,000 genomes project has begun consenting participants to its main programme through a network of 11 NHS Genomic Medicine Centres (GMCs) spanning over 70 local delivery partner institutions. It has four main aims: (1) to bring benefit to patients; (2) to create an ethical and transparent programme based on consent; (3) to enable new scientific discovery and medical insights; and (4) to kick-start the development of a UK genomics industry. The project focuses on patients with a rare disease and their families (approximately 50,000 genomes), as well as patients with certain common cancers (about 25,000 tumour-normal pairs). Whole genome sequencing of DNA extracted from blood samples is performed to at least 30x depth for germline samples and 75x for tumour samples, using Illumina's HiSeq X Ten sequencing platform. PCR-free library preparation is employed when feasible. All germline samples are required to achieve at least 15x high-quality coverage over 95% of the autosomal genome. One of the innovations of the project is the collection of phenotype data from the GMCs in a comprehensive and standardised manner, either through direct data entry or by the population of data models directly from Electronic Health Record systems. Data models for each of the 120 currently eligible rare genetic conditions, as well as for cancers, have been developed in consultation with clinical experts to support clinical data capture and phenotyping. This approach was designed to enable clinical interpretation and large-scale genomic research. Clinical data models include questions about the presence or absence of human phenotype ontology (HPO) terms, additional clinical tests, and family history. To date, data models include 1370 different HPO terms, with a median 37 terms per condition and range 2 (hyperinsulinism) to 116 (mitochondrial disorders). Over 200 phenotypes have been proposed for addition to the HPO. One of the important benefits of the programme will be to obtain HPO term frequencies based on large numbers of patients, rather than occurrence in OMIM entries, informing more powerful variant prioritisation strategies.

2852W

Inherited disorders in apparently acquired severe aplastic anemia. *B. J. Ballew[1], S. Gadalla[1], S. Spellman[2], M. Haagenson[2], S. Lee[2], S. A. Savage[1], NCI DCEG Cancer Genomics Research Laboratory, NCI DCEG Cancer Sequencing Working Group.* 1) Clinical Genetics Branch, Division of Cancer Epidemiology and Genetics, National Cancer Institute, NIH, Rockville, MD, USA; 2) Center for International Blood and Marrow Transplant Research, Minneapolis, MN, USA.

Severe aplastic anemia (SAA) is associated with increased risk of myelodysplastic syndrome, leukemias, and possibly solid tumors. A subset of patients with isolated SAA may have an underlying inherited bone marrow failure syndrome (IBMFS). The IBMFS require distinct medical management compared with acquired SAA. For example, the IBMFS do not respond to immunosuppressive therapy, the mainstay of treatment in acquired SAA. Moreover, hematopoietic cell transplant (HCT) regimens must be modified to reduce morbidity in IBMFS patients. In collaboration with the Center for International Blood and Marrow Transplant Research, we are exploring the genetic etiology of SAA by performing whole exome sequencing (WES) on ~600 individuals who underwent matched-unrelated HCT for SAA. We analyzed WES data on a test set of 293 unrelated SAA individuals, 91 of whom had been diagnosed with an IBMFS based on clinical criteria. Variants were called using GATK Unified Genotyper, GATK Haplotype Caller, and FreeBayes. We removed variants of low quality or with a MAF>1% in the NHLBI Exome Sequencing Project and 1000 Genomes data. We then evaluated variants present in 56 genes known to be associated with 20 IBMFS, and separated the variants into 3 categories: likely pathogenic, possibly pathogenic, and likely non-pathogenic. These distinctions were based on a variant's proximity to known deleterious mutations, impact on the protein, and *in silico* predictions. This resulted in an average of 4 potentially deleterious variants per individual. Based on known IBMFS inheritance patterns, we were able to identify potentially causal mutations in ~75% of the 91 individuals with a known IBMFS diagnosis; this is consistent with expected number based on the literature. Notably, ~20% of the 202 SAA individuals without an IBMFS diagnosis had a potentially causal mutation. 602 healthy controls, sequenced on the same platform and called concurrently, did not have potentially causal mutations in these 56 genes. We have sequenced a second validation set of SAA individuals and analysis is underway. Additionally, because individuals with IBMFS are more at risk of complications following HCT conditioning, we are assessing the association between a putative pre-existing IBMFS and outcomes following transplant. These findings may have significant clinical implications regarding genetic testing of individuals presenting with SAA to shape treatment decisions.

2853T

Genetic determinism of Primary Osteoarthritis: the EXORHUM project. *C. Bauge[1,2], J. AURY-LANDAS[1,2], S. LECLERCQ[3], C. MARCELLI[4], K. BOUMEDIENE[1,2].* 1) Normandie Université, France; 2) UNICAEN, EA4652 MILPAT, Caen, France; 3) Service de Chirurgie orthopédique, Hôpital privé Saint Martin, Caen, France; 4) Service de Rhumatologie, CHU, Caen, France.

Osteoarthritis (OA) is the most common joint disease observed worldwide and affects nearly 10 million adults in France and 27 million adults in USA. OA is mainly characterized by the gradual loss of the articular cartilage, particularly affecting the knee, hip, spine, hand and foot. Although the multifactorial nature of the vast majority of OA cases is well recognized, genetic risk factors have been found to be strong determinants of the disease. About 50% of hip and hand OA may be genetically determined. However, currently, only few genetic alterations responsible for OA determinism have been identified mostly in genes involved in the cartilage extracellular matrix. These alterations have been mainly detected in patients with syndromic early-onset OA like pseudoachondroplasia, multiple epiphyseal dysplasia or spondyloepiphyseal dysplasia tarda. The EXORHUM project is based on the recruitment of a well clinically characterized cohort of patients with non syndromic early-onset OA. The main aim is to identify new genetic alterations, exclusive to primary OA in patients with a familial presentation, strongly suggestive of a genetic determinism. Exome sequencing will be performed on two distant affected family members without known alterations. The sub aim is to assess the prevalence of known mutations in primary non syndromic OA. In conclusion, the EXORHUM project will help us to improve the understanding of molecular processes involved in pathogenesis of OA and to better understand the complexity of OA. This is essential to improve patient diagnosis and to identify new therapeutic targets.

2854F

Molecular etiology of arthrogryposis in a cohort of families of Turkish origin. *Y. Bayram[1], E. Karaca[1], Z. Coban Akdemir[1], H. Aydin[2], A. Gezdirici[3], D. Torun[4], S. Tug Bozdogan[5], S. Isikay[6], M. M. Atik[1], T. Gambin[1], A. Karaman[7], D. Pehlivan[1], H. Aslan[8], O. Ozalp Yuregir[9], S. N. Jhangiani[10], E. Boerwinkle[10,11], R. A. Gibbs[10], N. Elcioglu[12], B. Tuysuz[13], J. R. Lupski[1,10,14,15], Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) Department of Medical Biology, Namik Kemal University Medical Faculty, Tekirdag, TURKEY; 3) Department of Medical Genetics, Kanuni Sultan Suleyman Training and Research Hospital, Istanbul, TURKEY; 4) Department of Medical Genetics, Gulhane Military Medical Academy, Ankara, TURKEY; 5) Department of Medical Genetics, Mersin University Faculty of Medicine, Mersin, TURKEY; 6) Department of Pediatric Neurology, Gaziantep Children's Hospital, Gaziantep, TURKEY; 7) Center of Genetics Diagnosis, Zeynep Kamil Women`s and Children's Diseases Training and Research Hospital, Istanbul, TURKEY; 8) Department of Medical Genetics, Eskisehir Osmangazi University Faculty of Medicine, Eskisehir, TURKEY; 9) Genetics Diagnosis Center, Seyhan Practice Center, Adana Numune Training and Research Hospital, Adana, TURKEY; 10) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 11) Human Genetics Center, University of Texas Health Science Center at Houston, Houston, TX, USA; 12) Department of Pediatric Genetics, Marmara University School of Medicine, Istanbul, TURKEY; 13) Department of Pediatric Genetics, Istanbul University Cerrahpasa Medical Faculty, Istanbul, TURKEY; 14) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 15) Texas Children's Hospital, Houston, TX, USA.

The term "arthrogryposis" is clinically defined as congenital joint contractures in two or more body areas. Arthrogryposis is a symptom rather than a specific diagnosis. To date, more than 400 different disorders have been described as having arthrogryposis and around 150 of these have been associated with a responsible gene alteration. Here we report whole exome sequencing (WES) data of 50 patients from 46 families (22 of which are consanguineous) with clinical findings that include arthrogryposis. While variants in known genes were found in affected individuals from 24 families (52%), WES analysis revealed deleterious variants in candidate genes that were not previously associated with arthrogryposis in 5 families (11%). The subjects from 17 families remained unsolved; the initial overall solved rate was calculated as 63%. The most common genes that we detected as harboring homozygous variants were *CHRNG* (in 6 patients) and *ECEL1* (in 4 patients). The identified variants in novel genes express different mode of inheritance such as recessive-homozygous (*VPS8*), recessive-compound heterozygous (*MYPBC2*), X-linked hemizygous (*ITGB1BP2*), *de novo* heterozygous (*FBN3*), and autosomal dominant (*PSD3*) in different families. Using WES as a genomic sequencing method enables us to investigate potential oligogenic inheritance or blended phenotype models (i. e. deleterious homozygous or compound heterozygous variants in two different loci or known genes in one proband) in some patients. For example, in addition to homozygous variants in *CHRNG* in a more severely affected patient with multiple pterygium syndrome, we identified another homozygous deleterious variant in *ERCC2*, which is also a known gene for an arthrogryposis related disorder. We suggest that increasing use of genome-wide technologies will provide opportunities to better understand molecular mechanisms of genetically heterogeneous disorders such as arthrogryposis.

2855W

Homozygous mutation in the eukaryotic translation initiation factor 2alpha phosphatase gene, *PPP1R15B*, is associated with severe microcephaly, short stature, and intellectual disability. *K. D. Kernohan[1], M. Tetreault[2, 3], U. Liwak-Muir[1], M. T. Geraghty[1, 4], W. Qin[1], S. Venkateswaran[5], J. Davila[6], M. Holcik[1], J. Majewski[2, 3], J. Richer[7], K. M. Boycott[1, 7], Care4Rare Canada Consortium.* 1) CHEO Research Institute, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 2) Department of Human Genetics, McGill University, Montreal, Quebec, Canada; 3) McGill University and Genome Quebec Innovation Centre, Montreal, Quebec, Canada; 4) Division of Metabolics and Newborn Screening, Department of Pediatrics, University of Ottawa, Ottawa, Ontario, Canada; 5) Division of Neurology, Department of Pediatrics, University of Ottawa, Ottawa, Ontario, Canada; 6) Department of Radiology, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada; 7) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, Ontario, Canada.

Protein translation is an essential cellular process initiated by the association of a methionyl–tRNA with the translation initiation factor eIF2. The Met-tRNA/eIF2 complex then associates with the small ribosomal subunit, other translation factors, and mRNA, which together comprise the translational initiation complex. This process is regulated by the phosphorylation status of the α subunit of eIF2 (eIF2α); phosphorylated eIF2α attenuates protein translation. Here we report a consanguineous family with severe microcephaly, short stature, hypoplastic brainstem and cord, delayed myelination, and intellectual disability in two siblings. Whole-exome sequencing identified a homozygous missense mutation, c. 1972G>A; p. Arg658Cys, in protein phosphatase 1, regulatory subunit 15b (PPP1R15B), a protein which functions with the PPP1C phosphatase to maintain dephosphorylated eIF2α in unstressed cells. The p. R658C PPP1R15B mutation is located within the PPP1C binding site. We show that patient cells have greatly diminished levels of PPP1R15B-PPP1C interaction, which results in increased eIF2α phosphorylation and resistance to cellular stress. Finally, we find that patient cells have elevated levels of PPP1R15B mRNA and protein, suggesting activation of a compensatory program aimed at restoring cellular homeostasis which is ineffective due to PPP1R15B alteration. PPP1R15B now joins the expanding list of translation associated proteins which when mutated cause rare genetic diseases.

Mutations in the glutaminyl-tRNA synthetase gene cause early-onset epileptic encephalopathy. *H. Kodera[1], H. Osaka[2,5], M. Iai[2], N. Aida[3], A. Yamashita[4], Y. Tsurusaki[1], M. Nakashima[1], N. Miyake[1], H. Saitsu[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Kanagawa, Japan; 2) Division of Neurology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Division of Radiology, Clinical Research Institute, Kanagawa Children's Medical Center, Yokohama, Japan; 4) Department of Molecular Biology, Yokohama City University School of Medicine and Graduate School of Medical Science, Yokohama, Japan; 5) Department of Pediatrics, Jichi Medical School, Tochigi, Japan.

Aminoacylation is the process of attaching amino acids to their cognate tRNA, and thus is essential for the translation of mRNA into protein. This direct interaction of tRNA with amino acids is catalyzed by aminoacyl-tRNA synthetases. Using whole exome sequencing, we identified compound heterozygous mutations [c. 169T>C (p. Tyr57His) and c. 1485dup (p. Lys496*)] in *QARS*, which encodes glutaminyl-tRNA synthetase, in two siblings with early-onset epileptic encephalopathy (EOEE). Recessive mutations in *QARS*, including the loss-of-function missense mutation p. Tyr57His, have been reported to cause intractable seizures with progressive microcephaly. The p. Lys496* mutation is novel and causes truncation of the QARS protein, leading to a deletion of part of the catalytic domain and the entire anticodon-binding domain. Transient expression of the p. Lys496* mutant in neuroblastoma 2A cells revealed diminished and aberrantly aggregated expression, indicating the loss-of-function nature of this mutant. Together with the previous report, our data suggest that abnormal aminoacylation is one of the underlying pathologies of EOEE.

2857F

Exome sequence analysis identifies novel candidate genes associated with neuronal migration disorders. *W. Wiszniewski[1], P. Gawlinski[2], T. Gambin[1], S. Jhangiani[3], D. Muzny[3], J. Bal[2], E. Boerwinkle[3, 4], R. Gibbs[3], J. Lupski[1, 3, 5, 6].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Institute of Mother and Child, Warsaw, Poland; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 4) Human Genetics Center and Institute of Molecular Medicine, University of Texas-Houston Health Science Center, Houston, TX; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 6) Texas Children's Hospital, Houston, TX.

Neuronal migration disorders (NMDs) are a group of developmental defects caused by the abnormal migration of neurons in the developing brain with over 100 causative genes identified to date. Whole exome sequencing (WES) of 29 individuals with NMDs and their parents identified apparent causative mutations in ~62% (18/29) of families. Mutations were found in known NMDs genes and novel candidate genes in 31% (9/29) and 20% (6/29) subjects respectively. Three additional patients (3/29) were found with mutations in known genes, *CACNA1A, SYNE1* and *FRAS1*, that have been already associated with human pathology but not with isolated brain abnormalities, thus they likely represent an example of phenotypic expansion. Three patients (3/29) represented a familial form of NMDs with mutations inherited from an affected parent in AD (*RELN*) and X-linked (*FLNA* and *L1CAM*) fashions. Patients with no family history of NMDs were found with compound heterozygous mutations suggestive of AR inheritance in 28% (8/29) of families and *de novo* variants in 24% (7/29). These findings provide us with information on distribution of mutations in known NMDs genes as well as potential new candidate genes involved in a process of neuronal migration. Identification of novel genes may contribute to our understanding of brain development in health and disease and improve a clinical classification of neuronal migration disorders.

2858W

Identification of a rare variant in *POLD1* in a family with familial multiple lipomatosis. *C. Mirlene[1], S. Raskin[2], J. You[3,4], J. Jurgens[3,4], M. Migliavacca[1], D. Valle[4,5,6], N. Sobreira[4].* 1) Clinical Genetics, Department of Morphology and Genetics, Universidade Federal de São Paolo, Rua Coronel Lisboa, 966, 04020-041, São Paulo, SP, Brazil; 2) Genetika Laboratory, Curitiba, Brazil; 3) Predoctoral Training Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 4) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 5) Center for Inherited Disease Research, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21224, USA; 6) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA.

Lipomatosis, also referred as familial multiple lipomatosis (FML, MIM151900) is a rare autosomal dominant phenotype characterized by multiple overgrowths of mature adipose tissue and multiple lipomas on the trunk and limbs. Cytogenetic studies have shown that rearrangements involving chromosomes 12 and 3 are often associated with FML and *HMGA2* has been suggested as a causative gene but no molecular explanation has been defined. Here we report a family submitted to the Baylor-Hopkins Center for Mendelian Genomics with FML. Four affected with (male proband, his father, paternal uncle and paternal aunt) and 1 unaffected in which the phenotype co-segregates with a rare variant in *POLD1* (V70F, c. 208G>T) detected by WES. The proband also had short stature and Arnold-Chiari malformation. We analyzed the WES data using the PhenoDB variant analysis tool (http://phenodb. org) to identify rare functional variants that fit the autosomal dominant inheritance mode. Of the 98 variants identified by this analysis, none mapped to chr12q14 or chr3q27-q28. A variant in exon 3 of *POLD1* (V70F, c. G208T) was present in all 4 affected individuals and not present in the proband's unaffected brother. This variant is predicted to be a damaging with a Sift score of 0. 06, and a Polyphen score of 0. *POLD1* encodes the 125-kDa catalytic subunit of DNA polymerase delta. DNA polymerase delta possesses both polymerase and 3' to 5' exonuclease activity and plays a critical role in DNA replication and repair. Previously, homozygous mice with inactivating point mutation in the proofreading domain of polλ(D400A) are prone to cancer including lymphomas at a young age and have a high incidence of epithelial tumors later in life. Based on this information, we selected the *POLD1* variant as our strongest candidate. In 2013, Weedon et al. described 4 unrelated individuals (2 previously reported by Shastry et al. , 2010) with mandibular hypoplasia, deafness, progeroid feature and lipodystrophy (MDPL) syndrome all with a *de novo* heterozygous in-frame deletion (S605del, c. 1812_1814delCTC) of a single codon in *POLD1* affecting the polymerase active site. We suggest that the variant in our family may confer a gain of function effect causing the overgrowth of the adipose tissue and FML phenotype in contrast to the lipodystrophy phenotype described in the patient with the heterozygous in-frame deletion.

2859T

Novel gene discovery across a large cohort of patients with syndromic craniofacial anomalies. *E. J. Bhoj, D. Li, M. H. Harr, L. Tian, T. Wang, Y. Zhao, H. Qiu, F. Mentch, C. Kim, E. H. Zackai, H. Hakonarson.* Children's Hospital of Philadelphia Philadelphia PA.

For many complex disorders it can be difficult to identify patients with single-gene disorders suitable for novel gene discovery. Many such conditions can also result from multigenic and environmental insults, which dilute discovery cohorts for research sequencing efforts for novel Mendelian genes. We have addressed this issue by creating an international highly-informative cohort of patients with craniofacial anomalies and at least one other medical condition to enrich for families affected by single-gene disorders. Additional findings in this cohort include congenital heart disease, brain malformations, seizures, cardiomyopathy, autism, hypotonia, and anomalies of the limbs, kidneys, liver, genitourinary system ordiaphragm. Over 200 families with an undiagnosed craniofacial syndrome have been carefully screened for known mutations and enrolled in our study, over 50 have had exome sequencing performed. Initial discoveries from this cohort included SPECC1L mutations in Teebi Hypertelorism Syndrome, MYRF andHox3B mutations in Hardikar syndrome, and the identification of over a dozen genes not previously implicated in human disease, including MACF1, SUV420H1, H3F3A, ZNF599, FAT3, CDH18, RRAS2, MYRF,HOX3B, ZNRF3, Radil, and DCHS2. As these genes appear to play a role beyond the craniofacial pathology in these families, we were able to discover novel candidate genes underlying over twenty separate medical conditions.

2860F

Accelerating the pace of Mendelian gene discovery via multi-modal data sharing: Geno$_2$MP, the UW-RMD Family Portal, and MyGene^2. *J. X. Chong[1], J-H. Yu[1], Q. Yi[2], S. Jamal[1], H. K. Tabor[1,3], J. Shendure[2], D. A. Nickerson[2], M. J. Bamshad[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Department of Pediatrics, University of Washington, Seattle, WA; 2) Department of Genome Sciences, University of Washington, Seattle, WA; 3) Treuman Katz Center for Pediatric Bioethics, Seattle Children's Research Institute, Seattle, WA; 4) Division of Genetic Medicine, Seattle Children's Hospital, Seattle, WA.

Since the first application of exome and whole-genome sequencing to Mendelian gene discovery in 2010, the rate of reported gene discoveries has increased ~40%, from an average of ~166/year from 2005-2009 to ~231/year from 2010-2014. However this increase is perhaps more modest than anticipated for many reasons including limited adoption of open sharing of sequence data and candidate genes/variants. Furthermore, existing resources explicitly target professional users such as researchers, clinicians, and diagnostic laboratories. We introduce three new, related resources that will help tackle these issues: Geno2MP, the University of Washington Repository of Mendelian Disorders Family Portal (FP), and MyGene2. Geno2MP ("Genotype to Mendelian Phenotype") (http:// geno2mp. gs. washington. edu) is a browser that, in its initial form, releases de-identified, aggregated variant data linked to structured phenotypic data for ~3,000 individuals sequenced by the UW-CMG. Geno2MP is intended to facilitate candidate variant prioritization and identification of individuals with variants in a shared candidate gene not necessarily selected for follow-up analysis. It has already been used to identify two unrelated patients sharing a phenotype caused by nonsense mutations in the same novel gene. Family-driven social networking to identify "second families" sharing the same Mendelian gene/phenotype was pioneered by parents of children with *NGLY1* deficiency and led to the delineation of a novel disorder. However, replicating their success requires families to have some technical knowledge and resources. Following our involvement in a similar effort, we developed the FP to expedite this process. After consenting to broad data sharing, families (and/or investigators) without a diagnosis may submit their existing phenotypic and genomic data through the FP (http://uwcmg. org/#/family), giving them access to in-house clinical and analysis expertise. All candidate genes/variants resulting from a standard analysis will be deposited in MyGene2. org, a publicly-accessible and family-friendly site that can be searched by gene and inheritance model. Users who identify a variant of interest may then contact the submitting families, investigators, or clinicians to follow-up. We encourage researchers, clinicians, diagnostic labs, and families worldwide to contribute data to Geno2MP and MyGene2, which will increase the utility of both databases for the entire human genetics and patient communities.

2861W

***De novo* variants in *CHAMP1* associated with neurodevelopmental abnormalities and dysmorphic features.** *A. Telegrafi[1], A. J. Tanaka[2], M. T. Cho[1], J. R. Jones[3], C. Nowak[4], J. Douglas[4], Y. H. Jiang[5], A. McConkie-Rosell[5], B. Schaefer[6], J. Kaylor[6], K. Retterer[1], G. Douglas[1], K. G. Monaghan[1], W. K. Chung[2].* 1) GeneDx, Gaithersburg, MD; 2) Columbia University Medical Center, New York, NY; 3) Greenwood Genetic Center, Greenwood, SC; 4) Boston Children's Hospital, Boston, MA; 5) Duke University Medical Center, Durham, NC; 6) Arkansas Children's Hospital, Little Rock, AR.

Next generation sequencing has enabled the identification of many novel genes contributing to Mendelian disorders. Previously, *de novo* loss-of-function variants in the *chromosome alignment-maintaining phosphoprotein* (*CHAMP1*) gene (MIM 616327) have been reported to be associated with non-syndromic intellectual disability and developmental disorders. *CHAMP1* is located on chromosome 13q34, encodes a mammalian zinc finger protein involved in kinetochore-microtubule attachment and is required for the proper alignment and segregation of chromosomes during mitosis. Here we provide detailed molecular and clinical characterization of four unrelated individuals with an as yet undefined disorder consisting of neurodevelopmental and dysmorphic features associated with novel *de novo* predicted pathogenic variants in *CHAMP1*. All patients were identified through whole exome sequencing (WES) after previous comprehensive diagnostic genetic testing on all patients had been unrevealing, and connection between the cases was facilitated through GeneMatcher. All of the patients had *de novo* heterozygous variants which were either nonsense or frameshift and predicted to be deleterious. No other variants identified via WES were deemed as likely candidates to explain the patients' phenotype. All variants were clustered in exon 3 in the *CHAMP1* gene (NM_001164144. 1) and none of the variants were present in the Exome Variant Server, 1000 Genomes, Exome Aggregation Consortium (ExAC) or our internal GeneDx database. Our patient cohort included three children and one adult ranging in age from 3-23 years old. The clinical phenotype was dominated by severe developmental delay, intellectual disability and dysmorphic features. The common dysmorphic features included upslanting palpebral fissures, epicanthal folds, hypertelorism, flat and broad nasal bridge, and short philtrum. Additional clinical features enriched among these patients include microcephaly in three of the patients, hypotonia, seizures, behavioral issues, sleep disturbances, and gastrointestinal issues. Our findings provide further evidence that predicted loss of function variants in *CHAMP1* are responsible for a severe neurodevelopmental phenotype characterized by developmental delay, intellectual disability, microcephaly, and dysmorphic features.

2862T

Left ventricular hypertrabeculation and gastropathy associated with *MIB2* variants altering NOTCH signaling. *S. Attanasio[1], P. Piccolo[1], R. Sangermano[1], C. Strisciuglio[2], E. Miele[2], G. Limongelli[3], M. Mutarelli[1], S. Banfi[1], T. Pons[4], S. Campione[5], F. D'Armiento[5], G. Nardone[6], A. Staiano[2], T. C. Lynnes[7], P. B. Celestino-Soper[7], K. G. Spoonamore[7], M. Vatta[7], N. Brunetti-Pierri[1,2].* 1) Telethon Institute of Genetics and Medicine, Pozzuoli, Italy; 2) Department of Translational Medicine, Federico II University, Naples, Italy; 3) Monaldi Hospital, Second University of Naples, Naples, Italy; 4) Structural Biology and BioComputing Programme, Spanish National Cancer Research Centre (CNIO), Madrid, Spain; 5) Advanced Biomedical Sciences, Federico II University, Naples, Italy; 6) Department of Clinical Medicine and Surgery, Gastroenterology Unit, Federico II University, Naples, Italy; 7) Department of Medical and Molecular Genetics and the Krannert Institute of Cardiology, Division of Cardiology, Department of Medicine, Indiana University School of Medicine, Indianapolis, IN, USA.

We performed exome sequencing in patients from a family of Italian descent with an autosomal dominant gastropathy resembling Menetrier disease, a premalignant disorder of the stomach with epithelial hyperplasia and enhanced EGFR signaling due to local overproduction of TGF-α. Menetrier disease is believed to be an acquired disorder but its etiology is unknown. In affected patients, we found a missense p. V742G variant in *MIB2*, a gene regulating NOTCH signaling that has not been previously linked to human diseases. The mutation segregated with the disease in all nine affected members available for analysis. It affects a highly conserved amino acid residue, it was predicted to be deleterious, and it was found with a frequency of 0. 0015-0. 003 in control populations. In addition, the purified mutant protein showed reduced ubiquitination activity in vitro and white blood cells from patients exhibited reductions of *HES1, NOTCH3*, and *NRARP* expression reflecting alteration of NOTCH signaling. Because mutations of MIB1, the homolog of MIB2, have been recently found in patients with left ventricle non-compaction (LVNC), we screened members of the family with Menetrier-like disease for this cardiac abnormality by cardiac ultrasound and MRI. Left ventricular hypertrabeculation was detected in 2 out 4 members carrying the *MIB2* variant who were both free of cardiac symptoms at the time of evaluations. Finally, in a screening of *MIB2* mutations in a series of patients with LVNC, we found one affected patient carrying the p. V984L variant which was found in 1 out 10,2118 alleles of control populations. This variant was predicted to affect protein stability and when transfected in cells it resulted in significantly reduced levels of MIB2 protein compared to wild-type. The low frequency of the p. V742G variant in the control population and the rare occurrence of Menetrier-like syndrome suggest that *MIB2* mutations might not be the only cause for the gastropathy. Additional genes or environmental factors, such as *H. pylori* or CMV that have been previously associated with Menetrier disease, might be necessary for clinical expression of the gastropathy in addition to *MIB2* mutations. In conclusion, we report the first example of left ventricular hypertrabeculation with germline *MIB2* mutations resulting in altered NOTCH signaling that might be associated with a gastropathy clinically overlapping with Menetrier disease.

2863F

Mutations in VEGFR3 signaling pathway explain a third of familial primary lymphedema. *E. Fastre[1], M. J Schlögel[1], A. Mendola[1], N. Revencu[2], I. Quere[3], L. M. Boon[1,4], P. Brouillard[1], M. Vikkula[1,4,5].* 1) Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Department of Vascular Medicine, Montpellier University Hospital, Montpellier, France; 4) Center for Vascular Anomalies, Plastic Surgery Division, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Belgium; 5) Walloon Excellence in Lifesciences and Biotechnology (WELBIO), Université catholique de Louvain, Brussels, Belgium.

Background: Lymphedema, caused by dysfunction of lymphatic vessels, leads to disabling swelling that occurs mostly on the extremities. Lymphedema can be either primary (congenital) or secondary (acquired). Familial primary lymphedema commonly segregates in an autosomal dominant or recessive manner. It can also occur in combination with other clinical features. Nineteen mutated genes have been identified in different isolated or syndromic forms (Brouillard et al. , 2014). However, the prevalence of primary lymphedema that can be explained by genetic alterations in these genes is unknown. In this study, we investigated systematically 17 of these genes by targeted next generation sequencing. **Methods:** We screened 416 index patients, a quarter of which were from families with inherited primary lymphedema. A targeted NGS panel for IonTorrent (Personal Genome Machine, PGM) was designed. Data analysis was performed with the in-house developed Highlander software (Helaers et al. , in prep.). The filtering criteria were: checked manually with IGV (true), allelic depth proportion of the alternative allele (≥ 0. 25), less than 30 patients with the same change in our series, 1000 genome (< 10), goNL (≤ 5), consensus of impact predicted by 6 programs (≥ 3) and variant evaluation probably disease-causing. Validations and cosegregations were done using Sanger sequencing. **Results:** The filters allowed us to keep 227 variants among the approximately 19,500 detected. We limited this number to 100 by validations and cosegregation analyses, thus explaining the etiology in 24 % of the cases. We currently perform more detailed clinical phenotyping for those patients. We also identified 109 variants of unknown significance (VUS), which we are in the process of characterization. **Discussion:** The genetic cause of primary lymphedema remains unexplained for about 60 % of patients with a family history and 85 % of patients with sporadic or unspecified occurrence. Identification of the genes is important for understanding etiopathogenesis, stratification of management and generation of disease models for future development of therapies. Interestingly, most of the proteins that are encoded by the genes mutated in primary lymphedema seem to act in a common functional pathway involving VEGFR3 signaling. This underscores the important role this pathway plays in lymphatic development and function, and suggests that the unknown genes may also have a role in this pathway.

2864W

Mutations in YY1AP1 cause fibromuscular dysplasia in patients with Grange syndrome. *D. Guo[1], E. S. Regalado[1], L. Gong[1], X. Duan[1], L. Mellor-Crummey[1], R. L. P. Santos-Cortez[2], M. J. Bamshad[3], J. Shendure[3], D. A. Nickerson[3], S. M. Leal[2], A. Schinzel[4], K. Lieberman[5], A. Braverman[6], D. K. Grange[7], D. M. Milewicz[1], University of Washington Center for Mendelian Genomics.* 1) Department of Internal Medicine, University of Texas Health Science Center, Houston, Texas, USA; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; 3) Department of Genome Sciences, University of Washington, Seattle, Washington, USA; 4) Institute for Medical Genetics, University of Zurich, Zurich, Switzerland; 5) Pediatric Nephrology, Joseph M. Sanzari Children's Hospital, Hackensack University Medical Center, Hackensack, New Jersey, USA; 6) Cardiovascular Division, Department of Medicine, Washington University School of Medicine, St. Louis, Missouri, USA; 7) Division of Genetics and Genomic Medicine, Department of Pediatrics, Washington University School of Medicine, St. Louis, Missouri, USA.

Fibromuscular dysplasia (FMD) is a non-atherosclerotic arterial disease for which the molecular basis is unknown. FMD ischaracterized by arterial stenoses due to neointimal lesions rich with cells with a smooth muscle phenotype. It commonly affects the renal arteries, presenting as hypertension, and the internal carotid arteries, presenting as ischemic strokes. Grange syndrome is an autosomal recessive disease with FMD and additional complications, including variable brachydactyly and syndactyly, bone fragility, and learning disabilities. Exome sequencing was performed using DNA from three affected siblings with Grange syndrome and their parents. Previously described variant filtering strategies were used and variants with heterozygous genotypes in parents and homozygous or compound heterozygous genotypes in affected children were identified. The only variants that met these criteria were two *YY1AP1* (NM_001198903. 1) nonsense variants, c. 724C>T (p. Gln242*) and c. 2390T>G (p. Leu797*). The mother with the p. GLn242* variant has late onset hypertension and unilateral renal artery stenosis, suggesting that heterozygous YY1AP1 mutations may predispose to a milder form of FMD. To further investigate if mutations in *YY1AP1* cause Grange syndrome, two unrelated probands with Grange syndrome underwent Sanger DNA sequencing and each proband had a unique homozygous *YY1AP1* variant: c. 1903_1906delTCTG (p. Ser635Serfs) and c. 2401G>T (p. Glu801*); these variants are not found in the ExAC database. Two-point linkage analysis using Superlink software resulted in a combined LOD score of 2. 40. *YY1AP1* encodes YY1 associated protein 1, which is an activator of the transcriptional activity of ying yang 1 (YY1). *YY1* is rapidly induced in smooth muscle cells (SMCs) after vascular injury and suppresses SMC proliferation; conversely, loss of YY1 leads to increased SMC proliferation. YY1AP1 has not been extensively studied and encodes multiple isoforms. We determined that human smooth muscle cells express an isoform of 2391 bp, leading to an 88 kDa protein. The mutations identified in patients with Grange syndrome are predicted to lead to little to no expression of *YY1AP1*, decreased YY1 transcriptional activity, and thus increased SMC proliferation. In summary, *YY1AP1* is the first gene identified for FMD, and indicates that this condition can be due to underlying genetic alterations, leading to inappropriate hyperplasia of SMCs and occlusion of arteries.

2865T

Mutation spectrum in a Pulmonary Arterial Hypertension (PAH) cohort and identification of associated truncating mutations in *TBX4*. *C. Gonzaga-Jauregui[1], L. Ma[2], A. King[1], E. Berman Rosenzweig[2,3], U. Krishnan[2], J. G. Reid[1], J. D. Overton[1], F. Dewey[1], W. K. Chung[2,3], Regeneron Genetics Center.* 1) Regeneron Genetics Center, Regeneron Pharmaceuticals Inc. , Tarrytown, NY; 2) Department of Pediatrics, Columbia University Medical Center, New York, New York, USA; 3) Department of Medicine, Columbia University Medical Center, New York, New York, USA.

Pulmonary arterial hypertension (PAH) is a rare disorder characterized by sustained elevated pulmonary arterial pressure that can eventually lead to right ventricular hypertrophy with right heart failure and is often fatal. Genetic studies in families with PAH identified mutations in *BMPR2* as the major causative gene for the disorder, accounting for approximately 80% of cases. Additional genes (*SMAD9*, *CAV1*, *KCNK3*) have been implicated in a smaller percentage of familial cases, while PAH associated with hereditary hemorrhagic telangiectasia has been found in patients with mutations in *ENG* and *ACVRL1*. We performed whole-exome sequencing in a cohort of 60 probands with PAH and family members when available (180 total individuals) without a molecular diagnosis after most of the series was screened for mutations in *BMPR2*. We identified mutations in the known PAH genes *BMPR2* and *ACVRL1*. In addition we identified novel truncating variants in *TBX4* occurring *de novo* or inherited from an asymptomatic parent in 6 patients and a *de novo* predicted deleterious nonsynonymous variant in one additional patient. *TBX4* is a transcription factor of the T-box gene family. It is expressed in a variety of tissues during early mouse development including the atrium of the heart, the limbs, and the mesenchyme of the lung and trachea. TBX4, jointly with TBX5, has been shown to interact with FGF10 during lung growth and branching. Mutations in *TBX4* have been previously reported to cause small patella syndrome (SPS; MIM# 147891), an autosomal-dominant skeletal dysplasia characterized by patellar aplasia or hypoplasia and anomalies of the pelvis and feet, including disrupted ossification of the ischia and inferior pubic rami. Subsequently, another study (Kerstjens et al. , 2012) identified an association of *TBX4* mutations with PAH in 6 patients. We identified 7 different predicted deleterious mutations in *TBX4* (2 inherited and 5 *de novo*) in our cohort of patients ascertained for primary pulmonary arterial hypertension, accounting for ~10% of the probands in this series. Our results confirm the role of *TBX4* as an important cause of hereditary PAH.

2866F

Whole genome sequencing of cytogenetically balanced germline chromosomal rearrangements identify gene disruptions in both phenotypically normal and clinically affected individuals. *A. Lindstrand[1,2,3], M. Pettersson[1,2], P. Gustavsson[1,2,3], A. Fürster[1,2], W. Hofmeister[1,2], J. Wincent[1,2], B-M. Anderlid[1,2,3], A. Nordgren[1,2,3], O. Mäkitie[1,2,3,5,6], V. Wirta[7], F. Vezzi[8], J. R. Lupski[9,10], M. Nordenskjöld[1,2,3], E. Syk Lundberg[1,2,3], C. M. B. Carvalho[9], D. Nilsson[1,2,3,4].* 1) Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 2) Center for Molecular Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 4) Science for Life Laboratory, Karolinska Institutet Science Park, Solna, Sweden; 5) Children's Hospital, Helsinki University Central Hospital and University of Helsinki, Helsinki, Finland; 6) Folkhälsan Institute of Genetics, Helsinki, Finland; 7) SciLifeLab, School of Biotechnology, KTH Royal Institute of Technology, Stockholm, Sweden; 8) SciLifeLab, Department of Biochemistry and Biophysics, Stockholm University, Stockholm, Sweden; 9) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, USA; 10) Texas Children's Hospital, Houston TX, USA.

Approximately 1/500 individuals carry a balanced chromosomal aberration (BCAs) and are generally healthy but may suffer from infertility, repeated miscarriages and a risk of having children with unbalanced rearrangements. However, in a small fraction of cases the BCA may associate with disease, usually neurodevelopmental disorders (NDDs) ranging from mild (ADHD, dyslexia) to severe (autism, intellectual disability, ID). We investigated low coverage (5X) mate pair whole genome sequencing (WGS) to characterize translocation breakpoints and to elucidate mechanisms of formation; 52 junctions from 24 carriers of balanced translocations and inversions including both phenotypically normal (n=9) and abnormal individuals (n=15) were characterized. In contrast to previous publications only one significant *de novo* copy number variant was detected in the abnormal cohort (6. 7%). Further, genes were disrupted at the breakpoints to the same extent in both cohorts (45% for normal and 47% for abnormal; P=1. 0). However, differences were observed: in the normal individuals 56% of the disrupted loci were known disease genes all with a recessive inheritance pattern (i. e. *LARGE, COG7, VDR, ALMS1, OCA2*) while only 20% of gene disruptions in the affected individuals were known disease genes, all linked to dominant NDDs (i. e. *EXO6B, GRIN2B,* and *CTNND2*). For 21 junctions (40%), WGS split read analysis delineated the breakpoint. In the remaining 31 junctions paired-end analysis mapped the breakpoint to within 2 Kb. Breakpoint junction features revealed a consistent pattern of interspersed short homology involving both chromosomes but restricted to only one of the junctions. This type of pattern resembles template-switching between homeologous sequences in yeast which can lead to translocations. It has been hypothesized that "islands of microhomology" flanking the breakpoint junctions contribute to determine strand-invasion. Furthermore, one of the junctions is usually blunt or presents microhomology whereas the other one shows SNVs confined to the junction; a mutational signature of human recombination coupled replicative repair. We propose that at least two mechanisms underlie the formation of BCAs: a replication-based mechanism such as break induced replication (BIR) followed by microhomology mediated BIR (MMBIR) or non-homologous end joining (NHEJ). Alternatively, MMBIR with iterative template switches could parsimoniously explain our observations.

Combined targeted sequencing and array CGH of ciliary genes reveals increased mutational load in Bardet-Biedl syndrome and identifies *CEP76* as a novel driver of BBS. *M. Kousi[1], S. Frangakis[1], A. Lindstrand[2,3], A. Sabo[4], J. Lu[5], R. Lewis[6], J. R. Lupski[4,6,7,8], R. A. Gibbs[4], E. E. Davis[1], N. Katsanis[1].* 1) Cell Biology, Duke University, Durham, NC; 2) Dept of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden; 3) Dept of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 5) Dept of Electrical Engineering, Duke University, Durham, NC; 6) Dept of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 7) Dept of Pediatrics, Baylor College of Medicine, Houston, TX; 8) Texas Children's Hospital, Houston, TX.

Bardet-Biedl syndrome (BBS) has served as a useful model to investigate pleiotropy, mutational burden, and ciliary biology. BBS is a multisystemic pediatric disorder characterized by retinal degeneration, obesity, hypogonadism, renal anomalies and learning disabilities. Further, BBS is frequently manifested under oligogenic inheritance paradigms in which *trans* alleles can modify the penetrance and/or expressivity of primary causal mutations. To date, mutations in >20 genes involved in the function of the cilium or its anchoring structure, the basal body account for ~75% of families of European descent. Here, we sought to resolve further the mutational landscape of BBS by a) identifying novel BBS candidate genes and b) evaluating comprehensively the combined effects of copy number variants (CNV)s and point mutations towards causing or modifying BBS phenotypes. We performed targeted sequencing of 785 genes encoding the ciliary proteome in a cohort of 100 individuals with BBS. In parallel, we used high-density array comparative genomic hybridization (aCGH) of 17 BBS, 20 intraflagellar transport (IFT) complex and 37 other causal ciliopathy genes to detect CNVs in the same cohort. We found that 80% of families harbor a recessive locus in a known BBS gene, suggesting that the remaining causal genes are likely to be ultra-rare contributors to the disorder. Among the affecteds for whom a known BBS locus did not segregate with the disease, we identified *CEP76*, encoding a centrosomal protein critical to cell cycle, as a novel primary causal locus in one pedigree. *In vivo* zebrafish assays that recapitulate the human retinal and renal phenotypes provided further supportive evidence for the physiological relevance and likely causal role of this locus in disease. Moreover, by comparing mutational burden between BBS cases and controls, we show that CNVs in BBS genes are enriched significantly in cases (18. 5% of our cohort) demonstrating a previously underappreciated role of such variants. To complement these data, we are evaluating the total number and effect of single nucleotide variants in BBS to test whether burden and/or specific pairwise combinations can be predictive of clinical outcome. Together, we have expanded the genetic spectrum of BBS through the discovery of *CEP76* as a novel causative locus, and through our mutational load studies, aim to better understand the disease mechanisms not only in BBS but also in the broader spectrum of ciliopathies.

2868T

Whole Exome Sequencing (WES) to Analyze the Genetic Basis of Cleft Lip and Palate. *M. Basha[1], M. Quentric[1], R. Helaers[1], N. Revencu[2], B. Bayet[3], M. Vikkula[1,2].* 1) Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Europe, Belgium; 2) Center for Human Genetics, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Europe, Belgium; 3) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires St-Luc, Université catholique de Louvain, Brussels, Europe, Belgium.

Background: Cleft lip with or without cleft palate (CL/P) is the most common craniofacial birth defect with an incidence of ~ 1/700 live births, varying with ethnicity and cleft type. It is a debilitating condition requiring an expensive and lifelong treatment. CL/P can occur isolated or as part of a syndrome. The etiology is still largely unknown. **Methods**: We performed whole exome sequencing (WES) on 85 CL/P subjects. The cohort predominantly consisted of non-syndromic (n=21/25) families. We selected at least two most distant relatives per family for WES (n=36). We also included few sporadic CL/P cases (n=12). The sub-phenotypes of these 73 patients ranged from a full- blown bilateral CL/P to a subtler velopharyngeal insufficiency (VPI). In addition, we WESed 8 unrelated individuals all affected with the rare Cerebro-oculo-nasal syndromethat has cleft lip and high arched palate as part of its spectrum. For two of the eight, parents were also WESed. **Results**: After bioinformatic processing of raw data with an in-house developed pipeline, we analyzed our samples on Highlander (a software developed in-house by R. Helaers). We retained variants for further analysis if they met the following criteria: (i) passed the GATK filter, (ii) reported allele frequency of ≤1% in the population from the 1000 genomes project, (iii) not reported in the population from the GO-NL (genome Netherlands) project, (iv) not reported in Exome Aggregation Consortium (ExAC), (v) and not occurring in our in-house WES controls (subjects affected with =different condition than CL/P). As "likely pathogenic" variants, we considered those with a high impact (premature termination codon=PTC) or a moderate impact (non synonymous-NS), as predicted by SnpEff software. On average, each family harbored 1 PTC and 30 NS variants. All NS variants were predicted as damaging by at least 3 softwares. Approximately 5 changes co-segregated with the phenotype. This led to identify the causative mutation in 3 cases in known CL/P genes (IRF6 and TBX1). For the remaining samples characterization of variants of interest is ongoing. **Discussion**: To be able to distill out the causal gene from the aforementioned data, we will WES additional affected subjects from multiplex families, for which continued collection is also ongoing.

2869F

Exome Sequencing in a Multiplex Family with Cleft Palate Only Identifies a Novel Damaging Mutation in *ARHGAP29*. *A. Butali[1], T Busch[1], I Gowans[1], H Liu[1], D Anand[2], S Lachke[2], N Nidey[1], B Amendt[1], R Cornell[1], J Murray.* 1) UNIVERSITY OF IOWA, IOWA CITY, IA; 2) Department of Biological Sciences.

Background: With advances in genomics research and availability of next generation sequencing approaches, scientists are now able to identify risk loci across the exome and the genome. In the current study, we present findings from an exome study conducted in a multiplex family with cleft palate only (CPO). Methods: Exome sequencing was conducted in 5 individuals with high quality DNA in a family of 8 affected individuals. The Ilumina HiSeq 2000 was used for sequencing and Agilent Sure Select for enrichment capture. Quality control (QC) steps included aligning raw sequence to the human genome build hg19 using BWA software, SNP and In/Dels analyses using PICARD, SAMTOOLS and GATK. WANNOVAR was used to functionally annotate the SNPs and In/Dels. Several filtration methods were applied in order to identify variants with minor allele frequencies ≤1% in 1000genomes, EVS and dbSNP138 including clinically associated variants that segregate in affected individuals. The bioinformatics tool *SysFACE* (Systems tool for craniofacial expression-based gene discovery) was used to prioritize cleft candidates from our list of variants. Sanger sequencing was used to validate identified variants in affected and unaffected relatives. Results: A yield of 3. 4Gbases per sample passed the quality control step. A missense variant predicted to be probably in exon 15 of *ARHGAP29* (pSer552Pro) was identified. This variant segregates in all 5 individuals. The pSer552Pro variant is novel and not in all of the known databases and has never been previously reported. This variant was validated using Sanger sequencing and none of the 4 unaffected individuals including a CEPH control carried the variant. We also identified 2 clinically associated variants in *FRGB3* gene (rs145018822 and rs201563622) previously reported for malignant melanoma in the ClinVar study. Functional experiments are ongoing to understand the biological effect of the pSer552Pro variant in Zebrafish and cell based assay.

2870W

Whole Exome Sequencing in a Family with Primary Open Angle Glaucoma. *HF Nunes[1], JPC Vasconcellos[2], I Lopes-Cendes[3], BS Carvalho[3], MG Borges[3], NIT Zanchin[4], MB Melo[1].* 1) Center of Molecular Biology and Genetic Engineering, University of Campinas; Campinas SP, Brazil; 2) Department of Ophthalmology, Faculty of Medical Sciences, University of Campinas - UNICAMP, Campinas SP, Brazil; 3) Department of Medical Genetics, Faculty of Medical Sciences, Unicamp, Campinas, SP, Brazil; 4) Fiocruz, Curitiba PR, Brazil.

Background: Primary open-angle glaucoma (POAG) is a chronic neurodegenerative disease that leads to progressive damage of retinal ganglion cells resulting in visual field loss. Glaucoma is recognized as the main cause of irreversible blindness worldwide. Although the pathophysiology of glaucoma is not well understood, positive family history is one of the most important risk factors for its development. **Objective:** To identify genes associated with POAG in one family from the state of São Paulo, Brazil, with no mutations in the MYOC gene. **Methods:** Four individuals were analyzed through Whole Exome Sequencing (WES), including two affected and two unaffected. Nextera Rapid Capture Expanded Exome kit (Illumina™) was used to obtain 50X average coverage per sample. Sequencing was performed in a high-performance Hiseq Illumina 2500 DNA Analyzer (Illumina™). Bioinformatics analysis was performed using the GATK software package. Sequences were aligned using BWA algorithm and variant calling and functional prediction was performed using Variant Annotator and SnpEff tools. Before applying any filtering method, the main genes related with glaucoma were evaluated for the presence of mutations (WDR36, OPTN, NTF4, ASB10). **Results:** Filtering process started considering heterozygous mutations in autosomes segregating in affected individuals, which totalized 7951 variants. Next step included only non-synonymous, splice site, small indels and stop codon variants, remaining 2346. Considering those with relative pathogenicity 367 remained and out of these 42 were present in less than 1% of the general population. The last step was based on ocular tissue expression and protein function, resulting in 6 genes that require confirmation through Sanger sequencing in other members of this family. **Conclusion:** Properties related to apoptotic processes, aqueous humor production and outflow make the six candidate genes identified relevant for POAG pathophysiology. Further resequencing and experimental verification are still needed to confirm the causative gene in this family. **Supported by:** FAPESP.

2871T

Functional evidence for the involvement of *WNT10A* in failure of tooth development in humans and zebrafish. *M. Zhao[1,2], Q. Yuan[3], X. Liu[5], A. Zhang[1,2], R. Silva[1,2,4], J. T. Hecht[2,3,4], E. C. Swindell[3,4], A. Letra[1,2,4].* 1) Department of Endodontics, University of Texas Health Science Center School of Dentistry, Houston, TX; 2) Center for Craniofacial Research, University of Texas Health Science Center School of Dentistry, Houston, TX; 3) Department of Pediatrics, University of Texas Health Science Center Medical School, Houston, TX; 4) Pediatric Research Center, University of Texas Health Science Center Medical School, Houston, TX; 5) Department of Human Genetics, University of Texas Health Science Center School of Public Health, Houston, TX.

Tooth agenesis is the most common developmental abnormality in humans. Severe tooth agenesis (oligodontia) is characterized by the absence of six or more permanent teeth, and can be syndromic or nonsyndromic, sporadic or segregating in families. Candidate gene sequencing and association studies have suggested *MSX1, PAX9, AXIN2,* and recently *WNT10A* as etiologic genes in oligodontia. We used whole-exome sequencing (WES) to identify the cause of nonsyndromic oligodontia in a 9-year old girl missing eleven permanent teeth. No defects in tooth shape, hair, skin or nails were noted in the child or unaffected parents. Exome capture was performed using Agilent Sure Select 50MB Target Enrichment System followed by massive parallel sequencing in an Illumina HiSeq 2000 sequencing platform. Paired-end reads were aligned against the GRCh37 human reference genome using the Burrows-Wheeler Aligner. WES data was annotated using the dbNSFP database. ANNOVAR was used to annotate indels and identify variants causing frameshifts. A novel compound heterozygous missense mutation (c. 237G>A; c. 1070C>T), in *WNT10A* was identified in the child and predicted to be highly deleterious and possibly leading to gene loss-of-function. Sanger sequencing validated these mutations in the child while revealing the carrier status for each mutation in the unaffected parents. Zebrafish was used for functional analysis of *wnt10A* during tooth development. Using real-time PCR, we detected significantly higher *wnt10a* mRNA expression level mRNA expression during craniofacial development stages in zebrafish embryos. Two antisense morpholinos (MO) were used to block wnt10a translation and splicing in one-to two cell stage zebrafish embryos, which showed similar survival rates to uninjected controls at 1dpf. Thereafter, survival rates decreased albeit not significantly different than UIC. While MO-injected embryos had no gross whole-body abnormalities, tooth agenesis was arrested in 91% of the fish by 5dpf. In contrast, 100% of UIC presented normal teeth. Our results show a novel compound heterozygous mutation in *WNT10A* as the cause of recessive oligodontia and further provide the first functional evidence for a role of *WNT10A* in tooth development.

2872F

Deletions of the 5' HOXC genes are associated with lower extremity abnormalities including clubfoot and vertical talus. *D. M. Alvarado[1], M. B. Dobbs[1,2], C. A. Gurnett[1,3,4].* 1) Orthopaedic Surgery, Washington Univ, St Louis, MO; 2) Shriners Hospital for Children, St. Louis, MO; 3) Neurology, Washington University, St. Louis, MO; 4) Pediatrics, Washington University, St. Louis, MO.

Deletions of the HOXC gene cluster result in variable phenotypes in mice, but have been rarely described in humans. Here, we report four families with 30-176 kb chromosome 12q13. 13 microdeletions involving the 5'HOXC gene cluster that segregate with a spectrum of severe congenital lower limb birth defects, including clubfoot, vertical talus, hip dysplasia, lower extremity weakness, nail hypoplasia, and early-onset arthritis. Defects in limb morphogenesis are supported by the presence of shortened and overlapping toes, as well as peroneus muscle hypoplasia seen in two affected relatives with magnetic resonance imaging . While these deletions share minimal overlap within a noncoding region downstream of HOXC13, phenotypes vary depending upon inclusion of HOXC13, HOXC12 or the lncRNA HOTAIR within the deletion. Furthermore, we demonstrate reduced 5' HOXD gene expression in a fibroblast cell line from a patient with 175 kb 5' HOXC deletion, consistent with prior studies demonstrating that dosage of lncRNA HOTAIR alters expression of HOXD10 and HOXD11 genes in trans. Because HOXD10 has previously been implicated in the etiology of congenital vertical talus, variation in its expression may contribute to the lower limb phenotypes occurring with 5' HOXC microdeletions.

The role of combined SNV and CNV burden in patients with distal symmetric polyneuropathy. *C. R. Beck[1], D. Pehlivan[1,2], Y. Okamoto[1], T. Harel[1], S. N. Jhangiani[3], M. A. Withers[1], M. T. Goksungur[4], C. M. B. Carvalho[1], D. Czesnik[5], C. Gonzaga-Jauregui[1], W. Wiszniewski[1], D. M. Muzny[3], R. A. Gibbs[3], B. Rautenstrauss[6,10], M. W Sereda[5, 7], J. R. Lupski[1,3,8,9].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Section of Pediatric Neurology, Texas Children's Hospital, Houston, TX, USA; 3) Human Genome Sequencing Center, BCM, Houston, Texas; 4) Department of Neurology, Istanbul University, Istanbul Medical Faculty, Istanbul, Turkey; 5) Department of Clinical Neurophysiology, University Medical Center Göttingen, Göttingen, Germany; 6) Medizinisch Genetisches Zentrum, Munich, Germany; 7) Max-Planck Institute of Experimental Medicine, Göttingen Germany; 8) Department of Pediatrics, BCM, Houston, Texas USA; 9) Texas Children's Hospital, Houston, Texas USA; 10) deceased.

Charcot-Marie-Tooth (CMT) represents a heterogeneous group of genetic disorders of the peripheral nervous system. About 70 genes and 10 linkage regions have been identified for CMT-like distal symmetric peripheral neuropathies. Copy number variants (CNVs) are an important cause of CMT, as duplication of *PMP22* underlies ~70-80% of CMT1 cases. Indeed, a recent study of >17,000 neuropathy patients (DiVincenzo, *et al*. 2014, PMID25614874) found that *PMP22* CNVs accounted for ~80% of molecular diagnoses (dup 56. 7% and del 21. 9%). We hypothesized that CNVs involving genes other than *PMP22* and/or single nucleotide variants (SNVs) might exist in CMT patients where the molecular genetic etiology is not elucidated. Two hundred CMT patients who were negative for both SNV mutations in several CMT genes and for CNVs involving *PMP22* were screened for CNVs by high-resolution oligonucleotide array comparative genomic hybridization. Putatively causative CNVs were identified in five subjects (~2. 5%); four of the five map to known neuropathy genes. Breakpoint sequencing for each of these CNVs revealed *Alu-Alu* mediated junctions as a predominant contributor (present at 3/5 junctions). Exome sequencing additionally identified *MFN2* SNV in two of the individuals that are likely to underlie the neuropathy phenotypes. In one individual, a *de novo* CNV in *PRICKLE1* combines with a *de novo* point mutation in *MFN2* to give rise to a composite neurological phenotype including tonic-clonic seizures, developmental delay, and neuropathy. Our findings suggest that neuropathy-associated CNV outside of the *PMP22* locus are rare in CMT cohorts, and that these non-recurrent rearrangements are largely driven by *Alu*-mediated mechanisms. Nevertheless, there is potential clinical utility in testing for CNVs in CMT cases negative for the CMT1A duplication particularly if exome sequencing has also been conducted. Moreover, our findings suggest that complex phenotypes including neuropathy can be caused by a combination of SNV and CNV affecting more than one disease-associated locus.

New genetic insights into the spectrum of disorders of glycosylation: a patient with multiple congenital anomalies. *H. H. Arts[1,2], M. M. Oud[1], N. van Vlies[3], A. de Bruin[4], R. J. A. Wanders[5], Z. Ren[4], M. Alders[5], D. A. Braun[6], J. Lawson[6], F. Hildebrandt[6], S. T. Pals[4], H. G. Brunner[1], J. Cobben[7], R. Roepman[1], T. W. Kuijpers[7].* 1) Department of Human Genetics, Radboudumc, Nijmegen, Netherlands; 2) Department of Biochemistry, Robarts Research Institute, University of Western Ontario, London, Ontario, Canada; 3) Department of Pediatric Metabolic Diseases, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands; 4) Department of Pathology, Academic Medical Center, University of Amsterdam, Amsterdam, The Netherlands; 5) Laboratory of Genetic Metabolic Diseases, Academic Medical Centre, Amsterdam, The Netherlands; 6) Department of Medicine, Boston Children's Hospital, Harvard Medical School, Boston, Massachusetts; 7) Department of Pediatrics, Academic Medical Center University Hospital, Amsterdam, The Netherlands.

Introduction: Glycosylation is essential for human development. More than 100 clinically diverse inherited disorders are known to result from glycosylation defects. One subtype of the congenital disorders of glycosylation (CDG) is caused by defects in glycosaminoglycan (GAG) synthesis. Here, we describe an infant from a consanguineous family with a GAG-CDG. Phenotypic features include respiratory insufficiency, discrete skeletal anomalies, renal insufficiency, and T-cell depletion. **Methods:**We performed whole-exome sequencing (WES) on patient leucocyte DNA to identify the causative mutation. Immunocytochemistry was conducted to characterize the identified mutations functionally in patient-derived and control fibroblasts. The antibody that was used was validated with CRISPR/Cas9 experimentation. Synthesis of different GAG chains was measured in fibroblasts and urine from the patient and several controls. Mutated genes were screened with next-generations sequencing in a cohort of 96 patients with nephronophthisis and skeletal involvement. **Results:** Through WES we detected two homozygous missense mutations in highly conserved regions of two glycosylation genes regulating GAG synthesis. It remains unclear whether mutations in one or both of the genes contribute to the clinical phenotype. We found that one of the mutated proteins that normally localizes to the Golgi apparatus was absent in this organelle in patient cells. Immunocytochemical analysis of the other mutated protein failed. Finally, heparan sulphate GAG chains were significantly reduced in patient-derived fibroblasts, though within the normal range in urine. Mutation screening of both mutated genes in a cohort of 96 patients with renal and skeletal defects did not identify additional mutations. **Conclusion:** We describe an infant with multiple congenital anomalies. WES analysis revealed mutations in two glycosylation genes. One of the mutated proteins mislocalizes in patient-derived fibroblasts. Our data indicate that this patient has a rare GAG-CDG.

2875F

***De novo* mutations in novel histone and epigenetic regulator genes cause multiple genetic syndromes.** *D. Li[1], E. J. Bhoj[1,2], L. Tian[1], M. H. Harr[2], H. A. Dubbs[2], C. Hou[1], C. E. Kim[1], F. D. Mentch[1], R. Chiavacci[1], E. McCormick[2,4], M. J. Falk[2,3,4], E. H. Zackai[2,3], H. Hakonarson[1,2,3].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Division of Metabolic Disease, The Children's Hospital of Philadelphia, Philadelphia, PA.

The post-translational modification of histones is emerging as an important mechanism for regulation of organism development and associated cellular function. Epigenetic dysregulation is observed in many human diseases, including cancer and neuropsychiatric disorders. Here we report genetic mutations in genes that encode histone and epigenetic regulator cause monogenic syndroms with complex phenotypes. We obtained clinical data and performed whole exome sequencing (WES) for 2 kindreds. The affected boy in the first family had 1-2-3 toe syndactyly on the left foot, agenesis of the corpus callosum, atrial septal defect, micrognathia, broad thumbs, microcephaly, failure to thrive, developmental delay, very short stature, and craniosynostosis. *H3F3A*, H3 histone family 3A, was the leading disease-causing candidate because histones play a central role in transcription regulation, DNA repair, DNA replication and chromosomal stability. Recent studies have emphasized its role during early development processes in mouse models that involves both major genome reorganization, discrete changes to sustain cell fate specification, and pluripotency. A dominant zebrafish mutant (D123N in *h3f3a*) showed variable reductions of the jaw-support skeleton, where wild type h3f3a rescued head skeletal development in mutants. Functional assessment in the zebrafish model is underway to elucidate the role our detected *H3F3A* mutation (p. A16G) plays in multiple congenital anomalies. A second, unrelated proband had developmental delay with no speech, congenital hypotonia, congenital heart disease, pulmonary hypertension, chronic lymphocytopenia and multiple dysmorphic features (sagittal craniosynostosis, midline cleft, hypertelorism, large hands and feet, long fingers and toes). He had a nonsense mutation (R1019X) in *KAT6A*, a histone acetyltransferase (HAT) gene, which was recently implicated in a cohort with variable findings of many overlapping clinical features. Knockout mice in *kat6a* show H3K9 hypoacetylation and reduced transcription at Hox gene loci. Our identification of mutations in *H3F3A* and *KAT6A* in patients with multiple congenital anomalies emphasizes the importance of epigenetic control of gene expression programs in diverse human disorders, including syndromic disease.

2876W

Whole exome sequencing detects variants in *MBTPS2* and *ITGB4* in a Brazilian patient with severe ichthyosis congenita and limb malformations. *M. P. Migliavacca[1], S. Raskin[2], J. Jurgens[3], D. Valle[3], N. L. M. Sobreira[3].* 1) Clinical Genetics, Department of Morphology and Genetics, Universidade Federal De São Paulo, São Paulo, SP, Brazil; 2) Genetika Laboratory and Pontifícia Universidade Católica do Paraná, Curitiba PR, Brazil; 3) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, 733 N. Broadway Street Suite 512, Baltimore, MD 21205, USA.

The IFAP syndrome with or without BRESHECK syndrome (MIM 308205) is a phenotypically variable X-linked multiple congenital anomaly characterized by ichthyosis follicularis, atrichia, and photophobia (IFAP) with or without additional features affecting the skeletal, genitourinary, and central nervous systems. This phenotype is caused by variants in *MBTPS2*, which encodes a developmentally integral zinc metalloprotease. Heterozygous or homozygous variants in the integrin beta 4 gene *ITGB4* are associated with epidermolysis bullosa, which is distinguished by severe cutaneous symptoms. Here we describe a Brazilian patient harboring a *de novo* variant in *MBTPS2* and compound heterozygous variants in *ITGB4* with developmental anomalies including intrauterine growth retardation, microcephaly, patent foramen ovale,ichthyosis congenita, atrichia, cryptorchidism, and limb malformations including bilateral radius aplasia. We performed whole exome sequencing on the proband and his unaffected parents through the Baylor-Hopkins Center for Mendelian Genomics. Selecting for rare (MAF<0. 01), functional single nucleotide variants and indels, we identified a novel hemizygous *de novo* variant in exon 6 of *MBTPS2* (c. 727C>T, Pro243Ser) and compound heterozygous variants in *ITGB4* (c. 1940C>T, Thr647Met; c. 4217G>C, Arg1406Pro). Using Sanger sequencing, we validated the presence of the *MBTPS2* variant in the proband and absence of the variant in his unaffected mother, father, and brother. Sanger sequencing also confirmed that the unaffected mother, father, and brother of the proband each had only one of the two *ITGB4* variants found in the proband. Pietrzak et al. (2012) described a Polish patient with an *MBTPS2* variant and similar cutaneous and skeletal features to those observed in our patient, although our patient has much more severe skin anomalies. Interestingly, our patient also has features overlapping those of epidermolysis bullosa. While the phenotype of our patient may be attributed to the *MBPTS2* variant alone, his skin phenotype may also be caused by the combination of the *MBPTS2* and *ITGB4* variants.

2877T

Targeted NGS reveals a high incidence of digenic inheritance in monogenic diabetes and congenital hyperinsulinism. *A. Campos-Barros[1,2], A. De la Peña-Abad[1], A. Del Pozo[1,2], K. Ibáñez[1], J. C. Silla[1], V. E. F. Montaño[1], A. Gómez-Núñez[1], P. D. Lapunzina[1,2], K. E. Heath[1,2], E. Vallespín[1,2], ENDOSCREEN-CM CONSORTIUM.* 1) INGEMM (Institute of Medical & Molecular Genetics), IdiPAZ, Hospital Universitario La Paz, UAM, Madrid, Madrid, Spain; 2) CIBER de Enfermedades Raras (CIBER-ER) U 753, ISCIII, Madrid, Spain.

Background: Monogenic diabetes (MoDiab) and congenital hyperinsulinism (CHI) constitute a group of Mendelian genetic diseases caused by gain/loss-of-function mutations resulting in an inappropriate secretion of insulin by the pancreatic β-cells, which may cause hypo- (CHI) or hyperglycaemia (MoDiab). *Aim:* The overlapping clinical features and phenotypic heterogeneity of MoDiab andCHI patients, together with the increasing number of implicated genes, makes a genetic diagnosis often difficult to obtain using a traditional gene cascade sequencing approach. Therefore, we aimed to design and validate a targeted NGS assay to screen 13 selected candidate genes involved in the etiology of MoDiab or CHI. *Methods:* An exon-capture assay was designed to enrich coding regions and splice sites of *ABCC8, GCK, HNF-1α, HNF-4α, HNF-1β, INSR, KCNJ11, AKT2, GLUD1, HADH, SLC16A1, UCP2,* and *DIS3L2* relevant transcripts. To evaluate its performance, a total of 24 patient samples with 24 known mutations, were retested. *Results:* 99% of captured bp had a coverage >20x; 96% of exons were well captured, and 100% of the previously identified 24 variants were detected, including 17 SNVs, 7 indels (<21 bp) and 2 CNVs (1x whole gene deletion and 1x intragenic duplication). Interestingly, this targeted NGS approach allowed the identification of a second genetic hit in 7/24 (29. 2%) of the retested samples, in which five different coding variants, potentially relevant to the pathological entities under study, were identified and confirmed by Sanger sequencing: NM_152383. 4(*DIS3L2*): c. 1448G>A (p. Arg483Gln) (n=3); NM_152383. 4(*DIS3L2*): c. 410A>G (p. Tyr137Cys); NM_005271. 3(*GLUD1*): c. 1568G>A (p. Arg523His); NM_000162. 3(*GCK*): c. 56T>A (p. Ile19Asn); and NM_000208. 2(*INSR*): c. 3034G>A (p. Val1012Met). *Discussion:* Though cases of digenic inheritance in MoDiab and CHI have been considered to be very rare, our preliminary results obtained during the validation of a targeted NGS assay indicate that their incidence may be under ascertained due to the traditional sequential single candidate gene testing strategy, which implies that once a mutation in one of the candidate genes is found, the analysis of additional genes is not undertaken. The implementation of NGS will reveal the true prevalence of digenic/polygenic inheritance in these disorders and the influence of co-inheritance of additional mutations/variants which may act as modifiers on the clinical phenotypic expression.

2878F

Molecular characterization of Epidermolysis Bullosa in Iran. *H. Vahidnezhad[1,2,3], L. Youssefian[1,2], S. Zeinali[3], MR. Barzegar[4], S. Sotoudeh[2], A. Ertel[1], N. Mozaffari[4], P. Fortina[1], J. Uitto[1].* 1) Thomas Jefferson University, Philadelphia, PA; 2) Tehran University of Medical Sciences, Tehran, Iran; 3) Pasteur Institute of Iran, Tehran, Iran; 4) Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Epidermolysis bullosa (EB) is a clinically and genetically heterogeneous group of heritable blistering diseases caused by mutations in at least 18 genes. There are 4 types of EB based on the ultrastructural level of tissue separation: EB simplex (EBS), junctional EB (JEB), dystrophic EB (DEB), and the Kindler syndrome (KS). There is currently no comprehensive study about the molecular epidemiology of EB in Iranian populations. We exploit the principles of whole-genome homozygosity mapping via 240K Human Exome Beadchip and immunofluorescence mapping as screening methods before formal mutational analysis in an attempt to facilitate the molecular diagnosis of EB. In the present study, we are assessing a cohort of 181 DEB patients for pathogenic sequence alterations in the *COL7A1* gene with 118 exons. Results from Sanger sequencing of 124 patients show 46 distinct mutations, 23 being previously unreported. Among the mutations 14 were missense, 14 small indels, 4 splice-junction mutations, 11 nonsense, and 3 large indel mutations. Targeted sequencing of COL7A1 was also performed on the IonTorrent PGM, using an AmpliSeq 3-pool primer design designed to capture all *COL7A1* exons plus 50-bp flanking regions in 57 patients disclosed 34 different mutations. A recurrent c. 6269_6270delC (p. Pro2090LeufsX116) was found in 14 lorish and azeri families. Haplotype analysis of the 20 Mb flanking region of COL7A locus on chromosomal region 3p21. 1 identified 2. 5Mb conserved haplotypes in all 14 families indicating a founder effect. Sanger sequencing of *KRT5* and *KRT14* in 10 EBS families revealed 9 recurrent and novel mutations in 8 families. We also examined a total of 21 Iranian families with KS, including 70 affected individuals. Sequencing of *FERMT1* revealed 14 distinct mutations in 17 families, 12 of the mutations being novel. Two novel mutations, p. Q226X and c. 1253delA, were found in more than one family (4 and 2, respectively). Haplotype analysis of the 9 Mb flanking region of the *FERMT1* locus in these families indicated the presence of a conserved haplotype, indicating founder effect. In two families, no mutation in *FERMT1* gene was found and autozygosity mapping excluded this locus. Careful examination of patients in these two families revealed unusual clinical features suggesting new entities with clinical overlapping features with KS. Our data emphasize the need for population-specific diagnostic and management approaches for EB.

2879W

***De novo* truncating mutations *MSL3* cause a new recognizable syndrome.** *A. L. Bruel[1,2], I. van der Burgt[3], J. Morton[4], J. St-Onge[1,2], S. El Chehadeh-Djebbar[5], A. Hoischen[3], C. Gilissen[3], L. Vissers[3], R. Pfundt[3], C. Thauvin-Robinet[1,2], H. G. Brunner[3], J. B. Rivière[1,2], L. Faivre[1,2], J. Thevenon[1,2].* 1) Team EA4271 GAD, Université de Bourgogne, Dijon, Bourgogne, France; 2) FHU-TRANSLAD, Université de Bourgogne/CHU Dijon, Dijon, Bourgogne, France; 3) Clinical Genetics Unit, Birmingham Women's Hospital, Birmingham, United Kingdom; 4) Radboud University Medical Center, Department of Human Genetics, Nijmegen, The Netherlands; 5) Centre de Génétique, CHRU de Strasbourg, Strasbourg, France.

Whole-exome sequencing has proven to be successful for the identification of the molecular basis of heterogeneous conditions such as intellectual disability with congenital anomalies. A large number of results remain non-conclusive because the diagnosis of ultra-rare conditions limits the genotype-phenotype correlations. Broad international data-sharing catalyzes the identification of additional cases and allows the delineation of new syndromes. A female patient presented with developmental delay and moderate intellectual disability, absent speech, facial dysmorphism, severe constipation. Paraclinic and genetic investigations did not orientate the diagnosis. A proband whole-exome sequencing was performed with no causative variant was identified with a diagnostic interpretation. Data were further processed in a research setting looking for compound heterozygous or *de novo* variants with parental segregation by means of Sanger sequencing. A *de novo* acceptor-splice variant of *MSL3* was identified. The *MSL3* gene, located on the X chromosome encodes a transcriptional regulator implicated in the KAT8-complex and directly interacting with *KANSL1*. To assess the relevance of this finding, international collaborators were asked for patients with *de novo MSL3* truncating variants. Two additional European cases were identified with a *de novo* frameshift variant affecting the same splice-site in a female patient and *de novo* non-sense variant in a male patient. Reverse phenotyping of the cases evidenced a recognizable facial dysmorphism, developmental delay, intellectual disability and severe constipation. Interestingly, de *novo* loss-of-function of *KANSL1* causes the Koolen-De Vries syndrome, with clinical features overlapping the reported condition. Based on molecular and clinical evidences, we report on the first implication of *MSL3* in a human disorder with *de novo* truncating variants causing a new recognizable ultra-rare condition.

2880T

Investigating the genetic architecture of Congenital Hypothyroidism using next-generation sequencing. *E. Goncalves-Serra[1], A. Nicholas[2], VK. Chatterjee[2], CA. Anderson[1], N. Schoenmakers[2], UK10K Consortium.* 1) Human Genetics, Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Cambridge, Hinxton, United Kingdom; 2) University of Cambridge Metabolic Research Laboratories, Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, United Kingdom.

Congenital hypothyroidism (CH) is the most common endocrine disorder among newborns but its genetic aetiology is still largely unknown, with mutations identified in less than 20% of the cases. The increased CH frequency in consanguineous populations and in relatives of CH cases suggests the genetic contribution to CH might be greater than previously expected. Known CH genes have not previously been screened comprehensively in a CH cohort with gland-in-situ (GIS). We evaluated the relative contribution of mutations in eight known causative genes (*TG*, *TPO*, *DUOX2*, *DUOXA2*, *SLC5A5*, *SLC26A4*, *IYD* and *TSHR*) in 50 CH cases with GIS from 35, ethnically diverse families, using exome and targeted next-generation sequencing. Patient genotypes were correlated with biochemical phenotype and pathogenicity of mutations was analysed in silico using deleteriousness and conservation scores (PolyPhen2, SIFT and GERP) and protein structural modelling. Twenty-eight cases harboured likely, disease-causing, mutations. Nineteen cases with single gene defects, involving *TG* (12 cases), *TPO* (4 cases), *DUOX2* (2 cases) and *TSHR* (1 case), were documented. Novel variants were identified in *TG* (5 variants), *TPO* (5 variants) and *DUOX2* (2 variants). Nine cases harboured pathogenic variants in two different genes: *TG* and *TPO* (1 case), *SLC26A4* and *TPO* (2 cases) and *DUOX2* and *TG* (6 cases), yet no clear correlation between genotype and biochemical phenotype was found in these cases. We demonstrated that our case set is enriched for mutations in known-CH genes when compared to ~2,000 exome-sequenced healthy individuals and that the probability of double-hit mutations in the above gene pairs was unlikely to have occurred by chance. Genetic aetiology was not ascertained in 22 patients, generally with milder biochemical CH and some familial cases. Exome-wide gene-based burden tests in these cases and controls did not reveal novel CH genes. Still, gene prioritization analyses are ongoing to highlight biologically relevant candidate genes to be included in future screens of larger CH-GIS cohorts. In conclusion, the aetiology of CH with GIS is complex, with only 56% being due to mutations in known CH-genes. Combinations of defects in two different genes are common, especially in consanguineous families (57%). Severe CH is most commonly mediated by biallelic *TG* or *TPO* mutations. A high proportion (~44%) of unsolved cases suggest contribution of hitherto unknown genes or environmental factors to GIS CH.

2881F

***De novo* mutations in the eukaryotic translation elongation factor, EEF1A2 cause epileptic encephalopathy.** *G. L. Carvill[1], J. M. McMahon[2], A. Schneider[2], C. Myers[1], R. S. Moller[3], I. E. Scheffer[2], H. C. Mefford[1].* 1) Department of Pediatrics, Division of Genetic Medicine, University of Washington, Seattle, WA 98195; 2) Epilepsy Research Center and Department of Medicine, University of Melbourne, Austin Health, Australia; 3) Danish Epilepsy Centre, Dianaland, Denmark.

Epilepsy is one of the most common neurological disorders, with a lifetime incidence of 3%. The epileptic encephalopathies are the most severe of all the epilepsies. Patients typically present with refractory epilepsy with multiple seizure types, cognitive arrest or regression, and have a poor prognosis. *De novo* mutations have been increasingly recognized as causative for these disorders, and mutations in over 30 genes have been described. Recently, *de novo* mutations in *EEF1A2* were described in patients with intellectual disability and epilepsy. To define the role of this gene in epilepsy more broadly, we performed targeted resequencing of *EEF1A2* in 683 patients with epileptic encephalopathy. Overall, on average we sequenced 82% of the gene at a coverage of >50X across all samples. We identified four patients with likely pathogenic mutations, three patients had a recurrent Asp91Asn mutation and a fourth had a *de novo* Ala125Glu mutation. We review the phenotypes of these patients and contrast with those previously described. *EEF1A2* encodes for the alpha subunit of the eukaryotic translation elongation factor that controls the delivery of tRNAs to the ribosome. The function of this protein reveals a novel biological mechanism for epileptogenesis and broadens our appreciation for the complex mechanisms that underpin epilepsy. Future functional studies will not only enhance our understanding of epileptogenesis, but also potentially illuminate new options for therapeutic developments.

2882W

A missense variant in KRT25 causes autosomal recessive woolly hair. *M. Ansar[1,2], S. I. Raza[1], K. Lee[2], S. Shahi[1], A. Acharya[2], H. Dai[2], J. D. Smith[3], J. Shendure[3], M. J. Bamshad[3], D. A. Nickerson[3], R. L. Santos-Cortez[2], W. Ahmad[1], S. M. Leal[2], University of Washington Center for Mendelian Genomics.* 1) Department of Biochemistry, Faculty of Biological Sciences, Quaid-i-Azam University, Islamabad 45320, Pakistan; 2) Center for Statistical Genetics, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas 77030, USA; 3) Department of Genome Sciences, University of Washington, Seattle, Washington 98195, USA.

A novel gene *KRT25* that encodes Keratin, type I cytoskeletal 25 (K25) protein, was identified for woolly hair (WH), which is primarily characterized by tightly curled hair with abnormal growth. We analyzed two consanguineous Pakistani families with non-syndromic autosomal recessive (AR) WH. Seven individuals, from these families present with tightly curled brittle scalp hair since early childhood. In both families homozygosity mapping and linkage analysis identified overlapping regions within 17q21. 1-q22. Exome sequencing of a DNA sample from each family result in the identification of a homozygous missense variant c. 950T>C (p. (Leu317Pro)) within *KRT25*. The variant segregates with ARWH in both families and has a combined maximum two-point LOD score of 7. 9 at λ=0. The KRT25 p. (Leu317Pro) variant is predicted to be deleterious by multiple bioinformatics tools. Molecular modeling of K25 protein with the variant predicted disruption of the second α-helical rod domain, which probably perturbs the helix structure resulting in the loss of surface contact residues. These perturbations possibly interfere with heterodimerization of K25 with type II keratins within the three inner root sheath layers of the hair follicle and the medulla of the hair shaft. In the hair follicle, KRT25 is expressed in Henle layer, Huxley layer and in the inner root sheath cuticle. Additionally *Krt25-/- mice* have fragile and curled fur. Furthermore micewith*Krt25*mutationshave mislocalized K71 protein as well as irregularlayers within the inner root sheath. In humans variants in *KRT71* have previously been shown to underlie non-syndromic WH. Our findings implicate a novel gene involved in human hair abnormality and are consistent with the curled, fragile hair found in *Krt25-/-* mice, and further support the role of inner root sheath-specific type I keratins in hair follicle development and maintenance of hair texture.

2883T

De Novo Variants in *GABBR2* Associated with Developmental Delay, Hypotonia, and Cyanosis. *N. J. Boczek[1], M. A. Cousin[1], P. R. Blackburn[1], A. N. Sigafoos[1,2], R. A. Urrutia[2,3], R. H. Gavrilova[4], K. J. Clark[1,2], E. W. Klee[1,5].* 1) Center for Individualized Medicine, Mayo Clinic, Rochester, MN; 2) Department of Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN; 3) Department of Biophysics, Mayo Clinic, Rochester, MN; 4) Departments of Medical Genetics and Neurology, Mayo Clinic, Rochester MN; 5) Department of Biomedical Informatics, Mayo Clinic, Rochester, MN.

Whole exome sequencing (WES) is a sequencing strategy utilized in diagnostic odyssey cases in attempt to identify the underlying genetic substrate responsible for the patient phenotype. Recent publications have reported that WES reveals the genetic cause in ~25% of these cases, and is most successful when applied to children with neurological disease. The residual ~75% of cases remain genetically elusive until more information becomes available in the literature or applicable functional studies are pursued. Our diagnostic odyssey case presented at 6 months of age with severe developmental delay and hypotonia, with a normal brain MRI. At five years of age the patient began having spells of altered breathing rate with cyanosis with no documented seizure activity. In addition, she has repetitive hand movements and intermittent posturing of her legs. The patient is currently 7 years of age and unable to stand, walk unassisted, communicate, or follow instructions. Clinical WES testing by Baylor College of Medicine did not identify a genetic variant with clear causal association with this patient's phenotype. Subsequent research WES was performed at Mayo Clinic on the proband and her unaffected parents. Utilizing an in house variant prioritization tool, a de novo heterozygous variant within *GABBR2* was identified as the top candidate variant. *GABBR2*, encoding the G-protein coupled receptor, gamma-aminobutyric acid beta receptor 2, is known for its regulation of neurotransmitter release in the brain. The de novo variant, p. M702V, falls is within the highly conserved 6th transmembrane spanning region of GABBR2 and is absent in the publically available exome/genome databases including NHLBI ESP, ExAC, and the 1000 Genomes Project. A recent manuscript examining epileptic encephalopathy identified de novo GABBR2 variants, p. S695I and p. I705N, in the 6th transmembrane spanning domain of GABBR2 in two cases with almost identical phenotypes to our proband. The identification of de novo mutations in a neurologically expressed gene in our patient as well as two other individuals with comparable phenotypes, suggests the *GABBR2* variants within the 6th transmembrane spanning domain may be responsible for phenotypes consistent with developmental delay, hypotonia, and cyanosis. We are currently pursuing functional studies within zebrafish to confirm these findings.

2884F

Compound heterozygous loss of function variants in the signaling transducer *GNB5* in two sisters with severe hypotonia and hyporeflexia, cognitive deficit and epilepsy. *P. De Nittis[1,2], L. Gueneau[2], D. Cocciadiferro[1], A. A. Alfaiz[2], V. Napolioni[3], B. Augello[1], M. T. Pellico[1], L. Zelante[1], A. Reymond[2], G. Merla[1].* 1) Medical Genetics Unit, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Foggia, Italy; 2) Center for Integrative Genomics, University of Lausanne CH-1015 Lausanne; 3) Department of Neurology and Neurological Sciences, Stanford University School of Medicine, Stanford, CA, USA.

We identified two Italian sisters affected by the same multisystem disorder, defined by a global developmental impairment, psychomotor disability, delayed speech development, learning deficiency, nystagmus, epileptic seizures, generalized muscular weakness, bradycardia, hyporeflexia and characteristic facial features. Exome sequencing of the two affected siblings and their non-consanguineous healthy parents uncovered bi-allelic loss-of-function variants in the *GNB5* gene in both siblings. *GNB5* encodes the fifth member of the heterotrimeric G-protein β-subunit family, which integrate signals between receptors and effector proteins. It is a 353-aminoacids protein, principally expressed in brain and tissues such as pancreas, heart and kidney. GNB5 differentially governs the proteinstability of G protein signaling regulators (RGS), and is thus involved in the control of complex neuronal G protein signaling pathways. Further, RGS6/GNB5 complex modulates parasympathetic regulation ofheartrate in mice. The paternal missense variant r. [249G>A;249-250ins25] alters splicing accuracy, as assessed by RT-PCR and subsequent sequencing of the amplified products. The retention of 25bp of the intervening intron results in a frame-shift that shortens the encoded amino acid sequence. The maternal allele variant c. 994C>T results in a stop gain. Both variants appear to target the corresponding mRNA transcripts to nonsense-mediated mRNA-decay. Consistent with the possible involvement of these variants in the phenotype of the two sisters, knock-out of the paralogous gene in mice results in marked neurobehavioral developmental delay, impaired gait, motor learning and coordination deficiencies. *Gnb5*-deficient mouse models also display defective visual adaptation and abnormal functioning of retinal bipolar cells. Further validation of these findings through identification of more patients with variant in *GNB5* is warranted.

2885W

Identification of New Genes and Pathways for Rare Infantile Forms of Myopathies and Neuromuscular Disorders. *J. M. Hunter[1], C. Balak[1], M. E. Ahearn[1], W. Liang[1], M. Russell[1], M. Huentelman[1], D. Craig[1], J. Carpten[1], S. M. Bernes[2], L. Baumbach-Reardon[1].* 1) Integrated Cancer Genomics, TGen, Phoenix, AZ; 2) Phoenix Children's Hospital, Phoenix, AZ.

Neuromuscular disorders and myopathies account for a significant proportion of infant and childhood mortality and chronic disease. The phenotypes and genetics of these disorders cover a broad spectrum but have many overlapping features. As we learn more about the etiology of human disease we have found that most severe disease causing variants are very rare, only occurring in a single or a few individuals. Developing treatments for these individual diseases begins with identification of the underlying genetic mutations. Our goal is to use next generation sequencing to identify mutations that cause neuromuscular disorders and muscular dystrophies. In many of the cases we have studied, prior genetic testing and histology, which was often very extensive and spanned many years of evaluation, did not reveal the genetic etiology of disease. Over the past 2 years we have completed whole exome sequencing on 172 individuals including 64 affected individuals and family members. From this data set, we have identified novel probable pathogenic mutations in genes known to cause disease as well as in genes not previously associated with disease in ~30% of cases. We highlight some of our results and will summarize all of our findings. First, we identified novel compound heterozygous *PLA2G6* pathogenic variants in a male infant with regression of acquired motor skills, progressive cerebellar atrophy, and generalized hypotonia. Second, we studied a male child with a form of limb girdle muscular dystrophy, generalized weakness and dystrophic muscle biopsy results. We identified novel micro deletion and frameshift compound heterozygous mutations in *COL6A2* for a genetic diagnosis of Bethlem myopathy. Third, we describe a severe case of *possible* Nemaline myopathy caused by compound heterozygous splice mutations in *NEB*. The child presented with congenital global hypotonia, arthrogryposis, deformed diaphragm, and was ventilator dependent. Finally we present a child with a severe congenital neuromuscular disease presenting with global severe hypotonia, contractures, severe myofiber disorganization, and fractures. We identified a novel frameshift and premature truncation in TTN which we suspect is the cause of disease. The diversity of our results demonstrates the necessity of using next-generation sequencing to find answers for families with these rare and devastating diseases.

2886T

A comprehensive genomic analysis reveals the genetic landscape of mitochondrial respiratory chain complex deficiencies. *M. Kohda[1], Y. Tokuzawa[1], Y. Kishita[1], Y. Moriyama[1,2], Y. Mizuno[1], T. Hirata[1], Y. Yatsuka[1], Y. Yamashita-Sugahara[1], Y. Nakachi[1], H. Kato[1], S. Tamaru[3], H. Nyuzuki[1], N. N. Borna[1], H. Harashima[4], T. Yamazaki[4], M. Mori[5], K. Murayama[6], A. Ohtake[4], Y. Okazaki[1].* 1) Research Center for Genomic Medicine, Saitama Medical University, Hidaka, Japan; 2) Department of Anatomy II and Cell Biology, Fujita Health University School of Medicine, Toyoake, Japan; 3) Department of Obstetrics and Gynecology, Saitama Medical University, Saitama, Moroyama, Japan; 4) Department of Pediatrics, Saitama Medical University, Moroyama, Japan; 5) Department of Pediatrics, Matsudo City Hospital, Matsudo, Japan; 6) Department of Metabolism, Chiba Children's Hospital, Chiba, Japan.

We present the first report of a comprehensive genomic analysis of a cohort of patients with mitochondrial respiratory chain complex deficiencies. Using high-throughput sequencing and chromosomal aberration analysis, we ultimately identified 31 novel mutations in genes previously reported to be linked to mitochondrial disorders, and novel mitochondria-related genes (*NDUFB11*, *COQ4*, *GTPBP3*, and etc) as novel causative genes. We also identified noncanonical mitochondria-related disease genes (*MECP2* and *TNNI3*) and 3 chromosomal aberrations (6q24. 3-q25. 1, 22q11. 21, and 17p12) in patients with mitochondrial respiratory chain complex deficiencies. Using comprehensive genomic analyses, we achieved firm genetic diagnoses in 49 of 142 patients (34. 5%). Comprehensive genomic analyses also enabled us to identify closely related disorders, which will be important for patient care and the application of an efficient drug repositioning. We demonstrated that extensive clinical heterogeneity exists in this disorder, and comprehensive genomic analyses could reveal its clinical and genetic heterogeneity for better understanding this complex disorder.

2887F

Genetic analysis of autosomal recessive primary microcephaly in Indian population. *A. Kumar[1], S. C. Girimaji[2].* 1) Molecular Reproduction, Development & Genetics, Indian Institute of Science, Bangalore 560012, Karnataka, India; 2) Department of Child and Adolescent Psychiatry, National Institute of Mental Health and Neuro Sciences, Bangalore 560029, Karnataka, India.

Human brain development is a complex process that involves generation of neural progenitors in periventricular zones, cell proliferation through symmetric and asymmetric cell divisions, and finally the migration of post-mitotic neurons to their final destinations. An understanding of the molecular mechanisms guiding the complex process is facilitated by discovery of causative genes for a cortical (brain) malformation disorder, autosomal recessive primary microcephaly (MCPH), which is characterized by a smaller than normal brain and intellectual disability. Interestingly, the brain volume (500 cc) of an MCPH patient is similar to early hominids, such as Australopithecus who lived 1. 8-4. 4 myr ago. Occasionally, MCPH patients also have other brain malformations, such as pachygyria, polymicrogyria, simplified gyral pattern etc. We have been working on the genetics of MCPH for some time, which led to discovery of the seventh MCPH gene *STIL* in 2009. So far, a total of 13 genes have been identified for MCPH: *MCPH1* on ch8p23. 1, *WDR62* on ch19q13. 12, *CDK5RAP2* on ch9q33. 2, *CASC5* on ch15q15. 1, *CEP152* on ch15q21. 1, *ASPM* on ch1q31. 3, *CENPJ* on ch13q12. 12*, STIL* on ch1p33*, CEP63* on ch3q22. 2, *CEP135* on ch4q12, *PHC1* on ch12p13. 31, *CDK6* on ch7q21. 2 and *SASS6* on ch1p21. 2**.** We have ascertained a total of 39 MCPH families. Using homozygosity mapping and Sanger sequencing, we have identified mutations in *WDR62* (3 families), *ASPM* (8 families) and *STIL* (6 families) genes only in our families, with a mutation detection rate of 43. 59% (17/39 families). Thus, the *ASPM* gene is found to be the most commonly mutated gene followed by *STIL* and *WDR62* in Indian population. There are still 22/39 families in our family dataset which do not harbor mutations in any of the known MCPH genes, suggesting the future discovery of additional novel gene(s). We are currently using homozygosity mapping and whole exome sequencing to identify the novel MCPH gene(s). A comprehensive analysis of our molecular genetic analysis of Indian MCPH families will be presented and discussed.

2888W

Description of a male with Microphthalmia Syndromic 2 and a rare *BCOR* missense variant. *A. L. Pilla[1], A. B. Alvarez Perez[1], M. P. Migliavacca[1], J. Jurgens[2], L. Brunoni[1], N. L. M. Sobreira[2].* 1) Clinical Genetics Dept. of Morphology and Genetics, Universidade Federal de São Paolo, São Paolo, SP, Brazil; 2) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, 733 N. Broadway Street Suite 512, Baltimore, MD 21205, USA.

Ramos-Arroyo syndrome (MIM122430) was described as a new syndrome by Ramos-Arroyo in 1987 in two brothers with corneal anesthesia, bilateral sensorineural deafness, patent ductus arteriosus, moderate intellectual disability and dysmorphic facial features. In 2008, Spurrier and Weaver described the same family including two other affected individuals and additional findings such as Hirschsprung's disease. The presumed mode of inheritance is autosomal dominant, and to date the molecular basis is unknown. In 2004, a variant in the *BCOR* gene (BCL6 corepressor) was identified in a family with Microphthalmia Syndromic 2 (MIM300166), characterized by X-linked dominant inheritance and eye abnormalities including microcornea, congenital cataracts and microphthalmia. These affected individuals also had short stature, dysmorphic facial features, patent ductus arteriosus and intellectual disability. Here we describe an individual with a clinical diagnosis of Ramos-Arroyo syndrome referred to the Baylor-Hopkins Center for Mendelian Genomics for whole exome sequencing (WES). He is the 3rd son of non-consanguineous parents. His mother used misoprostol in the 1st trimester of pregnancy, followed by a minor hemorrhage episode. He was born by uneventful normal delivery at term. His birth weight was 3500 g and height was 47 cm. His mother reported hypotonia and little eye movement since the neonatal period. Later ophthalmologic examination diagnosed corneal anesthesia and alacrimia. An eye surgery was performed at 7 months for suture of the eyelids. He had delayed psychomotor development. His physical examination at 7 years 8 months showed weight: 17 kg (<p3), height: 1. 18 cm (p25), PC: 52 cm (p50), prominent front, hypertrichosis and flattening in the face, anteverted nostrils, and hypoplasia of the middle face. WES identified a rare missense variant (c. 2288G>T, p. Arg763Leu) in exon 4 of *BCOR*, located on chromosome Xp11. 4. To date, many affected females have been described with truncating variants in *BCOR* and Microphthalmia Syndromic 2, also known as oculocardiofaciodental syndrome. Affected males have been described in only 3 families, all with the p. Pro85Leu missense variant in *BCOR*. Based on our patient's phenotypic similarity to Microphthalmia Syndromic 2, we suggest that his p. Arg763Leu *BCOR* variant is pathogenic and that he has Microphthalmia Syndromic 2. We also suggest that *BCOR* should be tested in individuals with the clinical diagnosis of Ramos-Arroyo syndrome.

2889T

Whole exome sequencing analysis of intracranial aneurysm in multiplex families. *A. Powell[1], B. Fernandez[1], F. Maroun[2], K. Mahoney[1], M. Woods[1].* 1) Discipline of Genetics, Faculty of Medicine, Memorial University, St. John's, NL, Canada; 2) Department of Surgery, Faculty of Medicine, Memorial University, St. John's, NL, Canada.

An intracranial aneurysm (IA) is a dilatation of the wall of a cerebral artery. The weakened vessel walls of IAs have the potential to rupture and lead to subarachnoid hemorrhage, a devastating type of stroke. In addition to environmental factors, numerous studies have supported genetic predisposition as a risk factor for IA development and rupture. However, no causal genes have been identified. The purpose of this study is to identify genetic variants that cause susceptibility to familial IA in the Canadian province of Newfoundland and Labrador. This involved the recruitment of 53 families that have a history of IA, and an additional 33 sporadic IA cases. Currently, we are focusing on two multiplex families, each with greater than ten affected individuals, and pedigrees consistent with Mendelian inheritance. A pilot study of twelve individuals was selected from this cohort, for whole exome sequencing of genomic DNA. To identify disease-causing genes, we developed a filtering strategy for variant prioritization. We focused on variants with potentially high or moderate effect (non-synonymous SNVs, frameshifts, splice-site acceptors and donors) that were shared by multiple affected individuals within a single family. Common variants with a minor allele frequency greater than 1% in public databases and a population of control exomes were excluded. Bioinformatics tools such as SIFT and Polyphen2 were also used to predict pathogenicity, along with data concerning the functional relevance of affected proteins. Our comprehensive method of filtering resulted in an initial list of 67 variants in 58 genes from the 12 exomes. This was further reduced to 20 variants of interest in 16 genes, as greater emphasis was placed on novel variants shared by all exomes within a family. Sanger sequencing was used for the validation of variants and to test for segregation in additional family members. After filtering, there were no rare variants shared by the two families. As well, these families did not share any different variants in the same gene. The identification of rare and novel variants in familial cases of IA is a significant step toward furthering our understanding of the genetic etiology of this disease. Variants that were identified through this study may have significance in other populations. Greater knowledge at the molecular level could assist in the future diagnosis and treatment of asymptomatic unruptured IA, and aid in genetic counseling of families.

2890F

Molecular genetic studies of the oculocutaneous albinism phenotype in the Pakistani population. *M. Shahzad[1], S. YOUSAF[1,2], T. KAUSAR[2], Y. M. WARYAH[3], H. GUL[4], U. MEHMOOD[1], N. TARIQ[2], M. A. KHAN[4], M. ALI[5], M. A. KHAN[4,6], A. M. WARYAH[3], S. RIAZUDDIN[1], R. S. SHAIKH[2], Z. M. Oculocutaneous albinism (OCA) is a rare genetic disorder characterized by variable hypopigmentation in hair, skin, and eyes with or without other clinical manifestation. Currently, mutations in at least 18 genes have been causally linked to OCA phenotype in human. Our objective here is comprehensive genetic screening of known OCA genes in Pakistani families segregating various types of OCA phenotype. We ascertained 132 families with multiple affected individuals from different provinces of Pakistan, after obtaining IRB approvals and informed written consents. Sanger sequencing of common *OCA* genes followed by whole exome sequencing was performed for the identification of pathogenic variants in these families. We identified 42 new and 18 reported variants, in nine known *OCA* genes responsible for OCA phenotype in 121 families. These mutations include, thirty-six missense, seven splice site, six nonsense, four frame shift, one six base in-frame and six gross deletions. In our cohort, mutations in *TYR* (OCA1) are more prevalent (40. 91%) followed by *OCA2* alleles (34. 09%), *TYRP1* (OCA3; 3. 79%), *SLC45A2* (OCA4; 3. 79%), *SLC24A5* (OCA6; 2. 27%) and *HPS1* (2. 27%). We also identified single variants in *HPS3*, *HPS4*, *HPS6* and *HPS9* and a compound heterozygous mutation in *LYST*. Our findings indicate that p. (Arg278*) and p. (Gly419Arg) alleles of *TYR* and c. 1045-15T>G and p. (Asp486Tyr) of *OCA2* are recurrent mutations in Pakistani population. Therefore, we developed tetra primer screening assays for the detection of these highly prevalent recurrent mutations. In remaining 11 families, we did not identify mutations in known OCA genes, indicating the existence of yet unidentified *OCA* gene(s). To the best of our knowledge, this study represents the most comprehensive documentation of *OCA* alleles in the Pakistani population. Overall, our study contributes to the development of genetic testing protocols, future diagnosis, genetic counseling and molecular epidemiology of OCA in Pakistan.

Systematic evaluation of patients with idiopathic short stature using whole exome sequencing. *C. T. Thiel[1], N. N. Hauer[1], S. Schuhmann[1], E. Schoeller[1], M. T. Wittmann[1], S. Uebe[1], A. B. Ekici[1], H. Sticht[2], H. -G. Doerr[3], A. Reis[1].* 1) Institute of Human Genetics, Friedrich-Alexander-Universitét Erlangen-Nürnberg, Erlangen, Germany; 2) Institute of Biochemistry, Friedrich-Alexander-Universitét Erlangen-Nürnberg, Erlangen, Germany; 3) Department of Pediatrics and Adolescent Medicine, Friedrich-Alexander-Universitét Erlangen-Nürnberg, Erlangen, Germany.

Shortness of stature is a common medical concern in childhood and has an incidence of 3% in the general population. After excluding defects of the growth hormone pathway and recognizable syndromes the underlying cause remains unknown in approximately 70-80% of patients. In some of these patients the underlying diagnosis is omitted by the lack of clinical features characteristic for known syndromic forms of short stature. To address this in patients with idiopathic short stature we thoroughly built a study group of more than 500 families with idiopathic short stature. We systematically selected 100 individuals where growth hormone defects, common genetic causes of short stature or copy number variations were excluded and performed whole exome sequencing. Variants were selected unbiased based on all modes of inheritance in agreement with the segregation in the families and their potential effect on protein function using our NGS Variant Analyzer software. We confirmed mutations in known short stature genes in 11 patients. All these syndromes have been reported to be associated with further clinical issues providing mandatory medical guidance for these patients. In addition, we recognized novel candidate genes involved in epigenetic modification, cell cycle regulation, ubiquitination and protein synthesis in up to 54 % of the patients with idiopathic short stature. Even though, recessive, dominant and x-linked inherited variants were observed in these candidate genes, we confirmed autosomal dominant de novo as the predominant inheritance model in idiopathic short stature. Thus, our data underlines the rare variant – frequent disease hypothesis for the extreme end of the growth spectrum. In conclusion, whole exome sequencing identified the underlying genetic defect in up to 65% of the patients with idiopathic short stature. As the clinical spectrum of most genetic defects is yet to be explored, an unbiased genetic analysis of patients with idiopathic short stature can establish a diagnosis in these cases.

Expansion of the Troyer Syndrome phenotype by discovery of mutations in Turkish families. *H. Unal Gulsuner[1], O. Ceyhan-Birsoy[2,3], S. Gulsuner[1], O. E. Onat[4], T. Walsh[1], H. Shahin[5], M. K. Lee[1], A. B. Tekinay[6], M. -C. King[1], A. H. Beggs[7], T. Ozcelik[4,6], H. Topaloglu[8].* 1) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA, USA; 2) Laboratory for Molecular Medicine, Partners HealthCare, Cambridge, MA, USA; 3) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA, USA; 4) Department of Molecular Biology and Genetics, Bilkent University, Ankara, Turkey; 5) Department of Life Sciences, Bethlehem University, Bethlehem, Palestine; 6) Institute of Materials Science and Nanotechnology, National Nanotechnology Research Center (UNAM), Bilkent University, Ankara, Turkey; 7) Manton Center for Orphan Disease Research, Department of Genetics and Genomics, Boston Children's Hospital and Harvard Medical School, Boston, MA, USA; 8) Department of Pediatric Neurology, Faculty of Medicine, Hacettepe University, Ankara, Turkey.

We report two unrelated Turkish families, both consanguineous, with two and one affected children, respectively, with progressive spasticity and weakness of the legs, spastic gait, developmental delay, and intellectual disability. Parents and all other family members were unaffected. Clinical evaluation suggested that all three children suffered from the same disorder, but did not establish a differential diagnosis. We exome sequenced genomic DNA from the three affected individuals. In the first family, both affected children were homozygous for SPG20 p. G580R (c. 1780G>A); in the second family, the affected child was homozygous for SPG20 p. Q229X (c. 685C>T). No other gene harbored homozygous damaging alleles in all three affected children. Neither mutation appears in any public database. SPG20 p. G580R lies at a residue completely conserved in all sequenced species, in a highly conserved domain. *SPG20* (spastic paraplegia 20) encodes spartin, a 666-residue protein that localizes to the mitochondria and is involved in endosomal trafficking. *SPG20* is widely expressed in both developing and adult brain. *Spg20-/-* mice have been reported to show significant defects in gait, in axon branching of cerebral cortical neurons, and in BMP signaling. Homozygosity for loss-of-function mutations in *SPG20* has previously been reported to cause Troyer syndrome, an autosomal recessive complicated spastic paraplegia, in the Old Order Amish and in an extended Omani kindred. Additional clinical evaluation and magnetic resonance imaging (MRI) of our patients revealed neurological symptoms similar to those reported for the Amish and Omani Troyer syndrome patients, and also several important differences. Both affected children in the first family in our study have early onset tremor, which is not reported in any other Troyer syndrome cases; and all three children in our study lack any skeletal abnormalities, which are reported to be present in all other Troyer syndrome cases. In conclusion, SPG20 mutations in two Turkish families are likely responsible for a Troyer syndrome phenotype that shares neurological and developmental features of previously reported cases, but including, in one family, early onset tremor, and without skeletal abnormalities.

2893F

Genetic characterization of childhood-onset cardiomyopathies in the Finnish population. *C. Vasilescu[1], C. Carroll[1], V. Brilhante[1], A. Hiippala[2], J. Lohi[3], E. Jokinen[2], T. Tyni[4], T. Ojala[2], A. Suomalainen[1,5].* 1) Research Programs Unit, Molecular Neurology, Biomedicum Helsinki, University of Helsinki, Helsinki, Finland; 2) Department of Pediatric Cardiology, Children's Hospital, Helsinki University Central Hospital, Helsinki, Finland; 3) Department of Pathology, Helsinki University Central Hospital, Helsinki, Finland; 4) Department of Pediatric Neurology, Helsinki University Central Hospital, Helsinki, Finland; 5) Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland.

Childhood-onset cardiomyopathies (CMPs) are severe heart disorders, mainly of genetic origin, with autosomal dominant, *de novo*,recessiveormaternal inheritance. In this study we aim to characterize the collection of disease genes and mutations causing childhood-onset cardiomyopathies in the Finnish population. We used Next Generation Sequencing (NGS) to screen a group of 89 pediatric patients from the sole clinic in Finland treating severe childhood-onset CMPs. These are patients in whom the genetic diagnosis was not achieved with standard candidate gene approaches. Nine of the patients were screened by whole-exome sequencing (WES), 37 by a HaloPlex custom-designed panel of 117 CMP-related genes, and 43 with a commercial panel of 101 genes of nonsyndromic and syndromic forms of CMP (BluePrint Genetics). Variants were prioritized with respect to frequency and pathogenicity prediction. Candidate mutations were further verified to match the disease segregation in the families and to be absent in Finnish controls under the implicated mode of inheritance. Dominant mutations were confirmed in nine patients, affecting proteins involved in sarcomere structure and function (*MYH7* - 3 distinct mutations, *TNNC1*, *TNNI3*), calcium handling (*CALM1*, *CACNA1C*), autophagy/apoptosis (*BAG3*), and cellular energy sensing (*PRKAG2*). Among these, screening of family members revealed *de novo* mutations in six cases. Furthermore, a recessive mutation was found in JPH2, which encodes a protein with both structural and calcium regulation roles. Additional candidates in *TAZ*, *PTPN11*, *MAP2K2*, *JPH2*, *MYH7*, *ACTC1*, *TBX20*, and *NEXN* are under investigation. Overall, we estimate a diagnostic success rate of around 25%. The mutations in our cohort are private for families and most of them novel. *De novo* mutations were found to be a common cause of early-onset cardiomyopathy and recessive mutations explain only a small fraction of cases, even in a genetic isolate such as Finland.

Genetic and Functional studies of *MC1R* alleles associated with hypopigmentation phenotype in human. *S. Yousaf[1,2], M. Shahzad[1], J. Campos[3], N. Tariq[2], C. Serrano[3], R. Yousaf[1], C. Cervantes[3], Y. Waryah[4], T. Kausar[2], M. Ali[5], A. Waryah[4], S. Riazuddin[1], S. Shaikh[2], J. Garcia-Borron[3], Z. Ahmed[1,2,5].* 1) Department of Otorhinolaryngology Head and Neck Surgery, School of Medicine, University of Maryland, Baltimore, MD, USA; 2) Institute of Molecular Biology & Biotechnology, Bahauddin Zakariya University, Multan, Pakistan; 3) 3Department of Biochemistry and Molecular Biology, School of Medicine, University of Murcia and IMIB-Arrixaca, Murcia, Spain; 4) Molecular Biology & Genetics Department, Medical Research Center, Liaquat University of Medical & Health Sciences, Jamshoro, Pakistan; 5) Government College University, Faisalabad, Pakistan.

Background: Skin pigmentation is one of the most visible phenotypes in humans. Loss of pigmentation is a group of disorders caused by either complete absence or deficiency of melanin in skin, hair and/or iris. Our goal here is to identify and characterize the *MC1R* alleles associated with hypopigmentation disorders in the Pakistani population. We enrolled consanguineous Pakistani families segregating hypopigmentation phenotype with normal fundus. **Methods:** Sanger sequencing was performed for the known genes followed by linkage analysis and Whole-Exome enrichment and sequencing (NGS). *Ex-vivo* studies were carried out in transiently transfected cells with cDNAs encoding either the wild type or mutant proteins. **Results:** Bioinformatic analysis of NGS data revealed four missense, one in-frame deletion (p. (Val174del) and a nonsense mutation (p. (Tyr298*)) in *MC1R* co-segregating with the hypopigmentation phenotype in seven families. *MC1R* encodes a seven-transmembrane G-protein coupled receptor mainly present on the membrane of melanocytes. *Ex-vivo* studies revealed destabilization of *MC1R* due to p. Val174del and p. Tyr298* mutations. The p. Tyr298* mutant *MC1R* showed no agonist-induced signaling to the cAMP or ERK pathways, nor detectable agonist binding. Flow cytometry and confocal imaging studies revealed reduced plasma membrane expression of p. Val174del and p. Tyr298*. **Conclusion:** Our data provide further insight on the relationship of MC1R functional status with hypopigmentation. Our data support the current view that functional characterization of new variants might allow for a prediction of phenotypic effects for low frequency alleles that cannot be reliably analyzed by genetic epidemiology association studies, or for mutations not easy to analyze *in silico*. Our results also reveal the complexity of determinants of normal MC1R trafficking to the plasma membrane.

2895T

Compound heterozygous mutations leading to loss of JAK2 function cause an immune dysregulatory syndrome. *X. Yu[1], M. Chi[1], S. Pitaluga[2], S. Siegel[3], J. Niemela[4], J. Milner[1].* 1) Genetics and Pathogenesis of Allergy Section, NIAID, Bethesda, USA; 2) Laboratory of Pathology, NCI, Bethesda, USA; 3) New York Medical College, Westchester Medical Center, Valhalla, USA; 4) Department of Laboratory Medicine, Clinical Center, Bethesda, USA.

We have followed an infant who developed a shoulder abscess at one month of age followed by severe ichthyosis, hepatosplenomegaly, lymphadenopathy, histiocytic inflammation, and consumptive anemia. Laboratory analysis showed decreased NK and CD8 killing, panhypogammaglobulinemia, extraordinary polyclonal T-cell lymphocytosis, normal B-cell numbers without any class-switched B-cells, and a lack of B-cell follicles. Almost no PD-1 CXCR5+ circulating T-follicular helper (TFH)-like cells were found in blood, and staining for PD-1+ or BCL-6+ TFH cells in the lymph node was completely negative. Without a diagnosis at the time, the patient received systemic immune suppression and a matched unrelated bone marrow transplantation and is healthy now. Whole-exome sequencing was performed in the affected patient and his unaffected parents. Common variants (MAF > 0. 01) were filtered from exome data. We identified compound heterozygous mutations Ser46Tyr (MAF < . 001) and Leu393Val (MAF . 01) in *JAK2*, the gene encoding Janus kinase 2 (JAK2). Computer modeling based on the crystal structure of human tyrosine kinase 2 predicts that two mutations disrupt FERM-SH2 and receptor-binding domains of JAK2. While gain of function JAK2 mutations are associated with a number of proliferative disorders and blood dyscrasias, western blots for JAK2 showed a decrease in protein expression in PBMCs from the patient, and Stat3 and Stat1 activation after stimulation with JAK2 dependent cytokines IL-6 and IL-27 was low, despite normal pSTAT3 responses to non-JAK2 dependent cytokines. The patient had profoundly decreased peripheral T-cell IFN-γ production, consistent with a focal defect in T-helper 1 T-cell differentiation, which is highly dependent upon IL-12 and IFNg signaling, both of which require JAK2 for signaling. IL-2, Th2, and Th17 cytokine expression, was normal, consistent with their ability to be generated by non-JAK2 dependent cytokines. These data indicate that loss of function *JAK2* mutations can lead to a profound immune deficient and dysregulatory state. While lethality of JAK2 loss of function in mice has precluded specific examination of Thelper cell differentiation, JAK2 appears to be required for normal Th1 and TFH differentiation, but not IL-2 prodcution, Th2 or Th17 differentiation in humans. Study of the extrahematopoetic symptoms in this transplanted patient over time will further add to our understanding of the consequences of impaired JAK2 signaling in humans.

2896F

Novel and previously reported mutations in MSX1 gene in three Mexican families with non-syndromic dental agenesis. *E. A. Ramirez-Ramirez[1,2], KL. Valdes-Morales[2], F. Hernandez-Teran[1,3], LD. Mayoral-Amador[3], HM. Diaz-Martinez[3], FF. Gonzalez-Galarza[2], HM. Arredondo-Carrera[2], JE. Gaytan-Arocha[2], RD. Arellano-PerezVertti[2], D. Delgadillo-Gozman[2], AY. Garcia-Marin[1], FO. Gonzalez-Galarza[1], JR. Arguello[1,2], RI. De la Cruz-Granados[2].* 1) Bioinformatics, Instituto de Ciencia y Medicina Genómica, Torreon, Coahuila, Mexico; 2) Facultad de Medicina. Universidad Autónoma de Coahuila. Torreón, Coahuila, México; 3) Facultad de Odontología. Universidad Autónoma de Coahuila. Torreón, Coahuila, México.

IntroductionCongenital dental agenesis consists in the lack of one or multiple permanent teeth in the oral cavity, as a result of molecular anomalies during the first stages of tooth development. Non-syndromic familial hypodontia is usually an autosomal dominant disease, which features incomplete penetrance and variable expression. Mutations related with this disease may present a hypodontia or a saw-like incisors phenotype. Most common mutations occur in MSX1 and PAX9 genes. The aim of this study was to asses mutations on MSX1 gene in patients with non-syndromic hypodontia. **Methods**Non-syndromic dental agenesis of three Mexican families was confirmed with clinical and radiographic findings. For all patients, DNA was obtained through extraction of blood samples. End-point PCR was performed to amplify exons 1 and 2 of MSX1 gene and the 5'à3' byproducts were processed for automatic Sanger sequencing. All sequences were compared with the reference sequence for MSX1 gene published by the NCBI with BioEdit 7. 0 software. **Summary of results**A total of three individuals and both of their parents were included in the study. Family 1, both the subject and father presented hypodontia, while the mother had a saw-like incisors phenotype. The three of them shared the same two mutations: A SNV in position 1423 of 3'UTR region of MSX1 (rs12532) with an AG genotype, and a previously unreported SNV in position 1301 of 3'UTR of MSX1 with an AG genotype. Family2, subject and father had hypodontia. Both of them shared a CC genotype in rs36059701 on exon 1 and a CT genotype on rs8670 in the 3'UTR region. After analysis of both mutations on Polyphen-2, the mutation in rs36059701 is probably not the causal variant of the phenotype. In Family 3, the subject solely presented hypodontia , both parents were unaffected. However, both the subject and the mother presented a heterozygous mutation on rs1095 on 3'UTR region of MSX1. **Conclusion**We have demonstrated five different mutations in MSX1 gene. Four of them have been previously reported on the literature, and we have found a novel variant of unknown clinical significance, due to the fact that it is present along with a known variant, further studies will be required to prove its causative effect. On the other hand, we found an incomplete penetrance and a variable expression in two mutations, phenomena that have been previously described in the literature.

2897W

Achieving genetic diagnosis in families with enlarged vestibular aqueduct using massively parallel sequencing. *C. C. Wu[1,2], Y. H. Lin[1,3], Y. H. Lin[1], C. J. Hsu[1,4], P. L. Chen[3,5].* 1) Department of Otolaryngology, National Taiwan University Hospital, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University College of Medicine, Taipei, Taiwan; 4) Department of Otolaryngology, Taichung Tzu-Chi Hospital, Taichung, Taiwan; 5) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan.

Enlarged vestibular aqueduct (EVA) is a common inner ear malformation associated with sensorineural hearing impairment in children. Although not all, the majority of EVA patients are linked to Pendred syndrome (PS) and non-syndromic DFNB4, two autosomal recessive disorders caused by mutations in *SLC26A4*. However, a significant percentage of EVA patients carry only 1 or 0 mutant *SLC26A4* allele, constituting a dilemma in genetic diagnosis and counseling. In the present study, we designed a massively parallel sequencing (MPS) panel targeting the whole length of three PS/DFNB4 genes (*SLC26A4*, *FOXI1* and *KCNJ10*) and all exons of ten other genes which have been related to EVA. We then compared the diagnostic yields between this one-step MPS panel and the convention genetic examination, i. e. combination of Sanger sequencing and MLPA, in a total of 157 EVA families with non-diagnostic *SLC26A4* genotypes. Using the MPS panel, we identified the second mutant *SLC26A4* allele in 19 (59%) of 32 families with 1 common *SLC26A4* mutant allele detected, including 18 with point mutations and 1 with a novel large 7666-bp deletion (g. -1066C_6602Adel). Meanwhile, the MPS panel confirmed genetic diagnosis in 6 (55%) of 11 families with 0 common *SLC26A4* mutant allele detected, including 3 families with bi-allelic *SLC26A4* mutations, 2 families with dominant *EYA1* mutations (p. R264Q and p. R328X), and 1 family with a dominant *SIX1* mutation (p. T120I). On the other hand, combination of Sanger sequencing and MLPA achieved genetic diagnosis in 52 (58%) of 90 families with 1 common *SLC26A4* mutant allele and 7 (17%) of 24 families with 0 common *SLC26A4* mutant allele, respectively. Our results demonstrated the utility of MPS in addressing EVA families by identifying various types of mutations with satisfactory diagnostic yields in one step.

2898T

Introduction of an effective gene-panel for DNA diagnosis of epidermolysis bullosa and skin fragility. *H. H. Lemmink[1], P. van den Akker[1], K. Abbott[1], M. Meems-Veldhuis[1], A. Scheper[1], M. Viel[1], M. Pasmooij[2], I. Turcan[2], K. Gostynska[2], M. Jonkman[2], R. Sinke[1].* 1) Genetics, University Medical Centre Groningen, Groningen, Netherlands; 2) Dermatology, University Medical Centre Groningen, Groningen, Netherlands.

AimThe number of candidate genes in patients suspected of having epidermolysis bullosa (EB) is large and testing them time consuming. Our aim was to develop a targeted next generation sequencing (NGS) gene panel that enables to analyze the large number of EB-genes in patients with EB and skin fragility at relatively low cost and high speed. MethodsAn EB-panel of 33 genes involved in EB and related skin fragility disorders was developed using the Agilent Sure Select Target Enrichment® for simultaneous mutation detection and validated in 15 patients with 21 gene variants previously identified through Sanger sequencing. The samples were sequenced using 151 base pair paired-end reads on an Illumina MiSeq® sequencer and analyzed using Softgenetics' NextGENe® and Cartagenia's Benchlab NGS® software. Subsequently, for diagnostic purposes, the targeted EB-panel was used to analyze 27 patients, in whom a pathogenic mutation had not been identified. Results and ConclusionIn the validation phase, 20/21 pathogenic mutations, unclassified variants and neutral polymorphisms detected previously were identified by the EB-panel except for one large duplication of 77bp. In 14 out of 27 patients, novel mutations were identified which were all confirmed by Sanger sequencing. The use of this gene panel facilitates a much faster analysis of the large number of currently known EB-genes for mutation analysis than the single gene approach. In three patients, mutations were identified in genes not considered the prime candidates at initial clinical evaluation. Gene panel analysis thus adds to fine tuning of the clinical phenotype and expands the genotype-phenotype correlations for EB. The EB-panel contains genes having known pseudogenes (i. e. KRT5, KRT14, etc) and exons with high sequence homology. Nonetheless, mutations could be accurately mapped to the correct genes based on the accurate detection of single nucleotide variations between genes-pseudogenes and homologous exons by analyzing the sequence of single reads without the need of additional and elaborate techniques.

2899F

Clinical and genetic analysis of Wiedemann–Steiner syndrome caused by *KMT2A* mutations. *N. Miyake[1], Y. Tsurusaki[1], E. Koshimizu[1], N. Niikawa[2], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Health Science University of Hokkaido, Hokkaido, Japan.

Wiedemann–Steiner syndrome (WSS, MIM#605130) is an autosomal dominant congenital anomaly syndrome characterized by hairy elbows, dysmorphic facial appearances (hypertelorism, thick eyebrows, downslanted and vertically narrow palpebral fissures), pre- and post-natal growth deficiency, and psychomotor delay. WSS is caused by heterozygous mutations in *KMT2A* (lysine [K]-specific methyltransferase 2A; NM_001197104. 1, previously called *MLL*), a gene encoding a chromatin methyltransferase. To date, only eight *KMT2A* mutations have been reported with limited clinical features. Here, we identified six novel *KMT2A* mutations in six WSS patients using whole exome sequencing. We confirmed four mutations occurring *de novo*. Interestingly, some of the patients were initially diagnosed with atypical Kabuki syndrome probably owing to overlapping clinical features including similar facial expressions and/or hypertrichosis. Kabuki syndrome is another autosomal or X-linked congenital anomaly syndrome which is caused by mutations in *KMT2D* or *KDM6A*, which are also involved in histone methylation as *KMT2A*. Then, we clinically re-evaluated them and retrospectively diagnosed five of six patients were WSS. Only one patient was initially diagnosed with atypical Kabuki syndrome but could not be clinically re-evaluated because she is now untraceable. Furthermore, we compared 56 clinical features between KS and WSS whose causative mutations have been identified. Long palpebral fissures, ectropion of the lateral third lower eyelids, and short fifth fingers were more commonly observed in KS patients with *KMT2D* mutations. As expected, generalized hypertrichosis was more commonly observed in WSS patients with *KMT2A* mutations. Interestingly, postnatal growth retardation was observed in all WSS patients while it was observed in less than half of KS patients with *KMT2D* mutation. These features may be hallmarks for differential diagnosis, with the other features observed in both WSS and KS. Clinical similarity between WSS and KS may be explained by the common protein function of KMT2A, KMT2D, and KDM6A, as they all play important roles in histone modification, and activate gene expression via H3K4 methylation (KMT2A and KMT2D) or H3K27 demethylation (KDM6A).

2900W

A Novel *OFD1* Missense Mutation Causes an Autosomal Recessive Dyskeratosis Congenita-Like Disorder Further Complicating the Clinical Heterogeneity of *OFD1* Mutations. *H. Shaath[1], A. Fadda[2], Y. Al-Sharraj[1], S. Tomei[3], E. Wang[3], H. El-Shanti[1,4], M. Kambouris[5,6].* 1) Medical Genetics Center, Qatar Biomedical Research Institute, Doha, Qatar; 2) Biomedical Informatics, Sidra Medical & Research Center, Doha, Qatar; 3) Research Branch, Sidra Medical & Research Center, Doha, Qatar; 4) Pediatrics, University of Iowa, Iowa City, IA, USA; 5) Pathology-Genetics, Sidra Medical & Research Center, Doha, Qatar; 6) Genetics, Yale University School of Medicine, New Haven, CT, USA.

A consanguineous [first cousin marriage] family of Arabic ethnic origin with four unaffected siblings and two male siblings affected by a Dyskeratosis Congenita-like disorder, was studied by Genome-Wide SNP homozygosity mapping, functional and positional candidate gene screening by Sanger sequencing,and Whole Genome Sequencing [WGS] to identify the offending gene and mutation. The disorder is marked by short stature, sparse hair including eyelashes, leukoplakia, dental carries and early tooth loss, osteoporosis, skin atrophy and hyper pigmentation, nail dystrophy with longitudinal ridging and splitting without bone marrow involvement. The offending gene was mapped to two possible homozygous genomic regions on chromosomes 3p and 6q cumulatively spanning 24Mb containing 86 protein-coding genes. Functional and positional candidate gene screening by Sanger sequencing for *ARL6IP, BCKDHB, DKC1, DNAH17, EEF1A1, LRIG1, ORC3, POLA1, SLC17A5* and *SYNCRIP*did not identify causative pathogenic mutations. Analyses and mining of WGS data for homozygous variants within the homozygous regions and X-linked variants [as only males are affected] in X-shared regions among affected siblings, identified a homozygous missense c. C2353T/p. P785S mutation in the *OFD1* gene, at Xp22. 2. The mutation co-segregates with the disease phenotype within the family, is absent in all public databases and in 500 ethnically matched control chromosomes. *OFD1* is a 1012 aa protein component of centrioles, controlling centriole length and involved in cilium biogenesis. *OFD1* mutations cause Oral-facial-digital syndrome 1, Simpson-Golabi-Behmel Syndrome Type 2, Joubert Syndrome 10 and Retinitis Pigmentosa 23 displaying significant phenotypic heterogeneity and clinical variability. The c. C2353T/p. P785S mutation ads a Dyskeratosis Congenita-like phenotype to the wide spectrum of *OFD1* disease phenotypes. In addition, it demonstrates that when applying WGS data to clinical diagnoses, all significant variants should be considered and scrutinized for their clinical impact, irrespective of the observed clinical presentation.

Retinitis pigmentosa (RP) is a rare inherited retinal disease affecting 1 in 3,000 to 7,000 of the population. It is featured by juvenile or adult-onset progressive retinal degeneration. The genetic etiology of RP is remarkably heterogeneous, with over 70 disease-causing genes identified. RP can be isolated with no extra-ocular symptoms manifested, or can be syndromic, which is frequently seen in ciliopathies and other syndromes. Recently, occasional reports showed that mutations in syndrome-causing (SDC) genes can also lead to non-syndromic RP. These reports helped to reveal the tissue-specific roles played by those genes and differential damaging effect of their disease-causing variants. However, due to the rarity of these studies, the proportion of non-syndromic RP cases involving SDC genes has never been evaluated. Here, by capture sequencing screening mutations in all genes involved in retinal degeneration phenotype, we systematically evaluated the genetic basis of over 1,200 non-syndromic RP cases. Specifically, we have identified about 20 cases which can be solved by mutations in SDC genes with good confidence. These genes include *BBS1*, *BBS5*, *BBS9*, *IFT140*, *WDR19*, *CLRN1*, *VPS13B*, etc. . The results provide the first estimate that mutations in SDC genes account for approximately 2% of non-syndromic RP cases. Our findings highlight the benefit of including all genes involving retinal degeneration phenotype during molecular diagnosis and provide hints for the retinal biology of these genes and their variants.

2902F

A truncating mutation in *CLMN* is associated with intellectual disability. *A. Alkhateeb[1,2], W. Habbab[1], R. Thompson[1], S. Aburahma[2].* 1) Qatar Biomedical Research Institute, Doha, Qatar; 2) Jordan University of Science and Technology, Irbid, Jordan.

Objectives: Rare autosomal recessive disorders have a higher occurrence in Arab countries due to higher rate of consanguinity. Here, we identified a consanguineous Arab family co-segregating a phenotype of intellectual disability in two out of a seven sibs, all children were females. We aimed to characterize the genetic etiology causing the phenotype in this family. **Methods:** One patient and the parents were genotyped by Illumina chip microarray to identify homozygous intervals. This was followed by whole exome sequencing. Mutations were filtered using Ingenuity variant analysis and validated by Sanger DNA sequencing. **Results:** Homozygosity intervals were identified in chromosomes 5, 8, 11, 13, 14, 18, 19, 20. After filtration, only 3 mutations were identified in the homozygosity intervals. Two missense mutations were reported previously and one frameshift mutation has not been reported in any database; c. 2585_2586insT (K863*) in *CLMN* gene (NM_024734. 3) results in truncation of the protein and a loss of 140 amino acids from the c-terminal domain which includes the transmembrane domain. The mutation was validated by Sanger sequencing and it was neither found in 200 controls from the same community nor found in any database. *Clmn* is needed both for all-trans retinoic acid to induce mouse neuroblastoma cells exit of cell cycle (requisite step in neuronal differentiation) and for the promotion of elongation and outgrowth of neurites. In addition, *Clmn* downregulates the expression of cyclin D1, which plays a key step in the decision to move through the G1 to S transition and cell cycle progression. In developing mouse embryos, *Clmn* is expressed in actively proliferating cells and in differentiating neurons. **Conclusion:** We have identified a novel truncating mutation in *CLMN* gene in a consanguineous family segregating intellectual disability phenotype. *CLMN* gene product plays an important role in neurogenesis and is found in regions where newly differentiated neurons are located and it is expressed in adult hippocampus and cerebellum, thus considered a plausible candidate gene. This is the first study to implicate *CLMN* gene in the pathogenesis of intellectual disability. Functional analysis should confirm the role of this mutation.

An Integrative Approach to Characterizing Human Diseases and Identifying Human Disease Genes. *A. Chhibber, J. Li, N. B. Asadi, H. Y. K. Lam.* Bina Technologies, Roche Sequencing, Redwood City, CA.

As the accessibility of sequencing data grows, exploration of potential disease-causing genetic events across the exome have become more and more commonplace. In such studies, mutations or other genetic perturbations that impact disease causality must be culled from the complex genetic background in individuals. For example, identification of disease-causing mutations from sequencing data typically involves narrowing thousands of variants down to a set of potentially pathogenic events. However, given that even healthy individuals carry on the order of 100 loss-of-function events, determining precisely which genes play a role in disease causality remains a significant challenge without extensive experimental follow-up. Computational approaches to gene-disease association can aid in identification and prioritization of candidates. A number of characteristics have been identified that each independently show modest utility in separating disease genes from non-disease genes, including the number and type of interactions with other genes or proteins, evolutionary conservation and polymorphism across human populations, and the size of the gene, among others. However, given that human diseases vary greatly in their pathogenesis and clinical severity, it is likely that different features will be valuable in identifying gene-disease relationships for different disease types.

In this study, we use the Human Phenotype Ontology to study the characteristics of human disease causing genes by disease type, and identify unique signatures of disease genes for different human disease classes. Further, we create a comprehensive database of genic features (including network centrality measures from protein-protein and coexpression networks, presence and role in biological pathways, gene expression signatures, known or predicted function, direct and indirect interacting genes, conservation across species, variation across human populations, as well as additional sequence and structural features) for human genes that can be used to facilitate interpretation of human disease-gene studies and identify potential novel disease genes.

Progressive encephalopathies in children: Clinical and molecular characterization. *E. Frengen[1], C. R. J. Pedurupillay[1], T. Barøy[1], A. Holmgren[1], M. D. Vigeland[1], T. Hughes[1], J. R. Helle[1], N. Skauli[1], I. Akkouh[1], E. Carlsen[1], S. S. Amundsen[1], M. Fannemel[1], D. Misceo[1], P. Strømme[2].* 1) Department of Medical Genetics, Oslo University Hospital and University of Oslo, Oslo, Norway; 2) Women and Children's Division, Department of Clinical Neurosciences for Children, Oslo University Hospital and University of Oslo, Oslo, Norway.

Progressive encephalopathies (PE) in children are clinically and genetically heterogeneous. Affected individuals usually exhibit developmental arrest before regression, and cerebral MRI show loss of neural tissue or abnormal signaling intensity. Our aim was to identify disease-causing genetic variants in undiagnosed PE and to perform functional analyses in novel disease genes. CNS infection, trauma, vascular accidents and sequelae after asphyxia and/or prematurity were ruled out. We have so far collected 80 PE patients from 50 families presumed to have a genetic etiology. Neurological signs included: ataxia, epilepsy, dystonia, autism, spasticity, retinopathy (stationary or progressive), dementia, intellectual disability, peripheral neuropathies and encephalopathies. Cerebral MRI examinations revealed cortical atrophy, subcortical white matter changes, cerebellar degeneration, or basal ganglia abnormalities. Congenital anomalies and dysmorphic traits, also those outside the nervous system, were evaluated using the London Medical Database for syndrome identification. After karyotyping, aCGH and analysis of candidate genes by MLPA and/or Sanger sequencing, we performed Whole Exome Sequencing (WES) in family trios (one child and parents) or inverted trios (two children and one parent) and continued with data filtering (population frequency, estimated severity of variants, inheritance pattern). Genetic variants were verified with Sanger sequencing and studied *in silico*. Hypotheses about their molecular consequences were explored in *in vitro* experiments in cell lines mostly established from the patients. We have so far detected the putative disease causing gene variant in 24 out of 50 families. In six families the genetic findings immediately led to a change in treatment: e. g. diet adjustment, hematopoietic stem cell transplantation (HSCT), or administration of NMDA receptor antagonists or a dopamine agonist. Six of the disease-causing variants were identified in genes not previously linked to human disease. These are studied functionally. We perform Whole Genome Sequencing on selected families where we have not detected clinically relevant WES results.

2905F

Canine disorders as models for corresponding human conditions - new mutations and aspects of rare diseases. *M. K. Hytönen[1,2,3], M. Arumilli[1,2,3], S. Hundi[1,2,3], E. Salmela[1,2,3], A. K. Lappalainen[4], T. Jokinen[4], P. L. Lukinmaa[5], E. Sarkiala-Kessel[4], A. Iivanainen[2], J. Kere[3], P. Nieminen[5], H. Lohi[1,2,3].* 1) Research Programs Unit, Molecular Neurology, Faculty of Medicine, University of Helsinki, Helsinki, Finland; 2) Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland; 3) Folkhälsan Research Center, Helsinki, Finland; 4) Equine and Small Animal Medicine, Faculty of Veterinary Medicine, University of Helsinki, Helsinki, Finland; 5) Department of Oral and Maxillofacial Diseases, Faculty of Medicine, University of Helsinki, Helsinki, Finland.

Dog has established its position as a comparative model for human medicine due to shared genes, disorders and physiology with man. Our canine disease genetics program aims not only to improve canine health but also to provide information about the gene function and disease pathology that can be applied in human medicine. In this study, we have utilized various clinical, pathological and genetic approaches e. g. genome wide association study (GWAS), whole exome sequencing (WES) and whole genome sequencing (WGS) to clinically and genetically characterize several canine Mendelian diseases. First, we have encountered a dental disease with hypomineralized dentine resulting in severe attrition of teeth. Through WGS of affected and control dogs and filtering according to recessive model, we identified a mutation in FAM20C gene that has previously been associated with human hypophosphatemia conditions (Raine syndrome). Second, we describe a novel developmental disorder with prominent mandibular prognathia and joint hyperlaxity. We performed GWAS and mapped a locus overlapping human 22q11. 2 deletion syndrome region. Subsequently, we performed targeted resequencing for the associated region using two cases and three controls. We identified a homozygous variant likely causing the disease, and are currently validating the variant to confirm its causality. In addition, we have ongoing WES and WGS analyses on several other disorders that are expected to reveal a number of new disease mutations. This study establishes large animal models for human rare disorders for improved understanding of gene functions, disease mechanisms and comparisons of phenotypic overlaps across species. Dogs share many rare disorders with human and could serve as important preclinical models for new therapeutic approaches.

A point mutation in *PDGFRB* causes autosomal dominant Penttinen syndrome. *J. J. Johnston[1], M. Y. Sanchez-Contreras[2], K. Keppler-Noreuil[1], J. Sapp[1], M. Crenshaw[1], V. Cormier-Daire[3], R. Rademakers[2], V. P. Sybert[4], L. G. Biesecker[1].* 1) Medical Genomics and Metabolic Genetics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 2) Department of Neuroscience, Mayo Clinic, Jacksonville, FL; 3) INSERM, Département de Génétique, Université Paris Descartes Sorbonne Paris Cité, Institut Imagine, Hôpital Necker-Enfants Malades, Assistance Publique-Hôpitaux de Paris, Paris; 4) Division of Medical Genetics, University of Washington School of Medicine and Group Health Cooperative, Seattle, WA.

Penttinen syndrome is a distinctive disorder characterized by a prematurely aged appearance with lipoatrophy, epidermal and dermal atrophy along with scar-like hypertrophic lesions, thin hair, proptosis, underdeveloped cheekbones, and marked acro-osteolysis. All patients have been sporadic. Exome sequencing of an affected individual identified a *de novo* c. 1994T>C p. Val665Ala variant in *PDGFRB*, which encodes the platelet-derived growth factor receptor b. Three additional unrelated individuals with this condition were shown to have the identical variant in *PDGFRB*. Surprisingly, mutations in this gene have previously been associated with three other disorders. Distinct mutations in *PDGFRB* have been shown to cause infantile myofibromatosis, idiopathic basal ganglia calcification type 4, and an overgrowth disorder with dysmorphic facies and psychiatric symptoms, none of which overlaps with the clinical findings in Penttinen syndrome. Based on these substantially heterogeneous clinical phenotypes, we hypothesized that at least three of the four disorders were caused by gain of function mutations that activated distinct downstream signaling effectors. We evaluated the functional consequence of the Penttinen variant on the PDGFRB signaling pathway by transfecting mutant and wild-type cDNA into HeLa cells, showing that this mutation leads to ligand-independent constitutive signaling through STAT3 and PLCγ. We are currently evaluating the signaling consequences of other putative gain of function mutations in this gene. Based on these results, we conclude that Penttinen syndrome is a clinically distinct genetic condition caused by a gain of function mutation in *PDGFRB* that is associated with a specific and unusual perturbation of receptor function with aberrant STAT3 and PLCγ signaling.

2907T

The mutation spectrum of a large Brazilian inherited retinal disease cohort. *E. M. Jones[1, 2], Z. Soens[1, 2], S. A. Sampaio[3], I. F. G. Sena[4], K. C. S. Magalhaes[4], Y. Li[1, 2], S. Xu[1, 2], R. T. Simoes[4], F. B. O. Porto[3, 5], R. Chen[1, 2].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) INRET - Clínica e Centro de Pesquisa, Belo Horizonte, Minas Gerais, Brazil; 4) Instituto de Ensino e Pesquisa da Santa Casa de Belo Horizonte, Belo Horizonte, Minas Gerais, Brazil; 5) Departamento de Retina e Vítreo, Centro Oftalmológico de Minas Gerais, Belo Horizonte, Minas Gerais, Brazil.

Inherited retinal dystrophies (IRDs) affect approximately 1 in 2,000 individuals. These disorders range from most severe cases of congenital blindness to more delayed cases of progressive visual and retinal degeneration in adulthood. A significant amount of clinical and genetic heterogeneity among these disorders makes diagnosis difficult without comprehensive sequencing of potentially causative genes. IRDs, moreover, can manifest in autosomal dominant, autosomal recessive, and X-linked inheritance patterns, adding to the complexity. Cohort studies in multiple populations have highlighted distinct genetic effects based on population. Here we characterize the molecular cause of IRDs in a large Brazilian cohort, a prominent world population that has largely remained unstudied. We report on the molecular diagnosis of 231 individuals in an available cohort of 1,492 Brazilians affected by IRDs. Through targeted capture and next-generation sequencing of 224 known retinal disease genes, we identify the leading molecular causes of retinitis pigmentosa (RP), Leber's congenital amaurosis (LCA), Stargardt's disease, and Usher syndrome among numerous other IRDs in our cohort. The solving rates for IRDs found within our cohort are slightly higher than generally reported rates in the current literature. This is likely in part a result of improved access to reported pathogenic variants in numerous publicly accessible databases. Roughly 35% of pathogenic variants in our cohort have been previously reported to cause retinal disease. The other 65% are novel variants likely to be pathogenic as either putative loss-of-function variants or predicted damaging variants in a gene associated with the expected diagnosis. Notably, 11% of RP individuals were found to have pathogenic or likely pathogenic variants in *GPR98*. This is a much higher percentage than what is seen in other populations and may highlight the presence of a founder mutation. Furthermore, in LCA individuals the most common genes were *CRB1* (12%) and *ABCA4* (12%) with less than 1% of individuals affected by *CEP290* variants, differing significantly from that observed in Caucasian populations. These findings highlight the need for a precise and population-based molecular diagnosis of IRDs. With the development of current gene therapies for diseases such as LCA, an accurate molecular diagnosis is essential for appropriate genetic counseling and informed treatment recommendations.

2908F

A *PPP1R21* Frame-Shift Insertion Mutation Causes a Novel Autosomal Recessive Neuro-Developmental Disorder. *M. Kambouris[1,2], A. Rajab[3], A. Fadda[4], H. Shaath[5], Y. Al-Sarraj[5], S. Tomei[6], E. Wang[6], H. El-Shanti[5,7].* 1) Pathology-Genetics, Sidra Medical & Research Center, Doha, Qatar; 2) Genetics, Yale University School of Medicine, New Haven, CT, USA; 3) National Genetic Center, Ministry of Health, Muscat Oman; 4) Biomedical Informatics, Sidra Medical & Research Center, Doha, Qatar; 5) Medical Genetics Center, Qatar Biomedical Research Institute, Doha, Qatar; 6) Research Branch, Sidra Medical & Research Center, Doha, Qatar; 7) University of Iowa, Pediatrics, Iowa City, IA, USA.

A consanguineous [second cousin marriage] family of Arabic ethnic origin with two unaffected male siblings and two female siblings affected by a novel neuro-developmental disorder, was studied by Genome-Wide SNPhomozygosity mapping and Whole Genome Sequencing [WGS] to identify the offending gene and mutation. The disorder is marked by cognitive impairment, severe global developmental delay, and congenital malformations that include macrocephaly, coarse facial features, prominent forehead with bitemporal narrowing, telecanthus,blue sclerae, with convergent squint, prominent nasal bridge, long philtrum, low set ears, pectus carinatum, scoliosis, in-toeing and delayed bone age. Neurologic findings include attention deficit, dysarthria, hypotonia, clumsy ataxic gait and urinary and fecal incontinence. Brain MRI showed mild vermis hypoplasia, deep sulcation and thinning of the white matter at presylvian region bilaterally, in post portions of the brain, persistent cavum septi pellucidum. Additional findings include alternate esotropia, extensive caries and cardiac ASD in the older sibling, and myoclonus epilepsy in the younger. The offending gene was mapped to three possible homozygous genomic regions on chromosomes 2p, 10q and 20q, cumulatively spanning 20Mb containing 77 protein-coding genes. Analyses and mining of WGS data for homozygous variants within the homozygous regions from one affected sibling identified a homozygous protein-truncating c. 2169_2170insAGGT/p. K724fs, 4-bp insertion frame shift mutation in the *PPP1R21* gene, at 2p16. 3. *PPP1R21* [Protein Phosphatase 1, regulatory subunit 21] is a 780 aa protein with phosphatase binding properties and scant functional information. The c. 2169_2170insAGGT/p. K724fs insertion eliminates the last 45 C-terminal amino acids and causes a p. K724R substitution, immediately encountering a stop codon at position 725. The mutation co-segregates with the disease phenotype within the family, is absent in all public databases and in 500 ethnically matched control chromosomes. To date, this is the first report associating *PPP1R21* to an autosomal recessive neuro-developmental disorder.

2909W

A New Retinits Pigmentosa Gene Identified by Homozygosity Mapping and Whole Genome Sequencing. *N. H. Wang[1,2,3], S. J. Chen[4,5], C. F. Yang[2], H. W. Chen[2], H. P. Chuang[2], Y. H. Lu[6,7], Y. H. Huang[6,8], M. Y. Lo[6], C. H. Chen[2], Y. T. Chen[2], D. M. Niu[6,7], J. Y. Wu[2].* 1) Inst Biomedical Sci, Academia Sinica, Nankang, Taipei, Taiwan; 2) Molecular Medicine Program, Taiwan International Graduate Program; 3) Institute of Biochemistry and Molecular Biology, School of Life Sciences, National Yang-Ming University, Taipei, Taiwan; 4) Department of Ophthalmology, Taipei Veterans General Hospital, Taipei, Taiwan; 5) School of Medicine, National Yang-Ming University, Taipei, Taiwan; 6) Department of Pediatrics, Taipei Veterans General Hospital, Taipei, Taiwan; 7) Institute of Clinical Medicine, School of Medicine, National Yang-Ming University, Taipei, Taiwan; 8) Institute of Clinical and Community Nursing, School of Nursing, National Yang-Ming University, Taipei, Taiwan.

Retinitis Pigmentosa (RP) is an inherited retinal degeneration that leads to blindness and is characterized with broad heterogeneity both clinically and genetically. While more than 50 genes have been identified for the disease, these represent the cause in only 60% of the patients. To identify the gene mutation responsible for five families diagnosed with autosomal recessive RP (arRP) from a close community in Taiwan, we analysed the whole genome SNP genotypes of these family members with homozygosity mapping and located a 1. 8Mb region shared by all patients. Next generation sequencing was carried out and identified a missense mutation from this homozygous region. We have confirmed this mutation in all patients by Sanger sequencing and showed co-segregation in all five families. The identified mutation was cloned and expressed, and the protein was purified to compare the enzyme activity between wildtype and mutant proteins. We showed that the identified mutation resulted in decreased enzyme activity. The identified mutation locates in the coding region of an enzyme involved in glycosylation and was previously found to be responsible for several types of muscular dystrophies, including Walker-Warburg syndrome (WWS) or muscle-eye-brain disease (MEB), in addition to the less severe congenital form with mental retardation and a milder limb-girdle form. This is the first finding on the involvement of this gene in arRP.

2910T

***De novo* heterozygous *GMNN* mutations cause autosomal dominant primordial dwarfism associated with Meier-Gorlin syndrome.** *Y. Yang[1,6], L. C. Burrage[1], M. K. Eldomery[1], J. R. Willer[2], Z. Akdemir[1], M. Azamian[1], G. Zapata[1], W. Zhu[6], P. P. Hernandez[1], E. Davis[2], D. Lugtenberg[3], J. Schoots[3], S. Munnik[3], R. Roepman[3], S. Jhangiani[4], K. Katsanis[2], L. E. Vissers[3], H. G. Brunner[3], D. M. Muzny[4], R. A. Gibbs[1,4,6], C. M. Eng[1,6], J. R. Lupski[1,5], F. Xia[1,6], S. R. Lalani[1], E. M. H. F Bongers[3].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC; 3) Department of Human Genetics, Radboud university medical center, Nijmegen, the Netherlands; 4) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 5) Department of Pediatrics, Texas Children's Hospital, Houston, TX; 6) Exome Laboratory, Baylor Miraca Genetics Laboratories, Houston, TX.

Meier-Gorlin Syndrome (MGS) is a genetically heterogeneous primordial dwarfism syndrome caused by biallelic loss of function mutations in one of the five genes encoding pre-replication complex proteins: *ORC1*, *ORC4*, *ORC6*, *CDT1*, and *CDC6*. The molecular etiology was established in about three-fourths of MGS patients with disruption of the origin of replication initiation step as the primary cause and autosomal recessive as inheritance manner in all individuals studied. In about one-fourth of the clinically ascertained MGS patients, a molecular diagnosis is not obtained, suggesting the existence of additional causal genes for MGS. Here, we described three patients with a clinical diagnosis of MGS but who tested negative for pathogenic variants in the aforementioned known MGS disease genes. The patients shared clinical features including dwarfism, absent or hypoplastic patellae and microtia as well as the hallmark facial features of full lips with distinct ear abnormalities, narrow nose, high nasal bridge, microstomia, and micro/retrognathia. Heterozygous mutations located in the 5' end of the *GMNN* gene including p. K6X in patient 1 (nonsense), p. I12fs in patient 2 (frameshift) and p. K17R in patient 3 (missense) were identified by exome sequencing (patient 1 and 2) or Sanger sequencing (patient 3). Family studies did not detect the changes in the biological parents, indicating the three variants arose *de novo* in the patients. *GMNN* encodes geminin, an inhibitor of DNA re-replication that is expressed during the S and G2 phases of the cell cycle and degraded during the metaphase-anaphase transition by the anaphase-promoting complex (APC) recognizing the destruction box sequence in the geminin protein. Geminin acts by inhibiting DNA replication factor Cdt1, which has been known to be associated with MGS, and prevents loading of minichromosome maintenance proteins Mcm2-7 to the origins of replication. All the three *GMNN* mutations in our patients occurred 5' to the destruction box that is located from amino acid p. R23 to p. P31. We hypothesize that these MGS associated variants result in gain of function geminin proteins with diminished destruction signal, leading to increased protein stability, sequestered Cdt1 and decreased replication. In summary, gain of function de novo mutations in a candidate new disease gene *GMNN* causing inhibition of replication via sequestration of Cdt1 is the likely mechanism for the dominantly inherited MGS in the three individuals.

2911F

Mutation spectrum of autosomal recessive retinitis pegmentosa patients of India identified by whole exome sequencing. *X. J. Zhu[1], Y. Zhou[1], Y. Di[1], Z. Jiang[1], X. Zhu[1], P. Sundaresan[2], Z. Yang[1].* 1) Center for Molecular Genetics, Sichuan Provincial People's Hospital, Chengdu, Sichuan, China; 2) Department of Genetics, Aravind Medical Research Foundation, Aravind Eye Hospital, Madurai, Tamilnadu, India.

Retinitis pigmentosa (RP) is a group of inherited retinal diseases affecting the light-sensing photoreceptor cells. It is caused by mutations in at least 50 genes. However, known mutations can only explain around 55% of RP patients. To identify genetic mutations underlying autosomal recessive retinitis pigmentosa (arRP), we performed whole exome sequencing study on 14 consanguineous marriage Indian families. Here we reported identified mutations in *FAM161A, EYS, PDE6B*, *TRIM1*, *BBS10* and *NR2E3 in 10* families. Sequencing analysis revealed the presence of a novel homozygous frame shift mutation p. R592FsX2 in both patients of family RP-252 and family RP-182. We also identified two novel homozygous mutations *EYS* in families with arRP. Mutation types identified include missense mutation, frameshift deletion, and stopgain. Meanwhile, these mutations were absent in 1000 ethnicity-matched control samples screened by direct Sanger sequencing. In conclusion, we identified novel mutations of FAM161A, EYS, PDE6B, TRIM1, BBS10 and NR2E3 in arRP patients in India population. Our study expands our knowledge of mutation spectrum of arRP in India population.

2912W

The INVESTICATE project: Identification of New Variation, Establishment of Stem cells, and Tissue Collection Aimed at Treatment Efforts. *L. Crapper[1,2], R. Pujol[2], W. Al-Hertani[4], C. Ernst[3,4].* 1) Integrated Program in Neuroscience. McGill University, Montreal, QC; 2) McGill Group for Suicide Studies, Montreal, QC; 3) Department of Psychiatry, McGill University, Montreal QC; 4) Department of Medical Genetics, Alberta Children's Hospital, Calgary, AB.

Neurodevelopmental disorders (NDDs) are a large and complex group of disorders with varying etiologies. Recent advances in genomics and sequencing technologies have accelerated the pace of discovery of genes associated with NDDs, and suggested a large portion of non-syndromic NDDs are caused by rare, highly penetrant genetic variations. Exome sequencing studies and analysis of copy number variations in families are very effective in characterizing the genetic variability inherent in NDDs and suggesting that causal mutations cluster in several biological pathways, but so far they have not been successful in leading to the development of treatments for NDDs. The INVESTICATE project recruits patients for whom traditional genetic analysis has not identified the cause of their NDD, and uses exome or whole genome sequencing to provide state-of-the-art genetic information to families. After variant identification we generate patient derived induced pluripotent stem cells, which are used to determine functional information about the genetic variants we have identified. Stem cell data is complemented by the collection of whole brains from those cases that die during the course of the study. Finally we use high throughput screening to assess potential therapeutic molecules. INVESTICATE aims to provide genetic information to families not avialble through the pubic health system, understand how genetic variants cause neurological disease, and develop therapeutic strategies to provide treatment to affected individuals.

2913T

***HERC1*: a possible new candidate gene for Intellectual Disability.** *A. Das Bhowmik[1], S. Aggarwal[1,2], A. Dalal[1].* 1) Diagnostics Division, Centre for DNA Fingerprinting and Diagnostics, Hyderabad, India; 2) Department of Medical Genetics, Nizam's Institute of Medical Sciences, Hyderabad, India.

We studied a consanguineous family with unique phenotype of cognitive delay and dysmorphism in two affected children of both sexes. We did exome sequencing for both the affected children to assess coding sequence variants. Exome capture was performed on genomic DNA sample using Agilent SureSelect V5 exome capture kit. The libraries were sequenced to mean >80-100X coverage on Illumina HiSeq2000 platform. The reads obtained were mapped against human reference genome (GRCh37/hg19) followed by detection of SNPs and small indels. Variant annotation was performed using Annovar for location and predicted function. Exome sequencing analysis identified a novel c. 4906-2A>C 3' splice-site mutation variant in *HERC1* gene. The variant was shared by both the siblings. Array comparative genomic hybridization (CGH) was also performed in one affected child using Affymetrix CytoScan 2. 7M Array which identified a 12. 9 Mb LOH region on chromosome 15. *HERC1* gene was present in this region. Sanger sequencing in both the siblings and mother confirmed presence of the mutation in children and heterozygous status in mother. Further cDNA analysis using SuperScriptTM III First-Strand cDNA Synthesis assay system (Invitrogen) in both the patients revealed that this mutation results in a 10 base pair deletion in exon 27 leading to a frameshift that is likely to result in premature truncation of the protein at 1663 amino acids from start codon (original protein size 4861 amino acid). This is likely to affect the protein function which ultimately can lead to the disease. Herc1 is a giant protein with multiple structural domains, expressed ubiquitously in all human and mouse tissues, with the highest level of expression in testis and brain. This protein is believed to be involved in intra cellular membrane trafficking and ubiquitinization of specific targets which are essential for eukaryotic cell function. Recently another member of this group of protein family (Herc2) has been implicated in nonsyndromic intellectual disability and autism. Till date no other disease causing mutation in humans has ever been reported in *HERC1* gene. Hence we suspect *HERC1* could be a new candidate gene for intellectual disability. Further functional characterization of this mutation is in progress.

***De novo* mutations in *KAT6A* identified by whole exome sequencing cause a neurodevelopmental disorder with syndromic features.** *F. Millan[1], M. T. Cho[1], K. Retterer[1], K. G. Monaghan[1], R. Bai[1], P. Vitazka[1], D. B. Everman[2], B. Smith[2], N. L. Champaigne[2], L. M. Baggett[2], B. Angle[3], V. Roberts[3], L. Immken[4], H. Nagakura[4], M. DiFazio[5], E. Sherr[6], E. Haverfield[1], B. Friedman[1], A. Telegrafi[1], J. Juusola[1], W. K. Chung[7], S. Bale[1].* 1) GeneDx, Gaithersburg, MD, USA; 2) Greenwood Genetic Center, Greenwood, SC, USA; 3) Ann & Robert H. Lurie Children's Hospital of Chicago, Chicago, IL, USA; 4) Specially For Children Genetics, Austin, TX, USA; 5) Department of Neurology, Children's National Health Care System, Washington, DC, USA; 6) Institute of Human Genetics, University of California, San Francisco, San Francisco, CA, USA; 7) Departments of Pediatrics & Medicine, Columbia University Medical Center, New York, NY, USA.

Neurodevelopmental disorders (NDDs) affect 1-3% of the general population. Their underlying genetic cause remained unexplained in many patients until next generation sequencing became available in clinical practice. Clinical whole-exome sequencing (WES) has become a powerful tool for the identification of pathogenic variants leading to Mendelian disorders, among which NDDs represent a large proportion. Performing WES with a trio approach has proven to be extremely effective in identifying *de novo* variants as a common cause of NDDs. Recently, *de novo* pathogenic variants in *KAT6A* have been reported to cause syndromic intellectual disability, including hypotonia, microcephaly, facial dysmorphism, craniosynostosis and/or cardiac defects. The mutation spectrum included sequence variants in exons 17 and 18 resulting in premature stop of translation, and one gene deletion encompassing the entire reading frame of *KAT6A*. We report seven additional unrelated individuals with a strikingly similar NDD phenotype including hypotonia, severe speech delay, and facial dysmorphism. Two of them had microcephaly and one congenital heart disease. WES trio testing revealed that each proband was heterozygous for a novel, *de novo* variant in the *KAT6A* gene. These variants included 2 frameshift and 3 nonsense variants in exons 7, 17 and 18, 1 canonical splice site variant predicted to damage the acceptor site for exon 18 and 1 missense variant located at the catalytic MYST-type histone acetyltransferase domain of the protein. The *KAT6A* gene encodes a histone acetyltransferase that has long been known for its structural involvement in acute myeloid leukemia. Loss of protein function in a published mouse model demonstrated craniofacial and cardiac defects due to homeotic transformations of both the axial skeleton and neural tube, suggesting that *KAT6A* plays a crucial role in development of the brain, face, and heart. In summary, our data expand the mutation spectrum of this newly described condition and identify exons 17 and 18 of *KAT6A* as mutation hotspots. Furthermore, we demonstrate that loss of *KAT6A* function is associated with a recognizable and relatively consistent phenotype.

2915W

A founder mutation in *C12orf4* gene - A candidate gene for autosomal recessive non-syndromic intellectual disability (NSID). *A. K. Philips[1], M. Pinelli[2,3,4], Y. C. Chen[5], A. Mustonen[6], T. Järvelä[1].* 1) Department of Medical Genetics,University of Helsinki, Finland; 2) Department of Human Genetics, Nijmegen Centre for Molecular Life Science and Institute for Genetic and Metabolic disorders, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands; 3) Dipartimento di Medicina Molecolare e Biotechnologie Mediche Université, Degle Studi di Napoli "Federico II", Italy; 4) Telethon Institute of Genetics and Medicine, Pozzuoli, Italy; 5) Neuroscience Center, Institute of Biomedicine, Department of Anatomy, University of Helsinki, Finland; 6) Department of Clinical Genetics, Medical Research Centre Oulu, Oulu University Hospital and University of Oulu, Finland; 7) Joint Authority for Kainuu, Disability services, Kainuu, Finland; 8) Department of Biochemistry, University of Western Ontario, Medical Sciences Building Rm. 342, Ontario, N6A 5C1, London, Canada.

Background: Intellectual disability is a major health problem in our society. Non-syndromic intellectual disability (NSID) represents a heterogeneous group of diseases that is often a diagnostic challenge in clinical medicine. **Methods and Results**: To facilitate gene identification, we applied whole-exome sequencing (WES) in a family with non-syndromic ID (NSID). This family originates from an isolated population in North-Eastern Finland. We found a missense variant in*C12orf4*gene on chromosome 12 in a consanguineous family with four affected males. The variant is inherited as an autosomal recessive trait. This variant has a high CADD score (23. 4), a high phyloP score (5. 02) and was predicted to be deleterious by the Condel server. Screening of our cohort of 200 NSID patients let to the discovery of another consanguineous family with two affected females and one affected male with the same missense mutation. In addition, two heterozygous carriers with different phenotypes were also found. The variant is enriched in the North Eastern subisolate of Finland with a carrier frequency of 1:53, characteristic to a founder effect. Localization studies in SH-SY5Y neuronal cells indicate that both the normal and mutated constructs are localized to the cell cytoplasm. Clinical features of the affected individuals are characterized by mild to severe NSID and delayed speech development. A frameshift mutation in exon 6 of the*C12orf4*gene has been previously reported in a Saudi family with three affected individuals with intellectual disability, ADHD and non-specific MRI changes. Our preliminary findings suggest that mutation in*C12orf4*gene causes autosomal recessive non-syndromic intellectual disability. **Ongoing work**: The function of this gene is not yet known. We are currently in the process of functionally characterizing this gene in zebrafish.

2916T

Analysis of a cohort of Polish patients with X linked intellectual disability by the targeted X chromosome exome sequencing (NGS). *S. O. Rzońca[1], M. Gos[1], A. Landowska[1], A. Charzewska[1], A. Kutkowska-Ka%8;mierczak[1], J. Castaneda[1], M. Janeczko[2], R. Posmyk[3], P. Stawiński[4], M. Rydzanicz[4], J. Kosińska[4], E. Obersztyn[1], R. Ploski[4], J. Bal[1].* 1) Department of Medical Genetics, Institute of Mother and Child, Warsaw, Poland; 2) Department of Medical Genetics, University Children's Hospital of Cracow, Cracow, Poland; 3) Centre of Clinical Genetics GENETICS, Bialystok, Poland; 4) Department of Medical Genetics, Medical University of Warsaw, Warsaw, Poland.

X-linked intellectual disability (XLID) is a term describing clinical entities caused by mutations in genes located on the X chromosome. Until recently, around 114 genes have been shown to be involved in NS-XLID, making a systematic screen useless in the diagnostic routine. The new molecular approach, next generation sequencing (NGS), provides a unique opportunity to analyze almost entire coding sequence of the chromosome X and is a promising method for the discovery of rare, disease causing sequence variants. In our study, we have performed the X chromosome exome sequencing to identify potentially pathogenic mutations in novel and/or known genes in patients with unexplained ID with a family history suggesting the X-linked inheritance. Twenty patients with excluded chromosomal aberrations (aCGH) and mutation in *FMR1* gene, were examined by targeted X chromosome sequencing. The X chromosome exome libraries were prepared with SureSelectXT X-Chromosome panel (Agilent, CA, USA) and sequenced on HiSeq1500 Sequencer (Illumina, CA, USA). Eleven potentially pathogenic variants were selected based on the results of *in silico* prediction tests (e. g. MutationTaster, SIFT, CADD) and data from population frequency databases (1000Genomes, ExAC, NHLBI/EVS, in-house variant database). The cosegregation analysis of the selected variants with phenotype confirmed the possible pathogenicity for 5 variants. Together, we have identified novel, not previously described, variants in 3 known genes associated with XLID (missense variants: *UBE2A*, *MID1,* nonsense: *DCX*). Moreover, variants in 2 new candidate genes have been found (nonsense variant: *FRMPD4*, missense: *MID2*). The functional analysis of the gene product function indicated that the proteins encoded by these genes are involved in proliferation, differentiation, adhesion and cell growth as well as ubiquitination and neuronal migration process. In conclusion, we have identified likely pathogenic mutations in 25% of the investigated patients (5/20). To further confirm the relation of novel variants with the etiology of intellectual disability, additional functional studies are needed. However, the presented data confirms that the NGS technique is highly useful tool to search for new variants in genes related to X – linked intellectual disability.

2917F

DCHS2, a novel autosomal recessive cause of Van Maldergem Syndrome. *N. Voisin[1], L. Ambrozaityte[2], A. Morkuniene[2], L. Gueneau[1], K. Mannik[1], Z. Ciuladaite[2], E. Preiksaitiene[2], E. Pranckeviciene[2], T. Rancelis[2], L. Cimbalistiene[2], N. Guex[3], V. Kucinskas[2], A. Reymond[1].* 1) Center for Integrative Genomics, University of Lausanne, Genopode Building, CH-1015, Lausanne, Switzerland; 2) Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, 08661, Vilnius, Lithuania; 3) Swiss Institute of Bioinformatics, Genopode building, CH-1015, Lausanne, Switzerland.

Within the frame of a Swiss-Lithuanian collaboration, we enrolled 132 families with one or two members affected with intellectual disability (ID) or developmental delay. 17 patients/families (12%) were found to carry causative CNVs such as del10q22. 1-q22. 3, del6q16. 1-q22. 31, del17p13. 2-p13. 3 and mos dup8p11. 22-q11. 23. The remaining patients and their unaffected parents and siblings were subjected to exome sequencing. In families with multiple affected members, variants were filtered based on quality scores, population prevalence, predicted deleterious and adherence to either an autosomal recessive inheritance or being *de novo* in both patients. For instance, we identified a family where 2 brothers shared mild ID with developmental delay (delayed speech and walk), a long face with synophrys, dental malocclusion, optic nerve atrophy, clinodactyly and skeletal abnormalities (arthralgia, joint dislocations, disc hernia and scoliosis). The older brother showed additional features such as strabismus, ptosis, high arched palate, sleep disturbance and hippocampal hypoplasia, whereas the younger one displayed febrile seizures, microdontia and optic nerves chiasm. Consistent with an autosomal recessive pathology they both harbored 4 heterozygous variants in *DCHS2*, 2 maternally- and 2 paternally-inherited. This cadherin gene is a paralog, of *DCHS1* and *FAT4*, mutations of which were previously associated with Van Maldergem syndrome 1 and 2, respectively (VMLDS; OMIM 601390 and 615546). Characteristic features of these cerebro-facio-articular syndromes overlap with several traits displayed by our patients, such as ID, delayed speech, flat face, ptosis, abnormal teeth, high-arched palate, hand and feet abnormalities with clinodactyly, scoliosis and hypoplastic optic nerve chiasm. Even though VMLDS are also characterized by microtia resulting in hearing loss and renal hypoplasia, clinical features not observed in our cases, the considerable overlap of traits suggest that the 2 brothers are affected by an autosomal recessive form of VMLDS caused by compound heterozygous variants in DCHS2, a gene not previously associated with these rare but very distinctive syndromes. UNIGENE project has received funding from Lithuanian-Swiss cooperation program to reduce economic and social disparities within the enlarged European Union under project agreement No CH-3-_MM-0.

Disease gene discovery in familial amyotrophic lateral sclerosis. *J. A. Fifita[1], K. L. Williams[1], K. Zhang[1], G. A. Nicholson[1,2], D. Rowe[1], I. P. Blair[1].* 1) Faculty of Medicine and Health Sciences, Macquarie University, Sydney, NSW, Australia; 2) University of Sydney, ANZAC Research Institute, Concord Hospital, Sydney, NSW, Australia.

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig's disease, is a fatal neurodegenerative disease that is caused by the progressive death of motor neurons. Ten percent of cases are familial (FALS), with the remaining 90% considered sporadic (SALS). To date, the only known causes of ALS are gene mutations. Mutations in ALS genes, including *SOD1*, *TARDBP* and *C9ORF72,* only account for approximately 60% FALS and 10% of SALS. We aim to identify remaining gene mutations causing ALS. We apply both unbiased and hypothesis driven gene discovery strategies to analyze exome sequence data from Australian familial ALS cases. We have completed whole exome capture and sequencing of probands from 74 ALS families, as well as ten individuals from three multigenerational ALS families. Custom bioinformatics analysis of these families has produced small lists (5, 10, and 18) of novel candidate gene mutations. All variants were prioritized for functional studies based on factors such as protein predictions, conservation across species and gene function. The top-ranking candidates from each family will undergo functional studies to examine potential pathogenicity. Our ALS gene discovery strategies also include the identification and analysis of functional candidate genes, as well as mutation analysis of recently published ALS genes. Our standardized exome sequence data from probands allows rapid interrogation of candidate genes. This is illustrated by our recent analysis of *MATR3* a recently reported ALS gene, which demonstrates that mutations in this gene are a rare cause of Australian FALS. The penetrance of mutation-linked disease in familial ALS varies substantially, ranging from classic Mendelian inheritance to apparently sporadic disease. As such, familial ALS genes were also examined in apparently sporadic ALS cases. Rapid sequencing of 624 sporadic ALS cases using Fluidigm Access Array and Illumina MySeq sequencing is underway to identify variation in known ALS genes, including at least one novel gene identified by our laboratory. This has led to the identification of numerous novel non-synonymous variants in SALS cases, which may be a cause of, or contribute to ALS. The pathogenic basis of ALS remains poorly understood. The identification of novel ALS genes increases our knowledge of disease biology, adds to diagnostic regimes, and provides tools for the development of cell and animal models and long-term therapeutic discovery.

2919T

***CFTR* mutations in Chinese:Recurrent and novel mutations in cystic fibrosis.** *Y. Liu[1], J. Yang[1], X. Tian[2], K-F. Xu[2], X. Zhang[1]*. 1) Dept. of Medical Genetics, Peking Union Medical College, Beijing, Beijing, China; 2) Dept. of Respiratory Medicine, Peking Union Medical College Hospital, Beijing, China.

Background: Cystic fibrosis (CF) is a relatively common autosomal recessive disorder in Caucasians, caused by mutations in the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. The most common *CFTR* mutations have been well established among Caucasian CF patients. In Chinese, however, fewer than 40ChineseCFpatients are reported in the literaturesthus far. Previously, we reported on 7 Chinese CF cases and concluded that the mutations identified inChineseCFpatients seemed different from that in Caucasians. **Methods:**Here we further collected 8 more ChineseCFpatients, presented sequencing results in their*CFTR*gene, and summarized the recurrent and novel *CFTR* mutations from current (8) and our recent reported (7) ChineseCFpatients. The mutations were identified by sequencing the complete coding regions and flanking intronic sequences of the*CFTR*gene, followed by multiplex ligation-dependent probe amplification (MLPA) analysis in order to detect gene deletions or duplications. **Results:**In total, we identified 21 different mutations in 15 Chinese CF patients. We observed delF508, the most common *CFTR* mutation in Caucasians, in one patient as a heterozygote for the first time in Chinese CF patients. Four mutations are novel: ΔE7-E11; c. 3635delT, p. V1212AfsX15; c. 1997T>G, p. L666* and c. 2907A>C, p. A969A. Two mutations were recurrent: p. G970D, carried by 7 patients, was the most common one with a frequency of 23. 3% (7/30), and only seen in Chinese CFs previously; p. Q98R, carried by 2 patients, was the second common mutation with a frequency of 10% (3/30) and almost always seen in Asians. Furthermore, we noticed that another mutation together with p. G970D was always nonsense mutation, with only one exception (p. A969A). However minigene assay suggested that p. A969A led to skipping of exon 17 and generation of a premature stop codon after 3 codons. Other than delF508, we found only one more mutation (R553*) in one compound heterozygous patient that was included among the 32 common mutations in the screening panel for Caucasians. **Conclusion:**We further confirmed that the *CFTR* mutation spectrum ofChineseCFpatients was indeed quite different from that in Caucasians with p. G970D the most common one. Sequencing of the entire*CFTR*gene followed by MLPA analysis, rather than using the targeted sequencing-based screening panel for mutations commonly found in Caucasian populations, is recommended for genetic analysis in ChineseCFpatients.

2920F

Non-coding variants segregate with disease in South African families with keratolytic winter erythema (KWE). *T. Ngcungcu[1], B. Linghu[2], F. Yang[2], E. Oakeley[2], F. Staedtler[2], R. Bruccoleri[2], N. Nirmala[2], S. Buechmann-Moller[2], M. Marc Sultan[2], J. Szustakowski[2], M. Ramsay[1]*. 1) Division of Human Genetics, School of Pathology and the Sydney Brenner Institute for Molecular Bioscience, University of the Witwatersrand, Johannesburg, South Africa; 2) Biomarker Development, Translational Medicine, Novartis Institutes for BioMedical Research, Basel, Switzerland and Cambridge, USA.

Keratolytic Winter Erythema (KWE) is a rare skin disorder of unknown aetiology that is characterized by erythema, keratin layer thickening and centrifugal skin peeling of the palms and soles, especially in cold and dry conditions. KWE shows an autosomal dominant mode of inheritance and the causal mutation was localised to chromosome 8p22-p23 (KWE critical region). The aim of this study was to identify and characterize the causal mutation for KWE in South African families. Targeted resequencing (8p22-23) and exome sequencing were performed in 21 affected and 30 unaffected individuals using Illumina HiSeq and MiSeq sequencing platforms. Reads were aligned to the reference genome using the Burrows-Wheeler Aligner (BWA) and the Genome Analysis Toolkit (GATK) and Pindel were used to call small and large structural variants, respectively. We identified a 7. 67 kb tandem duplication within the KWE critical region, upstream of the *CTSB* gene and encompassing two enhancers. This tandem duplication was validated in all affected individuals, highlighting the potential role of large structure variants for manifesting Mendelian diseases. Additionally, an *FDFT1* intronic variant also segregates with the disease. The two variants are in strong linkage disequilibrium, but the mechanism of action leading to the disease phenotypes remains unclear. The fact that these variants are located in non-coding regions, suggest that they may result in altered gene expression regulation. Further functional analyses are required, but these findings enforce the need to look beyond the exome when trying to identify causal mutations for a subset of Mendelian diseases.

2921W

Mutations in *STAC3*, the gene responsible for Native American Myopathy, are not responsible for the phenotypically similar Carey-Fineman-Ziter syndrome. *S. M. Robbins[1,2], A. Telegrafi[8], N. L. M. Sobreira[1], L. Fleming[9], C. E. Speck-Martins[6], J. C. Carey[5], D. FitzPatrick[7], D. Valle[1,4], J. E. Hoover-Fong[1,3,4].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore , MD 21205, USA; 2) Predoctoral Training Program in Human Genetics, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 3) McKusick-Nathans Institute of Genetic Medicine, Greenberg Center for Skeletal Dysplasias, Johns Hopkins University School of Medicine, Baltimore, MD 21287, USA; 4) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 5) Department of Pediatrics, University of Utah, Salt Lake City, UT 84113, USA; 6) Genetic Unit, Sarah Rehabilitation Hospital, Belo Horizonte-MG, São Luiz-MA, Brasilia-DF, Brazil; 7) Human Genetics Unit, Medical and Developmental Genetics, University of Edinburgh Western General Hospital, Edinburgh, Scotland; 8) GeneDx, Gaithersburg MD 20877; 9) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892.

Carey-Fineman-Ziter syndrome (CFZ) is a rare autosomal recessive phenotype characterized by short stature, hypotonia, Moebius sequence, Pierre Robin sequence, and myopathic facies. The molecular basis is unknown and only 17 cases have been reported. We describe 2 Qatari sisters born to first-degree consanguineous healthy parents, clinically diagnosed with CFZ syndrome. The younger sister, age 8 years, has short stature, dolichocephaly and turricephaly, downslanting palpebral fissures, ptosis, cleft palate, kyphoscoliosis, and hypotonia. Her sister, age 18 years, has short stature, cleft palate, and hypotonia; 3 male sibs are unaffected. We performed WES in the 2 affected sisters and one unaffected brother and identified a homozygous W284S variant in *STAC3* in both sisters which was heterozygous in the unaffected brother. Horstick et al. (2013) previously reported homozygosity of this same *STAC3* variant (*STAC3*-W284S) as the cause of Native American Myopathy (NAM) in 5 Lumbee Native American families with 18 affected individuals whose characteristic features included susceptibility to malignant hyperthermia, kyphoscoliosis, cleft palate, and myopathic facies. They showed that *STAC3* encodes a protein involved in excitation-contraction coupling in skeletal muscles through membrane voltage studies in a zebrafish mutant. Given the phenotypic similarity of individuals affected with CFZ syndrome and NAM, we performed Sanger sequencing on *STAC3* in 4 additional unpublished CFZ probands and 3 individuals (2 families) previously reported by Carey et al. (1982) and Ryan et al. (1999) for a total of 7 individuals with CFZ from 6 families. We did not identify rare (MAF < 0. 5%) coding variants in *STAC3* in these individuals. While we cannot rule out the possibility that non-coding or regulatory *STAC3* variants are present in all these individuals (n = 7), our results suggest that despite their phenotypic similarity, CFZ syndrome and NAM are caused by mutations in different genes. We conclude that our 2 affected Qatari sisters actually have NAM caused by homozygous *STAC3*-W284S variants and are the first non-Native American cases. Given their phenotypic similarity, however, we suggest that individuals with a clinical diagnosis of CFZ syndrome should be tested for variants in *STAC3* and speculate that the gene responsible for CFZ may encode a protein that functions in the same network as that encoded by *STAC3*.

2922T

Sequential sequencing approach elucidates high proportion of monogenic obesity cases in a consanguineous population. *S. Saeed[1], A. Bonnefond[2,3,4], J. Philippe[2,3,4], E. Durand[2,3,4], J. Manzoor[5], H. Crouch[1], O. Sand[2,3,4], M. Arslan[6,7], P. Froguel[1,2,3,4].* 1) Genomics of Common Disease, Imperial College London, London, United Kingdom; 2) European Genomic Institute for Diabetes (EGID), Lille, France; 3) CNRS-UMR8199, Lille Pasteur Institute, Lille, France; 4) Lille University, Lille, France; 5) Department of Paediatric Endocrinology, Children's Hospital, Lahore; 6) Department of Biological Sciences, Forman Christian College, Lahore, Pakistan; 7) Centre for Research in Molecular Medicine, The University of Lahore, Lahore, Pakistan.

Objective: Although 40-70% of human obesity is attributable to underlying genetic factors, most of the genes predisposing an individual to increased adiposity remain elusive. Monogenic forms of obesity have provided critical insights into mechanisms governing energy homeostasis, mainly by controlling appetite. In outbred populations, only 3-5% of severely obese patients have been identified with monogenic obesity, but its prevalence in consanguineous populations has not been systematically ascertained. We searched for obesity-associated mutations through a step-wise multilevel sequence analysis in children with severe obesity from Pakistani consanguineous families. Methods: The present investigation is based on 145 unrelated children of consanguineous parents, with a weight-for-age percentile >97. All subjects were, initially screened for mutations in the coding regions of leptin (*LEP*) and melanocortin 4 receptor (*MC4R*) genes by Sanger sequencing. Subjects negative for loss-of-function mutations in these genes were screened using microdroplet PCR-enrichment followed by next generation sequencing (NGS). Genomic structural variations were assessed by genome-wide genotyping. Samples from probands in which pathogenic mutations in known obesity-associated genes could not be identified using the aforementioned procedures, were analysed by whole exome sequencing (WES). Results: Using Sanger and microdroplet-based sequencing and genotyping we identified 44 obese probands carrying 14 different loss-of-function mutations in 5 genes: *LEP* (n=28), leptin receptor (*LEPR*) (n=8), *MC4R* (n=4), Bardet–Biedl syndrome-2 (*BBS-2*) (n=1) and *BBS-10* (n=2). We also foundtwo neighboring homozygous deletions that result in removing large segment of the *LEPR*. All mutations were in homozygous state. Lastly, WES has so far provided indication of an involvement of homozygous mutations insix susceptible genes from seven individuals. Although regarded as strong candidate genes for obesity through genome-wide association studies (GWAS) and/or animal studies, their involvement in monogenic obesity in human is reported here for the first time. Conclusion: The study shows a high prevalence (36%) of known and novel pathogenic mutations causing severe obesity in a consanguineous population of Pakistan. These results also underscore the importance of systematic genetic analysis of other inbred populations to unravel novel genetic variants and signalling pathways modulating energy homeostasis.

2923F

A loss-of-function mutation in *JAK1* is associated with epidermodysplasia verruciformis. *R. Wang[1], J. liu[2], L. Zhang[1], J. Li[1], S. Shu[1], D. Ma[2], X. Zhang[1,2].* 1) McKusick-Zhang Center for Genetic Medicine, Chinese Academy of Medical Sciences-Peking Union Medical College; 2) Peking Union Medical College Hospital, Chinese Academy of Medical Sciences-Peking Union Medical College, Beijing, China.

Epidermodysplasia verruciformis (EV) is a rare genodermatosis characterized by persistent, refractory and disseminated skin lesions on sun-exposed areas, and it has a high risk of skin carcinoma that results from an increased susceptibility to a specific group of human beta papillomavirus, such as the oncogenic HPV-5 and HPV-8. EV is often inherited in an autosomal recessive manner, and approximately 75% of EV patients are caused by mutations in *EVER1* and *EVER2*, which encode proteins involved in intracellular zinc transportation. Recently, we recruited a four-generation Chinese family showing an autosomal dominant transmission of EV. Genomic DNA samples were obtained from 5 affected individuals and 9 unaffected individuals after informed consent. Mutations in *EVER1* and *EVER2* have been previously excluded by Sanger sequencing. We performed whole-exome sequencing on four affected individuals, and identified a novel heterozygousdonor-splice site mutation (NM_002227. 2 c. 3258+1 G>A) in the Janus kinase 1 gene (*JAK1*) on chromosome 1p31. 3. The splicing variant co-segregated with the phenotype of all the family members expect III-21. This variant is not present in dbSNP142, the 1000 Genomes draft database and NHLBI Exome Sequencing Project and was not detected in chromosomes from 173 ethnically matched control individuals. Sanger sequencing of the cDNAobtained from peripheral lymphocytes of the affected individuals revealed that the splicing mutation disrupted normal splicing, skipped exon 23, then disrupted the reading frame and led to a premature termination at codon 1050. Quantitative RT-PCR on total RNA isolated from peripheral lymphocytes of the family members showed that all affected and carrier individuals had significantly reduced JAK1 expression compared to the unaffected individuals, suggesting that the splicing mutation might destabilize the mRNA transcript via the nonsense-mediated mRNA decay. Furthermore, Western blot analysis revealed that mutant JAK1 produced a truncated protein and a reduced expression level compared to the wild-type JAK1. In additional 12 sporadic cases with EV, we also sequenced the 25 exons and their flanking intronic sequences of *JAK1* but found no mutation. In summary, we have identified a germline splicing mutation in *JAK1*and provided supportive evidence for its causality in EV.

2924W

The molecular anatomy of multiple Noonan Syndrome *PTPN11* mutations in the testes of normal men using Deep Sequencing. *J. Eboreime, P. Calabrese, N. Arnheim.* Molecular and Computational Biology, University of Southern California, Los Angeles, CA.

Some nucleotide sites with exceptionally high *de novo* germline mutation rates cause sporadic cases of different Mendelian diseases. Noonan syndrome (NS) is one such disease characterized by short stature, heart defects, intellectual disability, craniofacial abnormalities and a predisposition to certain cancers. NS has features (RAMP) in common with related genetic diseases: 1) Recurrent mutation 1,000 fold higher than the genome-average, 2) Autosomal dominant transmission, 3) Male-biased *de novo* mutations and 4) Paternal age effect (PAE). The increasing birth rates in older couples highlights the importance of understanding the PAE mechanism. Previously, we found the most common NS *PTPN11* mutation (c. 922A>G) was not uniformly distributed in the testes of normal men as hypermutation would predict. Rather the mutations were highly clustered with almost all of them found in small regions of the testis, suggesting RAMP mutations occur rarely but, when they arise, confer a selective advantage to mutant testis stem cells over wild type ones. We speculated that the high frequency of sporadic NS cases (~1/2,000 births) might be due to a small number of disease sites that confer such an advantage leading to high numbers of sperm carrying different disease mutations. To test this idea we dissected the testes of 3 normal men into 192 pieces each, and targeted a 171 bp *PTPN11* DNA segment. For each of the 576 libraries created, we tagged each original target DNA strand with a unique identifier to lower the impact of NGS errors. We measured the mutation frequency at all the sites in the segment, 10 of which are recurrent NS mutation sites. Due to heat-induced deamination and oxidation during the early PCR cycles this assay has a C>T and G>T background frequency of 9x10-5, compared to 4x10-6 for the other four mutation types. We found that for some, but not all, of the NS sites the mutations were clustered, supporting the selective advantage hypothesis. In one testis, e. g. , there were two adjacent pieces where the c. 188A>G mutation frequencies were greater than 10-3, while at this site all the other testis pieces had frequencies near or below the background frequency. Possible explanations for NS sites not showing clustering are: these mutations do not confer a selective advantage, the advantage is too slight to be observed with this assay, or due to the stochastic process of rare mutation followed by selective growth the clusters were not present in these testes.

2925T

Identification of 4 novel mutations in a cohort of tuberous sclerosis patients from Russia. *L. I. Shagam, M. Yu. Dorofeeva, A. R. Sadykov, A. V. Polyakova, D. M. Shatalova, V. S. Sukhorukov.* Research Institute of Pediatrics at Pirogov Russian Medical University, Moscow, Russian Federation.

Tuberous sclerosis is a rare autosomal dominant disorder characterized by highly variable clinical manifestations including seizures, developmental delay, intellectual disability and autism. About 80-85% of patients are known to bear mutation in either tuberin or hamartin gene. Our research was aimed at identification of mutations that cause tuberous sclerosis in a cohort of 8 patients from Russian population. The patients were diagnosed according to (Northrup et al. , 2013). We examined tuberin and hamartin genes of the study participants for germline mutations by targeted resequencing of coding exons and adjacent 5 bp intronic regions. The targets were amplified by means Ion AmpliSeq™ technology and sequenced on the Ion Torrent Personal Genome Machine. We have identified 6 mutations with 4 of them to the best of our knowledge being first described here. Herein we provide a brief account of the clinical features accompanying the mutations in the 4 unrelated cases. Patient #1, a 3-year-old girl is clinically characterized by drug-resistant epileptic seizures, polycystic kidney disease, facial angiofibroma and multiple hypomelanotic macules. Her parents are healthy. Family trio analysis has revealed a *de novo* frameshift deletion of tuberin gene *TSC2* (NM_000548): c. 1198delT, p. (Phe400fs*25). Patient #2, a 5-year-old boy characterized by presence of hypomelanotic macules, multiple cardiac rhabdomyomas, supraventricular extrasystole, vicarious hypertrophy of the right kidney, hepatic angiomyolipoma. His mother is healthy whereas his father also suffers tuberous sclerosis with hypomelanotic macules and multiple cardiac rhabdomyomas. The patient bears a hamartin gene nonsense mutation *TSC1* (NM_000368): c. 2527C>T, p. (Gln843Ter) inherited from his father. Patient #3, a 6-year-old boy characterized by drug-resistant epilepsy, subependymal giant cell astrocytoma, developmental delay; forehead fibrous plaque, hypomelanotic macules, facial angiofibroma; cardiac rhabdomyoma, renal angiomyolipomatosis, polycystic kidney disease and retinal hamartoma. His parents are healthy. The patient bears a *de novo* tuberin gene nonsense mutation *TSC2*: c. 1073G>A, p. (Trp358Ter). Patient #4, a 14-year-old boy characterized by symptomatic focal epilepsy, intellectual disability, autism spectrum disorder. He bears a tuberin gene mutation *TSC2*: c. 4183C>T, p. (Gln1395Ter).

2926F

Mutation spectrum in a cohort of patients with *ABCA4*-related retinal dystrophies. *Y. Xie[1], W. Lee[1], S. H. Tsang[1], G. A. Fishman[2], F. T. Collison[2], R. Riveiro-Alvarez[3], C. Ayuso[3], T. Gambin[4], J. R. Lupski[4], R. Allikmets[1].* 1) Department of Ophthalmology, Columbia University, New York, NY; 2) The Pangere Center for Hereditary Retinal Diseases, The Chicago Lighthouse for People Who Are Blind or Visually Impaired, Chicago, IL; 3) Department of Genetics, Instituto de Investigacion Sanitaria-University Hospital Fundacion Jimenez Diaz (IIS-FJD), Madrid, Spain; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Mutations in the *ABCA4* gene are responsible for a wide variety of retinal dystrophy phenotypes from autosomal recessive Stargardt disease (STGD1) to cone–rod dystrophy (CRD) and, in some advanced cases, generalized choriocapillaris dystrophy (GCCD) and retinitis pigmentosa (RP). Currently there are more than 800 diseases-associated *ABCA4* variants identified; the combined clinical and allelic heterogeneity has substantially complicated genetic analyses of *ABCA4*-associated retinal diseases. In a fraction of patients (10-15%) with clinical diagnosis of phenotypes compatible with *ABCA4*-associated diseases, no causal mutations were found after complete sequencing of the *ABCA4* gene, in 50 families and 31 sporadic cases. Here we describe a genetic analysis to determine the causal gene of the disease in these patients. Affected and available unaffected members from these families and sporadic cases, in total 175 individuals, were subjected to whole exome sequencing (WES). Possibly disease-associated variants were determined by filtering based on minor allele frequency and predicted pathogenicity. Variants were verified by Sanger sequencing followed by segregation analysis. The definite causal gene was identified in 30/50 families (60%). Analysis of 17/50 (34%) families resulted in several candidate genes, while no plausible candidate was found in only 3 families (6%). Of the 31 sporadic cases, 13 were solved, 9 had multiple plausible candidate genes, and 9 were not solved. The causal genes for the solved cases belong to the following categories: 1) phenotypic expansion in known retinal disease genes (11 cases; *CRB1, CRX*, etc.); 2) revised clinical diagnosis or ambiguous phenotypes (12; *RS1, PRPH2, RP1L1*, etc.); 3) new or re-assessed mutations in *ABCA4* (10); 4) new genes (3; *RDH11, RAB28*); 5) unusual clinical outcome (1; *MMACHC*); 6) other RP genes (9). The genetic causes of *ABCA4*-like phenotypes range from new genes to unusual clinical manifestations of known genes. Determining all genetic variation underlying retinal diseases is necessary for precise molecular genetic diagnosis and improved prognosis of these conditions.

Charcot-Marie-Tooth (CMT) disease is a clinically and genetically heterogeneous distal symmetric polyneuropathy, with over 70 causative genes identified to date. Whole exome sequencing (WES) of 40 individuals from 37 unrelated families with CMT-like peripheral neuropathy, in whom extensive genetic evaluation had failed to establish a molecular diagnosis, identified apparent causative mutations in ~45% (17/37) of families. Molecular diagnosis led to retrospective review and redefinition of the phenotype in eight subjects, underscoring the clinical utility of WES. Three novel candidate disease genes are proposed, functionally linked to well-established neuropathy genes and supported by *in vivo* studies. Remarkably, aggregate analysis of mutation data revealed a significantly increased number of rare variants across neuropathy associated genes in subjects versus controls, even after accounting for the apparent causative mutations. The elevated mutation burden was confirmed in a second ethnically discrete neuropathy cohort, suggesting its potential contribution to phenotypic variability. Neuropathy genes implicated by burden in families were shown to interact synergistically in a zebrafish assay, wherein pairwise co-injection of sub-effective doses of selected morpholinos yielded a neuronal phenotype beyond that expected for each morpholino alone. Our findings suggest that the combinatorial effect of rare variants contributes to disease burden and variable expressivity.

2928T

Identification of a 2nd family with a MYH14 p. Arg941Leu mutation confirms MYH14 as a gene causing Charcot-Marie-Tooth neuropathy and hearing loss. *C. S. Smith[1], G. Pfeffer[1,2], R. E. Lamont[1,3], F. P. Bernier[1,3,4], A. M. Innes[1,3,4], J. S. Parboosingh[1,3], Care4Rare Canada Consortium.* 1) Department of Medical Genetics, University of Calgary, Calgary, Alberta, Canada; 2) Department of Clinical Neurosciences, University of Calgary, Calgary, Alberta, Canada; 3) Alberta Children's Hospital Research Institute, Calgary, Alberta, Canada; 4) Clinical Genetics, Alberta Children's Hospital, Calgary, Alberta, Canada.

Mutations in myosin heavy chain 14 (*MYH14*), a non-muscle myosin, are generally associated with autosomal dominant nonsyndromic deafness (OMIM 608568). Herein, we report a three generation family where a dominant neuromuscular phenotype comprised of a CMT-like neuropathy and hearing loss segregates a heterozygous NM_001077186.1(*MYH14):* c. 2822G>T (p. Arg941Leu) variant identified by exome sequencing. A previous report associated this same variant with a complex neuromuscular phenotype consisting of neuropathy, myopathy, deafness and vocal hoarseness (PNMHH, OMIM 608568) in a large multigenerational Korean family. This suggests that the p. Arg941Leu mutation might cause an appreciably different phenotype from other reported mutations in *MYH14*. However, the reasons for these phenotypic differences have yet to be explored. Based on homology modeling of the MYH14 structure, the p. Arg941Leu mutation is predicted to interfere with the essential dimerization function of a coiled-coil domain in the tail segment of the protein. However, there are also nonsyndromic deafness mutations in the tail domain of the protein and thus, location of the variant within the broader tail domain fails to entirely explain the difference in phenotype. With this second report of a *MYH14* mutation causing a deafness-neuropathy phenotype, we suggest that this gene is one of the growing number that cause this combined phenotype. We intend to characterize the effect of this mutation on protein stability, localization and function *in vitro* using cell culture in order to explore why it causes a pleiotropic phenotype.

Mutations in phosphatidylinositol 4-kinase-beta cause autosomal-dominant non-syndromic hearing loss. *M. Gong[1], XL Su[2], J Zhang[3], S Rahman[4], F Rüschendorf[5], H Cui[2], J liang[6], L Fang[5], H Hu[7], S Froehler[9], Y Yu[5], G Patone[5], N Hubner[5], K Raile[1], M Gross[8], S Bähring[1], FC Luft[1], S Bähring[1], K Hussain[4], W Chen[9].* 1) 8 Experimental and Clinical Research Center (ECRC), a joint cooperation between the Charité Medical Faculty and the Max-Delbrueck-Center for Molecular Medicine in the Helmholtz Association (MDC), Lindenberger Weg. 80, 13125, Berlin, Germany; 2) Clinical Medicine Research Center of the Affiliated Hospital, Inner Mongolia Medical University, No 1 TongDao Northern Street, 010050, Huhhot, Inner Mongolia, China; 3) Affiliated Hospital of Guangdong Medical College, 57 Renmin Dadao Nan, 524001 Zhanjiang, China; 4) Genomic Medicine Programme, UCL Institute of Child Health and Great Ormond Street Hospital for Children, 30 Guilford Street, London WC1N 1EH, UK; 5) Max-Delbrueck-Center for Molecular Medicine (MDC), Robert-Roessle-Str. 10, 13125, Berlin, Germany; 6) Affiliated People Hospital, Inner Mongolia Medical College, Huhhot, 010050, Inner Mongolia, China; 7) Department of Human Molecular Genetics, Max Planck Institute for Molecular Genetics, Ihnestrabe 63-73, 14195 Berlin, Germany; 8) Deparment of Audiology and Phoniatrics, Charité-Universitàtsmedizin, Charitéplatz 1, 10117, Berlin, Germany; 9) Berlin Institute for Medical Systems Biology, Max-Delbrueck-Center for Molecular Medicine (MDC), Robert-Roessle-Str. 10, 13125, Berlin, Germany.

Early-onset or childhood autosomal-dominantly inherited non-syndromic sensorineural hearing impairment (ADNSSHI) is a heterogeneous genetic disorder. We combined linkage analysis and exome sequencing to identify an ADNSSHI locus (DFNA62) in a large multi-generational Chinese family. We identified a highly conserved missense mutation in the gene encoding phosphatidylinositol 4-kinase, catalytic-beta (*PI4KB)*. We next studied a small 57-member Chinese hereditary non-syndromic sensorineural hearing impairment (NSSHI) cohort from the same geographic area and found three highly conserved missense mutations in 5 patients that were absent from >1200 control Chinese chromosomes. We then observed that PI4KB protein expression in the organ of Corti of 11 and 15 week-old human fetal inner-ear sections. Transfected Hela-cell functional analyses showed cytoplasmic dilating vesicles, compared to wild-type PI4KB transfected cells. We also found that kinase activity in mutated PI4KB transfected HEK293 cells was increased compared to controls. Finally, up-regulation of Cx26 in the mutated PI4KB-transfected HEK293 cells suggested that rare alleles in *PI4KB* could be involved in the pathogenesis of ADNSSHI.

2930W

A dominant Limb Girdle Muscular Dystrophy with severe respiratory involvement; *HNRNPLD* as the new player. *S. E. Lipinski[1], M. J. Lipinski[2], R. N. Kurtzke[3], O. Goker-Alpan[1].* 1) O and O Alpan, LLC, Fairfax, VA; 2) Medstar Washington Hospital Center, Washington, DC; 3) Neurology Center of Fairfax, LTD, Fairfax, VA.

Limb-girdle muscular dystrophies are divided into autosomal dominant (LGMD 1) and autosomal recessive (LGMD 2) types. Little evidence exists about respiratory involvement in LGMD 1. More than 70% of cases of LGMD 2C–2F (sarcoglycanopathies) have respiratory muscle involvement with reduced FVC, and those with γ and α sarcoglycanopathy have severe respiratory insufficiency, with FVC reduced to <40% predicted. In LGMD 2A (calpainopathy), there is late respiratory muscle involvement with sparing of cardiac muscle. A 54 year old male was seen fordisproportionately severe respiratory muscle weakness with mild limb weakness and elevated creatinine kinase. At 52, he developed dyspnea on exertion, then at rest, with severe orthopnea and nocturnal dyspnea. Deltoid muscle biopsy showed denervation atrophy and non-specific non-inflammatory myopathic features. Exam was significant for respiratory accessory muscle use, gasping with 3 word dyspnea, mild weakness of proximal muscles and trace peripheral edema. Pulmonary function tests showed forced vital capacity (FVC) of 36%, forced expiratory volume (FEV1) of 43%, and FEV1/FVC of 106%. Sleep study demonstrated numerous oxygen desaturations, and CPAP ventilation was recommended. Chest Xray showed diaphragmatic paralysis and atelectasis. Echocardiography showed normal ventricular functions and chamber sizes with no valvular disease. Right heart catheterization was pursuedto rule out pulmonary hypertension as respiratory acidosis was noted. All pressures were normal. Whole Exome Sequencing found a candidate gene, *HNRNPLD,* as well as two genes associated with hypertrophic cardiomyopathy,*MYL3* and *ACTN2*. The patient is heterozygous for a deletion/insertion mutation in *HNRNPDL* (c. 110_113delAGCT), a deletion in the *MYL3* gene (c. 457delC), and for a variant of uncertain significance in *ACTN2* (c. 2147 C>T). The *MYL3* gene encodes the essential light chain of myosin and the *ACTN2* gene encodes alpha-actinin which anchors the sarcomeric actin filaments. Given the normal cardiac evaluation, these were concluded not to play a role in the phenotype. *HNRNPLD* mutations were reported previously in two families with Limb Girdle Muscular dystrophy. In zebrafish, this gene plays an important role in muscle development and thus, its dysfunction would be consistent with a myopathy. This is the first report relating *HNRNPLD* mutations at the heterozygote state, with an adult onset muscular dystrophy and severe respiratory muscle involvement.

Exome sequencing is a powerful and cost-effective tool that has become increasingly routine in Mendelian disease diagnosis; however, the current diagnostic rate for exome analysis across a variety of rare diseases is approximately 25-50%. Where exome data falls short, whole genome and RNA sequencing can offer additional insight. Whole genome sequencing provides more uniform coverage and improved identification of structural variants whereas RNA sequencing gives insight into the transcriptional landscape of the affected tissue allowing, for instance, the detection of aberrant splicing and allelic imbalance, all types of events rarely detectable from genotype data alone. Such analyses can empower molecular diagnosis by validating the transcriptional effects of variants proposed by exome data or by identifying novel variants. Here we describe an integrated approach of trio whole genome and patient muscle RNA sequencing in over 50 exome-unsolved cases with severe neuromuscular diseases. Our data consist of individuals for whom exome sequencing has prioritized variants predicted to alter gene expression or splicing as well as those for which there are no candidates from exome sequencing. We demonstrate the power of whole genome and RNA sequencing to validate candidate splice-disrupting mutations and to identify splice-altering variants in both exonic and deep intronic regions. We also apply both technologies to a set of undiagnosed Duchenne muscular dystrophy cases and demonstrate the value of both technologies for detecting and functionally validating complex structural rearrangements (such as inversions) invisible to standard diagnostic methods. Finally, we describe an analysis framework focused on the detection of transcript level changes that are unique to the patient, relative to a database drawn from over 150 skeletal muscle RNA-seq samples from the GTEx project, as well as query heterozygous predicted deleterious variants to identify evidence of allelic imbalance. Together, our results demonstrate the value of both whole-genome and tissue transcriptome data for the detection and interpretation of variants missed by standard exome-based approaches.

2932F

Deciphering of a rare autosomal recessive type of Osteogenesis Imperfecta (OI) in an Iranian family by Next Generation Sequencing (NGS). *G. Shariati[1,2], A. Saberi[1,2], M. Hamid[2,3], N. Mazaheri[2,4], J. Zeighami[2], M. Sarvari[2], H. Galehdari[2,4].* 1) Ahvaz Jundishapur University of Medical Sciences, Ahvaz, KHUZESTAN, Iran; 2) Narges Genetic diagnosis and PND Lab, Ahvaz, Iran; 3) Department of Biotechnology, Pasteur Institute, Tehran, Iran; 4) Department of Genetics, Shahid Chamran University, Ahvaz, Iran.

Introduction:Osteogenesis Imperfecta (OI) is a heterogeneous group of heritable skeletal disorder that characterized by bone fragility. Disease caused by alteration in the synthesis and folding of type I collagen and usually inherited in an autosomal dominant (AD) mode, with incidence in 6–7 per 100000. There are at least five recognized forms of Autosomal dominant OI. Type I is the mildest and most common form of OI with mild bone fragility, relatively few fractures, and minimal limb deformities. It accounts for 50 percent of the total OI population. Type II and III is the most severe type at infants and among children respectively but people with type IV, V and VI are moderate in severity nonetheless type VI is extremely rare. These types are result of mutations in the collagen encoding genes (*COL1A1* or *COL1A2*), but rarely recessive inherited OI has been also discovered . Types VII and VIII are recessively inherited types of OI that caused by mutations in two genes , *CRTAP* and *LEPRE1* respectively. Since then, another recessive form, Osteogenesis Imperfecta, Type XI [OI11 (MIM 610968)] that caused by homozygote mutation in an collagen chaperone protein, FK506-binding protein 10 gene (*FKBP10*) also has been shown. several mutations included missense and frame shift indels are identified for this type of OI. Therefore since different genes have been involved for several types of disease, Sanger sequencing is less efficient way to reach a molecular diagnosis. In order to evade these difficulties Next Generation Sequencing (NGS) technology has been installed in clinical laboratories as an ideal approach for the mutation analysis in a short time with low cost. Methods:Here we describe a large pedigree included three closely related Iranian families with OI-like bone fragility, sever to moderate bone deformity, short stature, scoliosis, joint laxity and osteopenia. For mutation analysis NGS was applied to test clinical sample from one severe patient as proband and validated by sanger sequencing. Results and Conclusions:NGS of proband sample resulted in detection of a mutation in *FKBP10* gene. This mutation was successfully validated by Sanger sequencing in other four patients and related parents. Therefore, we conclude that this new *FKBP10* mutation are a cause of recessive Osteogenesis Imperfecta in this related families and NGS provides an efficient strategy to reach to a molecular diagnosis in such inherited disorders.

2933W

Computational approach improves identification of *RPGR* ORF15 mutations for inherited retinal disease patients by Next-generation sequencing. *Z. Ge[1,2], L. Zhao[1,2,3], M. Xu[1,2], E. Jones[1,2], R. Chen[1,2,3,4,5].* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Structural and Computational Biology and Molecular Biophysics Graduate Program, Houston, TX; 4) The Verna and Marrs Mclean Department of Biochemistry and Molecular Biology, Baylor College of Medicine, Houston, TX; 5) Program in Developmental Biology, Baylor College of Medicine, Houston, TX.

Alterations in *RPGR* are major cause of inherited retinal diseases including Retinitis Pigmentosa (RP) and Cone Rod Dystrophy (CRD). Previous research showed that mutations in *RPGR* account for ~70% of X-linked RP and ~ 50% of X-linked CRD cases. In addition, ~15% of simplex male RP patients carry *RPGR* mutations. In particular, *RPGR* open reading frame (ORF) 15 is a mutation hotspot with about 60% mutations identified in *RPGR* located within ORF15. However, due to highly repetitive sequence and complex arrangement within *RPGR* ORF15, it is challenging to identify mutations in this region. This can lead to false negative diagnosis for some of the RP cases. To address this issue, we developed a computational algorithm, which is optimized for identification of mutations within the *RPGR* ORF15 region. When applied to 110 RP and 58 CRD patients previously unsolved, 9 patients were found to carry frameshift mutations in *RPGR* that were missed by previous analysis method. Further evaluation and optimization of our approach is current underway by testing on a large cohort of patient samples.

2934T

Impact of whole exome sequencing on identification of disease causing mutations among Iranian patients with Autosomal Recessive Retinitis Pigmentosa. *M. Beheshtian[1], S. Saee Rad[2], H. Hashemi[3], M. Babanejad[1], M. Mohseni[1], A. Eshghabadi[3], F. Hajizadeh[3], MR. Akbari[4,5], K. Kahrizi[1], M. Riazi Esfahani[3], H. Najmabadi[1].* 1) Genetics Research Center, University of Social Welfare and Rehabilitation Scienc, Tehran, Iran; 2) Vice dean for research affairs, Alborz University of Medical Sciences, Karaj, Iran; 3) Noor Ophthalmology Research Center, Noor Eye Hospital, Tehran, Iran; 4) Women's College Research Institute, Women's College Hospital, University of Toronto, Toronto, ON, Canada; 5) Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada.

Non-syndromic autosomal recessive retinitis pigmentosa (arRP) is a genetically heterogeneous disorder which results from mutations in a large number of genes and which can lead to blindness. We aimed to determine the power of next-generation sequencing (NGS) in identification of the genes responsible for non-syndromic arRP among Iranian patients. We used whole exome sequencing (WES), followed by Sanger sequencing to identify the underlying gene mutations causing non-syndromic arRP. Our study revealed disease-causing mutations in known arRP genes for 10 of the 13 families studied (76. 9%). These included two frameshift insertion/deletion mutations in *CRB1* and *ABCA4*, one splicing mutation in *PDE6B*, four missense mutations in *RP1*, *CRB1*, *PANK2* and *IFT140*, and three stop codon mutations in *RDH12*, *PRCD*, and *C2orf71*. The three remaining families harbored no mutation in previously known RP genes. Of the 10 disease causing mutations identified among the investigated Iranian patients with non-syndromic arRP, eight variants had not been reported previously, including *CRB1* (c. 1252dup; p. Ser418Phefs*3), *ABCA4* (c. 2927del; p. Leu976Argfs*55), *PDE6B* (c. 1060-1G>T), *RP1* (c. 679T>G; p. Phe227Val), *CRB1* (c. 2711G>A; p. Cys904Tyr), *PANK2* (c. 419T>C; p. Phe140Ser), *IFT140* (c. 3827G>A; p. Gly1276Glu), and *C2orf71* (c. 712A>T; p. Lys238*). We confirmed segregation of all 10 mutations with disease phenotypes in our studied population. This study supports the genetic heterogeneity of non-syndromic arRP in Iranian patients, and provides an opportunity to show the effectiveness of WES in identification of pathogenic mutations in 77% of the tested Iranian patients with non-syndromic arRP born to consanguineous parents.

2935F

Modifiers genes in Metabolic Pathway modulate the severity of Incontinentia Pigmenti phenotype. *F. Fusco[1], M. I. Conte[1], M. Paciolla[1], A. Pescatore[1], M. F. Branda[1], M. C. Girone[1], M. B. Lioi[2], M. V. Ursini[1].* 1) IGB ABT CNR, Naples, Italy; 2) University of Basilicata, Potenza 85100, Italy.

Incontinentia pigmenti (IP, MIM308300, 1/10. 000) is a rare X-linked dominant and male-lethal multisystemic disorder whose only genetic cause is the mutation of *NEMO* gene (*IKBKG/Nuclear Factor kappaB, Essential MOdulator*). *NEMO* encodes for the regulatory subunit of the IKK complex required for the activation of the NF-kB survival pathway. The skin defects are hallmarks of IP disease and the extra cutaneous alterations (ocular, dental, hair, nail and central nervous system-CNS- defects) may occur at variable frequency. Despite a genetic homogeneity, a highly heterogeneous inter- and intrafamilial clinical presentation has been reported in IP. The severity is related to the presence of neurologic impairment (seizures, encephalopathy, encephalomyelitis, ischemic stroke) in 30% of IP patients with the same genomic alteration (*NEMOdel4-10*). To identify genetic factors that modify clinical variability in IP, we performed a high-resolution exome sequencing of three IP families-trios belonging to our IP-Genetic Biobank (IPGB), to identify genetic variants that beyond the *NEMO* common loss-of-function mutation (*NEMOdel4-10*), can contribute to the severity of the CNS phenotype. Complex filtering analysis of exome variants allowed us to identify as candidate genes, variations in proteins belonging to the one-carbon metabolism pathway. These variations are reported to produce mild/severe increase of homocysteine plasma concentration and Folic Acid and VitamimB12 deficiency in carrier patients. The in-deep analysis of clinical metabolic phenotype of sequenced probands suggested the presence of a mild deficit in cobalamin metabolic pathway. To confirm the damaging effect of homocysteine in cells of CNS we used *Nemo(-)* Neuronal Precursor Cells (NPC) from conditional *Nemo* knockout mouse brain finding that in the absence of *Nemo*, the NPC are more sensible to cell death induced by low levels homocysteine. Collectively our data suggest that genes belonging to the one-carbon metabolism represent modifier factors in IP disease able to modulate the IP phenotype severity by producing mild elevation of homocysteine levels that trigger brain injury by affecting survival of CNS cells lacking *NEMO*/*IKBKG* gene.

2936W

A novel missense mutation in *NLRC4* gene causes an autoinflammatory disorder associated with hypercytokinemia, chronic meningitis and hearing impairment. *H. Oda[1,2], K. Nakagawa[2], K. [Background] NLR-family CARD domain-containing protein 4 (NLRC4) is one of the cytosolic receptors for bacterial components. When stimulated, NLRC4 forms a multiprotein complex called inflammasome and triggers the production of inflammatory cytokines such as IL1b and IL18. To date, three amino acid alterations of NLRC4, namely, p. Val341Ala, p. Thr337Ser, and p. His443Pro, have been reported in patients with autoinflammatory symptoms. However, the clinical courses of these patients vary substantially, in terms of the presence or absence of life-threatening systematic inflammation and/or persistent colitis. [Case presentation] The patient, 20-year old male, showed periodic episodes of fever, arthralgia, erythema and chronic meningitis (CSF cell count; 850/ul) from neonatal period. His white blood cell count is 16300/ul (neutrophil; 94%), CRP 21. 1 mg/dl, serum amyloid A 453 ug/ml, IL-1b 31 pg/ml, IL-6 16. 8 pg/ml (elevated to 1160 pg/ml during attacks), TNFa <5 pg/ml, and sTNFR1 1330 pg/ml. His intelligence quotient (IQ) was 49 (WISC-III). He showed bilateral hearing impairment (8 kHz, 50 dB). While he had suffered from multiple episodes of systemic inflammation, which sometimes necessitated steroid-pulse therapy or even hemodiafiltration, anti-IL1 (Anakinra) therapy dramatically improved his clinical course. [Methods and Results]We performed trio-based whole exome sequencing and detected c. 529A>G (p. Thr177Ala) variant in the patient, which is not reported in dbSNP, HGVD or ExAC databases. *In silico* structural analysis revealed that Threonine 177 is located close to ATP-binding site of NLRC4, which is also the case with other previously reported NLRC4 mutations. Transfection of NLRC4 T177A construct into THP1, a human monocytic cell line, induces increased cell death compared to WT-NLRC4, suggesting the pathogenicity of T177A mutation. [Conclusion]We identified a novel missense mutation of NLRC4 in a patient with hypercytokinemia and CNS symptoms. Further molecular investigation is needed to define the genotype-phenotype correlation of NLRC4-associated autoinflammatory disorders.

Changes in red blood cell membrane structure in G6PD deficiency and thalassemia: an atomic force microscopy study. *W. Jiang[1], J. TANG[1], C. R. JIANG[1], X. XIAO[2], Z. S. FANG[1], L. LI[2], L. H. HAN[1], A. Q. MEI[1], Y. FENG[1], Y. B. GUO[1], H. Y. LI[1].* 1) Department of Medical Genetics, Zhongshan School of Medicine, Sun Yat-sen Univer, Guang Zhou, China; 2) Department of Clinical Laboratory Medicine, the third affiliated Hospital of Guangzhou medical University, Guangzhou,China.

Anemia is a major source of morbidity and mortality worldwide. Anemia may be caused by a variety of pathologic conditions, including such congenital disease as thalassemia and G6PD deficiency. The hemolytic anemia in G6PD deficiency is usually triggered by oxidative stress, but the mechanism remains uncertain. Moreover, the relationship between thalassemia and RBCs membrane ultrstructure remains to be clarified. We have used atomic force microscopy (AFM) for studying changes in red blood cell membrane to provide new insights on the hemolysis mechanism of G6PD deficiency and thalassemia. G6PD activity assay and molecular genetic tests were used for molecular diagnosis, AFM for analyzing the ultra structure of RBC membranes from 33 G6PD deficient patients, five alpha-thalassemia and five beta-thalassemia individuals. We analyzed the ultrastructure of RBC membranes with or without Primaquine pretreatment and observed the protective effects of vitamin C by AFM. AFM imaging and quantitative analysis showed that G6PD deficient and thalassemias erythrocytes became heterogeneous roughness measurements of RBC membranes are increased, and different mutations may relate with roughness parameters. The width of thalassemias erythrocyte membranes is decreased, and the height increased, when compared with the control. Primaquine induces an increase roughness and height of erythrocyte membrane in normal and G6PD deficient erythrocytes, which could be prevented by vitamin C treatment in normal RBCs, but not in G6PD deficient erythrocytes. The ultra structures damages of erythrocyte membrane in G6PD deficient and thalassemia patients will give valuable information to explore the mechanism of hemolytic anemia.

2938F

From the Bcl-2-deficient mice to the human phenotype : an uncomplete demonstration requiring data sharing. *L. Duplomb-Jego[1], N. Droin[2], J. Thevenon[1], O. Bouchot[1], AL. Bruel[1], C. Thauvin-Robinet[1], E. Solary[2], L. Faivre[1].* 1) Dijon University Hospital, Dijon, France; 2) Gustave Roussy Institute, Villejuif, France.

Protooncogen BCL2 is a major repressor of apopotosis in diverse cell types. Mice knockouts for Bcl2 complete embryonic development, but present with a multisystemic progressive disorder with growth retardation and early mortality postnatally. Progressive hematological manifestation are reported with initially normal hematopoiesis and lymphocyte differentiation, evolving in massive apoptotic of thymus and spleen. Severe polycystic kidney disease characterized by dilated proximal and distal tubular segments and hyperproliferation of epithelium and interstitium lead to renal failure. bcl-2-/-mice turn gray with the second hair follicle cycle, implicating a defect in redox-regulated melanin synthesis. To date, no human disorder was demonstrated to be caused by BCL2 haploinsufficiency. A 31-year-old patient presented the unique association of polycystic kidney, lymphopenia with a personal history of T cell lymphoblastic lymphoma in early infancy, white hair since the age of 20 years. Additionally, he developed an abdominal aortic dissection, and ascending thoracic aortic aneurysm, scoliosis and learning difficulties. Only the PKD was found in the father and sister, and an inherited PKD2 mutation was evidenced. Based on the striking similarities shared by the patient and the bcl2-/- mice, we hypothesized that the patient phenotype could be due to the BCL2 haploinsufficiency. Repeated in vitro experiments performed on cultured patients lymphocytes demonstrated a severe apoptosis as compared to controls. Apoptosis phenotype could be rescued by anti-CD3 antibodies, suggesting BCL2 mediated apoptosis. In cultured lymphocytes, BCL2 expression was very low when quantified using real-time PCR and immuno-imprint. Intermediate results were found for both parents, suggesting an autosomal recessive inheritance. Direct sequencing of the exons, promotors and 3'UTR region failed in identifying any *BCL2* pathogenic variant, as well as mRNA sequencing of *BCL2*. Array-CGH was normal. Exome sequencing of the patient, the parents and sister failed in identifying a variant in a gene interacting with *BCL2*. The methylation of *BCL2* promotor was normal, and miRNA sequencing revealed an overexpression and underexpression of miRNA interacting with *BCL2*. Data sharing is required in order to identify other patients with a similar clinical or cellular phenotype. The hypothesis of the presence of a modifying factor modulating the expression of the *PKD2* variant cannot be excluded.

2939W

A potential founder variant in *RLTPR* in 3 Norwegian families with warts, molluscs and T cell dysfunction. *H. Sorte[1], L. T. Osnes[2], B. Fevang[3,4], H. C. Erichsen[5], T. G. Abrahamsen[3,5], T. Øverland[5], P. Samarakoon[1], T. Gambin[6], Z. H. C. Akdemir[6], O. K. Rødningen[1], R. Lyle[1], J. R. Lupski[6,7,8,9], A. Stray-Pedersen[6,10].* 1) Department of Medical Genetics, Oslo University Hospital and University of Oslo, Norway; 2) Department of Immunology, Oslo University Hospital, Oslo, Norway; 3) Institute of Clinical Medicine, University of Oslo, Oslo, Norway; 4) Section of Clinical Immunology and Infectious Diseases, Oslo University Hospital, Oslo, Norway; 5) Department of Pediatrics, Oslo University Hospital, Oslo, Norway; 6) Baylor-Hopkins Center for Mendelian Genomics (BHCMG) of the Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, US; 7) Human Genome Sequencing Center of Baylor College of Medicine, Houston, TX, US; 8) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, US; 9) Department of Pediatrics, Baylor College of Medicine, Houston, TX, US; 10) Norwegian National Unit for Newborn Screening, Oslo University Hospital, Oslo, Norway.

RLTPR (RGD-, leucine-rich repeat-, tropomodulin domain-, and proline-rich domain containing protein) is a protein of undetermined function. However a role in T cell activation has been suggested and *RLTPR* expression has been shown to be downregulated in psoriatic skin. The mouse protein homolog (Rltpr) is essential for costimulation of T cell activation via CD28 and the development of regulatory T cells. Four affected individuals from three different families were exome sequenced as part of a larger study for detecting genetic causes of primary immunodeficiencies. No disease-causing variants were identified in known primary immunodeficiency genes or in OMIM genes. The same homozygous missense variant was identified in all 4 patients. In each family the variant was located within a narrow region of homozygosity, representing a potential region of autozygosity. All 3 families are of Norwegian origin, but without known inter- or intra-consanguinity. All four patients had a common skin phenotype of warts, molluscs and eczema since early childhood. Gastrointestinal disease, childhood asthma, BK virus induced cystitis were observed to a variable degree. All had eosinophilia. Immuno-phenotyping demonstrated reduced number of CD4+ memory and follicular CD4+ in 3/4, and reduced regulatory T cells in 2/4 affected individuals. Normal NK cell numbers and function. Low number of IgM memory and class switched B-cells, and/or hypogammaglobulinemia were observed in 3/4 individuals. We report a novel primary immunodeficiency, and a differential molecular diagnosis to *CXCR4* (WHIM), *DOCK8*, *GATA2*, *MAGT1*, *TMC6* and *TMC8* related diseases. The specific variant may represent a Norwegian founder variant segregating on a population specific haplotype.

2940T

Mendelian Genomics approach identifies novel disease causal genes for human immunological disorders. *Y. Zhang[1,2], A. Oler[1], X. Yu[1,3], H. Matthews[1,4], M. Similuk[1], J. McElwee[5], A. Freeman[6], J. Milner[1,3], H. Su[1,2], M. Lenardo[1,4], NIAID Clinical Genomics Program.* 1) NIAID Clinical Genomics Program, National Institutes of Health, Bethesda, MD; 2) Laboratory of Host Defenses, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD; 3) Laboratory of Allergic Diseases, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD; 4) Laboratory of Immunology, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD; 5) Merck Research Laboratories, Merck & Co. Inc. , Boston, MA; 6) Laboratory of Clinical Infectious Diseases, National Institutes of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD.

Genomic sequencing approaches have been widely used to identify causative rare variants in families with Mendelian diseases. The discoveries of new genes and pathways for human immune disorders provide new insights into our understanding of the regulation of human immune system, as well as improving clinical diagnosis and targeted therapy for drug development. The NIAID Clinical Genomics program, in conjunction with the NIAID Primary Immune Deficiency Clinic, was set up to exploit new genomics technologies for identification of novel disease genes in patients who have a spectrum of diagnoses without known molecular etiology. The immunological disorders under our investigation include primary immunodeficiencies, immune homeostasis disorders, autoimmune conditions, and allergic disorders. We have preformed about 400 whole exome sequencing (WES) for more than 100 enrolled patients and family members. WES revealed deleterious mutations for previous established diagnosis in 15% of the sequenced patients. Most of those patients were noted to have atypical clinical features comparing to previous reported cases. Potential disease causal variants were identified in novel candidate genes in about 40% of the WES families. With functional validation and characterization, we have successfully discovered more than 10 new immunological genetic disorders, including discoveries for expanding our knowledge of previous known immunology essential genes (CTLA4, PIK3CD, STAT3 GOF etc.), discoveries of new functions of previously known immunology relevant genes (TPPII etc.) and discoveries of novel genes without previous association or involvement in immunology (MAGT1, PGM3 etc.). Those discoveries have already led to several treatment protocols applied to our patients (Magnesium for XMEN patients, N-acetylglucosamine/triacetyluridine for PGM3 patients, PIK3 inhibitor trial etc.). We are currently expanding our Mendelian genomics efforts by collaborating with investigators and clinicians across multiple countries, as well as industry. Recently, we also switched our sequencing platform to whole genome sequencing (WGS) and have performed 313 WGS from 120 families. The WGS samples include previous WES families without a clear deleterious variants candidate and new enrolled families/patients. Those data sets provide a comprehensive comparison of WES vs. WGS about efficiency and sensitivity for detecting potential disease causal mutations.

2941F

Frequency and effect of α-thalassemia mutations on the hematological phenotype in Mexican mestizo patients with β-thalassemia. *L. delC. Rizo de la Torre[1,2], V. M. Rentería López[2], B. Ibarra[1,3], F. J. Perea Díaz[1,2].* 1) Doctorado en Genética Humana, CUCS, Universidad de Guadalajara, Guadalajara, Jalisco, Mexico; 2) División de Genética, Centro de Investigación BioMédica de Occidente (CIBO), Instituto Mexicano del Seguro Social (IMSS), Sierra Mojada No. 800, Guadalajara Jalisco, México; 3) Instituto de Genética Humana "Enrique Corona Rivera", Centro Universitario de Ciencias de la Salud (CUCS), Universidad de Guadalajara (UdG), Sierra Mojada No. 950, Guadalajara Jalisco, México.

Introduction. β-thalassemia (β-thal) is one of the most frequent monogenic disorders worldwide, it is caused by reduction (β+) or absence (β0) of β-globin chains synthesis by mutations in *HBB*, leading to microcytic hypochromic anemia. β-thal is a clinically heterogenous disease. There are other known genetic factors that modify the phenotype such as reduction of α-globin chains (-α/αα, -α/-α or --/αα), therefore co-inheritance of α-thalassemia (α-thal) is benefical for patients with β-thal. Objective. To estimate the frequency of α-thal mutations in Mexican mestizo patients with β-thal and it's effect on the hematological phenotype. Methodology. DNA of 109 β-thal heterozygote patients was studied. β-thal mutations were identified by Amplification Refractory Mutation System and DNA sequencing, α-thal mutations by Gap-PCR, besides one patient's α-thal allele was identified by MLPA. Hematological phenotype of β-thal carriers according to α-thal genotype was compared using IBM SPSS Statistics for Macintosh, Version 21. 0. Results. Four α-thal alleles (-α3. 7, --SEA, --FIL, --MEX2) and one triplication (ααα3. 7) were identified. Ten patients (9. 1%) had α-thal, the following genotypes were observed: five (4. 6%) -α3. 7/αα, two (1. 8%) --SEA/αα, one (0. 9%) -α3. 7/-α3. 7, one (0. 9%) --FIL/αα and one (0. 9%) -α3. 7/--MEX2, four other patients (3. 7%) were carriers of the ααα3. 7 allele. No α-thal mutations were found in 93 (85. 3%) patients, two (1. 8%) patients remained unidentified. Regarding β-thal, a total of 14 different *HBB* mutations were observed (eight b0 and six b+). b0 alleles were observed in 78. 9% of the patients, while 21. 1% were b+. The most frequent ones were c. 118C>T (39. 4%), c. 92+1 G>A (20. 2%) and c. 93-21 G>A (14. 7%). According to the hematological phenotype, double heterozygotes b0 and -α/-α or --/αα showed less severe phenotye than simple heterozygotes (Hb=12. 0±2. 6 *vs* 11. 6±9. 6 g/dL; MCV=65. 5±2. 1 *vs* 61. 1±7. 0 fL; HCM=21. 2±0. 4 *vs* 19. 6±2. 6 pg). Also, b+ carriers showed a slight increment on MCV (65. 5±9. 2 *vs* 63. 9±4. 3 fL) and MCH (21. 9 ± 3. 1 *vs* 20. 7 ± 1. 6 pg) when co-inherit -α/αα alleles. However, in all cases the comparative analysis did not show statistical significance ($p > 0.05$). Due to the reduced number of patients with α-thal, genotype-phenotype correlation could not be established. Conclusion. Presence of α-thal mutations is frequent in Mexican mestizo patients with β-thal. We observed no association of α-thal mutations with the hematological phenotype.

2942W

Molecular analysis of a novel mutation (CD16 GGC →GGT) in the exon 1 region of the human β-globin gene, associated with an unexpectedly severe β thalassemia intermedia phenotype. *F. Taghavifar[1], G. Shariati[2], M. Hamid[2,3], A. Metzenberg[1].* 1) Department of Biology, California State Univeristy, Northridge; 2) Narges Medical Genetics & PND Laboratory; 3) Department of Molecular Medicine, Biotechnology Research Center, Pasteur Institute of Iran.

β thalassemia is an autosomal recessive disorder, which is caused by mutations in the HBB gene that codes for β–globin chains of the hemoglobin protein. β thalassemia is associated with a reduced or absent synthesis of the β–globin chains, which resulst in insufficient hemoglobin production, mild to severe anemia and ultimately organ damage and poor overall growth of the affected individuals. A novel mutation, CD16 (GGC→GGT), in the exon 1 region of the β-globin gene has been found by DNA sequencing in a mother and daughter of an Iranian family. The father was heterozygous for a common β thalassemia allele (CD36/37 –T) and he displayed a classic minor β thalassemia phenotype. The mother was asymptomatic for β-thalassemia, but had hemotological parameters that were borderline. Their daughter, who was a compound heterozygote for both the maternal novel and the paternal mutations, showed an unexpectedly severe intermediate β thalassemia phenotype. Physical examination of the proband showed paleness and mild splenomegaly, and she had a history of transfusion dependence. Therefore, the novel CD16 mutation affected the normal expression of the β-globin gene, either alone or in combination with another mutation. To investigate the molecular basis of the observed β thalassemia phenotype in the family, we analyzed the structural and functional effects of the CD16 mutation on HBB gene expression, using bioinformatics and RT-qPCR experiment**.** Analysis showed that the C→T transition in the novel gene created a cryptic splice site, with homology to the 6 middle nucleotides of the donor consensus sequence at the exon 1- intron 1 boundary. It has been reported that this homologous sequence in exon 1 causes alternative splicing, reducing the efficiency of the normal donor splice site. RT-qPCR analysis revealed that the novel mutation was associated with a down-regulation of the HBB gene. This study describes the first report of a novel mutation in the HBB gene, which creates a cyptic splice site, down-regulating the β-globin gene expression. We are currently investigating the effects of this mutation on the express of other globin and non-globin genes, using the HiSeq 2000 system from Illumina. These data will provide important information for genetic counceling centers working on the premarital and prenatal diagnosis of thalassemia.

2943T

Uncovering the etiology of ICF syndrome: new disease genes and functional insight in the molecular processes underlying the immunodeficiency. *S. M. van der Maarel[1], P. E. Thijssen[1], Y. The immunodeficiency, centromeric instability, and facial anomalies (ICF) syndrome is clinically characterized by recurrent and often fatal infections as a consequence of hypo- or a-gammaglobulinemia in the presence of B cells. ICF syndrome has been considered an exemplar epigenetic disease with half of the patients carrying loss of function mutations in the *de novo* DNA methyltransferase 3B gene (*DNMT3B,* referred to as ICF1), resulting in genome-wide hypomethylation, predominantly affecting the pericentromeric satellite repeats of chromosomes 1, 9 and 16. ICF syndrome is a genetically heterogeneous disorder with another 30% of patients carrying mutations in the zinc finger and BTB domain containing 24 (*ZBTB24*) gene (ICF2). Here we report mutations in the cell division cycle associated 7 (*CDCA7*) and the helicase, lymphoid-specific (*HELLS*) genes in the majority of unexplained ICF cases. By transient depletion of each of the individual ICF genes in mouse embryonic fibroblasts we demonstrate that all four ICF genes have a role in the establishment and/or maintenance of CpG methylation at pericentromeric satellite repeats. While these and other studies have firmly established a causal relationship between the ICF gene mutations and the major epigenetic changes observed in ICF syndrome, the molecular mechanisms underlying the immune defect have thus far remained largely elusive. We now demonstrate that ZBTB24 has a role in the non-homologous end-joining-dependent repair of DNA double strand breaks during class switch recombination, explaining the immunodeficiency in ICF2 patients. This, for the first time, provides a mechanistic link between the chromatin modifiers mutated in ICF syndrome and the associated immunodeficiency phenotype.

2944F

Carriers of the complex allele *HFE* c. [187C>G;340+4T>C] have increased risk of iron overload in São Miguel Island population (Azores, Portugal). *L. Mota-Vieira[1,2,3], C. T. Gomes[1], L. De Fez[1], S. Bulhões[1], M. J. Brilhante[1], T. Pereirinha[1], R. Cabral[1], C. C. Branco[1,2,3].* 1) Molecular Genetics and Pathology Unit, Hosp of Divino Espirito Santo of Ponta Delgada, Azores Islands, Portugal; 2) Instituto Gulbenkian de Ciência; Oeiras, Portugal; 3) BioISI - Biosystems & Integrative Sciences Institute, Faculty of Sciences, University of Lisboa, Lisboa, Portugal.

Iron overload is associated with acquired and genetic conditions, being the most common the hereditary hemochromatosis (HH) type I, caused by *HFE* mutations. Despite recent advances, a better understanding of molecular basis of iron overload is needed, to improve patient's outcome through early diagnosis and treatment. Here, we performed a hospital-based case-control study of 41 patients from São Miguel Island (Azores, Portugal), 6 belonging to a family with HH type-I pseudodominant inheritance, and 35 unrelated individuals fulfilling the biochemical criteria of iron overload compatible with HH type-I. To that end, we genotyped the most common *HFE* mutations –c. 845G>A [p. Cys282Tyr], c. 187C>G [p. His63Asp], and c. 193A>T [p. Ser65Cys] –, by TaqMan real-time PCR. Results revealed that 10 (24. 4%) patients were homozygous for the c. 845A mutation, and 5 (12. 2%) were c. 845A/c. 187G compound heterozygous. Sanger sequencing of *HFE* exons, where these mutations are located (exons 2, 4, and their intron-flanking regions), did not reveal other mutation but allowed the identification of c. 340+4C [IVS2+4C] splice variant in 26 (74. 3%) patients. In terms of functionality, the c. 340+4C may generate alternative splicing by *HFE* exon 2 skipping, and, consequently, a protein missing the α1 domain, which is essential for the interaction of HFE with the transferrin receptor 1. Moreover, we found that 21 (60. 0%) patients have at least two *HFE* mutations/variants, placed *in-cis* or *in-trans* position, that may explain the iron overload. Further, we investigated these mutations/variants configuration with iron overload, by determining the *HFE* haplotypes and genotypic profiles. Results evidenced that carriers of the *HFE*-c. 187G allele also carry the -c. 340+4C, suggesting that they are *in-cis* configuration. This data was corroborated by the association analysis, where carriers of the complex allele *HFE*-c. [187C>G;340+4T>C] have an increased risk for iron overload (RR=2. 08, 95% CI=1. 40-2. 94, p<0. 001). Therefore, homozygous for this complex allele are at risk to have iron overload, since they will produce two altered proteins – the p. 63Asp [c. 187G] protein, and the protein lacking 88 amino acids encoded by exon 2. In summary, we provide evidence that the complex allele *HFE*-c. [187C>G;340+4T>C] has a role, as genetic predisposition factor, on iron overload in the São Miguel population (Azores, Portugal). Independent replication studies in other populations are needed to confirm this association.

2945W

Coordinated regulation of splicing events within *SLC12A3* and implications to Gitelman Syndrome. *C. Mercado, X. Wang, Y. C. Chang.* School of Medicine, University of Maryland, Baltimore, MD 21201, USA.

The majority of human multi-exon genes undergo alternative splicing (AS), resulting in structurally different transcripts and functionally distinct protein isoforms that are differentially expressed across tissues. *SLC12A3* encodes Na+/Cl- cotransporter (NCC), which is involved in salt reabsorption along the distal nephron. Inactivating mutations within *SLC12A3* cause Gitelman syndrome (GS), an autosomal recessive disorder characterized by chronic salt wasting and hypotension. Previous findings indicate that AS of *SLC12A3* exons 7 and 8 leads to transcript isoforms missing either exon 7 (Dexon7) or both exons (Dexon7-8). Isoform Dexon7 contains a premature stop codon in exon 9 and, presumably, activates nonsense-mediated decay, leading to little or no NCC synthesis. However, -exon7-8 results in an in-frame deletion of a highly conserved extracellular domain of NCC (p. (Ala285_Lys365del)). All 3 isoforms are found in normal human blood cells and kidneys, with Dexon7 and Dexon7-8 much less abundant in both tissues. Importantly, a splicing mutation (IVS7-1G>A; 965_976>CCGAAAATTTT) leads to a higher abundance of isoform Dexon7-8 and is thought to be pathogenic in GS patients. However, the exact mechanism as to how this mutation, changes in isoform abundances, or the small NCC protein isoform leads to GS is not known. In this study, we performed RNA-seq to analyze the human and mouse kidney transcriptomes. Several human- and kidney-specific *SLC12A3* AS isoforms were detected and confirmed by conventional RT-PCR. In addition to the known AS involving exons 7 and 8, we identified a novel AS event that occurs within the 3'UTR. Splicing in this region results in a shorter 3'UTR lacking an internal 171 bp segment. Using isoform-specific primers, we established that isoform Dexon7-8 with the larger 3'UTR is abundantly expressed in kidney. In contrast, isoform Dexon7-8 with the smaller 3'UTR is not detected, suggesting that AS in these 2 regions is coordinately regulated. Interestingly, the spliced 3'UTR segment harbors a putative microRNA-binding site for hsa-miR-4722-3p. Therefore, isoform Dexon7-8 might be targeted for miRNA-mediated mRNA degradation or translational suppression, resulting in little or no NCC with p. (Ala285_Lys365del). In summary, microRNA binding to isoform Dexon7-8 can potentially suppress the translation of an abnormal NCC protein. In this case, the GS-causing splicing mutation is functionally a null mutation due to coordinated splicing at 2 sites.

2946T

Novel defects of *FOG2/ZFPM2* including 3. 2 Mb deletion lead to isolated 46, XY disorders of sex development and 46, XX ovarian dysfunction. *D. Baetens[1], N. Reynaert[3], F. de Zegher[3], E. De Baere[1], M. Cools[2].* 1) Center for Medical Genetics, Ghent University, Ghent, Belgium; 2) Department of Pediatrics, Division of Pediatric Endocrinology, Ghent University Hospital and Ghent University, Ghent, Belgium; 3) Department of Pediatric Endocrinology, University Hospitals Leuven, Leuven, Belgium.

Background: *FOG2* (Friend of GATA2; also known as *ZFPM2*) mutations and copy number variants (CNVs) have been associated with congenital cardiac anomalies and diaphragmatic hernias for more than a decade. In addition, *FOG2* has recently been implicated as novel disease gene for isolated 46, XY disorders of sex development (DSD). Here, we report the first CNV encompassing *FOG2* and other genes in a patient with isolated 46, XY DSD and his mother with 46, XX ovarian dysfunction. In addition, a 46, XY DSD cohort was screened for coding *FOG2* mutations. Results: ArrayCGH revealed a heterozygous 3. 2 Mb deletion (chr8: 104348705-107509840) encompassing *FOG2* and nine other genes in a neonate with penoscrotal hypospadias and bilateral cryptorchidism. This deletion is of maternal origin. Endocrinological investigations showed low testosterone, anti-Møllerian hormone (AMH) and inhibine B levels, suggestive of gonadal dysgenesis. Cardiac ultrasound was normal. The mother had a low serum AMH value (0. 57 µg/l [0. 9-9. 5]), suggestive of ovarian dysfunction. We screened a cohort of 58 patients with 46, XY DSD for coding *FOG2* mutations or CNVs using a flexible targeted next-generation sequencing approach (MiSeq) and qPCR (Roche) respectively. This uncovered a novel heterozygous missense variant in a single case: c. 2432T>G p. (Val811Gly). This missense variant is predicted to be deleterious by several algorithms and affects an amino acid that is highly conserved up to chicken. The physicochemical distance between Val and Gly is 109, suggesting a possible effect on protein function. The variant is not known as a SNP and is absent in the ExAc browser. Segregation testing and functional characterization of this variant is ongoing. Conclusion: There are several reports of *FOG2* mutations and translocations disrupting *FOG2* in patients with congenital cardiac defects with or without gonadal abnormalities. Recently missense mutations of *FOG2* were identified in two patients with isolated 46, XY DSD without cardiac involvement. To the best of our knowledge, we present here the first genomic rearrangement encompassing*FOG2* as the underlying cause of isolated 46, XY DSD and of 46, XX ovarian dysfunction. This is emphasizing its dosage sensitivity and its strict tissue-specific regulation. Finally, we identified a novel missense variant in 46, XY DSD. Taken together, we have expanded the molecular spectrum of *FOG2* mutations in isolated 46, XY DSD and in 46, XX ovarian dysfunction.

2947F

Phenotypic interaction between GH-releasing hormone (GHRH) receptor mutation detected by exome sequencing and non-classical congenital adrenal hyperplasia. *I. Arnohold[1], Q. MA[2], F. CORREA[1], M. FRANÇA[1], Q. FANG[2], T. BACHEGA[1], A. RODRIGUES[1], J. LI[2], B. MENDONCA[1], A. JORGE[1], S. CAMPER[2], L. CARVALHO[1].* 1) Hospital das Clinicas da Faculdade de Medicina da Universidade de Sao Paulo, Sao Paulo, SP, Brazil; 2) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI.

Background: Isolated Growth Hormone Deficiency (IGHD) is the most common pituitary hormone deficiency and can result from genetic or acquired causes. Patients with GH deficiency usually have a retarded bone age. **Objective:** To diagnose the genetic cause of IGHD and clarify the unusual clinical presentation of advanced bone age in one patient born to consanguineous parents. **Patient:** A 7. 5 year-old boy presented with severe short stature (height 102. 5 cm, SDS-3. 7), high-pitched voice, blue sclerae and prominent forehead. Genital examination was prepubertal and bone age was 6 years. Parents were second-degree cousins. Clonidine and combined pituitary stimulation test (insulin, TRH and GnRH), revealed GH deficiency (GH peak 0. 6 ng/ml) and was compatible with partial ACTH deficiency (cortisol peak=16. 1 mcg/dl). Pituitary MRI was normal. The patient was successfully treated with rGH (33 mcg/kg/day) with a first year growth velocity of 11. 7 cm/yr. Surprisingly, at 10. 8 years his bone age had advanced to 13 years, but physical exam, LH and testosterone levels remained prepubertal. **Methods:** Sanger-sequencing of *GH1*, *GHRH, GHRH receptor* and *CYP21A2* (using an active gene-specific exon 3 primer) followed by whole exome sequencing (WES). MLPA of the *CYP21* unit. **Results:** An ACTH stimulation test disclosed a basal 17-hydroxyprogesterone of 9. 4 ng/ml and peak of 52 ng/ml indicating non-classical adrenal hyperplasia due to 21-hydroxylase deficiency and treatment with cortisone acetate was added. Sanger sequencing of *CYP21A2* revealed homozygous c. 844G>T, p. Val282Leu mutation, but *GH1*, *GHRH* and *GHRH receptor* were read as normal. MLPA indicated a *CYP21A1P* and *C4B* duplication, but no major deletion or conversion. WES revealed a homozygous mutation in *GHRHR* (c. T431A, p. Leu144His) which had been overlooked by initial Sanger sequencing but could be identified when the electropherogram was re-examined. This recurrent mutation had been previously identified in Brazilian, Spanish and US patients with IGHD. Interestingly, WES indicated the CYP21A2 p. Val282Leu mutation in heterozygous state, probably due to the presence of a normal sequence in at least one copy of the pseudogene. **Conclusion:** A patient born to consanguineous parents presented with two recessive endocrine diseases modifying the phenotype: GH deficiency due to a *GHRH receptor* mutation diagnosed by WES and non-classical CAH diagnosed correctly only by Sanger sequencing specific to the active gene *CYP21A2*.

2948W

Phenotypic spectrum from cerebral midline defects to hypopituitarism: examples from HESX1 mutations. *Q. Fang[1], Q. Ma[1], A. Sadeghi-Nejad[2], I. J. P. Arnhold[3], F. Correa[3], A. B. Ozel[1], J. Z. Li[1], S. A. Camper[1], L. R. S. Carvalho[3].* 1) University of Michigan, Department of Human Genetics, Ann Arbor, MI; 2) Tufts University School of Medicine, Boston, MA; 3) University of Sao Paulo, Clinicas Hospital, Brazil.

Congenital hypopituitarism occurs approximately 1/4000 births and can be life threatening if not identified and treated effectively. About a dozen different genetic causes have been reported, but most of the patients have no molecular diagnosis. Mutations in the transcription factors POU1F1 and PROP1 are typically nonsyndromic and associated with recessive inheritance, while mutations in several other causal genes present as dominant with incomplete penetrance with variable clinical features, sometimes including craniofacial and eye defects. HESX1 is a member of the *paired* (*prd*) class of homeodomain proteins and functions as a transcriptional repressor. Mutations in *HESX1* can be dominant or recessive and cause septo-optic dysplasia (SOD), combined pituitary hormone deficiency (CPHD) or isolated growth hormone deficiency (IGHD). There are no obvious genotype-phenotype correlations. The diverse effects on head development are not surprising because *Hesx1* is expressed in embryonic stem cells, the anterior midline during gastrulation, the ventral prosencephalon, the ventral diencephalon and the pituitary primordium. Here we report mutations in *HESX1* found by exome sequencing that explain hypopituitarism in two unrelated patients. The familial pituitary aplasia case is a compound heterozygote for missense mutations in the homeodomain: p. R159W/p. R160H. Cell culture studies reveal that these mutations diminish the repressive activity of HESX1 on PROP1. In previous reports homozygosity for p. R160H caused CPHD, not aplasia, while homozygosity for p. R160C caused SOD. We also identified a homozygous p. I26T missense mutation in the second case from consanguineous parents with evolving CPHD and eutopic posterior pituitary. A patient with the same mutation was previously reported to have evolving CPHD with ectopic posterior pituitary. These cases illustrate the variable features that can result from loss of function mutations in the same gene. We propose that the severity of the clinical presentation is related to the genetic load of deleterious variants in other genes that contribute to head development. We are testing this idea by exome-sequencing and analyzing more patients.

2949T

Germline mutations identification in familial isolated prolactinoma through whole-exome sequencing. *F. Melo[1], R. CARDENAS[2], L. BASTOS-RODRIGUES[3], P. COUTO[1], A. BALE[4], J. NG[5], T. CURRAN[5], P. DE MARCO[1], S. PENA[2], E. FRIEDMAN[6], L. DE MARCO[1].* 1) Department of Surgery, Universidade Federal de Minas Gerais, Belo Horizonte; 2) Departments of Biochemistry, Universidade Federal de Minas Gerais, Belo Horizonte; 3) Department of Basic Sciences, Universidade Federal de Juiz de Fora, Brazil; 4) Department of Genetics, Yale University School of Medicine, New Haven, USA; 5) Cell & Developmental Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia; 6) The Susanne Levy Gertner Oncogenetics Unit, Chaim Sheba Medical Center, Tel-Hashomer, Israel.

Introduction: Prolactinomas are the most common type of pituitary tumors, being associated with hyperprolactinemia that can lead to hypogonadism and mass-effect related symptoms. Rarely, prolactinoma is diagnosed in a familial context either as part of Multiple Endocrine Neoplasia Type I syndrome (MEN 1) or as an independent entity, that can be referred to as Familial Isolated Prolactin-secreting Pituitary Adenoma. Germline mutations in *MEN1, AIP* and *PRLR* genes have been identified in a subset of prolactinoma-affected families as disease causative mutations. However, in the majority of familial prolactinoma cases the causal gene mutation remains unknown. In order to identify potential isolated Prolactin-secreting pituitary adenoma candidate genes, DNA from a Brazilian affected family were subjected to whole exome sequencing (WES). **Materials and methods**: The family is comprised of ten siblings (ages ranging from 44 to 64 years old) and three were diagnosed with hyperprolactinemia and isolated Prolactin-secreting pituitary adenomas. The mother and seven siblings were clinically asymptomatic. The father died of unrelated disease. **Results**: Direct DNA sequencing of *MEN1*, *AIP* and *PRLR* genes revealed no mutations. Genomic DNA from all affected siblings and their mother were subjected to whole-exome (WES) capturing and sequencing using the Roche NimbleGen V2 chip and the Illumina HiSeq2000 sequencing platform. Two different analytical approaches to identify rare genetic determinants were used: *Ingenuity® Variant AnalysisTM* and *Mendel, MD* (unpublished). Variant calling from WES of the genotyped DNA resulted in 19,134 common single nucleotide variations (SNV) in 8,729 genes. The mean base call quality was 1546 and average read depth was 82. For the filtering approach, we excluded variants with a minor allele frequency > 0. 01 in public datasets and identified a remaining set of functional variants, predicted to be deleterious using Sift, PolyPhen, Condel and CADD. **Conclusion**: A final list of 12 genes was generated and the mutations are being validated by Sanger sequencing approach. This work gives a new insight into unveiling FIPA-causing mutations for those patients that are negative for *MEN1*, *AIP* and *PRLR* gene molecular alterations.

2950F

Examining the genetics of Hereditary Pancreatitis (HP) in adult patients with Chronic Pancreatitis. *H. Azimi[1,3,4,5], S. Ghavimi[7], J. Brown[2], J. Sleza[6], S. Emamian[8].* 1) PsychoGenome, Ottawa, Ontario, Canada; 2) Toronto University School of Public Health, Toronto, Ontario, Canada; 3) All Saints School of Medicine, Dominica; 4) Carleton University, Ottawa, Ontario, Canada; 5) Shahid Beheshti University School of Medicine, Tehran, Iran; 6) Ottawa University, Ottawa, Ontario, Canada; 7) Howard University Hospital, Dept. of Medicine, Washington, DC, USA; 8) Indiana University, Bloomington, Indiana, USA.

Objective: To study the genetics of hereditary pancreatitis (HP) in adult patients with Chronic pancreatitis. Methods: This outpatient study was conducted on 100 Patients who came to the clinic of Tajrish's Hospital and wore diagnosed with Chronic Pancreatitis. We examined the patients and their parents for Hereditary Pancreatitis. HP defined as those with trypsinogen gene (PRSS1) mutation on the long arm of chromosome seven (7q35). DNA was extracted from peripheral blood leukocytes, and exons 2 and 3 of the gene were individually amplified by polymerase chain reaction and sequenced. Results: Of 100 adult patients with a pancreatitis, 28 (28%) were diagnosed with adult onset of Hereditary pancreaitis. From the 28 patient with positive mutation on the trypsinogen (PRSS1) gene, 13 of them had one parent with mutation of the trypsinogen gene (PRSS1). The route of inheritance is Autosomal Dominant. From the 13 adult patients who had parents with the mutations of the trypsinogen gene (PRSS1), 11 (85%) recalled of their babies or young children, with having been diagnosed with epigastric pain, severe vomiting and nausea both after birth and during early childhood. From the 28 patients who wore diagnosed with having the mutation and (HP), 6 (21%) indicated that one of their parents has been deceased or currently diagnosed with Pancreatic Cancer. From the 28 patients with (HP) and gene mutation 8 (29%) also had Type 1 Diabetes Mellitus. Conclusions: Adult patients born to mothers or fathers with pancreatitis have an increase chance of having hereditary pancreatitis. Also babies born to parents whom are diagnosed with adult onset of hereditary pancreatitis have a high chance of having hereditary pancreatitis. It is clear that hereditary pancreatitis is autosomal dominant. The natural history of HP follows a similar pattern to alcohol-associated chronic pancreatitis, but there are important differences, for example, HP has an earlier age of onset of pancreatitis although malabsorption and diabetes mellitus occur at a later stage in the disease. Families are defined as having (HP) if the phenotype is consistent with highly penetrant autosomal dominant inheritance. We can conclude that majority of patients that develop hereditary pancreatitis in early childhood or adulthood had a parent with hereditary pancreatic disorder if diagnosed or pancreatic cancer in older age. Also HP patients should avoid environmental factors that cause pancreatic cancer.

2951W

Quantitative missense mutation profiling points to the root of phenotypic variability in Autosomal Dominant Polycystic Kidney Disease (ADPKD). *V. G. Gainullin[1], B. M. Paul[1], S. L. R. Klein[2], C. M. Heyer[1], P. C. Harris[1].* 1) Division of Nephrology and Hypertension, Mayo Clinic, Rochester, Minnesota, USA; 2) Macalester College, St. Paul, Minnesota, USA.

As whole exome sequencing is increasingly used to resolve monogenic and complex diseases, determining the significance of missense variants is of great importance. High-throughput cellular analyses of protein stability, folding, trafficking and protein-protein interactions are pivotal for determining likely pathogenicity and even to estimate penetrance. Here we investigate the pathogenic significance of 58 unique missense variants of uncertain significance to *PKD1* and *PKD2,* the genes causing the common nephropathy, autosomal dominant polycystic kidney disease (ADPKD). ADPKD generally results in renal failure in late middle age, but the phenotype is highly variable ranging from in utero onset to only a few cysts in old age, with allelic effects implicated. The two proteins encoded by the ADPKD genes, polycystin-1 (PC1) and PC2 interact while folding in the ER, and PC1 maturation and cell surface localization requires the ER chaperone function of PC2. Although it is known that truncating mutations to either gene result in ER-retained protein, the effect of the many missense mutations has not been quantified. Here, we use a quantitative flow-cytometry-based approach in combination with biochemical characterization of glycosylation and processing to analyze maturation and surface delivery of mutant polycystins. Computing the cumulative pathogenicity scores we found that 9% of *PKD1* and 53% of *PKD2* missense mutations fully disrupted protein folding, 45% of *PKD1* and 29% of *PKD2* were incompletely penetrant and 45% of *PKD1* and 18% of *PKD2* did not disrupt protein folding or localization. Furthermore, 83% of the *PKD1* and 85% of *PKD2* folding mutants were temperature-sensitive: rescued to wild-type status with 30°C incubation, suggesting molecular chaperone potential in treating some but not all patients inheriting missense mutations. Hence, this quantitative analysis can gauge relative penetrance of single alleles as well as allele combinations in ADPKD patients. Taken together, our comprehensive analyses show the potential of high-throughput screening methods to evaluate and estimate the penetrance of pathogenic missense variants.

2952T

Enzymatic properties of mouse chitotriosidase expressed in *Escherichia coli*. *M. Kimura, K. Ishikawa, K. Sekine, S. Yoshikawa, S. Wakita, A. Sato, A. Kashimura, M. Sakaguchi, Y. Sugahara, F. Oyama.* Department of Chemistry and Life Science, Kogakuin University, Hachioji, Tokyo, Japan.

Chitotriosidase (Chit1) was the first mammalian chitinase to be purified and cloned. Chit1 have attracted considerable attention due to their increased expression in individuals with different pathological conditions. Chit1 rise to Gaucher disease, chronic obstructive pulmonary disease (Chronic Obstructive Pulmonary Disease, COPD), Alzheimer's disease, in smokers, and Niemann-Pick disease and atherosclerotic tissue. These data strongly suggest that Chit1 plays important roles in many pathophysiological conditions. However, the contribution of Chit1 to the pathophysiology of these diseases remains to be determined. To understand its pathophysiological roles, we cloned mouse Chit1 cDNA into the vector pEZZ18 for intracellular expression in *E. coli* as a fusion protein of Protein A-Chit1-V5-His. The recombinant protein showed a robust peak of activity with a maximum activity at pH 5. 0, where the optimal temperature was 50°C. This recombinant protein can be used to elucidate detailed biomedical functions of the mouse Chit1.

2953F

Expression and characterization of catalytic domain of mouse AMCase in *Escherichia coli* . *F. Oyama, A. Kashimura, M. Kimura, K. Okawa, H. Suzuki, A. Ukita, S. Wakita, K. Okazaki, M. Ohno, M. Sakaguchi, Y. Sugahara.* Dept Chemistry and Life Science, Kogakuin Univ, Hachioji, Tokyo, Japan.

Acidic mammalian chitinase (AMCase) has been implicated in asthma and other allergic inflammations, and food processing. Mouse AMCase is composed of an N-terminal catalytic domain (CatD) and a C-terminal chitin-binding domain (CBD). Here, we report the expression of the CatD of mouse AMCase as a recombinant fusion protein with Protein A and V5-His in *E. coli* and its functional properties. The chitinolytic activity of the recombinant CatD against 4-nitrophenyl *N, N'*-diacetyl-β-D-chitobioside was equivalent to that of the full-length AMCase with regard to its specific activity, pH and temperature optima as well as pH and thermal stabilities. CatD bound to chitin beads; cleaved the hexamer of N-acetylglucosamine, colloidal and crystalline chitin as well as shrimp shell; and released primarily N, N'-diacetylchitobiose fragments at pH 2. 0. Thus, the CatD of mouse AMCase can recognize chitin substrates and degrade them in the absence of CBD.

2954W

A partially inactivating mutation in the sodium-dependent lysophosphatidylcholine transporter MFSD2A causes a non-lethal microcephaly syndrome. *V. Alakbarzade[1, 2], A. Hameed[3], D. Q. Y Quek[4], B. A Chioza[1], E. L Baple[1,5,6], A Cazenave-Gassiot[7], L. N Nguyen[4], M. R Wenk[7], A. Q Ahmad[8,9], A Sreekantan-Nair[1], M. N Weedon[1], P Rich[1,11], T. T Warner[2], D. L Silver[4], A. H Crosby[1].* 1) Institute of Biomedical and Clinical Science, University of Exeter Medical School, RILD Wellcome Wolfson Centre, Exeter, UK; 2) Reta Lila Weston Institute of Neurological Studies, Department of Molecular Neurosciences, University College London Institute of Neurology, London, UK; 3) Institute of Biomedical and Genetic Engineering (IBGE), Islamabad, Pakistan; 4) Signature Research Program in Cardiovascular and Metabolic Disorders, Duke-National University of Singapore Graduate Medical School, Singapore; 5) Human Genetics and Genomic Medicine, Faculty of Medicine, University of Southampton, Southampton, UK; 6) Wessex Clinical Genetics Service, Princess Anne Hospital, Southampton, UK; 7) Life Sciences Institute, National University of Singapore, Singapore; 8) Department of Physical Medicine and Rehabilitation, Indiana University-Purdue University Indianapolis (IUPUI), Indianapolis, Indiana, USA; 9) Rehabilitation Hospital Indiana, Indianapolis, Indiana, USA; 10) Department of Neuroradiology, St. George's Hospital, London, UK; 11) Southwest Thames Regional Genetics Service, St George's Healthcare National Health Service (NHS) Trust, London, UK.

The major pathway by which the brain obtains essential omega-3 fatty acids such as docosahexaenoic acid (DHA) from the circulation is through a sodium-dependent lysophosphatidylcholine (LPC) transporter (MFSD2A), expressed in the endothelium of the blood-brain barrier, which is essential for normal brain growth and cognitive function. We investigated an extensive Pakistani pedigree with multiple interlinking nuclear families with individuals affected by an autosomal recessive progressive neurological condition involving microcephaly, intellectual disability, spasticity, absent speech and dysmorphic features. A whole genome SNP scan of family members identified a single notable homozygous region peculiar to all affected family members on chromosome 1p34. 2. Whole exome sequencing identified single likely deleterious sequence variant located within the disease locus, in *MFSD2A* (chr1:40433304C>T), affecting a highly conserved residue (p. Ser339Leu). The variant cosegregated with the disease phenotype and was absent in online genomic databases and regional controls. Our subsequent studies determined that the p. Ser339Leu alteration does not affect protein or cell surface expression of MFSD2A but rather significantly reduces, although not completely abolishes, transporter activity. Notably, affected individuals displayed significantly increased plasma concentrations of LPCs containing mono- and polyunsaturated fatty acyl chains, indicative of reduced brain uptake, confirming the specificity of MFSD2A for LPCs having mono- and polyunsaturated fatty acyl chains. Together, these findings indicate an essential role for LPCs in human brain development and function and provide the first description of disease associated with aberrant brain LPC transport in humans.

2955T

Transforming growth factor beta receptor stability and signaling in LTBP4-related cutis laxa. *Z. Urban[1], J. W. Huang[2], C. K. Chiang[2], E. C. Lawrence[1], B. Dabovic[3], C. T. Su[1].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Division of Nephrology, Department of Internal Medicine, National Taiwan University Medical College and Hospital, Taipei, Taiwan; 3) Department of Cell Biology, New York University School of Medicine, New York, NY.

Latent transforming growth factor beta binding protein 4 (LTBP4) mutations cause autosomal recessive cutis laxa associated with severe pulmonary, gastrointestinal and urinary involvement. To elucidate the molecular mechanisms of LTBP4-related cutis laxa, we investigated the consequences of LTBP4 loss on transforming growth factor beta (TGFß) signaling. *LTBP4* mutant human dermal fibroblasts showed elevated extracellular TGFß activity, however, downstream signaling molecules of the TGFß pathway, including pSMAD2 and pERK, were reduced. In addition, TGFß receptors 1 and 2 (TGFBR1 and TGFBR2) were diminished. TGFb1 supplementation led to an initial rapid increase followed by a sustained deficit in receptor abundance and activity. TGFBR1 was co-localized with lysosomes, and inhibitors of TGFBR1 kinase activity, endocytosis or lysosomes, normalized the levels of TGFBR1 and TGFBR2 in mutant cells. Co-immunoprecipitation demonstrated a molecular interaction between TGFBR2 and LTBP4. TGFb receptor abundance and signaling was reduced by LTBP4 depletion in normal cells and treatment with recombinant LTBP4 enhanced these measures in mutant cells. TGFb receptor levels and signaling were reduced, but normalized upon TGFBR1 kinase inhibition in Ltbp4 knockout mice. Thus, LTBP4 is required for TGFb receptor stability both *in vitro* and *in vivo*. TGFBR1 kinase inhibition stabilizes the receptors and normalizes signaling in *LTBP4* mutant cells and animals, suggesting a possible treatment approach for LTBP4-related cutis laxa.

2956F

The spectrum of *NOTCH1* mutations in Adams-Oliver syndrome highlights an important role for the ligand-binding domain in disease etiology. *L. Southgate[1,2], M. Sukalo[3], A. S. Karountzos[4], E. J. Taylor[4], W. Wuyts[5], M. Zenker[3], R. D. Machado[4], R. C. Trembath[1].* 1) Barts & The London School of Medicine & Dentistry, Queen Mary University of London, Charterhouse Square, London, United Kingdom; 2) Division of Genetics and Molecular Medicine, King's College London, Guy's Hospital, London, United Kingdom; 3) Institute of Human Genetics, Otto-von-Guericke-Universitét Magdeburg, University Hospital Magdeburg, Magdeburg, Germany; 4) School of Life Sciences, University of Lincoln, Brayford Pool, Lincoln, United Kingdom; 5) Department of Medical Genetics, University and University Hospital of Antwerp, Edegem, Belgium.

Adams-Oliver syndrome (AOS) is a rare developmental disorder characterized by terminal transverse limb defects and scalp aplasia cutis congenita (ACC). Notable cardiac and/or neurological involvement is also apparent in a proportion of cases. Recent studies exploring the genetic basis of AOS have highlighted a key role for the Notch signaling pathway, in particular the NOTCH1 receptor. The purpose of this study was to examine the mutation spectrum and functional impact of identified *NOTCH1* mutations. We screened a cohort of 74 unrelated subjects diagnosed with either AOS or isolated ACC. Using whole-exome (n=21) or Sanger (n=53) sequencing, we identified 12 *NOTCH1* mutations, accounting for 16% of our cohort. Taken together with previous reports, there are now 31 independent *NOTCH1* mutations described in AOS. Of these, the majority (n=19; 61%) are missense mutations, approximately one third of which are cysteine substitutions, anticipated to disrupt disulfide bonds critical for maintaining protein structure. The remainder predominantly comprise frameshift (n=6; 19%) or nonsense (n=4; 13%) mutations, with only a single splice variant and one large deletion reported to date. Of note, 19% of all described mutations are located within the ligand-binding domain, defined by EGF-like repeat domains 11-13, which only represents 4. 5% of the full-length NOTCH1 receptor. When extended to the flanking domains EGF10-14 (7. 5% of the protein), previously reported to stabilize the ligand-receptor interaction, the proportion of AOS-related mutations rises to 32%, highlighting a potentially key role for the NOTCH1 ligand-binding domain in the etiology of this disorder. Indeed, we have previously demonstrated by real-time PCR that AOS mutations within this region of the receptor lead to dysregulated Notch signaling, with a significant reduction of *HEY1* and *HES1* transcript levels. To further examine the functional impact of missense mutations within the ligand-binding domain of NOTCH1, we have generated mutagenized constructs for use in X-ray crystallography studies. Bioinformatic predictions indicate that a significant proportion of AOS-related mutations will disrupt key amino acids, leading to a destabilization of protein structure and calcium binding. Experimental analysis of this critical domain is now required to aid interpretation of the pathogenicity of identified variants and to further develop our understanding of the cellular processes predisposing to this condition.

2957W

Mutations in human homologue of chicken *talpid-3* gene (*KIAA0586*) cause a hybrid ciliopathy with overlapping features of Joubert and Jeune syndromes. *M. Gunay-Aygun[1,7], T Vilboux[1,3], J Stephen[1], D Maglic[1], L Mian[1], D Konzman[1], J Guo[2], D Yildirimli[1], J Bryant[1], R Fischer[1], WM Zein[4], J Snow[5], M Vemulapalli[6], A Young[6], J Mullikin[6], C Toro[3], BD Solomon[2,7], J Niederhuber[3], WA Gahl[1,2,7], MC Malicdan[1,2].* 1) MGB, NIH/NHGRI, Bethesda, MD; 2) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, 20892 Maryland, USA; 3) Inova Translational Medicine Institute, Falls Church, 22042 Virginia, USA; 4) Ophthalmic Genetics & Visual Function Branch, National Eye Institute, National Institutes of Health, Bethesda, 20892 Maryland, USA; 5) Office of the Clinical Director, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, 20892 Maryland, USA; 6) NIH Intramural Sequencing Center (NISC), National Human Genome Research Institute, National Institutes of Health, Bethesda, 20892 Maryland, USA; 7) Office of the Clinical Director, National Human Genome Research Institute, National Institutes of Health, Bethesda, 20892 Maryland USA.

Statement of Purpose: In chicken, loss of *talpid-3* results in nonfunctional cilia and short-rib polydactyly syndrome. This phenotype is caused by a frameshift mutation in the chicken ortholog of the human *KIAA0586* gene, which encodes a novel coiled-coil domain protein essential for primary ciliogenesis, suggesting that *KIAA0586* can be associated with ciliopathy in humans. **Methods:** In our patients with ciliopathy (enrolled in NIH protocol "Clinical and Molecular Investigations into Ciliopathies", www. clinicaltrials. gov: NCT00068224, approved by the Institutional Review Board of the National Human Genome Research Institute), we performed whole exome sequencing on DNA from affected individuals and their parents. We analyzed gene expression on fibroblast cell line, and determined the effect of gene mutation on ciliogenesis in cells derived from patients. **Results:**We identified biallelic null mutations in the human talpid-3 ortholog, *KIAA0586*, in six children with findings of overlapping ciliopathies. Jeune syndrome, also known as asphyxiating thoracic dystrophy, is a skeletal ciliopathy characterized by a small thorax due to short ribs, disproportionate short stature due to short long bones, polydactyly, and renal, hepatic and retinal involvement. Joubert syndrome is a ciliopathy characterized by distinctive midbrain and cerebellar malformations that result in the "molar tooth sign" on axial brain images as well as hypotonia and developmental delay. Fibroblasts cultured from one of the Jeune-Joubert syndrome patients exhibited more severe cilia defects than fibroblasts from patients with only Joubert syndrome; this difference was reflected in *KIAA0586* RNA expression levels. Rescue of the cilia defect with full-length wild type *KIAA0586* indicated a causal link between cilia formation and KIAA0586 function**Conclusions**: Our results show that null allele mutations in *KIAA0586* lead to Joubert syndrome with or without Jeune asphyxiating thoracic dystrophy. Furthermore, our results confirm that KIAA0586/Talpid3 is essential in cilia formation in humans, expand the *KIAA0586* phenotype to include features of Jeune syndrome, and provide a pathogenetic connection between Joubert and Jeune syndromes, based upon aberrant ciliogenesis.

2958T

N-linked glycosylation in renal and cardiac diseases: the role of ALG13 short isoform 2. *T. Esposito[1], G. De Stefano[1], I. Di Lorenzo[1], F. Napolitano[1], A. M. Saleem[2], F. Gianfrancesco[1].* 1) Institute of Genetics and Biophysics "ABT" National Research Council of Italy, N, Naples, Italy, Naples, Italy, Italy; 2) Academic Renal Unit, School of Clinical Sciences, University of Bristol, Bristol, UK.

N-glycosylation, a post-translational modification process, has an important role in protein folding, intracellular trafficking and membrane targeting, as well as in the regulation of protein function. Mutations affecting N-linked glycosylation sites of some podocyte (e. g. , Nephrin and TRPC6) and cardiomyocyte (e. g. ,TRPM4b) proteins have a very important role in focal segmental glomerulosclerosis (FSGS) and progressive cardiac conduction defect (PCCD) respectively. Recently, we identified two missense mutations (p. R113W and p. T141L) in two novel X-linked genes (*NXF5* and *ALG13*) associated with FSGS and PCCD in an extended Australian pedigree. *ALG13* codifies for a glycosyltransferase that catalyses the second sugar addition of the highly conserved oligosaccharide precursor in the endoplasmic reticulum (ER). The most conserved isoforms of *ALG13* gene are the long isoform 1 (1137 aa) and the short isoform 2 (165 aa, ALG13-is2). Mutations, which occur in the C-terminal region of the long isoform, cause congenital disorders of glycosylation type I, epileptic encephalopathies and nonsyndromic intellectual disability. We demonstrate that the mutation c. 421-422 AC>TT [p. T141L], identified in the FSGS/PCCD patients, alters the C-terminal alpha-helix structure of the short isoform 2 (ALG13-is2), a region highly conserved in mouse (100% identity at nucleotide level) which is important for the localization of the protein in the ER. ALG13-is2 shows a specific high level of expression in human and mouse podocytes and cardiomyocytes which increases during differentiation, both at mRNA and protein level. Knock-down of the ALG13-is2, in human podocyte cells at 12 days of differentiation, results in the alteration of the N-glycosylation pattern of Nephrin, as demonstrated by the presence of an additional immune-staining band of about 130 kD in western blot, perturbed organization of the actin of the cytoskeleton and altered localization of Nephrin on the cellular membrane observed by immunofluorescence. We also demonstrate that the altered pattern of glycosylation induces over-expression of Bip and Calreticulin, suggesting ER stress. These results provide preliminary evidence that ALG13-is2 could be an important player in renal and cardiac defects.

ASXL3 regulates H2A deubiqutination and gene transcription in Bainbridge-Ropers syndrome. *S. Bielas[1], A. Srivastava[1], R. KC[1], Y. C. Tsan[1], A. M. Chinnaiyan[2,3], D. Martin[1,4], S. Bielas[1].* 1) Department of Human Genetics, University of Michigan Medical School, Ann Arbor, MI; 2) Howard Hughes Medical Institute, Michigan Center for Translational Pathology, University of Michigan Medical School, Ann Arbor, MI; 3) Department of Pathology, University of Michigan Medical School, Ann Arbor, MI; 4) Department of Pediatrics, University of Michigan Medical School, Ann Arbor, MI.

Bainbridge-Ropers Syndrome (BRS) is a phenotypically and genetically heterogeneous disorder characterized by failure to thrive, global developmental delay, primary microcephaly, intellectual disability, dysmorphic features and feeding problems. We identified a novel *de novo* nonsense mutation c. 1448dupT, T484NfsX5 in *ASXL3 (additional-sex combs like 3)* in a BRS patient. *De novo ASXL3* nonsense mutations described for BRS localize within a ~700 nucleotide interval of exon 11, coined the "mutational cluster region". To investigate the impact of *ASXL3* mutations on histone modifications and transcription regulation, we established an *ASXL3* patient fibroblast cell line. A stably expressed truncated protein is not observed in *ASXL3* patient cells, implicating haploinsufficiency in the pathogenicity of this dominant disorder. Similar to ASXL1 and ASXL2, we found that ASXL3 interacts with BAP1, the ligase that removes the mono-ubiquitin from Histone 2A (H2AK119Ub1) as part of the Polycomb repressive deubiquitination (PR-DUB) complex. Consistent with this interaction, we found H2AK119Ub1 is increased 5-fold in *ASXL3* patient fibroblasts. This was not accompanied by a change in the level of histone H3 trimethylation at lysine 27 (H3K27me3). To investigate the impact of this finding on transcriptional regulation, we performed RNA-sequencing on *ASXL3* patient fibroblasts and two unrelated fibroblast controls. Out of 700 differentially expressed genes, 35% were upregulated and 65% were downregulated in *ASXL3* patient fibroblasts. Among these, Polycomb repressive complex 1 (PRC1) target genes were significantly misregulated. These findings indicate that *ASXL3*, as part of the PR-DUB complex, removes ubiquitin from H2AK119Ub1, an important repressive histone post-translational modification generated by PRC1. Covalent histone modifications are an important layer of transcriptional regulation that occur at the level of chromatin structure. While histone ubiquitination was discovered more than three decades ago, its functions in transcriptional regulation and epigenetic repression are still less well understood than other histone modifications. This study suggests a functionally important role for dynamic H2AK119Ub1 remodeling in transcriptional regulation and the pathophysiology of BRS.

2960W

Identification of the Molecular Pathways Affected by Mutations in the Lysine Acetyltransferase, KAT6A and associations with phenotypic variability. *V. A. Arboleda[1], H. L. Lee[1], Z. C. Chen[2], H. A. Amartino[3], K. L. Low[4], R. N. Newbery-Ecob[4], S. N. Nelson[1,2].* 1) Pathology and Laboratory Medicine, UCLA, Los Angeles , CA; 2) Department of Human Genetics, David Geffen School of Medicine, UCLA; 3) Department of Pediatric Neurology, Hospital Universitario Austral, Buenos Aires, Argentina; 4) Department of Clinical Genetics, Bristol Royal Hospital for Children.

Histone acetyltransferase and deactylase enzymes affect fundamental cellular processes including the cell-cycle, cell differentiation, metabolism, and apoptosis. Nonsense mutations in *KAT6A*, a lysine acetyltransferase, result in global developmental delay, microcephaly and craniofacial dysmorphism. We recently reported the first description of *de novo* heterozygous nonsense mutations in *KAT6A* (a. k. a. *MOZ, MYST3*) that were identified by clinical exome sequencing (CES) in 4 families. Similar mutations have now been identified in more than 20 patients. From our initial report, the core features are consistently observed, however there is a larger phenotypic variability that is now apparent in regard to cardiac, gastrointestinal, and hematologic manifestations. For example, while the majority of reported patients have structurally normal brains, one patient was found to have dilated perivascular Virchow Robin spaces. Other patients have variable allergies, neutropenia, cardiac anomalies, or neurosensory deficits. In order to better understand the mechanism of mutated KAT6A, we have cultured dermal fibroblasts from three individuals with *KAT6A* mutations. Basal levels of *KAT6A* mRNA and protein were low in untreated fibroblasts. However, with Adriamycin treatment, immunofluorescence shows a nuclear localization. We performed RNA-seq analysis under resting and Adriamycin-treated conditions to stimulate nuclear KAT6A expression. In the untreated cells, there were minimal differences between control and *KAT6A*-mutant fibroblasts. However, upon stimulation with adriamycin, we observed significant differences in 300 300 genes between control and *KAT6A* mutated cells. Surprisingly, *KAT6A* mRNA levels were markedly decreased in all treated cells, suggesting that nuclear up-regulation of KAT6A is through post-translational regulation. Clinical exome sequencing is now a primary mode for diagnosis of children with syndromic congenital conditions, such as *KAT6A*. Since there is a growing body of collected phenotypic information, there is an opportunity to identify strong modifier alleles, which may contribute to the variability in phenotype. Additionally, KAT6A acts indirectly on gene regulation through alterations in histone acetylation which may have varied effects. Overlay of the expression patterns perturbed by KAT6A mutations with inherited DNA variants in those genes will provide insights to assess how *KAT6A* mutations affect downstream molecular pathways.

2961T

Autosomal Recessive Ehlers Danlos Syndrome in Three Patients with Congenital Adrenal Hyperplasia due to 21-hydroxylase deficiency. *A. Perritt[1], R. Morissette[1], W. Chen[2], V. Sachdev[3], H. Hannoush[3], A. Arai[3], D. P. Merke[1,4].* 1) NIH Clinical Center, Bethesda, MD; 2) PreventionGenetics, Marshfield, WI; 3) The Eunice Kennedy Shriver National Institute of Child Health and Human Development, Bethesda, MD; 4) National Heart, Lung and Blood Institute, Bethesda, MD.

Background: Congenital Adrenal Hyperplasia (CAH) due to 21-hydroxylase (21-OH) deficiency is an autosomal recessive endocrine disorder resulting in cortisol deficiency and androgen excess. *CYP21A2*, the gene encoding 21-OH, is located on the short arm of chromosome 6 and is flanked by *TNXB*, which encodes the extracellular matrix (ECM) protein tenascin-X (TNX). Approximately 30% of *CYP21A2* mutations are deletions. Both *CYP21A2* and *TNXB* have highly homologous pseudogenes, and during meiosis unequal crossover can occur resulting in either a *CYP21A1P*/*CYP21A2* or *TNXA*/*TNXB* chimera. We found that ~10% of CAH patients have a TNX chimera, termed CAH-X syndrome, which leads to Ehlers Danlos syndrome (EDS) phenotypes. We have identified two different autosomal dominant *TNXA*/*TNXB* chimeras. CAH-X CH1 is characterized by a 120 bp deletion in exon 35 in *TNXB* leading to TNX haploinsufficiency. CAH-X CH2 is characterized by the c. 1274C>G (C4058W) variant in exon 40 leading to a dominant negative effect. Three variants have been shown to travel with this mutation, two of which are predicted to be damaging. We have now identified three families with autosomal recessive CAH-X; therefore, we sought to further define the TNX genetic and protein status in these novel CAH-X patients. **Methods:** Dermal fibroblasts and tissue from patients and controls were used for wound healing assays, Western blots, and immunohistochemistry experiments. Southern blotting, multiplex ligation-dependent probe amplification, Sanger and next-generation sequencing were used to study genetic defects. **Results:** We identified three patients with autosomal recessive (AR) CAH-X with a more severe phenotype than autosomal dominant (AD) CAH-X patients. Each proband had unique *TNXB* mutations on both alleles. The AR patients have more severe EDS phenotypes than AD patients, including higher Beighton scores, joint and skin laxity, congenital heart defects, and multiple subluxations. Growth curves showed that AR patients have slower cell growth than AD and CAH control patients. TNX expression was unchanged in AD and AR patients. Immunohistochemical experiments testing collagens and other ECM markers are underway. **Conclusion:** Autosomal recessive CAH-X presents with more severe phenotypes than autosomal dominant. Slower growth rate suggests reduced cell proliferation in AR CAH-X patients. Investigations into the three variant cluster and the impact of mutations on both alleles on TNX's function in the ECM are underway.

2962F

Learning pathophysiology of Alport syndrome from RNA-seq of podocytes differentiated from amniotic-fluid derived patient progenitors. *A. M. Pinto[1,2], S. Da Sacco[3], C. Fallerini[1], S. Furini[4], I. Meloni[1], M. Baldassarri[1,2], E. Frullanti[1], F. Ariani[1], L. Perin[3], A. Renieri[1,2].* 1) Medical Genetics, University of Siena, Siena, Italy; 2) Genetica Medica, Azienda Ospedaliera Universitaria Senese, Siena, Italy; 3) Saban Research Institute, Children's Hospital University of Southern California, Los Angeles; 4) Department of Medical Biotechnologies, University of Siena, Siena, Italy.

Alport syndrome is a clinically heterogeneous nephropathy caused by mutations in collagen IV genes. It is characterized by haematuria, proteinuria, progressive renal failure and ultrastructural lesions of the glomerular basement membrane (GBM), such as thickening, thinning and lamellation often associated with sensorineural deafness and ocular lesions. The role of podocytes' abnormalities in the disease onset and in its progression hasn't been well characterized yet and a transcriptome profiling of Alport derived-cell lines has never been previously reported. We performed a trascriptome profiling on RNA from amniotic fluid-derived Alport renal progenitors and progenitors differentiated into podocyte like-cells using our established protocol to better understand the pathogenic mechanism of the disease and to shed light on the ultrastructural GBM lesions, a hallmark of this disorder. The corresponding renal progenitors and differentiated podocytes cell lines from amniotic fluid of healthy fetus were used as control. RNA-seq data were analyzed for expression levels'changes, splicing pattern changes and differential polyadenylation sites usage. Expression of several transcripts, markers of podocytes' differentiation, such as COL4 genes, drastically increases during the differentiation process in both control and Alport podocyte like-cells. Expression levels'analysis detected 413 and 49 genes down-regulated in Alport progenitors and podocyte like-cells, respectively. The same analysis identified 396 and 76 genes up-regulated in the two cell lines compared to the corresponding controls. Importantly, a gene ontology on the genes down-regulated revealed, in both cell lines, a statistically significant enrichment for transcripts encoding for proteins expressed in the extracellular compartment and implied in cell adhesion. This finding may explain the massive disruption of the glomerular filtration barrier and the GBM typical Alport lesions. Notably, in both Alport progenitors and podocyte like-cell we noticed a consistent up-regulation of IL-32 (21,2 fold change, P=0. 00025) expressed at the same level in control progenitors and podocytes. These data were confirmed by qRT-PCR. IL-32 induces IL-6 and IL-8 expression, both found upregulated in Alport cell lines supporting an implication of this pathway in the disease pathogenesis. IL-32 binds to PR-3, a serin-proteinase, which degrades extracellular matrix proteins such as elastin, fibronectin and collagen IV. Thus, we might hypothesize that IL-32 up-regulation could contribute to the GBM lesions. Although preliminary, our findings open up the possibility of new therapeutic strategies for Alport disease based on the usage of IL-32 inhibitors, already in phase of development for autoimmune disorders.

Genotype-dependent alterations in TGFβ signaling in *ELN*-related cutis laxa. *S. Alkan, Z. URBAN.* HUMAN GENETICS, UNIVERSITY OF PITTSBURGH, PITTSBURGH, PA.

Mutations in the elastin protein (*ELN*) cause autosomal dominant cutis laxa characterized by loose, inelastic and redundant skin that get worse by age. Previous studies indicate elevated canonical (SMAD-dependent), but unaffected non-canonical (SMAD- independent) TGFb signaling. Our goal was to evaluate the impact of *ELN* mutations on cellular signaling by TGFb, a growth factor known to be involved in a range of connective tissue diseases. Dermal fibroblasts from four patients with *ELN* mutations in exon 34 or exon 30 and four age and sex-matched controls were used in immunoblotting to assay for key components of the transforming growth factor beta (TGFb) pathway under baseline conditions as well as following TGFb1 or TGFb1 with TGFb receptor 1 (TGFBR1) inhibitor treatment. Under baseline conditions (serum and serum-free), SMAD2 phosphorylation was increased in exon 30 mutant cells. No significant difference was observed in pSMAD2 and pERK levels following TGFb1 and TGFb1 with TGFBR1 inhibitor treatments. The abundance of pERK was decreased in mutant cells at baseline (serum-free), but no significant difference was observed for this molecule between mutant cells and controls under any other treatment conditions. TGFBR1 protein levels were increased in *ELN* mutant cells at baseline conditions and remained increased relative to the controls upon TGFb supplementation. No significant difference was observed in the TGBFR1 levels upon TGFBR1 inhibitor treatment. On the other hand, no significant difference was observed in the levels of pSMAD2, SMAD2, ERK and pERK levels in any conditions in exon 34-mutant cells. Our results showed elevated canonical, but unaffected non-canonical TGFb signaling despite unaltered extracellular TGFb activity in exon 30-mutant cells, whereas cells with *ELN* mutations in exon 34 had normal TGFb signaling. Elevated TGFb signaling in exon 30 mutant cells was associated with increased levels of TGFBR1 but not TGFBR2. Our results indicate mutation-specific TGFb signaling changes in *ELN*-related cutis laxa patients, which may contribute to disease severity.

2964T

Knockout of *RP2* decreases GRK1 and rod transducin subunits and leads to photoreceptor degeneration in zebrafish. *M. Liu[1], F. Liu[1], S. Yu[1], J. Chen[1], X. Shu[2], J. Zou[3].* 1) Department of Genetics and Developmental Biology, Huazhong University of Science and Technolog, Wuhan, Hubei, China; 2) Department of Life Sciences, Glasgow Caledonian University; 3) Institute of Translational Medicine, Zhejiang University.

Retinitis pigmentosa (RP) affects about 1. 8 million individuals worldwide. X-linked retinitis pigmentosa (XLRP) is one of the most severe forms of RP. Nearly 85% of XLRP cases are caused by mutations in the X-linked retinitis pigmentosa 2 (*RP2*) and *RPGR*. RP2 has been considered to be a GTPase activator protein for ARL3 and to play a role in the traffic of ciliary proteins. The mechanism of how *RP2* mutations cause retinitis pigmentosa is still unclear. In this study, we generated an *RP2* knockout zebrafish line using TALEN technology. Progressive retinal degeneration could be observed in the *RP2* knockout zebrafish. The degeneration of rods' outer segments is predominant, followed by the degeneration of cones' outer segments. These phenotypes are similar to the characteristics of RP2 patients, and also partly consistent with the phenotypes of *RP2* knockout mice and morpholino mediated *RP2* knockdown zebrafish. For the first time, we found that *RP2* deletion leads to decreased protein levels and abnormal retinal localizations of GRK1 and rod transducin subunits (GNAT1 and GNB1) in zebrafish. Furthermore, the distribution of the total farnesylated proteins in zebrafish retina is also affected by *RP2* ablation. These molecular alterations observed in the *RP2* knockout zebrafish might probably be responsible for the gradual loss of the photoreceptors' outer segments. Our work identified the progression of retinal degeneration in *RP2* knockout zebrafish, provided a foundation for revealing the pathogenesis of retinitis pigmentosa caused by *RP2* mutations, and would help to develop potential therapeutics against retinitis pigmentosa in further studies.

The p. E229K variant in *CYP1B1*: mutation or polymorphism? *G. Chavarria-Soley.* Biology, University of Costa Rica, San José, Costa Rica.

The *CYP1B1* gene is mutated in over 80% percent of familial cases of primary congenital glaucoma (PCG; MIM 231300), which shows autosomal recessive inheritance. Around 150 missense and nonsense substitutions have been reported for *CYP1B1*. While some of these variants are either clearly disease causing mutations of clearly frequent polymorphisms, there are some with an unclear clinical significance. The p. E229K variant falls into the last category. It has been routinely reported in the literature as a mutation in *CYP1B1*, and has been found in several different ethnic gropus. The goal of the present study is to analyze all evidence available in an effort to clarify the role of p. E229K. As a first step, a PubMed search was performed in order to find all references to the variant in the literature. When family data was available, it was determined whether the variant segregates with the disease, and whether it is found in a homozygous or compound heterozygous form. All functional tests and models found in the literature for this variant were analyzed. Next, in order to determine the degree of conservation of the 229 position, a multiple sequence alignment was performed for the protein sequence of *CYP1B1* in 12 different animals. A prediction of the functional effect of the p. E229K missense variant was obtained with six different prediction tools. Finally, data for the frequency of the variant was obtained from the ExAC Browser. After analyzing the literature, no example of clear segregation of the variant with autosomal recessive PCG could be found. A structural analysis from the literature predicts a deleterious effect for the variant, while a functional study where mutated *CYP1B1* was expressed in yeast found no change in activity of the enzyme, but a reduced abundance. In the multiple sequence alignment, the Glu in the 229 position of *CYP1B1* is conserved in mammals, but not in the bird or fish included. Four out of the six tools for the prediction of functional effects, predicted p. E229K to be a neutral variant. In the data from the ExAC browser, an overall frequency of 1,4% was reported for all populations. Interestingly, in the South Asian population the variant has a frequency of 5,6%, and 35 individuals (out of 7245) are homozygous. Taken together, the different lines of evidence do not support the idea of p. E229K as a disease causing mutation in PCG. At most, the variant could be considered as a hypomorphic allele.

2966W

The miR-34c is upregulated in α1-antitrypsin deficient livers, induces β-catenin activation and impairs liver zonation. *P. Piccolo[1], A. Barbato[1], P. Annunziata[1], S. Attanasio[1], B. Granese[1], N. Pastore[1], L. R. Soria[1], C. Mueller[2], J. Teckman[3], N. Brunetti-Pierri[1,4].* 1) Telethon Institute of Genetics and Medicine, Pozzuoli, Italy; 2) Boston University Center for Regenerative Medicine (CReM), Boston, MA, USA; 3) Department of Pediatrics, Saint Louis University School of Medicine, Cardinal Glennon Children's Medical Center, Saint Louis, MO, USA; 4) Department of Translational Medicine, Federico II University, Naples, Italy.

Deficiency of α1 anti-trypsin (AAT) is the most common genetic cause of liver disease in children and liver transplantation is currently the only available treatment for severe cases. The vast majority of patients with AAT deficiency harbor a single amino acid substitution which results in protein misfolding, polymerization, and accumulation within the endoplasmic reticulum of hepatocytes. Intracellular retention of aberrantly folded mutant AAT in the liver results in hepatitis, cirrhosis, and hepatocellular carcinoma. PiZ transgenic mice expressing mutant human AAT recapitulate the features of the hepatic disease. On PiZ livers, we performed next generation sequencing of miRNAs which revealed 70 miRNAs differentially expressed between controls and PiZ mice. Among the dysregulated miRNAs, we focused on miR-34c that was increased in both liver and plasma of PiZ mice and its levels correlated with the abundance of hepatic mutant AAT. Importantly, miR-34c was also increased in livers of human patients with advanced hepatic disease. In both human (Huh-7) and mouse (Hepa1-6) hepatocytes, transfection of miR-34c down-regulated expression of murine AAT genes and HNF4A, a master regulator of hepatocyte spatial organization of metabolic pathways along porto-central axis of liver lobules, known as liver zonation. Interestingly, PiZ mice showed down-regulation of HNF4A and increased levels of active β-catenin, the other major determinant of liver zonation. PiZ mice exhibited impairment of liver zonation, as shown by alteration of glutamine synthase expression pattern, down-regulation of urea cycle enzymes, and defective ammonia metabolism. Injection of an AAV2/8 vector expressing miR-34c in wild-type C57BL6 mice resulted in down-regulation of murine AAT gene expression, activation of β-catenin, and impairment of liver zonation. In conclusion, we identified miR-34c as a potential novel biomarker of liver disease induced by AAT deficiency and a novel regulator of liver zonation.

2967T

Unique case of congenital diarrheal disorder with very short transit associated compound heterozygous variants of unknown significance in a gene related to myosin stability and function, *UNC45A*. *A. Bourchany[1,2], J. THEVENON[2,3], R. MAUDINAS[1], E. SAVAJOLS[4], F. HUET[1], A. BRUEL[2], N. GIGOT[2], Y. DUFFOURD[2], J. ST-ONGE[2], JB. RIVIERE[2,3,5], L. FAIVRE[2,3].* 1) Service de Pédiatrie 1 Hôpital d'Enfants CHU Dijon, et Université de Bourgogne, Dijon, France; 2) Equipe d'Accueil 4271, Génétique des Anomalies du Développement, Université de Bourgogne, Dijon, France; 3) Centre de Génétique et Centre de Référence Anomalies du Développement et Syndromes Malformatifs, FHU TRANSLAD, Hôpital d'Enfants, CHU Dijon et Université de Bourgogne, Dijon, France; 4) Département de Pédiatrie 2, Hôpital d'Enfants, CHU Dijon et Université de Bourgogne, Dijon, France; 5) Laboratoire de Génétique Moléculaire, FHU-TRANSLAD, Plateau technique de Biologie, CHU, Dijon, France.

Congenital diarrheal disorders (CDD), a group of rare inherited enteropathies with early-onset in life, lead to a diagnostic challenge for clinicians, geneticists and pathologists. They are responsible for chronic diarrhea of variable prognosis and of sufficient severity to require a parenteral nutrition support, even occasionally intestinal transplantation. The molecular bases of CDDs have been predominantly identified in the last years. Several mechanisms of the diarrhea linked to different type of intestinal cells failure have been described but none was related to intestinal muscle cells. Cells involved in diarrheal disorders pathophysiology are enterocytes, enteroendocrine or immune cells. Classifications retain defects in digestion, absorption and transport of nutrients and electrolytes ; disorders of enterocyte differentiation and polarization ; defects of enteroendocrine cell differentiation ; and disregulation of the intestinal immune response as potential 4 groups of mechanisms. We herein report a 3 year-old girl presenting with severe intractable diarrhea diagnosed the 4th day of life, characterized by a very short transit, and still requiring exclusive parenteral nutrition. Repeated intestinal biopsies did not show any villous atrophy. *MYO5B* and *EpCam* sequencing did not evidence any pathogenic variant. Severe bilateral deafness secondarily appeared. Exome sequencing identified compound heterozygotes variants in *UNC45A*, 1 *de novo* missense (p. Val423Asp) and one inherited stop-gained mutation(p. Arg262*). The Hsp90 co-chaperone protein Unc45 isoform a is widely expressed, present in intestinal tissue, and shows selectivity for the smooth muscle myosin motor domain. Indeed, *UNC45A* may be necessary for proper folding of myosin. Smooth muscle cells take action in intestinal wall during both patterns of intestinal peristaltism. Data-sharing will be needed in order to confirm or not the implication of *UNC45A* in this rare phenotype. Exome sequencing also revealed 2 *MYO15A* mutations that may explain the patient deafness.

2968F

The role of Filamin A in gastrointestinal developmental defects. *M. M. Alves[1], D. Halim[1], H. van der Linden[1], A. S. Brooks[1], A. J. Burns[1,2], R. M. W. Hofstra[1,2].* 1) Dept Clinical Genetics, Erasmus University Medical Center, Rotterdam, Netherlands; 2) Birth Defects Research Centre, UCL Institute of Child Health, London, UK.

Filamin A (*FLNA*) encodes a cytoskeletal protein that regulates cell shape by cross-linking actin filaments. Mutations in *FLNA* have been associated with a wide spectrum of disorders, and more recently with an X–linked form of Congenital Short Bowel Syndrome (CSBS). As CSBS patients frequently present with intestinal pseudo-obstruction (IPO), an involvement of the Enteric Nervous System (ENS) has been suggested to contribute to the reduced intestinal motility. However, histological analysis performed on bowel tissues of these patients show contradictory results. While some CSBS patients have signs of an ENS defect, others show abnormal gut smooth muscle. To understand the molecular mechanisms associated with *FLNA* mutations underlying IPO development in CSBS patients, we performed expression studies at different human embryonic stages, and a combination of *in vitro* and *in vivo* studies. We show that FLNA is expressed in the muscular layer of the small intestine from early embryonic stages. Furthermore, *FLNA* mutations associated with CSBS block expression of one of its two isoforms, possibly explaining why these patients only have intestinal complaints. Finally, by generating a transgenic zebrafish line using TALENs, we show that the longer FLNA isoform is required for intestinal development. *FLNA* mutant fish are phenotypically indistinguishable from wild-type fish, except for gut length, which is significantly reduced (20%). In conclusion, our results suggest that the intestinal motility defects associated with CSBS are caused by smooth muscle defects due to the absence of the longer FLNA isoform, together bringing new insights to IPO and CSBS pathogenesis.

2969W

Identification of *de novo* mutations in very early-onset inflammatory bowel disease (VEO-IBD). *N. Dawany[1], P. Mamula[1,2], C. M. Grochowski[1], K. E. Sullivan[1,2], R. N. Baldassano[1,2], D. Piccoli[1,2], M. Devoto[1,2], J. R. Kelsen[1,2].* 1) The Children's Hospital of Philadelphia, Philadelphia, PA. , USA; 2) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA. , USA.

Very early-onset inflammatory bowel disease (VEO-IBD) is considered to be a distinct subset of IBD. The severe presentation and early onset suggest a strong genetic etiology. The causes of and therapies for VEO-IBD are highly variable in children. While VEO-IBD has been associated with higher rates of affected first-degree family relatives, supporting the strong genetic component, we aimed to identify the contribution of *de novo* mutations to disease development. We analyzed whole exome sequencing data from 125 VEO-IBD patients whose age of onset ranged from 3 weeks to 4 years. We have previously examined the role of inheritance, including variants inherited through a compound heterozygous and a homozygous recessive model, and found possible causal variants in genes such as *DAPK1*, *IL10RA*, *CR2* and *POLE*. In this study we focused our analyses on patients whose parents had also been sequenced, including 1 quad, 67 trios and 18 mother/son duos. We then assessed the role of *de novo* occurrences of single base variants and copy number variations in the development of VEO-IBD. *De novo* variants identified in patients were filtered to include only those with an allele frequency less than 1% in the 1000 Genomes Project, EVS and ExAC, a minimum CADD score of 10 and a minimum depth of 20 in all members of a family. The percent of bases with the *de novo* variant and the presence of duplicate reads were examined to exclude possible artifacts. Copy number variation analysis was performed using the eXome-Hidden Markov Model (XHMM). Our analyses revealed candidate *de novo* mutations including a whole gene deletion in *XIAP* in a male who presented with severe IBD at 3 weeks of age and has been refractory to medical and surgical therapy. We also identified a *de novo* variant in *GPR35* (p. Pro74Ser) in a male diagnosed at 6 months of age with severe ileocolonic VEO-IBD. *GPR35*, a G coupled protein, is expressed on immune and intestinal epithelial cells and has been implicated in IBD. GPCRs, including *GPR35*, have recently been associated with gut homeostasis through regulation of metabolism and subsequent anti-inflammatory T cell regulatory response. While inherited variants have been previously implicated in the pathogenesis of VEO-IBD, in this study we have shown that in a subset of patients, *de novo* mutations are also critical in disease development.

2970T

Clinical spectrum of disease associated with *POLG* mutations. *P. Arumugam[1], R. Kothari Sonam[2], V. Jyothi[1], PS. Bindu[2], N. Gayathri[2], K. Thangaraj[1].* 1) Centre for Cellular and Molecular Biology, Hyderabad, India; 2) NIMHANS, Bangalore, India.

Mitochondrial diseases are a heterogeneous group of disorders caused by genetic defects in mitochondrial DNA or in nuclear genes. Human mitochondrial DNA (mtDNA) polymerase γ (pol γ) is the sole enzyme required to replicate the mitochondrial genome. Pol γ comprises two subunits - a catalytic p140 subunit encoded by the *POLG* gene and a smaller p55 accessory subunit encoded by the *POLG2* gene. Mutations in the *POLG* gene have emerged as one of the most common causes of inherited mitochondrial diseases in children and adults. This study sequenced the exons and intron-exon boundaries of the *POLG* gene from approximately 300 unrelated patients with clinical presentations suggestive of *POLG* related mitochondrial disease and DNA samples of 2000 healthy Indian controls were used to determine the carrier frequencies of common *POLG* (p. A467T, G848S, W748S) mutations. In this study, we identified several pathogenic reported (A467T, L304R, W748S + E1143G, H110Y and R1187W) and novel (Y837H, Q51H, K633T, R41Q and R42Q) mutations in the *POLG* gene. Their pathogenicity of novel mutations were assessed based upon (a) absence in 100 normal controls, (b) structurally non-conservative substitution of an evolutionary conserved amino acid, (c) location in protein regions of structural/functional importance, (c) mtDNA deletion and/or depletion. Several novel synonymous variants and insertions and deletions in the CAG repeats of *POLG* also were observed. The frequency of common *POLG* mutations is 0. 3% for A467T, 0. 15% for W748 and 0. 00% for G848S in India. In conclusion, the identification of *POLG* mutations is very important for diagnosis, proper medical management and appropriate genetic counseling.

2971F

CCG•CGG interruptions within CTG•CAG expansion mutation increase disease penetrance in SCA8. *B. A. Perez[1-3], Y. Ikeda[4], T. Ashizawa[1, 5], J. W. Day[6], S. H. Subramony[1, 5], L. P. W. Ranum[1, 2].* 1) Center for NeuroGenetics, University of Florida, Gainesville, FL; 2) Department of Molecular Genetics and Microbiology, University of Florida, Gainesville, FL; 3) Genetics Institute, University of Florida, Gainesville, FL; 4) Department of Neurology, Gunma University, Maebashi, Japan; 5) Department of Neurology, University of Florida, Gainesville, FL; 6) Department of Neurology, Stanford University, Stanford, CA.

Spinocerebellar ataxia type 8 (SCA8) is a dominantly inherited neurodegenerative disorder caused by a bidirectionally transcribed CTG•CAG repeat expansion. Both RNA and protein gain-of-function (GOF) mechanisms have been reported in SCA8: expanded transcripts can sequester MBNL proteins within RNA foci (RNA GOF) and expressnovel proteins in the absence of an AUG initiation codon by repeat-associated non-ATG (RAN) translation (protein GOF). A puzzling feature of SCA8 is its reduced penetrance, in which many individuals that carry the expansion mutation do not develop disease. Although SCA8 is transmitted in a dominant manner, the reduced penetrance of the disease makes SCA8 most often appear sporadic with no apparent family history. Among the 75 families we have collected samples from, 77% appeared sporadic, 16% recessive and only 7% dominant. Families with more than three affected individuals have CCG•CGG interruptions within the SCA8 CTG•CAG repeat tract at a higher frequency than families with lower disease penetrance. In the large MN-A family, members of a branch of the family showing high penetrance have variable numbers of CCG•CGG interruptions. In contrast, individuals with expanded alleles from an unaffected branch of the family have uninterrupted CTG•CAG repeats. In another family, an asymptomatic parent with a pure CTG•CAG expansion has both an asymptomatic child carrying an uninterrupted CTG•CAG expansion and an affected child with a CTG•CAG expansion with a *de novo* mutation of 3 CCG•CGG interruptions. To investigate the molecular effects of these sequence interruptions we generated vectors expressing pure or interrupted CAG expansions followed by C-terminal epitope tags in each reading frame to detect individual RAN proteins. Initial experiments show different patterns of cellular localization. We are performing additional experiments to assess changes these interruptions confer on the mutant RNAs and RAN proteins. Taken together, these data suggest CCG•CGG interruptions increase disease penetrance in SCA8 and alter cellular properties of the resulting protein products. Further investigations may provide significant insight into genetic counseling for SCA8 patients and for understanding the contribution of RAN protein toxicity in microsatellite expansion disorders.

2972W

Complete *APTX* deletion in a patient with ataxia with oculomotor apraxia type 1. *A. M. W. van den Ouweland[1], M. Guitart[2], C. Escofet[2], G. Yoon[3], P. Elfferich[1], G. M. Bolman[1], R. van der Helm[1], R. van de Graaf[1], R. van Minkelen[1].* 1) Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 2) Genetic Laboratory, UDIAT-Centre Diagnòstic, Neuropediatrics Unity, Corporació Sanitéria Universitéria Parc Taulí, Sabadell, Spain; 3) Division of Clinical and Metabolic Genetics, Department of Pediatrics, The Hospital for Sick Children and University of Toronto, Canada.

*Background*Ataxia with oculomotor apraxia type 1 is an autosomal-recessive neurodegenerative disorder characterized by a childhood onset of slowly progressive cerebellar ataxia, followed by oculomotor apraxia and a severe primary motor peripheral axonal motor neuropathy. Ataxia with oculomotor apraxia type 1 is caused by homozygote or compound heterozygote mutations in *APTX* (chromosome 9p13. 3). *Case presentation*Our patient has a clinical presentation that is typical for ataxia with oculomotor apraxia type 1 with no particularly severe phenotype. Multiplex Ligation-dependent Probe Amplification analysis resulted in the identification of a homozygous deletion of all coding *APTX* exons (3 to 9). SNP array analysis using the Illumina Infinium CytoSNP-850K microarray indicated that the deletion was about 61kb. Based on the SNP array results, the breakpoints were found using direct sequence analysis: c. -5+1225_*44991del67512, p. ?. Both parents were heterozygous for the deletion. Homozygous complete *APTX* deletions have been described in literature for two other patients. We obtained a sample from one of these two patients and characterized the deletion (156kb) as c. -23729_*115366del155489, p. ?. The more severe phenotype reported for this patient is not observed in our patient. It remains unclear whether the larger size of the deletion (156kb vs 61kb) plays a role in the phenotype; no extra genes are deleted besides the non-coding APTX exons 1A and 2. *Conclusion*Here we described an ataxia with oculomotor apraxia type 1 patient who has a homozygous deletion of the complete coding region of *APTX* instead of homozygosity or compound heterozygosity for *APTX* mutations. We were unable to confirm a more severe phenotype for ataxia with oculomotor apraxia type 1 patients with a complete deletion of *APTX*, however, more research is needed to study the exact breakpoints/sizes of these kind of *APTX* deletions.

2973T

Novel Mutation Identified in the SCN1A (Channelopathy) Gene Associated with Acute Onset Ataxia, Dystonia, and Afebrile Seizures. *M. Walke, A. Rajadhyaksha, I. Miller, P. Jayakar.* Nicklaus Children's Hospital , Miami , FL.

Channelopathies including mutations in theSCN1Agene are inherited in an autosomal dominant manner. Heterozygous mutations in these genesmay cause a wide range of phenotypes, from febrile seizures to severe intractable epilepsy, known as Dravet Syndrome (Miller et al, 2014). A rare presenting feature of chanelopathiesis acute onset ataxia. Case: Currently,a 4 year old,previously healthy patient presented at 30 months of age for an evaluation of acute ataxia, dystonia, and 3 afebrile seizures that started at 27 months. No triggering factors were noted on history. Extensive genetic, metabolic work up, and neuroimaging were all normal. Whole Exome showed a heterozygous de novo mutation in exon 6 of the SCN1A gene, p. Val250Ile (GTA>ATA): c. 748G>A (NM_001165936. 1). This de novo mutation has not been reported previously in literature databases. However, it has been detected in another patient with seizures at thetest performing laboratory. Therefore, this mutation was interpreted as a disease-causing mutation. Furthermore, in silico analysis predicted the mutation to be adamaging missense mutation, due to its location in the pore region. The phenotype of Dravet syndrome includes intractable epilepsy and comorbidities ofcognitive impairment,which are usually seen by one year of age followinginitial febrile seizures. The ataxia is predicted to be caused by mutations in the NaV1. 1 channels, impairing the sodium currents and action potential firing in hippocampal GABAergic inhibitory neurons. This also affects the Purkinje neurons of the cerebellum (Catterall, et al.). Truncating mutations in the pore region of the SCN1Ageneare associated with a more severe phenotype of Dravet Syndromeincluding severe myoclonic epilepsy of infancy (SMEI) cognitive impairment and progressive ataxia. Although, missense mutations in the pore region have not been seen with this particularpresentation. Conclusion: Patients may havea variable phenotype and mutation testing for channelopathies is recommended for atypical presentationofpatients presenting with ataxia, dystonia anda history of afebrile seizures. References:Oakley, et al; Insights into pathophysiology and therapy from a mouse model of Dravet syndrome. Epilepsia. 2011 Apr;52 Suppl 2:59-61. Miller, et al; *SCN1A*-Related Seizure Disorders. 2974F

Severe Optic Nerve and Chiasm Hypoplasia, Blindness, Autism and Cognitive Handicap Associated with BMP4 Mutation. *P. Bitoun[1,2], M. legendre[3], E. Pipiras[2], S. Amselem[3], B. Benzacken[2].* 1) GROUPE MEDICAL JARENTE, Genetique Medicale, Paris, France,; 2) Hopital Jean Verdier, Paris XIII University, APHP, Embryo-cyto Génétique Bondy, France,; 3) Hopital Armand Trousseau, Paris VI University, APHP, Genetique, Paris, France,.

Introduction : BMP4 mutations are associated with anterior segment dysgenesis, coloboma and retinal dystrophy, deletions with microanophthalmia and pituitary anomaly. The authors report a male patient with BMP4 mutation. **Material & methods:** Patient had a brain MRI , endocrine evaluation, array CGH and multiple gene tests including HESX1, OTX2, SOX2, SOX3, PITX2, PITX3, BCOR, BMP4. **Results:** 1. 5 year old patient seen for blindness, 4th of 6 otherwise healthy children born uneventfully,birth weight of 3420g, height of 50cm to non-consanguinous healthy parents of north African origin. He had bilateral microcornea, sclerocornea , aniridia and large eyebulbs with staphyloma. Brain MRi at 1. 5 years showed: severe malformation of the visual pathways, near agenesis of optic nerves and chiasm, very severe hypoplasia of the proximal optic tracts not seen at the brain stem level, geniculate bodies were also not seen. The pituitary was small with continuous stalk. A colpocephaly was present w/o gyration or myelination anomaly. Patient sat at 10 months , walked at 4 years, with cognitive delay and absent speech. Bone age delay 5 years/ 8 years. Endocrine evaluation showed normal thyroid and Cortisol levels. Arginine Insuline GH stimulation test peak at 8,4 ug/l : in favor of a GH deficiency but repeat glucagon test showed a normal GH peak at 23 ng/ml. Patient had severe hypotrophy with reduced muscle mass and hyperlaxity. He was reassessed at the age of 21 and showed severe cognitive delay, lack of speech, hypotrophy at 35 kg and height of 170cm. All gene tests and array CGH was normal. BMP4 sequencing confirmed the c. 451G>A predicted to cause p. Glu151Lys mutation identified by NGS analysis using the Illumina platform …. The mother was not carrying the mutation and the father was not available for sequencing. **Discussion**: The G to A mutation occurred in a CG dimer and the Glu 1511 is highly conserved across vertebral evolution and was absent from dbSNP, Ensembl, 1000 Genomes, ExAC databases. A previously reported truncating mutation c. 226del2 mutation (p. Ser76fs104X) was associated with microanophthalmia, retinal dystrophy, polydactyly and syndactyly, brain atrophy, widened sulci and partial agenesis of the corpus callosum. **Conclusions**: A BMP4 likely de novo missense mutation was associated with severe hypoplasia of the optic nerve, chiasm and tracts with cognitive motor and language delay thus expanding the phenotype of BMP4 mutations.

2975W

A study of the role of the *FOXP2* and *CNTNAP2* genes in persistent developmental stuttering. *T. Han[1], J. Park[2], C. Domingues[3], D. Moretti-Ferreira[3], E. Paris[1], E. Sainz[1], J. Guiterrez[1], D. Drayna[1].* 1) National Institute on Deafness and Other Communication Disorders, NIH, Bethesda, MD; 2) National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD; 3) Department of Genetics, Institute of Bioscience São Paulo State University, Botucatu, São Paulo, Brazil.

A number of speech disorders including stuttering have been shown to have important genetic contributions, as indicated by high heritability estimates from twin and other studies. We studied the potential contribution to stuttering from variants in the *FOXP2* gene, which have previously been associated with developmental verbal dyspraxia, and from variants in the *CNTNAP2* gene, which have been associated with specific language impairment (SLI). DNA sequence analysis of these two genes in a group of 703 cases, all with familial persistent developmental stuttering, revealed no excess of potentially deleterious coding sequence variants in the cases compared to a matched group of 671 well characterized neurologically normal controls. This was compared to the distribution of variants in the *GNPTAB*, *GNPTG*, and *NAGPA* which have previously been associated with persistent stuttering. Consistent with previous results, *GNPTAB* and *GNPTG* showed significantly different mutant frequencies in stuttering cases and normal controls ($P = 0.0005$ for *GNPTAB*, $P = 0.0095$ for *GNPTG*). No differences in mutation frequency in the *FOXP2, CNTNAP2,* or *NAGPA* genes were observed between cases and controls. To examine the pattern of expression of these five genes in human brain, real time quantitative reverse transcription PCR was performed on RNA purified from 27 different human brain regions. The expression patterns of *FOXP2* and *CNTNAP2* were generally different from those of *GNPTAB*, *GNPTG* in terms of relatively lower expression in cerebellum. This study provides an improved estimate of the contribution of mutations in the *GNPTAB* and *GNPTG* to persistent stuttering, and suggests that variants in the *FOXP2* and *CNTNAP2* are not involved in the genesis of familial persistent stuttering. This, together with the different brain expression patterns of *GNPTAB* and *GNPTG* compared to that of *FOXP2* and *CNTNAP2*, suggests that the genetic neuropathological origins of stuttering differ from those of verbal dyspraxia and SLI.

Statement of Purpose: Laminins are heterotrimeric glycoprotein complexes, consisting of α, b and γ subunits, that form a major component of basement membranes and extracellular matrix. Laminin complexes have different, but often overlapping, distributions and functions, and laminin defects have been associated with many different disorders. In this work, we define the clinical phenotype of LAMA1 deficiency with anxiety, cerebellar dysplasia with cysts, and severe myopia with retinal dystrophy. **Methods:** Under our NIH protocol, NCT00068224, we evaluated three individuals in two families presenting with anxiety, tics, cerebellar dysplasia with cysts, and myopia. We performed whole exome sequencing on affected individuals and available family members. To determine the effect of gene mutation in cells, we analyzed RNA and protein expression in fibroblasts derived from patient cells, as well as explore the mechanism that may explain the cell defect. **Results:** All affected individuals have null mutations in *LAMA1*, a gene that encodes an important component of the basement membrane. Our functional studies in cultured fibroblasts of subjects with LAMA1 deficiency identified impaired adhesion, reduced migration, abnormal morphology and increased apoptosis. Importantly, LAMA1-knockdown in human neuronal cells also showed abnormal morphology and filopodia formation, supporting the importance of LAMA1 in neuronal migration, and marking these cells as useful for further therapeutic explorations. **Conclusions:** We describe detailed clinical, neuroimaging, and functional studies of lamininopathy associated with *LAMA1* mutations, characterized by anxiety, cystic cerebellar dysplasia with cysts, and severe myopia associated with retinal degeneration. Whether tics, obsessive compulsive traits, and anxiety are a primary part of this phenotype will likely be determined after description of other patients with *LAMA1* mutations. Based upon population studies (1000 Genomes and NHLBI Exome Sequencing Project) potential null variants (stop gain, frame shift or splice variants) in *LAMA1* have an estimated frequency of 0.53%; this translates into a prevalence of 1 in 35,000 for this new disease. *LAMA1* should be considered a candidate gene in patients with anxiety, tics, cerebellar dyspasia with cysts and severe myopia with retinal dystrophy.

2977F

Identification of homozygous mutations in the *CHRNG* genes by whole exome sequencing in siblings presented with congenital arthrogryposis multiplex. *G-H. Kim[1], J-M. Kim[1], J. Cho[2], E. Kang[2], J-H. Choi[2], B. Lee[1,2], H-W. Yoo[1,2].* 1) Med Gen Clinics Center, Asan Med Ctr, Seoul, South Korea; 2) Department of Pediatrics, Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, South Korea.

Multiple pterygium syndrome(MPS) is a genetically heterogeneous disorder caused by germline mutations in the *CHRNG* gene. It is characterized by congenital contractures of multiple joints, scoliosis, muscle weakness, typical facial features, and multiple pterygium. This study describes two siblings with MPS presented with multiple joint contractures and their molecular characteristics. A 7-year-old girl presented to our institute for the evaluation of multiple joint contractures. She was born at term with a birth weight of 3. 4 kg with no perinatal problems to non-consanguineous parents. The patient manifested multiple joint contractures of both metacarpal joints after birth and experienced gait disturbance due to knee joint contractures as she grow older. Her younger brother was born at 37 weeks of gestation with a birth weight of 2. 6 kg. Polyhydramnios was detected by prenatal ultrasonography. Cardiac pacemaker was implanted due to sick sinus syndrome at the age of 3 months. He had both inguinal hernia, which were corrected surgically during infancy. He presented with multiple joint contractures, cervical spine kyphosis, both camptodactyly, vertical talus, and rocker bottom feet at the age of 5 years. Whole exome sequencing (WES) analysis of the trio family identified that the proband was homozygous for a p. Pro143Arg of *CHRNG*, which was predicted to be detrimental by PolyPhen-2 and SIFT. Also, this variant was not found in the 1000Genomes database (http://browser. 1000genomes. org/) and ClinVar (http://www. ncbi. nlm. nih. gov/clinvar/). Both parents were heterozygous for the variant. The variant was confirmed by Sanger sequencing and her younger brother also harbored homozygous mutation in p. Pro143Arg in *CHRNG*. The MPS is an extremely rare and phenotypically heterogeneous disorder from lethal to non-lethal forms. Both of them are caused by mutations in *CHRNG*, encoding the gamma subunit of the embryonic acetylcholine receptor which has a role in the muscle-relaxant effect. This study reports two siblings with MPS harboring homozygous mutation in *CHRNG* for the second time. The first two Korean MPS cases also carried the p. Pro143Arg mutation identified by WES, representing possible founder effect in Korean population. WES analysis is helpful to make rapid, confirmative diagnosis of ultra-rare disorder.

2978W

A family with Joubert and Meckel-Gruber Syndrome phenotypes associated with *TMEM231* mutations. *D. Maglic[1], T. Vilboux[1,5], J. Stephen[1], D. Konzman[1], J. Bryant[1], M. Vemulapalli[3], B. Maskeri[3], A. Young[3], J. Mullikin[3], W. A. Gahl[1,2,4], M. C. Malicdan[1,2], M. Gunay-Aygun[1].* 1) Medical Genetics Branch, National Institutes of Health, Bethesda, MD, MD; 2) NIH Undiagnosed Diseases Program, Common Fund, Office of the Director, National Institutes of Health, Bethesda, Maryland, USA; 3) NIH Intramural Sequencing Center and Comparative Genomics Unit, Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892, USA; 4) Office of the Clinical Director, NHGRI, National Institutes of Health, Bethesda, MD USA; 5) Inova Translational Medicine Institute, Falls Church, Virginia, USA.

Statement of Purpose: Joubert syndrome is defined based on a distinctive brain malformation (molar tooth sign) on brain imaging. Most Joubert syndrome patients display hypotonia, developmental delay, abnormal eye movements, and an abnormal respiratory pattern in infancy. Variable features include fibrocystic kidney disease, congenital hepatic fibrosis, retinal degeneration, retinal colobomas, and polydactyly. Meckel-Gruber syndrome, which is typically fatal perinatally, is associated with polycystic kidneys, occipital encephalocele and polydactyly. Both syndromes are genetically heterogeneous with multiple causative genes, some of which may cause either syndrome. In this paper we report a family with overlappingJoubert and Meckel-Gruber syndrome. **Methods:** Under our NHGRI ciliopathy study (www. clinicaltrials. gov, trial NCT00068224), we have evaluated over 100 patients with Joubert syndrome. Evaluations at the NIH Clinical center included family history and physical examination and comprehensive biochemical and imaging studies. Whole exome sequencing (WES) was performed on all affected and available members of the family. **Results:** Here, we report a family with 4 children with Joubert syndrome. None of first three children with Joubert syndrome had polydactyly and their kidney ultrasonograpy was normal at ages 4. 8 (twins) and 1. 2 years. The fourth sibling displayed polycystic kidneys on prenatal ultrasonography and unfortunately passed soon after birth. Interestingly, the children's paternal uncle and his wife had a fetal demise due to Meckel-Gruber syndrome. By WES we identified a homozygous missense variant (c. 712G>A, p. D238N) in *TMEM231*, a previously reported variant associated with Joubert syndrome, in all four affected siblings. Since the mother was the only parent heterozygous for this mutation, we suspect the affected children to be hemizygotes and the father to be a carrier of a big deletion not detectable by WES. We suspect that this deletion in *TMEM231* variant is also present in the fetus with Meckel-Gruber syndrome likely in combination with another severe variant (c. 334T>G, p. Trp112Gly) inherited from the mother. **Conclusion:** We describe a three-generation, non-consanguineous family who harbor several variants in *TMEM231* that resulted in a complex overlap of Joubert and Meckel-Gruber syndromes.

2979T

Novel autosomal recessive intellectual disability syndrome with manganese deficiency, muscular hypotonia, and cerebellar atrophy caused by mutation of the SLC39A8 transporter. *R. Abou Jamra[1,5], C. H. Beaulieu[2], A. Mhanni[3], O. H. Gebril[4], K. Kernohan[2], A. E. Chudley[3], H. Tawamie[5], F. Radwan[5], J. Schwatzentruber[6], . FORGE Canada Consortium[2], J. Majewski[6], S. Uebe[5], A. Ekici[5], A. Reis[5], A. M. Innes[7], S. Parboosingh[7], K. M. Boycott[2].* 1) Centogene, Rostock, MV, Germany; 2) Children's Hospital of Eastern Ontario Research Institute; University of Ottawa, Ottawa, Canada; 3) Section of Genetics and Metabolism; Children's Hospital and the Department of Pediatrics and Child Health; University of Manitoba, Winnipeg, Canada; 4) Department of Research on Children with Special Needs; National Research Centre (NRC), Cairo, Egypt; 5) Institute of Human Genetics; FAU Erlangen-Nürnberg, Erlangen, Germany; 6) McGill University and Genome Quebec Innovation Centre, Montreal, Canada; 7) Department of Medical Genetics; Alberta Children's Hospital and University of Calgary, Calgary, Canada.

We ascertained two Egyptian siblings of consanguineous parents both presenting with severe intellectual disability, hypotonia and hyporeflexia, strabismus, short stature, early-onset epilepsy or absences, and normal head circumference with brain atrophy in one child. Autozygosity mapping and exome sequencing revealed a candidate mutation in SLC39A8 (encoding the protein ZIP8) in a homozygous status that leads to an alteration on protein level; p. Gly38Arg. In silico simulations and molecular modelling showed that this is a highly conserved residue and that the alteration is probably pathogenic. Independently, further patients were identified within the FORGE (Finding of Rare Disease Genes) Canada project; five children of 5 families of Hutterite descent were also found homozygous for the p. Gly38Arg alteration. The patients presented severe developmental delay, severe hypotonia, short stature, cerebellar atrophy with normal head circumference, mild skeletal dysplasia, and connective tissue abnormalities. SLC39A8 is a member of the solute carrier gene (SLC) superfamily. The encoded protein ZIP8 is a Zn/HCO symporter, and also transports Mn and Cd across the plasma membrane. Evaluation of trace element levels in affected patients revealed low blood Mn levels in all the Egyptian and the Canadian patients, and low Zn levels in the Canadian patients, further supporting the pathogenicity of the alteration. Cell cultures of several tissues taken from hypomorphic Slc39a8(neo/neo) mice exhibit diminished zinc and iron levels, and die lately 48 h postnatally. Defects include severely hypoplastic spleen, hypoplasia of liver, kidney, lung, and lower limbs. We conclude that the variant we identified in SLC39A8 is pathogenic, and that it probably leads to a distinguishable autosomal recessive, severe intellectual disability syndrome with Mn deficiency, short stature, and muscular hypotonia. Further symptoms are brain atrophy with normal head circumference, seizures, strabismus, and osteopenia. Based on the severity of the symptoms of our patients and on the results of the hypomorphic mouse model, we think - at this stage - that the variant we identified in SLC39A8 influences the functions of the protein, but is not a loss of function. This is the first gene associated with a human Mn deficiency syndrome and this finding also provides insight into the role of Mn homeostasis in development and health.

Next generation genomic technologies have made a significant contribution to the understanding of the genetic architecture of human neurodevelopmental disorders. Copy number variants (CNVs) play an important role in the genetics of intellectual disability (ID). For many CNVs, and copy number gains in particular, the responsible dosage-sensitive gene(s) have been hard to identify. We have collected 18 different interstitial microduplications and one microtriplication of Xq25. There were 6 familial and 13 singleton cases (33 affected males and 10 carrier females). The critical overlapping region involved the *STAG2* gene, which codes for a subunit of the cohesin complex that regulates cohesion of sister chromatids and gene transcription. We demonstrate that *STAG2* is the dosage-sensitive gene within these CNVs, as gains of *STAG2* mRNA and protein deregulate disease-relevant neuronal gene networks in cells derived from affected individuals as determined by RNA-seq. We also show that *STAG2* gains result in increased expression of *OPHN1*, a known X-chromosome ID gene. Overall we define a novel cohesinopathy with behavioural problems due to copy number gain of Xq25 and *STAG2* in particular.

2981W

Contribution of Copy Number Variation to the Genetic Etiology of Duane Retraction Syndrome. *V. K. Robson, A. Digioia, W. M. Chan, C. Andrews, S. J. Bekele, E. C. Engle.* Neurology, Boston Children's Hospital, Boston, MA.

Duane Retraction Syndrome (DRS) is a congenital eye movement disorder associated with aberrant innervation of the lateral rectus muscle by the motor branches of the third and sixth cranial nerves. We previously reported the only known genetic causes of isolated (*CHN1* [MIM118423,604356]) and syndromic (*HOXA1*[MIM 142955, 126800]and *SALL4* [MIM607343,607323]) DRS. The genetic etiology of most DRS cases, however, remains unclear. Rare case studies of simplex syndromic DRS have implicated de novo chromosomal structural abnormalities that cause damaging copy number variants (CNVs). To investigate these structural variants in detail, we are conducting a systematic analysis of CNVs in a cohort of patients with syndromic DRS. From a cohort of 500 DRS probands without known mutations, we selected 84 simplex probands with syndromic DRS to clinically characterize and code according to phenotype. From among these 84 probands, 32 full and 10 incomplete trios were selected for CNV analysis. Whole genome genotyping data were generated for the 116 samples (42 affected probands, 74 unaffected family members) using a Human Omni2. 5 + Exome SNP Chip bead array from Illumina containing 2. 5 million unique SNPs and supplemental exonic coverage. Our deep phenotypic analysis allowed us to identify probands with known DRS-associated syndromes within our cohort, including Wildervanck (7 patients), Duane's Radial Ray (3), and Goldenhar (1) syndromes. Of the probands that do not fit into a clearly defined syndrome, abnormalities involve the following systems: musculoskeletal (24), neurological (18), hearing (17), ophthalmic (14), developmental motor delay (12), dysmorphia (12), cardiavascular (11), intellectual and social disability (9), gastrointestinal (7), and genitourinary (5). After preliminary investigation, we have identified a variety of de novo CNVs across the cohort, including a deletion on 7q31 and copy number gain on Xq23. Further work will confirm rare or novel CNVs by ddPCR, determine whether they are present among other probands in the cohort, and investigate their functional impact. Thus, this project will systematically define the role of CNVs in syndromic DRS in order to better inform the genetic diagnosis of this disorder, enhance the understanding of CNVs in human disease, and potentially provide new avenues of research for targeted therapeutics of neurodevelopmental disorders.

2982T

***NAA10* missense mutations cause neurodevelopmental delay in eight female patients.** *C. Saunier[1], C. Zweier[2], S. I. Støve[3], B. Gérard[4], A. Piton[4], M. Blenski[3], J. Thevenon[5,6], A. The *NAA10* gene encodes for *N*-alpha-acetyltransferase 10, the catalytic subunit of the N-terminal acetyltransferase A complex (NatA). NatA is the major enzyme responsible for N-terminal acetylation, one of the most frequent protein modifications harbored by approximately 80-90% of all human proteins. In mice, the *Naa10* gene is ubiquitously expressed in adults and highly expressed in the brain during embryonic development. It has also been suggested that NAA10 is involved in regulating dendrite growth, cell cycle and apoptosis. *NAA10* mutations have been described in eight males from two different families with X-linked severe lethal Odgen syndrome (OGDNS), linked to the same missense mutation (p. Ser37Pro) and in four related males with Lenz microphthalmia syndrome, linked to a splice donor site mutation (c. 471+2T>A)). Two other *NAA10* missense mutations (p. Val107Phe and p. Arg116Trp) have recently been implicated in a male and a female with non-syndromic developmental delay. N-terminal acetylation assays for the three previously published missense variants demonstrated an impaired acetyltransferase activity. We report on seven new female cases with *de novo NAA10* missense mutations and one with an inherited mutation (six independent cases with a hotspot p. Arg83Cys mutation and two cases with collocated p. Phe128Leu and p. Phe128Ile mutations). Like the previously published female patient, the new cases present severe intellectual disability, truncal hypotonia, microcephaly and minor similar facial dysmorphism. Functional testing of Naa10 Arg83Cys and Phe128Leu revealed distinct, but significant alterations in protein parameters for the two mutants. Both mutants have an impaired ability to carry out protein N-terminal acetylation. In conclusion, this report of eight new female cases strongly supports the involvement of *de novo NAA10* missense mutations in X-linked intellectual disability and particularly in females with severe intellectual disability, truncal hypotonia, borderline microcephaly and minor facial dysmorphism, linked to protein N-terminal acetylation defects. These data also confirm that *de novo* mutations on the X-chromosome can cause developmental disorders in females.

2983F

Characterization of *SCN8A* mutations and phenotypes in comparison to *SCN1A*. *D. Chen[1], A. Ishii[2,3], M. Hammer[4].* 1) Genetics, University of Arizona, Tucson, AZ; 2) University of Arizona Genomics Core, University of Arizona, Tucson, AZ; 3) Department of Pediatrics, Fukuoka University School of Medicine, Fukuoka, Japan; 4) Arizona Research Laboratories, University of Arizona, Tucson, AZ.

SCN8A, a voltage-gated sodium ion channel, is a large protein (260 kDa) with four repeats. Each of these repeats has six transmembrane domains with connecting loops in between them. It is in the same gene family as *SCN1A*, a causal gene of Dravet Syndrome (DS), a severe, infantile epilepsy. *SCN1A* and *SCN8A* are highly conserved and have high homology. Knockouts in *SCN8A* cause ataxic phenotypes in mice and have only recently been shown to cause seizures and major neurodevelopmental delay in humans. Since then, 42 additional pathogenic mutations have been reported. On the other hand, more than a thousand mutations in *SCN1A* have been reported and well studied, with phenotypes characterized by febrile seizures. Using what we know about *SCN1A*, we aim to characterize *SCN8A* mutations and their corresponding phenotypes and ultimately discover patterns that may be used to predict pathogenicity of new mutations. We will be using the 43 *SCN8A* mutations published in the literature as well as a sample of 270 Dravet patients with thorough genetic and phenotypic data.

In *SCN8A*, we have 38 (88%) mutations that are *de novo*, 2 (5%) inherited, and 2 (5%) with unknown inheritance patterns. All mutations are missense except for one nonsense mutation. Interestingly, the patient presented with ataxia, not epilepsy. In comparison, more than a half of the mutations in *SCN1A* are truncation mutations (151/270, 56%) and result in a more severe phenotype. 21 *SCN8A* mutations appear in transmembrane domains while 22 appear in the loops. Despite the loops being nearly three times longer than the transmembrane domains, mutations are significantly more likely to appear in transmembrane domains than the loops in between (Fisher's Exact Test, two-sided p-value=0. 0034). This may be because mutations in loops result in a milder phenotype and may be subclinical. *SCN1A* mutations do not have the same significance (Fisher's Exact Test, two-sided p-value=0. 3829).

We hope to increase our sample size over the next few years as more mutations are reported. We are also establishing a framework to crowdsource patient data by creating an online presence where parents of children with *SCN8A* mutations can contact researchers and each other for information. Although not ready to publish, we have already collected 33 responses. Future plans also include studying mouse models with different *SCN8A* mutations.

2984W

Whole exome sequencing identified a splice site mutation in ARV1 in a consanguineous family with intellectual disability, epilepsy and neurodegeneration. *Y. Guo[1], L. Worgan[2], L. Tian[1], C. Hou[1], F. Collins[3,4,5], H. Hakonarson[1,6], J. Christodoulou[4,5].* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Department of Clinical Genetics, Liverpool Hospital, Liverpool, NSW, Australia; 3) Clinical Genetics, The Children's Hospital at Westmead, Sydney, NSW, Australia; 4) University of Sydney, Sydney, NSW, Australia; 5) Western Sydney Genetics Program, Children's Hospital Westmead, Westmead, NSW, Australia; 6) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

In a large consanguineous family of Lebanese origin, a total of four children are diagnosed with intellectual disability, epilepsy, hypotonia and neurodegeneration. Numerous genetic as well as neurological tests were unrevealing thus we conducted whole exome sequencing (WES) on two of the affected children, each in a separate branch of the family. We identified a homozygous splice site mutation in ARV1, the homolog of S. cerevisiae gene ARV1. The mutation was validated in the family using Sanger sequencing. With only 2 heterozygotes in the ExAC database of more than 60,000 samples, this mutation is at a very conserved position, and could truncate the encoded protein. ARV1 was recently reported as a candidate gene in a family with convulsive disorder/developmental delay/epilepsy, and is involved in sphingolipid metabolism, malfunction of which is seen in other neurodegenerative disorders such as Nieman-Pick disease. At present, we are performing follow-up functional experiments to establish the mutation's deleterious impact on intracellular sterol trafficking as well as sphingolipid metabolism.

2985T

***TUBGCP4,* encoding a member of the γ-tubulin ring complex γTuRC, is a novel gene for autosomal recessive microcephaly with chorioretinopathy (MCMR).** *H. J. Dollfus[1], S. SCHEIDECKER[1], C. ETARD[2], L. HAREN[3], S. HULL[4,5], G. ARNO[4,5], V. PLAGNOL[5], S. DRUNAT[6], S. PASSEMARD[6], A. TOUTAIN[7], C. OBRINGER[1], V. KOOB[8], V. GEOFFROY[1], U. STRAHLE[2], P. OSTERGAARD[9], A. VERLOES[6], C. MERDES[3], M. MOORE[4,5], C. STOETZEL[1].* 1) Medical Genetics Laboratory , CARGO, IGMA, INSERM U1112 , Strasbourg University, Strasbourg , Alsace , France; 2) Institut für Toxikologie und Genetik Campus Nord, Karlsruher Institut für Technologie, Eggenstein-Leopoldshafen, Germany; 3) Centre de Biologie du Deéveloppement, Université Paul Sabatier, Toulouse, France; 4) Inherited Eye Diseases, UCL Institute of Ophthalmology, London, UK; 5) Moorfields Eye Hospital, London EC1V 2PD, UK; 6UCL Genetics Institute, London UK; 6) Unité Fonctionnelle de Génétique Moléculaire, Département de Génétique, Hôpital Robert Debré, Centre Hospitalier Universitaire Paris, Paris, France; 7) Département de Génétique Médicale, Centre Hospitalier Régional et Universitaire de Tours, Tours, France; 8) Service de RadioPédiatrie et Imagerie, Hôpitaux Universitaires de Strasbourg et Laboratoire ICube, Université de Strasbourg, Centre National de la Recherche Scientifique, Strasbourg, France; 9) Human Genetics, Cardiovascular and Cell Sciences Institute, St. George's University of London, London , UK.

In 1966, Pr V McKusick was the first to report on autosomal recessive microcephaly with chorioretinal in dysplasia in a Mennonite family (Arch Ophthalmol, 1966). Recently, mutations in *TUBGCP6* were identified for this unique family (Pfuffenberger, Plos one, 2012) with Autosomal recessive Microcephaly and Chorioretinopathy with or without Mental Retardation, abbreviated as MCMR. Autosomal dominant Microcephaly with or without Chorioretinopathy, Lymphoedema, or Mental Retardation (MCLMR) also known as Alzial syndrome has recently been attributed to mutations in *KIF11*(Oostergaard P, 2012). We have identified *TUBGCP4* variants in individuals with MCLMR with very specific retinal phenotypes. Whole exome sequencing performed on one family with two affected siblings and independently on another family with one affected child revealed compound heterozygous mutations in *TUBGCP4*. Subsequent Sanger sequencing was performed on a panel of individuals with microcephaly and ophthalmic manifestations and one other patient was identified with compound heterozygous mutations in *TUBGCP4*. *TUBGCP4* encodes the γ-tubulin complex protein 4, a component of the γ-tubulin ring complex (γTuRC) known to regulate the nucleation and organization of microtubules. Functional analysis of patient fibroblasts disclosed reduced levels of the γTuRC, altered nucleation and organization of microtubules, abnormal nuclear shape, and aneuploidy. Moreover, zebrafish treated with morpholinos against *tubgcp4* were found to have a reduced head volume and eye developmental anomalies with very specific chorioretinal dysplasia features. The identification of biallelic *TUBGCP4* mutations confirms the existence of autosomal recessive cases with microcephaly and chorioretinopathy that actually present a very specific phenotype in the syndromic microcephaly group.

2986F

A nonsense *C12orf65* mutation in Indian-Jewish monozygotic female twins with Leigh syndrome. *E. Imagawa[1], A. Fattal-Valevski[2], O. Eyal[3], S. Miyatake[1], A. Saada[4], M. Nakashima[1], T. Tsurusaki[1], H. Saitsu[1], N. Miyake[1], N. Matsumoto[1].* 1) Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 2) Paediatric Neurology Unit, Tel Aviv Sourasky Medical Centre, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 3) Paediatric Endocrinology Unit, Tel Aviv Sourasky Medical Centre, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 4) Monique and Jacques Roboh Department of Genetic Research and the Department of Genetic and Metabolic Diseases Hadassah-Hebrew University Medical Center, Jerusalem, Israel.

Leigh syndrome (LS: MIM#256000) is an early-onset neurodegenerative disorder leading to mitochondrial dysfunction. LS is characterized by elevated lactate/pyruvate together with bilateral and symmetric high-intensity signals in brainstem, basal ganglia, cerebellum and spinal cord on T2-weighted brain MRI. To date, approximately 50 nuclear genes have been reported in LS. Here, we present Indian-Jewish monozygotic female twins affected with LS. The affected twins were born to consanguineous parents, and showed a failure to thrive, developmental delay, ophthalmoplegia, optic atrophy, spastic paraparesis, muscle weakness of lower limbs, mild intellectual disability and cognitive impairment. They showed elevated serum lactate, symmetrical brain lesions in brainstem on T2-weighted MRI and decreased mitochondrial complex IV activity on muscle biopsy. To identify the genetic cause of them, we performed genetic analysis using whole exome sequencing. Based on the hypothesis of autosomal recessive model (homozygote and compound heterozygote), we identified one homozygous nonsense mutation in *C12orf65* (c. 346delG, p. Val116*; NM_001143905) in both affected twins. Its heterozygous change was identified in their parents and no mutation showed in their healthy sibling. *C12orf65* is a mitochondrial matrix protein belonging to the family of class I peptide chain release factors, associated with the mitochondrial translation termination. The *C12ore65* mutations have been already reported in LS, in addition autosomal recessive spastic paraplegia-55 (MIM #615035), Charcot-Marie Tooth type6 (CMT type 6, MIM #601152) and syndromic autosomal recessive intellectual disability. Interestingly, the previous reported mutations were all truncating, which produce the truncated C12orf65 protein due to escape of nonsense-mediated decay. It is known that clinical severity would be dependent on the residual length of the truncated C12orf65 protein. The identified mutation resulted in mid-length truncation, and the clinical features are moderate. The identical mutation has been previously reported in CMT type 6 patients by Tucci et al. but the presenting LS case displayed more severe phenotypes, thus the phenotypic variability may be altered by unidentified mutations/modifiers.

2987W

Linkage mapping and exome sequencing identifies a novel genetic cause of Charcot-Marie-Tooth neuropathy with pyramidal signs. *M. L. Kennerson[1,2,3], O. Albulym[1,2], A. P. Drew[1], M. Harms[4], M. Auer-Grumbach[5], A. Pestronk[4], A. Connolly[4], R. H. Baloh[6], S. R. Reddel[1,3,7], S. Zuchner[8], G. A. Nicholson[1,2,3].* 1) Northcott Neuroscience, ANZAC Res Inst, Concord, Australia; 2) Sydney Medical School, University of Sydney, NSW 2008, Australia; 3) Molecular Medicine Laboratory, Concord Hospital, NSW 2139, Australia; 4) Department of Neurology; Washington University School of Medicine St. Louis, Missouri USA 63110; 5) Department of Internal Medicine, Medical University of Graz, Austria; 6) Department of Neurology; Cedars Sinai Medical Center, Los Angeles, CA, USA; 7) Brain & Mind Research Institute, Sydney, New South Wales, Australia; 8) John P. Hussman Institute for Human Genomics, Miami University, US.

Introduction: Charcot-Marie-Tooth (CMT) disease is a group of degenerative disorders of human peripheral nerve affecting both the motor and sensory neurons. This genetically and clinically heterogeneous syndrome is the most common inherited neuromuscular disease affecting 1 in 2500 individuals. The CMT phenotype is characterised by progressive weakness and atrophy of distal muscles, high arched feet (pes cavus) and loss of deep tendon reflexes. In this study we have used a combination of genetic linkage and whole exome sequencing (WES) to identify the causative gene in an Australian family (CMT105) diagnosed with CMT2 and pyramidal signs. **Methods:** Genome wide microsatellite markers were genotyped and analysed using standard parametric genetic linkage analysis. WES was performed on selected individuals (3 affected, one normal). Segregation analysis and mutation screening of CMT2 families was performed using high resolution melt analysis (HRM). The GEM. app database was queried to identify additional families harboring mutations in genes of interest. **Results:** Linkage analysis revealed significant LOD scores ≥ +3 on chromosome 22q12. 1-q13. 2 and extended haplotype analysis mapped a new CMT2 locus to a 6. 6-Mb interval flanked by the markers D22S1154 and D22S280. WES identified a novel mutation c. 754C>T (p. R252W) in the *MORC2* gene which mapped within the linkage region and fully segregated with the disease phenotype in family CMT105. Screening additional families and querying the GEM. app database identified the p. R252W mutation in two unrelated early onset CMT2 families and a second mutation c. 707A>G (p. E263G) was identified in two unrelated CMT2 families. Both the mutations occurred at highly conserved amino acid residues and were absent in the normal population and 1000 in-house neurologically normal control chromosomes. **Conclusions:** We have identified a new locus for CMT2 and shown compelling genetic evidence that *MORC2* mutations are the likely pathogenic cause of axonal CMT in these families. *MORC2* encodes the human CW-type zinc finger 2 protein which is a chromatin modifier involved in the regulation of DNA repair as well as gene transcription regulation. Further studies are needed to define the role of MORC2 protein in motor and sensory neurons and to further understand the underlying pathogenic mechanisms in which *MORC2* mutations lead to axonal neuropathy. M. L. K. and O. A. contributed equally to this work.

2988T

Splicing of a 46bp sequence from central inton 9 of human *FMR1* gene results in a truncted FRMP peptide with altered subcellular distribution and different functions when overexpressed. *F. Lan, X. Fu, J. Liao, X. Guo, A. Yan, W. Yang, D. Zhang.* Departmentt of Medical Genetics, Fuzong Clinical College, Fujian Medical University, Fuzhou, Fujian , China.

FMRP is encoded by *FMR1*gene,disease gene of fragile X syndrome (FXS), andhas several isoforms resulted from alternative splicing of *FMR1.* Recent reports demonstrate that the alternative splicing of *FMR1* is far more complex than what has been recoginized. In the analysis of alternatively spliced *FMR1* transcripts in the blood cells from a patient with FXS-like phenotypes, we detected a 46bp sequence lying between sequences of exons 9 and 10, which was spliced from the middle of intron 9. Bioinformatics shows that there are cononical splicing signals around this sequence, indicating the potentiality of this sequence as a cryptic alternative exon. A genetic variation was found in upsteam intron 9, but this could not resulted in any preferred splicing of this exon, as shown by hybrid minigene splice assay. This sequence could also be detected in blood cells of 50 normal controls using semi-nested PCR, and the same results were obtained when commercially available cDNA libraries were used. Given that mRNAcontaining this exon would introduce a premature stop codon, we doubted whether such transcript could produce a protein product. In Western blot analysis of blood cell lysate from normal individuals, a band of 34 kDa,consistent in size with the molecular weight of the predicted truncated protein, was observed. Assays with cycloheximide also revealed that mRNA with this exon could evade NMD. FMRP is mainly localized in the cytoplasm, and can shuttle between the nuclear and cytoplasmic compartments because of the presence of NLS and NES. The truncated FMRP of translated lacks the carboxy-terminal domains of FMRP, including NES, the second KH domain and a RGG. In confocal immunofluorescence,the truncated protein displayed both nuclear and cytoplasmic localization in HEK293T and HeLa cells, while the full-length protein localized mainly in the cytoplasm. Overexpression of the truncated protein regulates FMRP downstream target genes in HEK293T cells, as shown by using RNA microarray analysis and quantitative real-time RT-PCR. Among the 117 regulated genes, the *SLC7A11* gene*,* solute carrier family 7 (anionic amino acid transporter light chain, xc- system), member 11 gene (also known as xCT), was the most prominent. This gene is highlighted for its function as cysteine/glutamate transporter in brain cells, as well as its role in mGluR stimulation. We termed this novel cryptic alternative exon the exon 9a of *FMR1* gene.

2989F

SOX10 Regulates an Alternative Promoter at the Charcot-Marie-Tooth Disease Locus *MTMR2*: Implications for a Nuclear Function in Schwann Cells. *E. A. Fogarty[1], M. H. Brewer[2], N. Steinberg[2], J. F. Rodriguez-Molina[3], W. D. Law[2], J. Svaren[4,5], A. Antonellis[1,2,6].* 1) Neuroscience Graduate Program, University of Michigan, Ann Arbor, MI; 2) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 3) Cellular and Molecular Pathology Program, University of Wisconsin-Madison, Madison, WI; 4) Waisman Center, University of Wisconsin-Madison, Madison, WI; 5) Department of Comparative Biosciences, University of Wisconsin-Madison, Madison, WI; 6) Department of Neurology, University of Michigan, Ann Arbor, MI.

Schwann cells are the myelinating glia of the peripheral nervous system and dysfunction of these cells causes motor and sensory peripheral neuropathy. The transcription factor SOX10 is critical for Schwann cell development and maintenance, and many SOX10 target genes encode proteins required for Schwann cell function. Loss-of-function mutations in the gene encoding myotubularin related protein 2 (*MTMR2*) cause Charcot-Marie-Tooth disease type 4B1 (CMT4B1), a severe demyelinating peripheral neuropathy characterized by myelin outfoldings along peripheral nerves. Previous reports indicate that the expression of *MTMR2* is ubiquitous making it unclear how loss of this gene causes a Schwann cell-specific phenotype. To address this, we performed computational and functional analyses at *MTMR2* to identify transcriptional regulatory elements important for Schwann cell expression. Through these efforts, we identified an alternative, SOX10-responsive promoter at *MTMR2* that displays strong regulatory activity in Schwann cells. This promoter directs transcription of a previously unidentified *MTMR2* transcript that encodes an N-terminally truncated protein isoform, both of which are enriched in immortalized Schwann cells compared to motor neurons. The expression of the endogenous transcript is induced in a heterologous cell line by ectopically expressing SOX10, and is nearly ablated in Schwann cells by impairing SOX10 function. Intriguingly, while overexpressing the two MTMR2 protein isoforms revealed that both localize to puncta in the nucleus, the shorter isoform displays higher nuclear localization compared to the full-length protein. Combined, these findings suggest a nuclear function for MTMR2 that may be particularly important for Schwann cells. Indeed, the loss of this nuclear function may be a critical factor in the etiology of CMT4B1.

2990W

Inheritance of repeat interruptions in spinocerebellar ataxia type 10 (SCA10) expansions. *K. N. McFarland[1], I. Landran[1], J. Liu[1], C. Mulligan[2,3], A. Rasmussen[4], T. Ashizawa[1].* 1) Department of Neurology, McKnight Brain Institute, College of Medicine, University of FLorida Gainesville, FL 32610; 2) Department of Anthropology, College of Liberal Arts and Sciences, University of Florida, Gainesville, FL 32611; 3) Genetics Institute, University of Florida, Gainesville, FL 32611 USA; 4) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK 73104 USA.

Spinocerebellar ataxia type 10 (SCA10), an autosomal dominant cerebellar ataxia with varying presentation of epilepsy, is caused by a non-coding ATTCT microsatellite repeat expansion in *ATXN10.* In a subset of SCA10 families, the expanded ATTCT repeat contains complex interruption motifs—the ATCCT interuption—at the 5' end of the expansion. This interruption region contains heptanucleotide motifs interspersed amongst stretches of pure ATTCT repeats. The presence of this repeat interruption correlates with an increased risk of epileptic seizures and greater overall expansion instability in intergenerational transmission, particularly in paternal lineages. In this study we examined the stability of the motif patterns of the ATCCT-interruption in these alleles across multiple generations of four SCA10 families by sequencing ATCCT-PCR products. Within the interruptions, we found the greatest instability occurred in stretches of pure ATTCT motifs while the interrupting sequences act as insulators against instability. The pure ATTCT stretches within this region are particularly unstable in paternal transmissions despite these the fact that these pure ATTCT stretches contain less than 20 ATTCT units, the number comparable to stable normal alleles. Overall, the change in length of the ATCCT interruption is only by one to three repeat units, which cannot explain the remarkable instability of the entire disease allele. We conclude that the AT-rich interruptions stabilize but do not abolish the instability of short stretches of pure ATTCT repeats, and that greater instability of SCA10 expansion alleles must occur outside of this region.

2991T

Rare Variant Identification in Saudi Children with Mendelian Neurologic Diseases. *W. Charng[1,2], E. Karaca[1,2], Z. Coban Akdemir[1,2], T. Gambin[1,2], M. M. Atik[1,2], S. N. Jhangiani[2,3], R. A. Gibbs[2,3], E. A. Faqeih[4], A. A. Asmari[4], M. A. M. Saleh[4], A. W. El-Hattab[5], J. R. Lupski[1,2,6,7].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX 77030, USA; 2) The Baylor-Hopkins Center for Mendelian Genomics, Houston, TX 77030, USA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX 77030, USA; 4) Section of Medical Genetics, Children's Hospital, King Fahad Medical City, Riyadh, Kingdom of Saudi Arabia; 5) Division of Clinical Genetics and Metabolic Disorders, Department of Pediatrics, Tawam Hospital, Al-Ain, United Arab Emirates; 6) Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030, USA; 7) Texas Children's Hospital, Houston, TX 77030, USA.

In order to identify new disease genes and variants involved in the neurodevelopment, we performed whole exome sequencing (WES) on 35 Saudi families exhibiting neurological features, among which 32 are consanguineous. The majority of samples have been pre-screened with karyotyping and array CGH (aCGH) without significant findings. There are 26 (74. 3%) single affected subjects and 9 (24. 7%) families with multiple affected members. Four were sequenced as trios in families with single probands, and cases with two affected individuals per family were sequenced along with multiple members of the pedigrees. Twenty-two (63%) families exhibited various structural brain malformations while 13 (37%) presented either syndromic or non-syndromic developmental delay/intellectual disability (DD/ID) without any brain abnormalities. In addition to the single nucleotide variations (SNV), we also investigated copy number variants (CNV) predicted from WES data using Convex and HMZDelFinder (an in-house homozygous deletion detection tool at the resolution of single exons). With these tools, we are able to evaluate the genomic regions not covered well in the clinical array and/or to detect variations too small to be identified by the resolution afforded by conventional clinical aCGH. Currently, 9 (25. 7%) families are solved by new variants (single nucleotide variation or indel) in known genes (including *ARSA*, *ACO2*, *SARS2*, *VPS13B*, *PHF6*, and *RNASEH2B*), 5 (14%) may be explained by known genes with phenotypic expansion (including *KIAA0226*, *C12ORF57*, and *ANKRD11*), and 1 (2. 8%) family is solved by homozygous deletion in *GRID2* by clinical array and HMZDelFinder. We identified 17 potential novel candidate genes in 14 (40 %) families. These genes function as histone demethylase, motor proteins, transcription factors, myelin protein, as well as regulators for apoptosis and autophagy. Our genomic approach enabled us to evaluate potential causative SNVs and CNVs more accurately and lead to the identification of numerous interesting findings in genetics and genomics methodology. The genes that we identified function in a wide range of cellular processes involved in cell growth, cell differentiation, cell migration, proliferation, and apoptosis. *In silico* analysis of functional and expression correlation among candidate and known disease genes helped us better understand the genetic and signaling network underlying these neurological traits.

2992F

X-linked intellectual disability related genes disrupted by balanced X-autosome translocations. *M. Moyses-Oliveira[1,5], R. Guilherme[1], V. Meloni[1], A. Di Battista[1], C. Mello[2], S. Bragagnolo[1], D. Moretti-Ferreira[3], K. Popadin[5], N. Kosyakova[4], T. Liehr[4], G. Carvalheira[1], A. Reymond[5], M. Melaragno[1].* 1) Genetics Division, Department of Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Psychobiology Department, Universidade Federal de São Paulo, São Paulo, Brazil; 3) Departament of Genetics, Instituto de BioCiências de Botucatu, Universidade Estadual de São Paulo, São Paulo, Brazil; 4) Jena University Hospital, Friedrich Schiller University, Institute of Human Genetics, Jena, Germany; 5) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland.

Detailed molecular characterization of chromosomal rearrangements involving X-chromosome has been a key strategy in identifying X-linked intellectual disability-causing genes. Patients with balanced chromosomal rearrangements involving an X-chromosome generally present a skewed X inactivation, with the normal X-chromosome being preferentially inactivated. Thus, a gene disruption on the X-chromosome frequently results in the absence of a functional copy of the gene mapping to the breakpoint. We fine-mapped the breakpoints in four women with balanced X-autosome translocations and variable phenotypes to investigate the corresponding genetic contribution to intellectual disability. Three out of four patients presented with cognitive impairment, confirming the association between the disrupted genes (*TSPAN7*, *KIAA2022* and *IL1RAPL1*) and intellectual disability (MRX58, MRX98 and MRX21/34 loci, respectively). RT-qPCR experiments in whole blood showed absence of *TSPAN7* and *KIAA2022* functional copies in patients while gene expression was detected in eight controls. Although *IL1RAPL1* gene is not expressed in peripheral blood under normal conditions (e. g. no expression was observed in eight controls), transcripts from exons 8 and 9 of this gene were detected in the patients' whole blood, suggesting that the der(X) is producing a fusion transcript *ZNF611-IL1RAPL1* under the control of the *ZNF611* promoter, a gene disrupted at the autosomal breakpoint. The X-chromosomal breakpoint definition in the fourth patient, a 42 years old woman with normal intellectual abilities (WAIS III indicated IQ score = 111), revealed disruption of the *ZDHHC15* gene (MRX91). The RT-qPCR in whole blood did not detect *ZDHHC15* gene expression in the patient and detected the gene expression in eight controls, thus exposing the necessity for validation of *ZDHHC15* as an intellectual disability-causing gene. Overall, this study emphasizes the precise breakpoints definition in balanced X-autosome rearrangements as an important tool for searching critical genes and correct diagnosis of the individual patients. The disruption of X-linked genes in patients with cognitive impairment may confirm the involvement of the corresponding genes in neurodevelopment. Furthermore, the breakpoints fine mapping in subjects with normal cognition might also lead to a better characterization of candidate genes for diseases.

Identification and functional characterization of *de novo FOXP1* variants in cases of autism, intellectual disability and language impairment. *E. Sollis[1], A. Vino[1], C. Gilissen[2], H. Frohlich[3], S. Graham[1], R. Pfundt[2], D. Dimitropoulou[1], H. Brunner[2,4], G. Rappold[2], S. E. Fisher[1,5], P. Deriziotis[1].* 1) Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen, the Netherlands; 2) Department of Human Genetics, Radboud Institute for Molecular Life Sciences and Donders Centre for Neuroscience, Radboud University Medical Center, Nijmegen, the Netherlands; 3) Department of Molecular Human Genetics, Ruprecht-Karls-University, Heidelberg, Germany; 4) Department of Clinical Genetics, Maastricht University Medical Centre, Maastricht, the Netherlands; 5) Donders Institute for Brain, Cognition and Behaviour, Radboud University, Nijmegen, the Netherlands.

Heterozygous variants disrupting the FOXP1 transcription factor (forkhead box protein P1; OMIM 605515) have been implicated in an emerging syndrome of global developmental delay, intellectual disability and autistic features (OMIM 613670). All etiological *FOXP1* variants reported to date have been *de novo*, and include whole gene deletions, translocations, nonsense variants, missense variants and frameshift variants. Speech and language impairments, which range from moderate to severe and affect expressive language to a higher degree than receptive language, are also consistently reported in individuals carrying *FOXP1* variants. The presence of speech and language deficits in this *FOXP1*-deficiency syndrome is of particular interest, because *FOXP1* is the closest paralogous gene to *FOXP2* (OMIM 605317), which is disrupted in a rare form of speech and language disorder (OMIM 602081). In this study, we report three novel heterozygous *de novo FOXP1* variants identified through clinical whole-exome sequencing in individuals diagnosed with intellectual disability and/or autism spectrum disorders. We performed detailed functional characterization of the three novel variants found here alongside three previously detected *de novo* etiological variants. Our assays examined the effects of the six *de novo FOXP1* variants on several aspects of protein function, including subcellular localization and transcriptional repression capability. In addition, because FOXP1 and FOXP2 are both expressed in the striatum where they may interact with the potential to co-regulate downstream targets, we investigated the effects of the six *de novo FOXP1* variants on FOXP1-FOXP2 interactions. Our findings provide further insight into the pathogenic mechanisms of *FOXP1*-deficiency syndrome, and highlight the value of combining clinical exome sequencing with functional analyses in understanding the molecular basis of neurodevelopmental disorders.

2994T

Two patients diagnosed with BPAN in infancy. *K. Takano[1], N. Shiba[2], K. Goto[3], T. Yamaguchi[1], K. Wakui[1], T. Kosho[1], Y. Inaba[2], Y. Fukushima[1].* 1) Department of Medical Genetics, Shinshu University School of Medicine, Matsumoto, Nagano, Japan; 2) Department of Pediatrics, Shinshu University School of Medicine, Matsumoto, Japan; 3) Department of Pediatrics, NHO Nishibeppu National Hospital, Beppu, Japan.

Beta-propeller protein-associated neurodegeneration (BPAN) is newly established as a subtype of neurodegeneration with brain iron accumulation (NBIA). BPAN is caused by mutations in the *WDR45* gene at Xp11. 23, which has an important role in autophagy. It has reported that both heterozygous female and hemizygous male are equally affected by this X-linked NBIA. BPAN is characterized by global developmental delay or intellectual disability until adolescent or early adulthood, followed by severe dystonia, parkinsonism and progressive dementia. Brain magnetic resonance images (MRI) of BPAN show iron deposition in the bilateral globus pallidus (GP) and substantia nigra (SN), hyperintensity of the SN with a central band of hypointensity in T1-weighted images and brain atrophy in adulthood. It is very difficult to diagnose BPAN in early childhood before the development of neurological deterioration. However, next-generation sequencing (NGS) technologies allow us early diagnosis of BPAN and have revealed early manifestations of BPAN, such as Rett-like phenotype and early iron accumulation in the GN and SN. We report clinical features of 2 unrelated patients, 3-year-old girl and 3-year-old boy, who were diagnosed with BPAN by targeted NGS. Both patients presented with severe developmental delay and moderate elevated level of serum aspartate transaminase (AST) and neuron specific enolase (s-NSE). The elevation of serum enzymes may be one of characteristic symptoms of BPAN in infancy.

2995F

Comprehensive molecular diagnosis of 265 individuals addressed for Leber congenital amaurosis or Early Onset Severe Retinal Dystrophy using targeted next generation sequencing. *I. Perrault[1], S. HANEIN[2], C. BOLE[3], P. NITSCHKE[4], N. DELPHIN[5], A. MUNNICH[5], J. KAPLAN[1], JM. ROZET[1].* 1) GENETICS IN OPHTHALMOLOGY, INSTITUT IMAGINE, INSERM UMR 1163, PARIS, FRANCE; 2) NGS MOLECULAR DIAGNOSIS,INSTITUT IMAGINE,INSERM UMR1163, PARIS, FRANCE; 3) GENOMICS PLATFORM,INSTITUT IMAGINE, INSERM UMR1163, PARIS, FRANCE; 4) BIOINFORMATIC PLATFORM,INSTITUT IMAGINE, INSERM UMR1163, PARIS, FRANCE; 5) GENETICS, INSTITUT IMAGINE, INSERM UMR1163, PARIS, FRANCE.

Introduction: Leber congenital amaurosis is the earliest and most severe retinal dystrophy, and a leading cause of blindness in children. The visual outcome of affected infants is variable, ranging from light perception, to low but measurable visual acuity in the first two decades of life. Blind infants with LCA are at risk of developing skeletal, neurologic and renal dysfunctions. Both the visual and extraocular outcomes strongly correlate with the disease-gene. The study presented here aimed at assessing targeted NGS (T-NGS) as a tool to improve patient care by allowing efficient and early molecular diagnosis in infants with severe visual deficiency. Methods: 265 index LCA cases were sequenced using a T-NGS array comprising 45 genes causing isolated or syndromic LCA and 10 genes of differential diagnoses. Mutations were confirmed by Sanger sequencing and familial segregation analysis. Results: We identified causative mutations, including 6 copy number variations, in 150/265 index cases, 119/150 of whom had mutations in genes for isolated LCA/EOSRD and 19/150 in genes for syndromic forms. In addition, we identified convincing mutations in genes for differential diagnoses in 12/265 individuals. Conclusions: T-NGS molecular diagnosis proved powerful to improve the care of infant with severe visual dysfunction by allowing *i)* early identification of children with differential diagnosis which outcome is highly favorable compared to LCA (12/265; <5%) and, *ii)* early discrimination of children at no risk of being affected with syndromic LCA (119/150; 79%) from those, far fewer, at risk of developing extraocular symptoms (19/150; 12%) who require extraocular explorations.

2996W

Molecular analysis and prevalence of Huntington's Disease in northwest of Iran. *M. Shekari khaniani[1], P. Aob[2], M. r. Ranjouri[2], S. Mansouri derakhshan[1].* 1) Medical Genetic Department, Faculty of Medicine, Tabriz University of Medical Sciences, Tabriz, Iran; 2) Medical Genetic Department, Faculty of Medicine, Zanjan University of Medical Sciences, Zanjan, Iran.

Background: Huntington Disease (HD) is a progressive adult-onset neurodegenerative disorder presenting an autosomal dominant inheritance. Onset of symptoms is in middle-age after affected individuals have had children, but the disorder can manifest at any time between infancy and senescence. HD is clinically characterized by involuntary chorea form movements, cognitive impairment and personality disorder tending to depression, anger and temper outbursts. **Objective:** Since there is no information on the frequency of HD disorder in northwest of Iran, the aim of the present study is to determine the frequency of Huntington disease and the number of CAG-trinucleotide repeats in the northwest of Iranian population. **Material and Methods:** Genomic DNA was extracted from the blood samples by salting-out. DNA samples were analyzed to determine the number of CAG trinucleotide repeats of HD gene. An abnormally large number of CAG repeats which is a diagnostic factor for the disease was detected by polymerase chain reaction (PCR) and agarose gel electrophoresis. **Results:** Of 40 cases, we identified 14 unrelative individuals with one expanded CAG allele at the IT15 gene. The frequency of the *HD* mutation in our group of patients was 35% (14/40). Expanded alleles varied from 36 to 70 CAG repeats (mean = 53 CAG units) and normal alleles in HD patients varied from 20 to 26 CAG units (mean = 23 CAGs). There was no significant difference in the size of the expanded alleles between affected males and affected females. **Discussion:** to our knowledge, This is the first study reporting molecular testing of HD patients in the Northwest of Iran. We found a significant correlation between age at onset of the disease and length of the expanded CAG tract. This indicates a tendency for age at onset to decrease as the CAG repeat length increases. Our results showed that not all patients with the "HD" phenotype carried the expansion at the IT15 gene and that autosomal dominant inheritance may not be clearly documented in all HD families.

2997T

Evidence that variants in *PIGG* cause intellectual disability with early onset seizures and hypotonia. *P. Makrythanasis[1,2], M. Kato[3], M. S. Zaki[4], H. Saitsu[5], K. Nakamura[3], F. A. Santoni[1], S. Miyatake[5], M. Nakashima[5], I. Mahmoud[4], M. Guipponi[1,2], H. Hamamy[1], N. Matsumoto[5], T. Kinoshita[6], S. E. Antonarakis[1,2,7], Y. Murakami[6].* 1) Department of Genetic Medicine and Development, University of Geneva, Geneva, Geneva, Switzerland; 2) Service of Genetic Medicine, University Hospitals of Geneva, Geneva, Switzerland; 3) Department of Pediatrics, Yamagata University Faculty of Medicine, Yamagata, Japan; 4) Department of Clinical Genetics, National Research Centre, Cairo, Egypt; 5) Department of Human Genetics, Yokohama City University Graduate School of Medicine, Yokohama, Japan; 6) Department of Immunoregulation, Research Institute for Microbial Diseases, and World Premier International Immunology Frontier Research Center Osaka University, Osaka, Japan; 7) iGE3, University of Geneva, Geneva, Switzerland.

Glycosylphosphatidylinositol (GPI) is a glycolipid that anchors 150+ proteins to the cell surface. There are at least 27 genes involved in the biosynthesis and transport of GPI anchored proteins. Among them, 12 different mendelian GPI deficiencies were reported up to now; mainly inherited as recessive traits. These deficiencies show intellectual disability, epilepsy, coarse facial features and multiple organ anomalies that vary in severity depending upon the molecular defect of the affected genes. Those symptoms are caused either by the decreased surface expression of GPI anchored proteins or by structural abnormalities of the GPI. Here we present two families, a consanguineous from Egypt and another from Japan in which the patients' main symptoms consisted of intellectual disability, early onset seizures and hypotonia. After exome sequencing, variants in a "new" gene in the GPI pathway, *PIGG* were identified. In the first family, it consisted of the homozygous nonsense NM_001127178. 2:c. 1515G>A: p. (Trp505*), while in the second family the patient was a compound heterozygote of a known rare missense variant, the NM_001127178. 2:c. 2005C>T, p. (Arg669Cys) that was predicted to be pathogenic with a 2. 4Mb deletion that involved PIGG. In both cases the parents were confirmed to be healthy carriers. *PIGG* is the enzyme which attaches ethanolamine phosphate to the second mannose. This ethanolamine phosphate is cleaved after GPI anchor is attached to the protein in the endoplasmic reticulum by PGAP5. In vitro studies using patients' B lymphoblasts, in which PIGG activity was almost completely abolished, GPI-APs were normally expressed on the surface and with normal structure, indicating that pathogenesis of PIGG deficiency is potentialy novel, not yet fully understood. The discovery of pathogenic variants in PIGG expands the spectrum of GPIpathies, and further enhances our understanding of this etiopathogenic class of intellectual disability.

Contribution of excitatory/inhibitory synaptic imbalance to *MECP2*, *CDKL5* and *FOXG1* related disorders. *E. Landucci[1], S. Amabile[1], T. Patriarchi[1, 2], E. Frullanti[1], A. M. Pinto[1, 3], C. Lo Rizzo[1], F. Ariani[1, 3], F. Mari[1, 3], M. A. Mencarelli[3], J. W. Hell[2], A. Renieri[1, 3], I. Meloni[1].* 1) Medical Genetics University of Siena, Siena, Italy; 2) Department of Pharmacology, University of California, Davis, CA, USA; 3) Genetica Medica, Azienda Ospedaliera Universitaria Senese, Siena, Italy.

MECP2, CDKL5 and *FOXG1* genes are responsible for the Rett spectrum of neurodevelopmental disorders. In spite of their involvement in the same phenotypic spectrum, a functional interaction between the three proteins has not been proven and disease mechanisms remain elusive. We recently established a human neuronal model based on patients-specific iPSCs and we characterized their expression profile to test the hypothesis that common alterations occur in cells mutated in the three genes. An excitation/inhibition imbalance has been suggested in *MECP2*-related Rett syndrome. In line with this finding, we recently reported that expression of the inhibitory presynaptic differentiation inducer GluD1 is increased in iPSCs-derived neurons from patients with mutations in *MECP2* and *CDKL5* (Livide et al, Eur J Hum Genet 2015). Here we describe an over-expression of GluD1 also in *FOXG1*-mutated cells. We also analyzed the expression of a panel of excitatory (VGLUT1, GluA1, GluN1, PSD-95) and inhibitory markers (GAD67 and GABA AR-α1) in iPSCs-derived neurons mutated in the three genes, demonstrating an excitation/inhibition imbalance. A consistent imbalance was also observed in embryonic FOXG1+/- mouse brain. However, a reduction of both excitatory and inhibitory markers is observed in FOXG1+/- post-natal mouse brain. This would suggest that an increase in inhibitory over excitatory synapses/neurons during early brain development might later on trigger counteracting mechanisms resulting in the loss of either inhibitory neurons or synapses. In conclusion, our data underline the essential contribution of an excitation/inhibition imbalance in *MECP2, CDKL5* and *FOXG1* related disorders, opening up the possibility of new therapeutic approaches.

2999W

Functional characterization of a large series of *NKX2-1* variants in Brain-Lung-Thyroid syndrome reveals diverse molecular mechanisms of disorder. *S. A. Graham[1], P. Deriziotis[1], R. Bojoh[1], S. B. Estruch[1], S. E. Fisher[1,2].* 1) Language and Genetics Department, Max Planck Institute for Psycholinguistics, Nijmegen 6525XD, The Netherlands; 2) Donders Institute for Brain, Cognition and Behaviour, Nijmegen 6525EN, The Netherlands.

Brain-Lung-Thyroid syndrome (MIM 610978) is an autosomal dominant disorder resulting from disruption of the homeobox transcription factor gene *NKX2-1* (MIM 600635). The disorder exhibits phenotypic variability, both between and within families, but is typically characterized by infant hypotonia that progresses to chorea and other movement abnormalities. Dysarthria (a motor speech disorder) and attentiveness disorder have recently been recognized as common neurological features of the syndrome. Most affected individuals also have thyroid dysfunction and/or lung problems such as neonatal respiratory distress and recurrent infections. Over 100 different lesions affecting the *NKX2-1* gene have been reported in cases of Brain-Lung-Thyroid syndrome, including a number of missense variants. However there has been little functional investigation of the effects of these variants to elucidate the molecular mechanisms of disorder. Here we report the functional characterization of forty *NKX2-1* variants, employing assay methodologies that could be extended for the high-throughput characterization of transcription factor gene variants identified by next-generation sequencing in disorders. By assessing the effects of *NKX2-1* variants on protein expression, subcellular localization, protein-protein interactions and transcriptional regulatory activity, we uncovered diverse molecular-level effects for etiological variants, highlighting the importance of examining multiple aspects of protein function when characterizing putative disorder-related variants. In addition, we confirmed that NKX2-1 interacts with the forkhead transcription factor FOXP2 (MIM 605317) and show that NKX2-1 can also interact with the FOXP2 paralogs FOXP1 (MIM 605515) and FOXP4 (MIM 608924). The interaction between NKX2-1 and FOXP transcription factors may be of significance in brain and lung development. Heterozygous disruption of *FOXP2* results in a severe speech/language disorder (MIM 602081). The presence of motor speech deficits as core features of both the *NKX2-1* and *FOXP2*-related disorders points to roles for both genes in the development of speech-related motor circuitry. Strikingly, we find that disorder-related variants in the DNA-binding domains of both NKX2-1 and FOXP2 abrogate the interaction between these proteins.

3000T

Pontine Tegmental Cap Dysplasia: a rare hindbrain malformation and the search of the genetic etiology. *M. Herlin[1], K. Varvagiannis[2], L. Gammelgaard[3], P. A. Gregersen[1], P. Makrythanasis[2], S. E. Antonarakis[2], M. B. Petersen[1].* 1) Department of Clinical Genetics, Aalborg University Hospital, Aalborg, Denmark; 2) Department of Genetic Medicine & Development, University of Geneva, Geneva, Switzerland; 3) Department of Radiology, Viborg Regional Hospital, Viborg, Denmark.

Pontine Tegmental Cap Dysplasia (PTCD) is a rare congenital malformation of the hindbrain characterized by hypoplasia and flattening of the ventral pons, vaulted pontine tegmentum, and vermian and cerebellar hypoplasia. The typical clinical findings include multiple cranial neuropathies, particularly sensorineural hearing loss, ataxia, and seizures. To date, only 25 cases have been reported in the literature and the cause still remains unknown. We present a case of a 14-year-old girl who, throughout her life, has been a diagnostic challenge displaying symptoms and clinical findings such as delayed developmental milestones, bilateral abducens palsy (Duane syndrome), congenital sensorineural hearing loss, ataxia, and butterfly configuration of the Th3-Th4 vertebrae. Due to inconclusive MRIs at 2 years of age, she was diagnosed with Wildervanck syndrome based on the clinical findings and shortly after she received bilateral cochlear implants, complicating further radiological examinations. However, a recent reevaluation of the MRIs found her to have malformations of the brainstem and cerebellum compatible with PTCD. Currently, we are investigating the genetic cause of PTCD in our case. CGH array revealed no copy number variations and thus, sequencing of all coding regions (Whole Exome Sequencing) has been performed on DNA from the patient and her parents. Variant analysis is still ongoing but it is our hope that data exchange through international collaborations will enable us to delineate the gene(s) associated with PTCD.

3001F

Loss of function variants highlight potential candidate genes in patients with brain malformation and epilepsy. *E. Karaca[1], T. Harel[1], D. Pehlivan[1], Z. Coban Akdemir[1], Y. Bayram[1], V. R. Lupski[1,9,10,11], Baylor-Hopkins Center for Mendelian Genomics.* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston 77030, TX, USA; 2) Department of Medical Genetics, Zekai Tahir Burak Woman Health Training and Research Hospital, Ankara 06230, Turkey; 3) Department of Medical Genetics, Bezmialem University, Istanbul 34093, Turkey; 4) Department of Medical Genetics, Mersin University, Mersin 33343, Turkey; 5) Department of Medical Genetics, Numune Training and Research Hospital, Adana, Turkey; 6) Department of Medical Genetics, Medical Faculty of Eskisehir Osmangazi University, Eskisehir 26480, Turkey; 7) Department of Medical Biology, Namik Kemal University School of Medicine, Tekirdag 59100, Turkey; 8) Department of Medical Genetics, Sami Ulus Children's Hospital, Ankara 06080, Turkey; 9) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX, USA; 10) Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA; 11) Texas Children's Hospital, Houston, TX, USA.

Human brain development is a precisely orchestrated process involving multiple genetic and epigenetic interactions and coordination of cellular and molecular mechanisms, perturbation of which leads to a multitude of neurodevelopmental phenotypes depending on the spatial and temporal effect of the disturbance. We used whole exome sequencing in a cohort of 125 mostly consanguineous families with both functional and structural brain malformations as a primary experimental approach to explore the potential genetic basis of brain development and function. Variant alleles were prioritized using a recessive inheritance model, bioinformatic prediction tools of potential pathogenicity, and co-segregation of the allele with the disease. In silico analysis of the gene for brain developmental, expression, interactome and pathway analysis of gene products, further prioritized variants potentially associated with the Mendelizing traits studied. Analysis of the data for both single nucleotide variants (SNVs) and copy number variants (CNVs) identified 40 candidate disease genes, 44 novel variants in known disease genes, and de novo or homozygous deletions in 10 families, with an overall solved rate of >85%. Among these, we observed rare homozygous loss of function variants in UBQLN1, SMARCA1, AGBL2, SNX14 and CPLX1 in patients with various severities of forebrain and hindbrain abnormalities and epilepsy. The respective encoded proteins are highly expressed in the nervous system and involved in crucial pathways such as ubiquitination machinery, SWI/SNF-like chromatin remodeling complex, posttranslational modification of tubulins and synaptic transmission. Thus, our study underscores the utility of small pedigree analysis in genetically heterogeneous disease.

3002W

DYT16/*PRKRA* founder mutation causes childhood-onset generalized dystonia in a family from Southern Italy. *M. Quadri[1], S. Olgiati[1], M. Sensi[2], F. Gualandi[3], E. Groppo[4], V. Rispoli[4], J. Graafland[1], G. J. Breedveld[1], G. Fabbrini[5], V. Bonifati[1].* 1) Departement of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands; 2) Department of Neurology and Rehabilitation, University -Hospital Arcispedale S. Anna, Ferrara, Italy; 3) Department of Reproduction And Growth, UOL of Medical Genetics, Universiy Hospital S. Anna, Ferrara, Italy; 4) Department of Biomedical and Specialistic Surgical Sciences, University-Hospital Arcispedale S. Anna, Ferrara, Italy; 5) Department of Neurology and Psychiatry, Sapienza University of Rome, and IRCSS Neuromed, Pozzilli, Italy.

Dystonias are movement disorders characterized by sustained muscle contractions and abnormal postures. Based on both genetic and clinical evidences, the dystonias are an heterogeneous group of diseases. Twenty-five DYT genetic loci have been described, so far. Clinically, the disorder can occur in isolation or in combination with other neurological signs. Onset age is variable, and the disease can affect different parts of the body. Here we report three brothers originating from a small village in Southern Italy with childhood-onset generalized dystonia and mild parkinsonism. We performed high-density SNP-arrays genotyping in the whole family, and high-coverage whole exome sequencing (WES) in the proband. The linkage analysis under an autosomal recessive mode of inheritance, and assuming distant parental consanguinity, yielded only one locus with a significant LOD of 3. 72. This locus lies on the long arm of chromosome 2 and contains a 4Mb-homozygous region. Within this region, WES uncovered a *PRKRA* c. 665C>T p. Pro222Leu mutation. Sanger sequencing confirmed the mutation in homozygous state in the three affected siblings, while the unaffected parents and the unaffected sister were found to be heterozygous carriers. The same mutation has been initially associated with early-onset dystonia-parkinsonism in two unrelated consanguineous families and one sporadic case from Brazil, and this locus was designated as DYT16. Very recently, the same and additional mutations were reported in three independent pedigrees of Polish, German and Brazilian ancestries, providing conclusive evidence for a disease-causing role of *PRKRA* mutations in DYT16. Our haplotype analysis shows that our Italian patients share a 0. 5 Mb identical homozygous region with all the nine DYT16 cases previously reported with the same mutation. These results support the contention that c. 665C>T is a founder mutation, as already suggested. Inspection of the Exome Aggregate Consortium (ExAC) shows that this mutation is present, although rarely, in several populations. Mutations in this gene might be more common than earlier thought, and *PRKRA* screening is warranted in all patients with dystonia compatible with autosomal-recessive inheritance. Our data contribute to a better delineation of the DYT16 genetic and clinical spectra.

3003T

Expanding the Phenotype of Type XII Collagen Myopathy: Congenital Cataracts, Microcephaly, and Global Developmental Delay? *G. E. Tiller[1], A. N. Filose[1], Y. Hu[2], C. G. Bonnemann[2].* 1) Dept Genetics, Kaiser Permanente, Los Angeles, CA; 2) NIH, National Institute of Neurological Disorders and Stroke, Bethesda, MD.

Hereditary congenital myopathies may be caused by mutations in genes encoding several classes of proteins, including extracellular matrix proteins, contractile proteins, and Golgi-resident modifying enzymes. The archetypal extracellular matrix proteins involved in congenital myopathies are the type VI collagens, which are defective in Bethlem and Ullrich myopathies. Recently, type XII collagen has been recognized as involved in a phenotypically similar congenital myopathy, and both autosomal dominant and recessive forms have been described. Here we report two siblings with a congenital myopathy who are compound heterozygotes for missense mutations in COL12A1, the gene encoding type XII collagen. As neonates they presented with hypotonia, which evolved to spasticity with hyperreflexia, finger flexion contractures, and inability to ambulate. Bilateral congenital cataracts were evident in both sibs, and one underwent unilateral phakectomy. Head circumferences at birth were normal but by age 3 years were below the 3rd centile; brain MRI at age one year in one sib was unremarkable. Both sibs, currently ages 3 and 8 years, are nonverbal. Whole exome sequencing revealed missense mutations in COL12A1 predicted to result in the amino acid substitutions Pro591Arg (maternal) and Ser2042Leu (paternal). Neither parent had a history of motor or cognitive delay or cataracts. Cultured skin fibroblasts from one sib exhibited decreased intracellular immunoreactivity and absent extracellular immunoreactivity against type XII collagen. In the absence of other exomic data to explain cataract formation, brain atrophy, and global developmental delay, we propose that compound heterozygosity for missense mutations in COL12A1 may play a role in the development of these additional clinical findings.

3004F

Somatic Mutations in mTOR and Tau pathways in Focal Cortical Dysplasia. *F. Torres[1], M. G. Mazutti[1], P. A. O. Ribeiro[1], S. H. Avansini[1], R. Secolin[1], M. G. Borges[1], F. Rogério[2], L. S. Queiroz[2], A. C. Coan[3], H. Tedeschi[3], F. Cendes[3], I. Cendes[3].* 1) Department of Medical Genetics, Unicamp, Campinas, Brazil; 2) Department of Pathology, Unicamp, Campinas, Brazil; 3) Department of Neurology, Unicamp, Campinas, Brazil.

Somatic mosaic mutations have been observed in malformations of cortical development (MCD), such as tuberous sclerosis (TS) and hemimegalencephaly (HMG). HMG, TS and focal cortical dysplasia (FCD) share histopathologic characteristics and aberrant expression of genes belonging to the mTOR and Tau pathways. These findings led us to investigate if somatic mosaic mutations in genes related to the mTOR and Tau pathways are present in FCD. Deep-Whole-Exome sequencing was performed in genomic DNA extracted from brain tissue resected by surgery (BTRS) and blood of four patients with FCD. We performed capture and enrichment with Nextera® Expanded Kit (Illumina®), samples were sequenced following a 200bp paired-end protocol in a Hiseq2500 (Illumina®) to achieve at least 200x of average coverage. Realignment around indels and SNP clusters were performed using the Genome Analysis ToolKit (GATK) realigner. Our analysis focused in genes belonging to the mTOR and Tau pathways. Only exons with at least 70x coverage were analyzed. We identified a total of 12 mosaic variants in mTOR genes and four in Tau pathway genes. These mutations are present only in DNA from brain tissue. They are localized in different genomic regions such as 3'UTR, intergenic regions, introns and splicing sites. One of the major genes of interest is *ULK2,* which is involved in axonal development. In conclusion, we have demonstrated that somatic mosaicism in genes related to mTOR and Tau pathways is present in FCD.

3005W

Clinical and Genetic Analysis of 87 Chinese Patients with Pelizaeus-Merzbacher Disease. *J. Wang, H. Ji, D. Li, Y. Wu, Q. Gu, Y. Yang, H. Xiong, Y. Zhang, X. Bao, X. Wu, Y. Jiang.* Pediatrics, Peking University First Hospital, Beijing, Beijing, China.

Pelizaeus–Merzbacher disease (PMD, OMIM 315080) is a rare X-linked recessive genetic disease with diffuse hypomyelination in white matter. Clinical manifestations include nystagmus, development retardation, hypotonia, spastic paraplegia and ataxia. Three different types of PMD have been identified: congenital, transitional, and classical PMD. PMD is caused by *PLP1*(proteolipid protein 1) mutation and it has 3 kinds of mutations: duplication, point mutation and deletion. **Objective** Identify *PLP1* mutations in 87 Chinese patients with PMD, offer genetic counseling and make prenatal molecular diagnoses for 31 families. **Method** Extract genomic DNA from peripheral blood of probands and their families. The fetus' DNA was extracted from Amniotic fluid/chorionic villus samples. We use MLPA (multiplex ligation-dependent probe amplification) to detect *PLP1* duplication/deletion mutations; then detect point mutation by Sanger sequencing for those with negative MLPA result. **Results** We found *PLP1* mutation in 87 cases. Among them, 64 patients are *PLP1* duplications (73. 6%) and 23 are point mutations (26. 4%) including 10 novel mutations. 87(100%) are male and have global development delay, 86(98. 9%) with nystagmus, 53(60. 9%) with hypotonia. All patients present hypomyelination on their brain MRI. 43(49. 4%) patients are classical, 23(26. 4%) are transitional, and 21(24. 1%) are congenital PMD. We preformed 31 prenatal diagnoses in 27 families, 17 cases are *PLP1* wildtype, 9 cases have same mutations as the probands', and 5 are *PLP1* mutation carriers. **Conclusion** Classical type is the most common subtype of PMD, while duplication is the most common kind of *PLP1* mutation. Duplication could be found in classical and transitional PMD while point mutations in congenital and transitional PMD. We have identified *PLP1* mutations in 87 PMD patients, in which 10 are novel mutations; and we also performed 31 prenatal diagnoses for 27 families, which will be useful and helpful. Systematic phenotype-based deconvolution of Intellectual Disability disorders into biologically coherent modules. *C. Zweier[1], K. Kochinke[2], B. Nijhof[2], M. Fenckova[2], P. Cizek[3], F. Honti[4], S. Keerthikumar[3], M. A. W. Oortveld[2], T. Kleefstra[2], J. M. Kramer[2], C. Webber[4], M. A. Huynen[3], A. Schenck[2].* 1) Institute of Human Genetics, Friedrich-Alexander-Universitét Erlangen-Nürnberg, Erlangen, Germany; 2) Department of Human Genetics, Donders Institute for Brain, Cognition and Behaviour, Radboud university medical center, Nijmegen, the Netherlands; 3) CMBI, Radboud Institute for Molecular Life Sciences, Radboud university medical centre, Nijmegen, the Netherlands; 4) MRC Functional Genomics Unit, Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford, United Kingdom.

Intellectual Disability (ID) disorders, due to their frequency and enormous genetic and phenotypic heterogeneity, represent a major unmet challenge in health care and diagnostics. A comprehensive and systematic understanding of ID disorders and their underlying biology is still limited. We established a curated database of 650 genes, currently known to be mutated in ID, linked them to various functional datasets and classified them according to ID manifestation and severity and 27 associated core clinical features such as organic or neurological anomalies. This catalog also contains genes mutated in autism spectrum disorders that are associated with cognitive impairment. Mutations in 62% of all 650 ID genes follow autosomal recessive inheritance, mutations in 21% are autosomal dominant (mainly de novo), and 16% are X-linked. Using this integrated resource we show that nearly half of all ID proteins physically interact with other ID proteins and that they show a more than 30% increase in connectivity. Furthermore, they are substantially enriched in co-expression, highest in the hippocampus. 86% of ID genes fall into 32 common Gene Ontology based molecular processes: metabolism and nervous system development among the largest, and hedgehog and glutamate signaling among the most enriched groups. Identification of highly enriched functional themes and phenotypes systematically revealed characteristic phenoprofiles of process-defined IDopathies including chromatin- and DNArepairopathies. Strikingly, all these findings are much more pronounced among subgroups of genes that share associated phenotypes, adding significant predictive power for ID gene identification. Furthermore, we utilized custom-made datasets on ID gene function in *Drosophila*. Early onset behavioral and specific morphological wing phenotypes were characteristic for ID genes in general, and several fly phenotypes were particularly representative for specific human clinical phenotype classes. Our study and resource provide systematic insights into the molecular and clinical landscape of ID disorders and prove the utility of systematic human and cross-species phenomic analyses in highly heterogeneous genetic disorders.

3007F

Synergistic activity of the DYT6-associated THAP1 protein and HCFC1 in regulating gene expression. *L. Kötter[1], R. Hollstein[1], B. Reiz[2], S. Schaake[3], K. Lohmann[3], FJ. Kaiser[1].* 1) Section for Functional Genetics at the Institute of Human Genetics, University of Lübeck, Lübeck, Germany; 2) Institute for Integrative and Experimental Genomics, University of Lübeck, Lübeck, Germany; 3) Institute of Neurogenetics, University of Lübeck, Lübeck, Germany.

THAP1, the gene mutated in DYT6 dystonia, encodes a transcription factor protein. While the THAP domain within the N-terminal part of the protein allows specific DNA-binding the functional relevance of the remaining part of THAP1 is largely unknown. Beside a coiled-coil domain and a nuclear localization signal at its C-terminus a stretch of four amino acids (134-137) within the 218 amino acids spanning protein was shown to be relevant for the interaction with the transcription regulator HCFC1. Interestingly, three mutations (Asn136Ser, Asn136Lys, Y137C) have been reported within this motif in DYT6 patients. By protein-protein interaction analyses we demonstrated that these substitutions within this HCFC1-binding domain (HBM) of THAP1 abolish HCFC1-THAP1 complex formation. Notably, HCFC1 co-localization was observed in >90% of the >3,500 chromatin regions loaded with THAP1 in publically available genome-wide ChIP data (ENCODE). To characterize the interaction between HCFC1 and THAP1 in the regulation of gene expression, we performed siRNA-mediated depletion of *HCFC1* or *THAP1*. By this, we detected similar dysregulation of THAP1 target genes in cells with HCFC1- or THAP1 downregulation-indicating synergistic activity of both transcription factors. To examine whether THAP1 mutations that abolish HCFC1-binding do affect THAP1 or HCFC1 recruitment to gene promoters, we used quantitative ChIP-seq on selected promoters. While none of the three THAP1 mutations significantly modified DNA-binding ability of THAP1, HCFC1 was strongly reduced. These findings suggest a THAP1-mediated recruitment of HCFC1 to THAP1 target sites further supporting an interplay of both transcription factors. In a final step, we investigated whether mutations in the THAP1 interacting domains of HCFC1 are a cause of dystonia. For this, we screened 160 dystonia patients but did not detect any clear mutation in *HCFC1*. Of note, mutations in *HCFC1* have been reported in X-linked intellectual disability (XLID) and Cobalamin type X (CblX), a VitaminB12 metabolic disorder with severe neurodevelopmental impairment. In conclusion, we demonstrate that THAP1 recruits HCFC1 to THAP1 target promoters and that both proteins are necessary for the transcriptional regulation. Importantly, DYT6-causing mutations within the 4-amino-acid interaction domain in THAP1 abolish the interaction. Thus, we highlight disturbed HCFC1 interaction as the consequence of three different DYT6-causing mutations.

3008W

***FOXC1* mutations and copy number variants in cases diagnosed with Primary Congenital Glaucoma.** *E. Souzeau[1], O. M. Siggs[1], B. Ridge[1], L. Mauri[3], M. Hayes[2], A. Dubowsky[2], F. Pasutto[4], J. E. Craig[1].* 1) Dept of Ophthalmology, Flinders University, Flinders Medical Centre, Adelaide, Australia; 2) SA Pathology, Adelaide, Australia; 3) Genetica Medica, Niguarda Ca'Granda Hospital, Milan, Italy; 4) Institute of Human Genetics, Friedrich-Alexander-Universitét Erlangen-Nürnberg, Erlangen, Germany.

Purpose: Primary Congenital Glaucoma (PCG) is an important cause of childhood glaucoma blindness. This developmental disorder is characterized by buphthalmos, Haab's striae, increased intraocular pressure, and optic neuropathy. The majority of cases are sporadic. *CYP1B1* mutations are identified in 20% of Caucasian cases, and display an autosomal recessive transmission, accounting for the majority of familial cases. Axenfeld-Rieger syndrome (ARS) is another developmental disorder characterized by anomalies of the anterior segment of the eye including the iris and the cornea, and is associated with a 50% risk of developing glaucoma usually of early onset. ARS is caused by gene defects in *FOXC1* and *PITX2*. *FOXC1* defects have been reported in patients with ARS and congenital glaucoma. Here we investigated the role of the *FOXC1* gene in PCG. **Methods:** Patients diagnosed with PCG were recruited through the Australian and New Zealand Registry of Advanced Glaucoma and the Institute of Human Genetics at the University of Friedrich-Alexander in Germany. Subjects with mutations in the *CYP1B1* gene were excluded. Exome sequencing was performed using the Agilent SureSelect and run on Illumina HiSeq 2500. Mutations and copy number variants were validated by Sanger sequencing and MLPA respectively. **Results:** Exome sequencing identified defects in *FOXC1* in 4% (3/68) of patients with PCG: Two frame-shift variants encoding a premature termination codon (p. Leu240ValfsTer65 and p. Asp117ThrfsTer63), and a deletion of the entire *FOXC1* gene from one allele, were detected in separate individuals. None of the three cases identified with *FOXC1* defects had apparent classical features of ARS. **Conclusions:** PCG has long been considered a sporadic condition, or an autosomal recessive condition due to mutations in *CYP1B1*. Here we report mutations and deletions in the *FOXC1* gene in 4% of cases diagnosed with PCG and without apparent classical features of ARS. These results have important implications for the genetic counseling of these families, including the recurrence risk for siblings and the risk of developing glaucoma in relatives.

3009T

Whole exome sequencing of family trios identifies novel genes in children with Rett syndrome (RTT) phenotype. *S. Rangasamy[1,2], K. M. Ramsey[1,2], S. Szelinger[1,2,3], N. Belnap[1,2], A. Claasen[1,4], A. L. Siniard[1,2], AA. Kurdoglu[1,2], A. L Courtwright[1,2], R. F. Richholt[1,2], M. De Both[1,2], JJ. Corneveaux[1,2], I. Schrauwen[1,2], M. J. Huentelman[1,2], D. W Craig[1,2], V. Narayanan[1,2].* 1) Neurogenomics Division, Translational Genomics Research Institute(TGen), Phoenix, AZ; 2) Center for Rare Childhood Disorders, Translational Genomics Research Institute(TGen), Phoenix AZ; 3) Molecular and Cellular Biology Interdisciplinary Graduate Program, School of Life Sciences, Arizona State University, Tempe AZ; 4) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium.

Rett syndrome (RTT) is an X-linked dominant neurological disorder caused by mutation of the MeCP2 gene. It is characterized by developmental regression, stereotyped hand movements and autistic features. Mutation in MeCp2 gene has been identified in 95% typical RTT cases. Key clinical features have been defined that allow for the recognition of a classical or typical RTT phenotype. An atypical RTT phenotype has also been defined based on clinical criteria. Mutations of genes encoding cyclin-dependent kinase-like 5 (CDKL5) and forkhead box G1 (FOXG1) are found in patients with variant forms of RTT. Although most children with MeCP2 mutations are female, there are male infants with a severe neonatal onset encephalopathy caused by mutations in MeCp2. An X-linked mental retardation phenotype is also reported with specific mutations in MeCP2; thus MeCp2 gene mutation is not synonymous with RTT. At our center, focused on discovering the genetic basis of neurodevelopmental disorders, we have enrolled over 290 families into our research study, and have completed whole-genome or whole-exome sequencing using our in-house bioinformatics pipeline and annotationin 217 families. In this group, we have identified a cohort of patients (n=11) who have phenotype similar to Rett syndrome. All the patients had the features that brought up the diagnosis of Rett syndrome, but neither had mutation in *MECP2*gene (MECP2 negative) nor deletion/duplication. In 7 of these cases, we identified a novel, heterozygous, *de novo* mutation. Four of the genes identified have previously been reported to result in epileptic encephalopathy (GRIN1, GNAO1, KCNQ2, and KCNB1) and one identified has been linked to a syndrome with intellectual disability, speech disorder, and epilepsy (GRIN2A). In the remaining two patients, one had a pathogenic mutation in the GABGR2 gene (associated with generalized epilepsy with febrile seizures), and the other patient had a variant in the ATP1A2 gene (linked to alternating hemiplegia of childhood). Our results suggest thata Rett-like phenotype is caused by mutations in a variety of genes associated with synapse development or function, and previously linked to epilepsy and intellectual disability. It is likely that such studies using exome sequencing will expand the list of genes linked to neurodevelopmental disorders with a phenotype that overlaps with typical or atypical RTT (Rett-like syndrome).

3010F

TMEM38B/TRIC-B deficiency causes an Osteogenesis imperfecta-like bone dysplasia by dysregulation of ER calcium homeostasis and collagen biosynthesis. *W. A. Cabral[1], M. Ishikawa[2], E. Makareeva[3], B. M. Owens[1], A. M. Barnes[1], M. Weis[4], F. Lacbawan[5], D. R. Eyre[4], S. Leikin[3], Y. Yamada[2], J. C. Marini[1].* 1) Bone & Extracellular Matrix Branch, NICHD/NIH, Bethesda, MD; 2) Molecular Biology Section, NIDCR/NIH, Bethesda, MD; 3) Section on Physical Biochemistry, NICHD/NIH, Bethesda, MD; 4) Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA; 5) Department of Medical Genetics, Children's National Medical Center, Washington, D. C.

Recessive osteogenesis imperfecta (OI) is caused by defects in proteins involved in post-translational interactions with type I collagen. Recently, a novel form of moderately severe OI was identified in Bedouins and a single Albanian proband due to null mutations of *TMEM38B*. *TMEM38B* encodes the integral ER membrane monovalent cation channel, TRIC-B, proposed to regulate Ca2+ release from intracellular stores. However, the molecular mechanisms by which *TMEM38B* mutations cause OI are unknown. We identified 2 patients with recessive defects in *TMEM38B* causing moderately severe bone dysplasia. Patient 1 is a 20-month old Saudi girl who is homozygous for the Bedouin founder mutation, a deletion of exon 4. Patient 2 is a 27-year old American male with compound heterozygosity for a maternal 1nt duplication in exon 1 and a paternal deletion encompassing exons 1 and 2, identical to that previously reported in the Albanian child. *TMEM38B* transcripts in proband fibroblasts and osteoblasts were significantly reduced to 25-70% of control levels. Absence of TRIC-B protein, confirmed by Western analysis, was associated with decreased intracellular and ER luminal Ca2+ concentrations that are more rapidly depleted upon ATP-induced Ca2+ flux. Lower Ca2+ levels are not due to altered expression or stability of SERCA2b or IP3R, the channels involved in ER Ca2+ loading and release, respectively. As expected, depletion of intracellular Ca2+ is associated with ATF4-mediated ER stress and increased BiP. Absence of TRIC-B dysregulated synthesis of type I collagen, which has increased electrophoretic mobility resulting from a 30% reduction in helical lysine hydroxylation. Collagen telopeptide hydroxylation is normal, despite decreased levels of Ca2+-dependent FKBP65. Although normal PDI protein levels are maintained, there is a 20-minute delay in procollagen chain assembly in proband cells. The resulting misfolded collagen is substantially retained in the cell, with a higher proportion of intracellular collagen observed in proband versus control cells, consistent with a 50-70% reduction in total secreted collagen. A lower-stability secreted collagen species detected by DSC is not deposited into extracellular matrix, which contained only normal stability collagen. These data support a role for TRIC-B in intracellular Ca2+ mobilization. Absence of TRIC-B causes bone dysplasia by dysregulation of multiple Ca2+-regulated collagen-specific chaperones and modifying enzymes in the ER.

Whole-Exome Sequencing Reveals Novel Gene Implicated in Multiple Epiphyseal Dysplasia and Primary Osteoarthritis. *M. Czarny-Ratajczak[1], V. Dasa[2], J. Eastwood[1], C. Blackstock[1], K. Kozlowski[3], S. M. Jazwinski[1].* 1) Department of Medicine, Center for Aging, Tulane University, School of Medicine, New Orleans, LA; 2) Department of Orthopaedic Surgery, Louisiana State University Health Sciences Center, New Orleans, LA; 3) Department of Medical Imaging, The Children's Hospital at Westmead, Sydney, Australia.

Multiple epiphyseal dysplasia (MED) is a relatively common chondrodysplasia characterized by delayed and irregular ossification of epiphyses and by early-onset osteoarthritis (OA). The first symptoms of MED include waddling gait, restriction of joint mobility, and pain and stiffness in the weight-bearing joints. To date, mutations in six genes have been found as the cause of 60% of MED cases; however, the genetic defects that are responsible for the remaining 40% of MED are unknown, suggesting that mutations in other genes are also involved in its pathogenesis. Furthermore, very little is known about the genetic predisposition to primary osteoarthritis. Currently, the overlapping multiple epiphyseal dysplasia/osteoarthritis phenotype is reinvestigated since it may provide new insights towards understanding the genetic basis for common forms of primary osteoarthritis. To identify novel candidate genes for MED we performed whole-exome sequencing utilizing the Ion Proton next-generation sequencing system (Ion Torrent/Life Technologies) and Ion TargetSeq™ Exome enrichment approach. Whole-exome sequencing was completed among direct relatives within Caucasian families with the autosomal dominant form of MED and early-onset OA. All known MED candidate genes were excluded in these families. Read mapping, determination of exome coverage metrics, and variant calling was completed with the Torrent Suite™ Software. Trio analysis of exome-sequencing data was performed with Ion Reporter ver. 4. 4 software (Ion Torrent/Life Technologies), which utilizes algorithms including PolyPhen, SIFT, PhyloP and Grantham scores to predict effects of the sequence changes. Using whole-exome sequencing we identified a novel candidate gene that plays a causative role in MED and potentially in primary OA. Furthermore, we analyzed co-segregation of identified changes in MED families as well a separate patient population undergoing elective surgery for primary knee osteoarthritis. Overall, our studies indicate a novel candidate gene for MED and provide new insight towards understanding the genetic basis for primary osteoarthritis. This research is supported by: NIH (NIGMS) grant no. U54-GM104940:551192K2 and Bone and Joint Initiative USA Scholarship for Young Investigators to M. C-R. Exomes were analyzed in the Genomics and Biostatistics Core funded by NIH (NIGSM), Mentoring Research Excellence in Aging and Regenerative Medicine grant no. P20GM103629 to S. M. J.

Bone Robusticity in Two Distinct Skeletal Dysplasias: an Evaluation of the Second Metacarpal, a Surrogate for Bone Strength. *J. MArino[1], K. Jepsen[2], E. Carter[1], C. Raggio[1].* 1) Ctr for Skeletal Dysplasias, Hospital For Special Surgery, New York, NY; 2) Orthopaedic Research Laboratories, University of Michigan, Ann Arbor, MI.

Radiographs of the second metacarpal are used to assess bone strength development in paediatric populations. Children with achondroplasia and osteogenesis imperfecta (OI) have known differences in bone strength. Details of how bone strength develops and compares within these populations to unaffected children are lacking. A data set for patients with achondroplasia and OI was established. A retrospective IRB-approved review of bone-age films(n=67; 1-11 films/patient) from patients(5mos to 16yrs+3mos old) with achondroplasia(6 males; 10 females) or OI(9 males; 11 females) was conducted. A sample of modern controls (diagnosis: leg-length discrepancy) matched historical measurements from the Bolton-Brush collection(6mos-16yrs). Metacarpal length(Le) was measured from the proximal end to the most distal ossified end along the midshaft axis. Outer and inner diameters were measured at 50% and 60% of the length, averaged, and used to calculate total cross-sectional area(Tt. Ar) and cortical area(Ct. Ar) using a circular approximation. To adjust for differences in body size, we compared robustness(Tt. Ar/Le) and relative cortical area(RCA=Ct. Ar/Tt. Ar) among groups. Achondroplasia patients tend to have robustness values above and RCA values below the most robust Bolton-Brush tertile. This robust phenotype was consistent with the reduced longitudinal growth seen in achondroplasia patients because of the constitutive activation of FGFR3. RCA values were decreased compared to but followed the distribution of the control population. OI patients did not follow the established Bolton-Brush pattern of robustness and RCA. OI patients fell into the most slender tertile for robustness and RCA values of OI patients were similar to that of controls. Patients did not separate based on OI subtype. No sexual dimorphism was noted in this study. The lack of sexual dimorphism in the dysplasia populations is in contrast to that reported in the unaffected population. We suggest that the underlying dysplasia overrides the sex-specific effects on bone strength development. The contribution of the specific mutation is unknown and needs to be further studied.

3013F

Variants in *ACTC1* cause distal arthrogryposis: a new skeletal muscle phenotype for a cardiac muscle gene. *C. T. Marvin[1], J. X. Chong[1], K. J. Buckingham[1], K. M. Shively[1], T. M. Harrell[1], A. G. Shankar[1], M. J. McMilliin[1], D. A. Nickerson[2], J. Shendure[2], Y. Alanay[3], A. S. Aylsworth[4], M. I. Roche[4], C. Turnbull[5], M. J. Bamshad[1, 2, 6], University of Washington Center for Mendelian Genomics.* 1) Dept. of Pediatrics, University of Washington, Seattle, WA, USA; 2) Dept. of Genome Sciences, University of Washington, Seattle, WA, USA; 3) Pediatric Genetics, Department of Pediatrics, Acibadem University School of Medicine, Istanbul, Turkey; 4) Departments of Pediatrics and Genetics, Division of Genetics and Metabolism, University of North Carolina, Chapel Hill, NC, USA; 5) Division of Genetics and Epidemiology, Institute of Cancer Research, Sutton, UK; 6) Seattle Children's Hospital, Seattle, WA, USA.

Contraction of the human sarcomere is the result of interactions between myosin cross-bridges and actin filaments. Mutations in genes such as *MYH7*, *TPM1*, and *TNNI3*, that encode parts of the cardiac sarcomere cause muscle diseases that affect the heart, such as dilated cardiomyopathy and hypertrophic cardiomyopathy. In contrast, mutations in homologous genes *MYH2*, *TPM2*, and *TNNI2*, that encode parts of the skeletal muscle sarcomere, cause muscle diseases affecting skeletal muscle, such as the distal arthrogryposis (DA) syndromes. To date, few genes that encode sarcomeric proteins have been found that contain mutations that affect both skeletal and cardiac muscle. Moreover, none of the known genes for DA have been found to contain mutations that also cause a cardiac phenotype. We report two families with dominantly inherited missense variants and one family with a *de novo* missense variant in the gene actin, alpha, cardiac muscle 1 (*ACTC1*). None of these variants were found in either EVS or ExAC. Sanger validation confirmed these variants track with affected individuals. Analysis metrics GERP and CADD indicate these loci are highly conserved and that the variants are predicted to be damaging. In family one, comprised of an affected father and daughter, a variant in exon 4 of *ACTC1* (c. 595G>A, p. Gly199Ser, GERP 5. 08, CADD 22. 3) was identified. This family presented with neck webbing, vertebral fusion, clubfeet, hypoplastic flexion creases, and a ventricular septal defect in the father. The second family, an affected mother and daughter, had a variant in exon 7 of *ACTC1* (c. 1120C>A, p. Arg374Ser, GERP 4. 92, CADD 22). Other features included a history of severe scoliosis, clubfeet, contractures, short stature, mild ptosis, and left eye coloboma in addition to a midline depression in the anterior chest in the daughter. The third case was simplex and presented with clubfeet and camptodactyly. The proband was found to have a variant in exon 3 of *ACTC1* (c. 203C>A, p. Thr68Asn, GERP 5. 49, CADD 18. 46). *ACTC1* is a highly conserved actin gene that binds to myosin and is expressed in both cardiac and skeletal muscle. Mutations in *ACTC1* have previously been found to cause atrial septal defect, dilated cardiomyopathy, hypertrophic cardiomyopathy, and left ventricular noncompaction. Our discovery delineates a new DA phenotype caused by mutations in *ACTC1* and suggests that some functions of actin, alpha, cardiac muscle 1 are shared in cardiac and skeletal muscle.

Analysis of a broad spectrum of mutations in the *EXT1* and *EXT2* genes in Brazilian patients with multiple osteochondromas. *S. C. L. Santos[1], I. M. P. O. Rizzo[2], R. I. Takata[1], C. E. Speck-Martins[2], C. Sollaci[3].* 1) Molecular Biology Lab, SARAH Network of Hospitals, Brasília, DF, Brazil; 2) Clinical Gentics Dept, SARAH Network of Hospitals, Brasília, DF, Brazil; 3) Orthopedics Dept, SARAH Network of Hospitals, Brasília, DF, Brazil.

Multiple Osteochondroma (MO; OMIM# 133700) is an autosomal dominant disease characterized by the formation of multiple cartilaginous tumors (osteochondromas). The great variability in size and number of osteochondromas reflects the clinical heterogeneity and variable severity, which is characterized by pain, abnormal skeletal growth, deformities and nerve compression. The most serious complication of MO consists in the malignant transformation to a chondrosarcoma (0,5 – 2% of cases). MO is genetically heterogeneous and 70-95% of patients present mutations in one of two tumor suppressor genes *EXT1* (MIM# 608177) or *EXT2* (MIM# 608210). To date, 713 different *EXT1* and 386 *EXT2* mutations have been described. This study is the first Brazilian research in MO, with a broad spectrum of mutations detected in 73 unrelated patients and 25 families affected. We first analyzed 117 probands for *EXT1* mutations by DHPLC analysis and subsequent direct sequencing of all samples with abnormal profile. Negative cases were then screened for *EXT2* mutations using the same approach. Negative cases for both genes were directly sequenced. If no mutation was detected, negative cases were analyzed by MLPA. Mutant allele was found in 79,3% of unrelated MO patients in which *EXT1* mutations were detected in 32,6% of cases and *EXT2* mutations were detected in 46,7%. Nineteen (20,7%) patients had no mutations detected. Mutations were detected in all families wherein 48% presented mutations in *EXT1* and 52% presented mutations in *EXT2* gene. We identified 51 different pathogenic mutations, 33 (14 frame-shift, 10 nonsense, 5 missense, 2 splice-site mutation and 2 large deletions) in *EXT1* and 18 (6 frame-shift, 6 splice-site mutation, 3 nonsense, 2 missense and 1 large deletion) in *EXT2*. Nineteen of the *EXT1* mutations were novel as were 9 of the *EXT2* mutant alleles. Three unrelated patients presented malignant transformation. Two of them had no mutation identified and the other one presented the most common mutation in both unrelated patients and families in the *EXT2* gene suggesting the presence of another site of alteration in the genome causing more severe types of MO. We found a different pattern of mutations in the genes involved in MO from the patterns in literature. Most other studies detected a greater number of mutations in *EXT1* than *EXT2* gene showing that Brazilian population has a unique genetic spectrum that differs from the European populations and other Latin American countries.

Novel FKBP10 mutation induces osteogenesis imperfecta type XI .
S. Seyedhassani[1,2], M. Yavari[1], F. Harazi[1], F. Hashemi-Gorji[2], V. Yasaee[2]. 1) Dr. Seyedhassani Medical Genetic Center; 2) Genomic Research Center, Shahid Beheshti University of Medical Sciences, Tehran, Iran.

Introduction: Osteogenesis imperfecta (OI) comprises a group of connective tissue disorders characterized by bone fragility and low bone mass. The disorder is clinically and genetically heterogeneous. OI type XI is an autosomal recessive form of OI . **Clinical Presentation:** The proband was a seven years old boy that born in a third degree consanguineous marriage by normal vaginal delivery. He had knee deformity at the birth time. Since day one he was diagnosed with blue sclera and experienced several bone fractures as OI, and therefore had five surgeries in knee and elbow joints. He was not enabling to standing and walking until now. Radiographic findings at birth time revealed enough bone evidence for OI. There were another two similar cases in familial pedigree that were occurred in fifth degree relatives. **Material and Methods:** Peripheral blood samples were obtained following informed consent adhering to the tenets of the Declaration of Helsinki. DNA was extracted using a Flexigene blood DNA kit (DNA fast, QIAGEN) according to the manufactures protocol and stored in TE buffer. **Results:** All of the exons and exon-intron boundaries of CRTAP and FKBP10 genes were amplified under standard PCR conditions. The other known genes were excluded based on clinical findings and inherritance pattern. PCR products were subjected to Sanger sequencing and output files were aligned to the human genome reference and analyzed by Finch TV 1. 4 software. In addition, Human Gene Mutation Database (HGMD), Exome Variant Server (EVS) and available literature were observed for minor allele frequencies and earlier reports of this novel mutation. Screening of all exons and adjacent introns revealed a homozygous deletion as ATCCCC(^324)GGGaTGGA in exon 6 of the FKBP10 gene resulting in protein alteration. Extended analysis verified that the novel mutation segregated within the family. **Conclusion:** We have identified a novel FKBP10 mutation. This finding can be useful in genetic counseling and detection of priority in molecular analysis of OI in Iranian population. Prenatal diagnosis is suggested to speculate the fate of the fetus in the next pregnancy.

Mutations spectrum of *COL1A1/COL1A2* in Chinese with osteogenesis imperfecta. *X. Zhao, J. Xiao, Y. Wu, C. Lu, H. Wang, X. Zhang.* McKusick-Zhang Center, Chinese Academy of Medical Sciences - Peking Union Medical College, Beijing.

Osteogenesis imperfecta (OI) is a group of clinically and genetically heterogeneous disorders with an incidence of 1/10000 in live births. The main clinicalmanifestations in OI include multiple fractures, blue sclera, short stature, dentinogenesis imperfecta, hearing loss and so on. Uptonow, fifteen different forms (OI type 1~OI type 15) have been recognized and classified, and at least thirteen genes(*COL1A1*, *COL1A2*, *IFITM5*, *SERPINF1*, *CRTAP*, *LEPRE1*, *PPIB*, *SERPINH1*, *FKBP10*, *SP7*, *BMP1*, *TMEM38B* and *WNT1*)have been reported to relate to OI. Lots of studies have shown that more than 90% affected individuals have mutations in either *COL1A1* or *COL1A2* which encode the chains of type I procollagen. In this study, we collected 202 OI cases (65 familial cases and 137 sporadic cases) and their family members. All the affected individuals showed notable OI phenotypes. We focused on mutation identification in *COL1A1/2* in all the 202 probands. All the coding region and exon/intron boundaries in *COL1A1/2* were amplified using 43 pairs of primers. Next generation sequencing was carried out to detect the candidate mutations in the probands, and all the mutations were verified by PCR-Sanger sequencing. The DNA from the unaffected parents of the sporadic cases was also screened to ascertain the absence of the de novo mutations. Novel mutations were validated in 50 normal unrelated samples by PCR followed by high resolution melting (HRM). In total, we found 127 mutations in 155 probands, including 79 mutations in *COL1A1* and 48 mutations in *COL1A2*. Among them, 63 mutations were novel and haven't been reported in human gene mutation database (HGMD), including 36 mutations in *COL1A* 1 and 27 mutations in *COL1A2*. In summary, we have set up a comprehensive platform including PCR, Sanger/ next generation sequencing and HRM to perform genetic diagnosis for the patients with OI. We extended the mutation spectrum of *COL1A1 /2* in Chinese OI cases.

3017W

Mutations in *MYLPF* cause a novel segmental amyoplasia manifest as distal arthrogryposis. *K. M. Shively[1], J. X. Chong[1], C. T. Marvin[1], A. E. Beck[1,2], T. M. Harrell[1], M. J. McMillin[1], K. J. Buckingham[1], A. S. Aylsworth[3], J. Shendure[4], D. A. Nickerson[4], M. J. Bamshad[1,2,4], University of Washington Center for Mendelian Genomics.* 1) Department of Pediatrics, University of Washington, Seattle, WA, USA; 2) Seattle Children's Hospital, Seattle, WA, USA; 3) Departments of Pediatrics and Genetics, University of North Carolina, Chapel Hill, NC, USA; 4) Department of Genome Sciences, University of Washington, Seattle, WA, USA.

The distal arthrogryposes (DA) are a phenotypically and genetically heterogeneous group of disorders characterized by congenital contractures of the limbs and subcategorized by the severity of the contractures and presence of additional features. Dominantly inherited or *de novo* mutations in *TPM2*, *TNNI2*, *TNNT3*, and *MYH3*, which encode proteins of the contractile apparatus of skeletal muscle, are the most common causes of DA but explain only ~60% of families. During analysis of exome sequencing data from a large cohort of individuals with various forms of DA, we identified two kindreds (Families A and B) with a novel form of DA. Family A was of European ancestry and consisted of two affected siblings whose unaffected parents were second cousins once removed. Each affected individual had severe contractures of the hands, fingers, wrists, elbows, hips, knees, ankles, and neck; pterygia of the elbows and knees; small mouths; and were below the tenth centile for weight and height. Family B consisted of a single, adopted proband of East Indian ancestry whose parents were likely first cousins based on analysis of high-density genotyping data (F=0. 0657). He had a small mouth, micrognanthia, scoliosis, contractures of the hands and wrists, and severe clubfoot that was recalcitrant to treatment, ultimately leading to amputation of the foot. Pathological exam of the foot reveal an absence of skeletal muscle that was confirmed histologically. All affected individuals shared the same homozygous mutation, c. 470G>T, p. (Cys157Phe), in exon 7 of myosin light chain, phosphorylatable, fast skeletal muscle (*MYLPF*). The mutation was observed once in 59,941 control exomes in the ExAC database, not seen in EVS or 1000 Genomes, and is predicted to be deleterious (Polyphen 0. 779, CADD 35. 0). Moreover, *Mylpf* null mice are 30% smaller than their wild type or heterozygous counterparts; they lack skeletal muscle in their whole body and die immediately after birth due to respiratory failure caused by lack of skeletal muscle in the diaphragm. Accordingly, the mouse model appears to recapitulate the human phenotype. These findings suggest that congenital contractures in these families is caused by a novel mechanism that results in hypoplasia or aplasia of skeletal muscle in the distal parts of the limbs.

3018T

Skeletal Ciliopathies – a molecular study of 17 patients with Short-Rib Thoracic Dysplasia (SRTD). *A. Hammarsjö[1, 2], M. Pettersson[1], K. Lagerstedt-Robinson[1, 2], H. Malmgren[1, 2], F. Short-rib thoracic dysplasia (SRTD [MIM 208500]) is a group of recessive skeletal ciliopathies characterized by extensive genetic and phenotypic overlap, with some differences in malformations and skeletal appearance. SRTD encompasses Ellis-van Creveld syndrome (EVC [MIM 225500]) and the diagnoses previously designated as Jeune syndrome, asphyxiating thoracic dystrophy (ATD), short rib-polydactyly syndrome (SRPS) and Mainzer-Saldino syndrome (MZSDS [MIM 266920]). Mutations in at least 13 genes have been reported to date (*IFT80, EVC, LBN, DYNC2H1, TTC21B, WDR19, NEK1, WDR35, WDR60, IFT140, IFT172, WDR34* and *CEP120*) all encoding proteins important for primary cilia function. There is also a phenotypic and genetic overlap with Sensenbrenner syndrome or cranioectodermal dysplasia (CED [MIM 218330]), which is caused by mutations in *IFT122*, *WDR35*, *WDR19* and *IFT43*. Nearly all genes that have been associated with SRTD are located in genes encoding proteins that are part of the intraflagellar transport (IFT) machinery or have a role in ciliary assembly but the exact mechanisms are not yet fully understood. The aim of our study was to extend the genetic and phenotypic characterization of skeletal ciliopathies. 17 unrelated individuals with a clinical and radiological diagnosis of SRTD (N=12) and CED (N=5) were recruited from six countries (Sweden, Canada, USA, Japan, India and Belgium). The DNA samples were analyzed by whole exome sequencing (WES) and were filtered against a defined clinically relevant gene panel of 347 genes including all known skeletal dysplasia and ciliopathy loci. Identified variants were validated in the probands and their parents using Sanger sequencing. The WES analyses from the first 13 families have identified the causal mutation in 77% of the cases. Specifically we identified 16 novel variants and six previously reported mutations in five genes (i. e. *WDR19, DYNC2H1, NEK1, C2CD3 and IFT140*). Our findings show that WES together with a gene panel is a powerful strategy to establish molecular diagnosis of SRTD, a disease with a heterogenous genetic entity. This study expands current knowledge about genetic and phenotype variability in skeletal ciliopathies leading to improved diagnosis and genetic counseling for the affected families.

3019F

Molecular analysis of 24 Ellis van Creveld syndrome (EVC) individuals using targeted Next Generation Sequencing (NGS) and array CGH technology. *C. Huber[1], B. BAUJAT[1], M. ZARHATE[2], C. The SRP group includes 4 lethal disorders and 2 disorders compatible with life, asphyxiating thoracic dysplasia (ATD) and Ellis-van Creveld (EVC) syndrome. Common characteristic features include constricted thoracic cage, short ribs, shortened tubular bones, and trident aspect of the acetabular roof. EVC is distinct by the presence of post-axial polydactyly, congenital cardiac defects, dysplastic nails and teeth and labio-gingival adhesions. EVC is caused by mutations either in *EVC* or in *EVC2*. Here, we report the molecular screening of 24 EVC individuals by targeted NGS of a customized ciliopathy gene panel, called ciliome, associated with array CGH technology for 6 cases. The series includes 14 fetuses and 11 postnatal cases. Among them, 18/24 (11 fetuses and 6 postnatal cases) were found to harbor variants (10 nonsense, 3 splice site, 1 missense, 4 deletions) either in *EVC* (11), *EVC2* (7) or *EVC*/*EVC2* (1). In 8 cases, the identification of i) an heterozygous variant only (4/8), ii) an "homozygous" variant confirmed only at the heterozygous state in the father (3/8), iii) the absence of any variant (1/8), prompted us to perform microsatellite analysis at the *EVC*/*EVC2* loci. We identified 2 heterozygous deletions, encompassing either *EVC* or *EVC*/*EVC2*. Because of the non informativity of the intragenic *EVC* microsatellite in 6 cases, we performed an array CGH, leading to the detection of 4 deletions encompassing *EVC*, always inherited from the mother. Finally, in 2/24 cases only one heterozygous variant was detected and in 7/24 cases, neither variant nor deletion were detected in *EVC*/*EVC2*, supporting the involvement of another disease gene. By combining ciliome analysis and array CGH, we conclude that *EVC* and *EVC2* account for 75 % of EVC cases. Our study emphasizes the high frequency of maternal deletion (half cases) of variable sizes. Finally, exome sequencing is in progress for the 7 remaining cases.

3020W

***SEC24D* causes non-syndromic autosomal recessive osteogenesis imperfecta.** *S. Moosa[1], B. Chung[2], J. Altmueller[1,3], H. Thiele[3], P. Nuernberg[3], G. Nishimura[4], B. Wollnik[1].* 1) Institute of Human Genetics, University Hospital of Cologne, Cologne, Germany; 2) Department of Paediatrics and Adolescent Medicine, Queen Mary Hospital, Hong Kong, China; 3) Cologne Center for Genomics (CCG), University of Cologne, Cologne, Germany; 4) Department of Pediatric Imaging, Tokyo Metropolitan Children's Medical Center, Tokyo, Japan.

Osteogenesis imperfecta (OI) is a heterogeneous group of disorders characterized by increased bone fragility, decreased bone mass and a propensity to fractures. Recently, biallelic mutations in *SEC24D* were shown to cause a novel form of syndromic OI, resembling Cole-Carpenter syndrome. Here, we report on the first patient with non-syndromic OI, with two novel compound heterozygous mutations in *SEC24D*. Using whole-exome sequencing (WES), we identified the c. 113dupC mutation in exon 2, which leads to a frameshift and premature stop codon (p. T39Nfs*16) and the c. G2496T (p. Q832H) mutation, which affects the last base of exon 19. *In vitro* analysis of constructs harbouring this mutation revealed abnormal splicing. Unlike the original *SEC24D* patients described, our patient does not show the dramatic facial phenotype and skull ossification defects associated with mutated *SEC24D* in patients and corresponding animal models. Here, we present her clinical features and the results of the molecular genetic analysis. Thus, our report expands the *SEC24D*-associated phenotypic and mutational spectrum, and confirms *SEC24D* as an additional gene underlying autosomal recessively inherited non-syndromic OI.

3021T

Tissue specific mosaicism for a lethal *COL1A1* mutation causes mild Ehlers-Danlos syndrome. *S. Symoens[1], W. Steyaert[1], L. Demuynck[1], F. Malfait[1], A. De Paepe[1], K. E. M. Diderich[2], P. J. Coucke[1].* 1) Center for Medical Genetics Ghent, Ghent University Hospital, Ghent, Oost-Vlaanderen, Belgium; 2) Department of Clinical Genetics, Erasmus MC, Rotterdam, The Netherlands.

Type I collagen is the predominant protein of multiple connective tissues such as skin and bone. Mutations leading to structural abnormal type I collagen mainly cause the brittle bone disease Osteogenesis imperfecta (OI), resulting in a wide spectrum of clinical severity ranging from few fractures to intra-uterine lethality with multiple fractures and malformations of the (long) bones. Until now, 1417 unique mutations in the type I collagen genes (*COL1A1* and *COL1A2*) have been reported, of which in-frame deletions account for only 3% and all are almost exclusively associated with a severe-to-lethal OI phenotype. We describe a patient who was referred because of clinical symptoms of Ehlers-Danlos syndrome, including fragile skin, recurrent luxations and easy bruising. Biochemical collagen analysis of the patients' dermal fibroblasts surprisingly showed dedoubling of the type I collagen bands, a finding specific for structural defects in type I collagen. Subsequent molecular analysis by Sanger sequencing detected an in-frame deletion in exon 44 of the *COL1A1* gene (c. 3150_3158del), resulting in the deletion of three amino acids (p. (Ala1053_Gly1055del)) in the triple helical collagen domain. This *COL1A1* mutation has hitherto only been identified in four probands with lethal OI. However, the peaks on the electropherogram corresponding to the mutant allele were decreased in intensity, suggesting the mosaic presence of the *COL1A1* mutation. We applied next generation sequencing in order to determine the possibility of mosaicism in skin and blood. While approximately 9% of the reads originating from DNA extracted from fibroblasts harboured the *COL1A1* deletion, the deletion was not detected in DNA extracted from blood, implying that the degree of mosaicism is different between tissues thereby explaining the mild phenotype of the patient. In conclusion, the biochemical and molecular characterization of the patient described in this study illustrates that the combined use of biochemical collagen analysis and next generation sequencing technologies is a powerful tool in guiding molecular analysis and in pinpointing the clinical diagnosis in those patients in whom the diagnosis is unclear.

3022F

Order of intron splicing is an important determinant of variant splice outcome in *COL1A1*. *J. Schleit[1], P. H. Byers[1, 2].* 1) Department of Pathology, University of Washington, Seattle, WA; 2) Department of Medical Genetics, University of Washington, Seattle.

Variants that alter mRNA splicing account for approximately 20% of inherited pathogenic variants. Often, the phenotype of the individual is dependent on the stability of the mRNA produced from the variant allele. Currently the prediction of splice outcome remains a challenge for molecular diagnostic labs. We sought to understand how variants alter mRNA splicing and why seemingly similar variants can result in different splice outcomes and disease phenotypes. We first analyzed the rate and order of splicing of introns 43-48 of the type I procollagen gene, *COL1A1*, in three wild-type samples using qPCR and capillary electrophoresis. All three samples displayed similar intron splice times and order of intron removal. Introns 45 and 47 were removed early in the order of splicing and introns 44 and 48 were removed last. In several instances we observed multiple splice order combinations consistent with multiple pathways in some regions. The time required to splice half the intron containing transcripts in this region varied from 6 to 45 minutes, the maximum time examined. To examine the effect of inherited variants on mRNA splicing we analyzed splice order in fibroblasts from four individuals with pathogenic splice donor variants in consecutive introns of *COL1A1*. Two variants, IVS44+2T>C and IVS46+1G>T, resulted in use of cryptic splice donor sites, an unstable mRNA and a mild OI phenotype. The remaining two variants, IVS45+2T>C and IVS47+1G>A, resulted in a stable exon skip transcript that resulted in a lethal OI type II phenotype. Both exon skip/OI type II variants were located in introns that were removed earlier in the local order. Variants in the rapidly removed introns resulted in delayed splicing of that intron and were resolved by exon skipping. In the sample containing the IVS47+1G>A the introns adjacent to the variant also showed delayed removal suggesting a "splice paralysis" had occurred on these transcripts. In contrast, variants in introns removed late in the order allowed splicing of the surrounding introns and led to use of cryptic sites, likely due to the absence of surrounding introns to induce skipping. Our findings indicate the order of intron removal is similar among samples from unrelated individuals and is an important determinant of splice outcome. Future work to identify the factors which determine the order of splicing should increase our ability to predict the outcome of variants which alter mRNA splicing.

3023W

Keratoconus (KC) is an eye disorder in which the cornea is swollen, thinned and deformed. . *f. Azadegan Dehkordi[1], a. Rashki[2], n. Bagheri[3], m. Hashemzadeh Chaleshtori[4], m. Hashemzadeh Chaleshtori[1].* 1) Cellular and Molecular Research Center, Shahrekord University of Medical Science, Shahrekord , Iran; 2) Faculty of Veterinary Medicine, Department of Physiopathology, University of Zabol, Zabol,; 3) Department of Microbiology and Immunology, Tehran University of Medical Sciences, Tehran; 4) Isfahan University of Medical Sciences.

Abstract

Objective: Keratoconus (KC) is an eye disorder in which the cornea is swollen, thinned and deformed. Despite extensive studies, the pathophysiological processes and genetic etiol- ogy of KC are unknown. The disease incidence is approxi- mately 1 in 2,000, and it is the most common cause of cor- neal transplantation in the USA. Many genes are involved in the disease, but evidence suggests a major role for *VSX1* in the etiology of KC. This study aimed to determine the fre- quency of mutations in exons 2, 3 and 4 of the *VSX1* gene in

Chaharmahal va Bakhtiari province in the southwest of Iran. *Study Design:* In this experimental study, mutations in 3 ex- ons, namely exons 2, 3 and 4, of *VSX1* were investigated in 50 patients with KC and 50 healthy control subjects. DNA was extracted using a standard phenol-chloroform method. PCR- single-strand conformational polymorphism/heteroduplex analysis was performed, followed by DNA sequencing to confirm the identified motility shifts. *Results:* H244R muta- tions were found in 1 patient and also in 1 healthy control subject. Furthermore, 12 polymorphisms were identified in patients with KC and 7 in healthy control subjects [rs6138482 and c. 546A>G (rs12480307)]. *Conclusion:* Our investigation showed that KC-related *VSX1* mutations were found in a very small proportion of the studied patients from Iran. Further investigations on other genes are needed to clarify their roles in KC pathogenesis.

3024T

Mutation screening and in-depth bioinformatic analyses of the cathepsin C gene in an Indian family with Papillon-Lefevre syndrome. *M. Raveendrababu[1], M. V. Rao[1], T. Y. Mehta[2], U. Ratnamala[3], U. Radhakrishna[4].* 1) Human Cytogenetics, Department of Zoology, Gujarat University, Ahmedabad, Gujarat, India; 2) Samarpan Centre for skin, Sexually transmitted diseases and Research Center, Modasa, India,; 3) Department of Pharmacology, Creighton University, Omaha, NE; 4) Green Cross Pathology & Molecular Laboratory, Ahmedabad, India,.

Papillon-Lefèvre syndrome (PLS), also known as palmoplantar keratoderma with periodontitis (PALS, MIM 245000) is an autosomal recessive disorder characterized by palmoplantar keratoderma and early onset severe periodontitis affecting both deciduous and permanent dentition. Many PALS families and sporadic cases with variable clinical presentation have been reported. Loss-of-function mutations in the gene encoding cathepsin C (CTSC) have been identified in many families, sporadic PALS individuals from various ethnic groups. We describe Papillon-Lefevre syndrome and an autosomal dominant form of palmoplantar keratoderma in the same Indian family and present the mutation analysis of the cathepsin C gene. Sequence analysis of known exons and splice junctions revealed a homozygous nucleotide substitution G to A at nucleotide position 901, resulting in a change from glycine (GGC) to serine (AGC) at amino acid position 301 (G301S) was observed in homozygous condition in an affected individual, and excluded many other affected members with severe palmoplantar keratoderma from the same family. This mutation was found to be at a highly conserved residue in of *CTSC* gene. Structure prediction and energetic analysis of wild-type *CTSC*, comparison with mutant (G301S) revealed that this change in amino acid does not imply any secondary structural change. However, prediction of functional effect(s) of this mutation is possibly damaging the protein structure and/or function. Moreover, based on the energy calculation and the modeled protein structure of the mutant is expected to be energetically unstable.

3025F

Recurrent *de novo* mutations affecting residue p. Arg138 of pyrroline-5-carboxylate synthase cause a novel progeroid form of autosomal dominant cutis laxa. *B. L. Callewaert[1], B. Progeroid disorders overlapping with De Barsy syndrome (DBS) are collectively denoted as autosomal recessive cutis laxa type 3 (ARCL3). They are caused by biallelic mutations in *PYCR1* or *ALDH18A1*, encoding pyrroline-5-carboxylate reductase 1 and pyrroline-5-carboxylate synthase (P5CS), respectively, which both operate in the mitochondrial proline cycle. We report here on eight unrelated individuals born to non-consanguineous families clinically diagnosed with DBS or wrinkly skin syndrome. We found three heterozygous mutations in the *ALDH18A1* gene leading to missense mutations of the same highly conserved residue p. Arg138 in P5CS. A *de novo* origin was confirmed in all six probands for whom parental DNA was available. Using patient derived fibroblasts and heterologous overexpression we found that the P5CS-R138W protein was stable, able to interact with wild type P5CS, but showed an altered sub-mitochondrial distribution. A reduced size upon native gel electrophoresis indicated an alteration of the structure or composition of P5CS mutant complex. Furthermore, we found that the mutated cells had a reduced P5CS enzymatic function leading to lower proline synthesis rates, which may account for observed alterations in collagen synthesis. In summary, recurrent *de novo* mutations of the highly conserved p. Arg138 residue of P5CS cause a novel autosomal dominant form of cutis laxa with progeroid features. Our data provide novel insights into the etiology of cutis laxa diseases and will have immediate impact on diagnostics and genetic counseling.

3026T

Single cell allele specific expression (ASE) in T21 and common trisomies: a novel approach to understand Down syndrome and common aneuploidies. *G. Stamoulis[1], P. Makrythanasis[1], F. Santoni[1], A. Letourneau[1], M. Guipponi[2], M. Garieri[1], N. Panousis[1], E. Falconnet[1], P. Ribaux[1], C. Borel[1], S. E. Antonarakis[1,2,3].* 1) University of Geneva, Geneva, Switzerland; 2) Service of Genetic Medicine, Geneva University Hospitals-HUG, Geneva, Switzerland; 3) iGE3 Institute of Genetics and Genomics of Geneva, University of Geneva, Switzerland.

Trisomy 21 is a model disorder of altered gene expression. We have previously used a pair of monozygotic twins discordant for trisomy 21 to study the global dysregulation of gene expression, without the noise due to genetic variation among individuals(*Nature:*508; 345-350;2014). The majority of previous studies on aneuploidies were conducted -n cell populations or tissues. However studies on gene and allelic expression of single cells (SC) may reveal important biological insights regarding the cellular impact of aneuploidy and elucidate the fundamental mechanisms of gene dosage. We calculated the allele specific expression (ASE) fromRNAseq of ~1000 single cells in different aneuploidies. We used 352 SC fibroblasts (172 Normal and 179 T21 cells) from the pair of monozygotic twins discordant for T21, 166 from a mosaic T21, 124 from a mosaic T18, 151 from a mosaic T8, and 146 SC fibroblasts from a mosaic T13. In the monozygotic twins, a considerable number of heterozygous sites throughout the non-chr21 genome were expressed monoallelically (Normal: 73. 2 % monoallelic in 559,134 observations, and T21: 78. 8 % monoallelic in 573,670 observations). There was also considerable monoallelic expression for chr21 sites in Normal and, surprisingly, in T21 cells as well (Normal: 67,2 % monoallelic in 4,985 observations, and T21: 76. 07 % monoallelic in 6,723 observations). We classified the genes on chr21 in three classes according to the level of the aggregate monoallelic expression of their corresponding sites (9 monoallelic, 29 intermediate, 2 biallelic). Our hypothesis is that each class of genes contributes in a specific way to the phenotypic variability of Down Syndrome. Similar results, i. e. extensive monoallelic expression of genes on the supernumerary chromosomes, were also observed in the other aneuploidies. Our analysis demonstrated that, for genes with monoallelic expression, the abnormal gene dosage induced by the aneuploid chromosome is actually rather due to the number of cells expressing the gene and not to the level of expression per gene. This difference in the fraction of expressing cells could contribute to the development and the variability of phenotypes in aneuploidies. This study provides a new fundamental understanding of the allele specific expression in T21 and common aneuploidies.

Investigation of Variants of Uncertain Significance Identified Through Exome Sequencing in 46,XY Disorders of Sex Development Using the C57BL/6J-Y^{POS} Mouse Model. *H. Barseghyan[1], R. Baxter[1], V. Arboleda[1], A. Eskin[1], S. Nelson[1], E. Delot[1,2], E. Vilain[1,2].* 1) Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Pediatrics, David Geffen School of Medicine, UCLA, Los Angeles, CA.

Disorders of Sex Development (DSD) are defined as “congenital conditions in which development of chromosomal, gonadal, or anatomic sex is atypical. ” These conditions have an approximate frequency of 0. 5-1% of live births and encompass a wide variety of urogenital abnormalities ranging from mild hypospadias to sex reversal. We have performed exome sequencing (WES) to identify the underlying genetic cause in patients diagnosed with 46,XY DSD. In the majority of cases a specific genetic diagnosis was not found, nevertheless WES yielded large numbers of variants of uncertain significance (VUS). To investigate the relevance of these VUS in regards to the patient’s phenotype, we utilized a powerful mouse model for studying undervirilization in 46,XY individuals, in which the presence of a Y chromosome originating from a *M. domesticus poschiavinus* strain (YPOS) on C57BL/6J (B6) background results in XY undervirilization and sex reversal. We hypothesized that abnormal gonadal expression of specific genes in B6-YPOS males during gonadal development would correlate with VUS in genes of 46,XY DSD patients identified through WES. We isolated gonadal tissue from wild type (WT) B6 and undervirilized B6-YPOS males at embryonic day 11. 5 and performed RNA sequencing in order to assess differential gene expression. We identified 110 genes whose expression was 1. 5-38 fold lower in B6-YPOS gonads compared to WT gonads, and in which a missense variant with an alternate allele frequency of less than 1% was identified in unexplained 46,XY DSD cases. Among these genes, three (*FBLN2*, *ADAMTS16*, *CYP26B1*) had variants predicted to be damaging by *in silico* tools. This method allowed identification of novel candidate genes, mutations in which could potentially prove to cause 46,XY DSD. Biochemical *in vitro* and knock-down *in vivo* experiments are in progress to validate the deleterious effects of the variants.

The *APOE* Locus and MicroRNA in Alzheimer’s Disease. *L. Bekris[1,3], M. Shaw[1], J. B. Leverenz[2], Y. Shao[1].* 1) Genomics Medicine Institute, Cleveland Clinic Lerner Research Institute, Cleveland, OH; 2) 2. Cleveland Clinic, Neurological Institute, Cleveland Clinic Lou Ruvo Center for Brain Health, Cleveland, OH; 3) Cleveland Clinic Lerner College of Medicine of Case Western Reserve University, Cleveland, OH.

Background: MicroRNA (miRNA) play an essential role in post-transcriptional gene regulation in the brain. Genetic variants located across the *APOE* locus are the strongest risk factors for late-onset AD described to date. A complex regulatory structure exists at the *APOE* locus that includes putative regulatory sites within the *TOMM40* gene. Little is known about the influence of miRNA post-transcriptional regulation at this locus. **Objective:** The aim of this investigation is to demonstrate that miRNA that are predicted to target the *APOE* locus are expressed differently in brain of AD compared to controls and associated with *APOE* and *TOMM40* brain expression. **Method:** MiRNA array and miRNA qRT-PCR were used to measure miRNA expression in post-mortem brain from AD (n=21) or cognitively normal age-matched control (n=21) hippocampus (HP) and cerebellum (CB). Quantitative RT-PCR was used to measure *APOE* and *TOMM40* mRNA. Western blots were used to measure brain *APOE* and *TOMM40* protein. Linear regression was used to determine if *APOE* and *TOMM40* mRNA expression correlate with protein or mRNA expression in AD (n=8) and cognitively normal age-matched controls (n=8) or in HP and CB. **Results:** MiRNA levels (miR-370, miR-331-3p, miR-744, miR-135a) correlate with brain *TOMM40* or *APOE* expression in AD and controls. **Conclusion:** These results suggest that a complex regulatory structure at the *APOE* locus may be fine-tuned by miRNA post-transcriptional modulation according to brain region or disease status.

A new method for the functional analysis of regulatory SNPs. *H. Guillen Ahlers[1], D. Perumalla[1], P. Rao[1], A. Jadhav[1], J. M. Proffitt[1], M. J. Montoya[1], M. R. Shortreed[2], L. M. Smith[2], M. Olivier[1].* 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Department of Chemistry, University of Wisconsin, Madison, WI.

A large number of disease-associated sequence variants have been identified in the human genome. Genome-wide association studies and, more recently, comprehensive whole-genome sequencing analyses have uncovered variants associated with a wide range of disease-related traits. Most of these associations are located in non-coding regions, indicating a likely regulatory mechanism. Not surprisingly, a number of these sequence variants are strongly associated with both disease-related traits and the expression of individual genes (expression quantitative trait loci, eQTL), reinforcing a functional link between gene expression regulation and disease risk. We recently developed a novel approach, Hybridization Capture of Chromatin-Associated Proteins for Proteomics (HyCCAPP), designed as a tool to identify all of the proteins bound to a specific target chromatin region by mass spectrometry. This approach does not require any prior knowledge of putative binding proteins, and helps discover novel proteins bound to a particular genome region. Here, we present the adaptation of the HyCCAPP approach for the analysis of luciferase reporter plasmid constructs commonly used to assess the impact of sequence variants on promoter activity, and apply the technology to the analysis of selected eQTL variants reported in the literature. As a proof of concept analysis, we analyzed a promoter variant, -105G/A, upstream of the selenoprotein S (*SELS*) gene. *SELS* is a gene involved in stress response and inflammation control. It has been shown before that this mutation leads to decreased levels of *SELS* expression. We tested the two alleles of the -105 variant in luciferase reporter assays introducing promoter-containing plasmids in HepG2 cells. The two variants resulted in differential activity in the reporter assay, suggesting that the two alleles likely result in altered gene expression. ChIP-seq data from ENCODE has not revealed the likely DNA-binding proteins mediating the observed effect. We are analyzing with mass spectrometry the DNA-protein interactions at the SELS promoter using our HyCCAPP technology. The method is being implemented in such a way that experiment conditions will be applicable to any promoter under 1 kb in length. Thus we are developing an application that will lead to the establishment of a new tool for scientists focusing on the functional characterization of putative regulatory variants associated with gene expression and a range of diseases.

3030T

Sequence variation affecting transcription factor occupancy in highly diverged mouse strains. *M. T. Maurano[1,2], J. M. Halow[3], R. Byron[4], M. Groudine[4,5], M. A. Bender[4,6], J. A. Stamatoyannopoulos[3,7].* 1) Institute for Systems Genetics, New York University Langone Medical Center, New York, NY 10016, USA; 2) Department of Pathology, New York University Langone Medical Center, New York, NY 10016, USA; 3) Department of Genome Sciences, University of Washington, Seattle, WA 98195, USA; 4) Fred Hutchinson Cancer Research Center, Seattle, WA 98109, USA; 5) Department of Radiation Oncology, University of Washington, Seattle, WA 98109, USA; 6) Department of Pediatrics, University of Washington, Seattle, WA 98195, USA; 7) Division of Oncology, Department of Medicine, University of Washington, Seattle, WA 98195, USA.

Assessment of the functional consequences of sequence variation at non-coding regulatory elements is complicated by their high degree of context sensitivity to both the local chromatin and nuclear environments. Allelic profiling of chromatin accessibility across individuals has shown that a minority of sequence variation affects transcription factor (TF) occupancy, yet the low sequence diversity in human populations means that no experimental data are available for the majority of disease-associated variants. Using deep allelic profiling of chromatin accessibility, we generated high-resolution maps of variants affecting TF activity at their native locus and chromatin environment in liver, kidney, lung and B cells from 5 increasingly diverged strains of F1 hybrid mice. The high density of heterozygous sites in these strains enables a precise quantification of the effect size and cell-type specificity of variants associated with altered chromatin accessibility throughout the genome. We show that functional variation delineates characteristic sensitivity profiles for hundreds of TF motifs, representing nearly all important TF families. Nevertheless, silent variants are found repeatedly at every position within the protein-DNA recognition interface, and the majority of variation is buffered in a site-dependent manner in vivo. We develop a compendium of TF-specific sensitivity profiles to account for genomic context effects and and model cell-type specific perturbations of the protein-DNA interface. Taking advantage of the high conservation of TF coding sequence among mammals, we apply these models to the classification of disease-associated single nucleotide polymorphisms in human. These models enable quantitative prediction of the effect of non-coding variation on TF activity across a variety of cellular contexts, facilitating both fine-mapping and systems-level analyses of common disease-associated variation in human genomes.

3031F

A high-throughput functional screening identifies non-canonical *cis*-regulatory sequences in the *OCT4* Locus. *Y. Shen[1,2], Y. Diao[2], B. Li[2], Z. Meng[3], J. Dixon[3], I. Jung[2], A. Lee[2], K. Guang[3], B. Ren[2,3].* 1) Institute for Human Genetics, San Francisco, CA; 2) Ludwig Institute for Cancer Research; 3) UCSD.

With less than 2% of the human genome coding for proteins, a major challenge confronting researchers today is to interpret the function of the non-coding DNA. Millions of regulatory sequences have been predicted in the human genome through the analyses of DNA methylation, chromatin modification, hypersensitivity to nucleases, and transcription factor binding, but few have been shown to regulate transcription in their native contexts. To begin to address this issue, we have developed a high throughput CRISPR/Cas9-based genome-editing strategy and used it to interrogate 174 candidate regulatory sequences within the 1Mbp *OCT4* locus in the human ES cells. We identified two classical regulatory elements - including a promoter and a proximal enhancer - that are essential for *OCT4* transcription in the ES cells. Unexpectedly, we also discovered three non-canonical *cis* elements that contribute to *OCT4* transcription in an unusual way: disruption of such sequences led to a temporary loss of *OCT4* transcription that is fully restored after a few rounds of cell division. These sequences harbor signatures of *cis*-regulatory elements but do not support reporter gene expression by themselves. These results demonstrate the utility of CRISPR/Cas9 for functional characterization of non-coding DNA, and reveal a previously unrecognized layer of gene regulation in human cells.

Genetic architecture of gene expression regulation via orthogonal tissue decomposition. *H. E. Wheeler[1,2], N. Knoblauch[3], N. J. Cox[4], D. L. Nicolae[2], H. K. Im[2], GTEx Consortium.* 1) Departments of Biology and Computer Science, Loyola University Chicago, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL; 3) Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL; 4) Division of Genetic Medicine, Vanderbilt University, Nashville, TN.

Regulatory variation has been shown to play a key role in the genetics of complex traits. While many common diseases have been shown to be polygenic, it is unclear whether gene expression levels are also polygenic or instead have simpler genetic architectures and how much these expression architectures vary across genes. First we sought to quantify the relative proportion of local vs. distal gene regulation by estimating the proportion of gene expression variance explained by each (i. e. local vs. distal heritability, h2). With 922 whole blood RNA-seq samples, the mean local h2 was 0. 13 and 54. 6% of genes had a positive 95% confidence interval (CI), while the mean distal h2 was 0. 076 and just 4. 2% of genes had a positive CI. In order to better understand the genetic architecture of tissue-specific and cross-tissue gene regulation, we developed a model called orthogonal tissue decomposition (OTD) and applied it to the tissue rich GTEx dataset. We found that estimates of the local h2 of cross-tissue gene expression generated with our OTD model have larger magnitude and lower standard errors compared to single tissue estimates due to the borrowing of information across all samples. We also assessed the ability of various models with different underlying assumptions to predict gene expression in order to understand the underlying genetic architecture of gene expression. Gene expression traits with sparse architecture should be better predicted with sparse models such as LASSO (Least Absolute Shrinkage and Selection Operator) while highly polygenic traits should be better predicted with ridge regression. The elastic net model combines both models by mixing these two penalized regression approaches, LASSO and ridge regression. A mixing parameter in the elastic net model controls the degree of sparsity of the model. For each tissue in GTEx, we varied the mixing parameter and assessed the prediction performance. We found that for the majority of genes, ridge regression performs worse than elastic net or LASSO supporting the hypothesis that for most genes the local genetic architecture is sparse rather than polygenic. We also found evidence that genes with large tissue-specific heritability are enriched in common complex disease genes discovered via GWAS.

3033F

Identifying compound heterozygous variants associated with gene expression. *R. Brown[1], G. Kichaev[1], N. Mancuso[2], B. Pasaniuc[1,2,3].* 1) Bioinformatics IDP, UCLA, Los Angeles, CA, USA; 2) Department of Pathology and Laboratory Medicine, Geffen School of Medicine, UCLA, Los Angeles, CA, USA; 3) Department of Human Genetics, Geffen School of Medicine, UCLA, Los Angeles, CA USA.

Compound heterozygotes, common in monogenic traits, are not well characterized by current models for complex and quantitative traits. This decreases the ability to find risk loci and may reduce fine-mapping performance. In this work we propose approaches that model compound heterozygotes to increase power for association and fine-mapping. We use mRNA expression from 373 European individuals in the Geuvadis data (Lappalainen et al. 2013 Nature) to show that our approaches increase performance over existing methods. For example in an exon of the NIPSNAP1 gene we find two variants with frequencies . 19 and . 27 in linkage disequilibrium (r) of -0. 25 that individually attain Bonferroni corrected p-values of 0. 033 and 0. 045 for association with the expression level. However, a compound heterozygote model of these variants yields a p-value of 8. 5e-8 Bonferroni corrected for the additional pairwise tests. Across all chromosome 22, 35% of exons show significant associations between expression level and a variant or compound heterozygote. 19% of the significant associations include a significant compound heterozygous association. In 1% of associated exons only compound heterozygotes reached Bonferroni significance demonstrating that our method uncovers novel associations.

β-hemoglobinopathies, such as sickle cell anemia and β-thalassemia, are amongst the most common genetic disorders worldwide. These diseases arise from mutations that affect the function or expression of adult β-globin (HBB). Treatment typically involves lifelong blood transfusion and chelation therapy, with the only curative option being allogeneic transplantation of hematopoietic stem cells. However, it has long been known that increased fetal hemoglobin (HbF) expression that persists into adulthood considerably ameliorates the clinical severity of these disorders. Reversing the perinatal silencing of HbF has thus become a primary focus of therapeutic efforts. In recent years, the transcription factor BCL11A has emerged as a key, and potent, repressor of HbF. Disrupting BCL11A function in an erythroid-specific fashion is rigorously being sought as a therapeutic option; however, the potential impact of such disruption in humans has been unclear. This is due, in part, to the scarcity of reported mutations affecting the coding region of *BCL11A*. Recently however, a number of patients have been described with shared neurodevelopmental defects arising from chromosome 2p15-p16. 1 microdeletions that variably cover segments of the *BCL11A* locus. Here, we have examined the hematological phenotype of three such patients with distinct *de novo* microdeletions. All three display modestly reduced *BCL11A* expression in erythroblasts, and elevated HbF in peripheral blood (approximately 5-10%). Interestingly, in one patient, the *BCL11A* coding gene is intact, with only a downstream region deleted. We have identified a number of potential regulatory elements within this segment that are co-occupied by multiple principal erythroid transcription factors. We are currently employing high throughput genome editing techniques to dissect the functionality of these candidate elements, with the anticipation that they might proffer attractive targets for therapeutic intervention in the treatment of β-hemoglobinopathies.

Functional footprinting of regulatory DNA. *J. Vierstra[1], A. Reik[2], K. H. Chang[1,3], S. Stehling-Sun[1], N. Psatha[1,3], C. M. O'Neill[2], A. Mich[2], J. Miller[2], G. Lee[2], S. Tan[2], H. Jiang[2], G. Stamatoyannopoulos[4], T. Papayannopoulou[3], E. J. Rebar[2], P. D. Gregory[2], F. D. Urnov[2], J. A. Stamatoyannopoulos[1,5].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Sangamo BioSciences, Pt. Richmond, CA; 3) Division of Hematology, Department of Medicine, University of Washington, Seattle, WA; 4) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle. WA; 5) Division of Oncology, Department of Medicine, University of Washington, Seattle, WA.

Transcription regulatory regions harbor the majority of human disease-associated sequence variants. However, our understanding of the impact of regulatory DNA variation is severely limited by the difficulty of precisely assigning the functional contribution of individual nucleotides to phenotypic outcomes. We describe a facile and scalable approach, functional footprinting, to map functional elements within regulatory DNA at nucleotide resolution. We exploit the error-prone nature of double strand break repair triggered during targeted genome editing yielding indels of variable size (1 to >10 nucleotides, typically 2-6 nt), which can be exploited to create a broad spectrum of variant regulatory alleles within a single experimental cycle. Coupling these alleles to a functional readout, such as protein or RNA levels, pinpoints the contribution of specific nucleotides to regulatory activity. We demonstrate the functional footprinting method on the erythroid enhancer of BCL11A, a transcriptional repressor of fetal hemoglobin production in adult erythroid cells. Naturally-occurring variants within this region are associated with reduced *BCL11A* expression, with consequent elevation of fetal globin (γ-globin) to levels that are clinically ameliorative for sickle cell disease and beta thalassemia. Our results reveal individual TF recognition sites within the erythroid enhancer that gate the majority of downstream regulatory function on a fetal globin expression and, critically, these disruptions have the potential to affect a therapeutically meaningful outcome. Functional footprinting encompasses a simple and generalizable strategy to dissect the function of individual *cis*-regulatory elements such that any molecular sensor (i. e. , protein, RNA, etc.) can be linked to the function of individual base pairs within non-coding DNA.

3036T

Deciphering the control of HLA-C expression using the 1000 genomes dataset. *N. Vince[1,2], H. Li[1], S. Anderson[1], M. Carrington[1,2].* 1) Cancer and Inflammation Program, Laboratory of Experimental Immunology, Leidos Biomedical Research Inc. , Frederick National Laboratory for Cancer Research, Frederick, MD; 2) Ragon Institute of MGH, MIT and Harvard, Boston, MA.

The cell surface expression of HLA-C is differentially regulated across alleles, with a continuum of expression level from low (e. g. HLA-C*03) to high (e. g. HLA-C*14). Higher HLA-C expression level associates with better HIV control and with increased risk of developing Crohn's disease. The regulation of HLA-C expression is yet to be fully characterized. One mechanism that accounts in part for differential expression involves an insertion/deletion polymorphism in the 3'UTR of the HLA-C gene, which regulates binding of the microRNA miR-148a. However, this polymorphism does not perfectly mark allele-specific HLA-C expression level, implicating additional mechanisms. In order to further understand the control of HLA-C expression we used the mean expression of HLA-C alleles (as determined by flow cytometry) to impute HLA-C expression levels of individuals from the 1000 genomes dataset (1KG) based on their HLA-C genotypes. Logistic regression was applied to test the association between HLA-C expression and SNPs in the HLA region; HLA-C expression was used as a continuous variable. The most significant association was identified for a SNP located 800 bp upstream of the transcription start site (rs2395471, p=4. 2x10-66). According to online prediction tools, this SNP is located within a potential binding site for transcription factors (TF) Oct1 (*POU2F1*), Oct2 (*POU2F2*) and Oct4 (*POU5F1*). We were able to confirm the presence of a TF binding site by performing an electrophoretic mobility shift assay (EMSA), in which we used Jurkat cell line nuclear protein extract and an oligonucleotide specific for each genotype of rs2395471. Next, using TF specific antibodies, we confirmed that Oct1, but not Oct2 or Oct4, binds this genomic site. Further experiments are planned to test the potential influence of rs2395471 on TF binding and promoter activity. In conclusion, using computational tools and the 1KG dataset, we were able to identify a promoter SNP strongly associated with HLA-C expression, which may provide a novel mechanism of HLA-C gene regulation.

3037F

A LARGE GENOMIC DELETION LEADS TO ENHANCER ADOPTION BY THE LAMIN B1 GENE: A SECOND PATH TO AUTOSOMAL DOMINANT LEUKODYSTROPHY (ADLD). *E. Giorgio[1], D. Robyr[2], M. Spielmann[3], E. Ferrero[1], E. Chromosomal rearrangements with duplication of the lamin B1 gene (*LMNB1*) underlie autosomal dominant adult-onset leukodystrophy (ADLD), a rare neurological disorder in which overexpression of *LMNB1* causes progressive CNS demyelination. However, we previously reported an ADLD family (ADLD-1-TO) without evidence of duplication or other mutation in *LMNB1* despite linkage to the *LMNB1* locus and lamin B1 overexpression. By custom array-CGH, we further investigated this family and report here that patients carry a large (~660 kb) heterozygous deletion that begins 66 kb upstream of the *LMNB1* promoter. Lamin B1 overexpression was confirmed in further ADLD-1-TO tissues and in a postmortem brain sample, where lamin B1 was increased in the cortex but not in cerebellum. Through parallel studies, we investigated both loss of genetic material and chromosomal rearrangement as possible causes of *LMNB1* overexpression, and found that ADLD-1-TO plausibly results from an enhancer adoption mechanism. The deletion eliminates a genome topological domain boundary, consenting normally forbidden interactions between at least three forebrain-directed enhancers and the *LMNB1* promoter, in line with the observed mainly cerebral localization of lamin B1 overexpression and myelin degeneration. This second route to *LMNB1* overexpression and ADLD is a new example of the relevance of regulatory landscape modifications in determining Mendelian phenotypes.

3038T

Analysis of transcriptional regulation by Dentatorubral-Pallidoluysian Atrophy protein (DRPLAp) that acts as transcriptional co-regulator. *K. Hatano[1], H. Date[1], H. Ishiura[1], J. Mitsui[1], J. Goto[1,3], J. Yoshimura[2], K. Doi[2], S. Morishita[2], S. Tsuji[1].* 1) Department of Neurology, Graduate School of Medicine, The University of Tokyo, Tokyo; 2) Department of Computational Biology, Graduate School of Frontier Sciences, The University of Tokyo, Chiba; 3) Department of Neurology, International University of Health and Welfare Mita Hospital, Tokyo.

Background: Dentatorubral-Pallidoluysian atrophy (DRPLA [MIM 125370]) is an autosomal dominant neurodegenerative diseases caused by unstable expansion of CAG repeats in the coding sequence of DRPLA gene (*ATN1*). Previous studies have shown that DRPLA protein (DRPLAp) functions as a transcriptional co-regulator. Its target genes, however, remains unknown. **Purpose:** To determine the target genes regulated by wild type DRPLAp based on expression profiling of RNAs in cultured cells expressing full-length wild-type DRPLAp, and to investigate altered transcriptional regulations exerted by mutant DRPLAp based on comparison of expression profiling of RNAs between cultured cells expressing wild-type DRPLAp and those expressing mutant DRPLAp. **Materials:** HEK293 cell lines which express GFP-fused full-length DRPLA (Q19 or Q88) under the control by Tet (tetracycline) -On/Off system were used (Flp-In T-REx 293 cell). **Methods:** RNA was extracted from the cells at 24 hours after induction of expression by Tet. Strand-specific cDNA libraries were generated from ribosomal RNA-depleted RNA with random primers. Expression profiling was achieved by RNAseq analyses using HiSeq2500. Comparison between Q19 (ON) and Q19 (OFF) (Analysis 1) was performed to investigate the physiological functions of DRPLAp. Altered transcription profiling was analyzed by comparison between Q88 (ON) and Q88 (OFF) (Analysis 2). **Result:** The reproducibility of expression data of all genes analyzed from the cDNA libraries in triplicates were confirmed by Spearman's rank correlation coefficient (rho>0. 98). The number of up- or down-regulated were determined for two independent experiments. Twenty one genes were up-regulated and another set of 21 genes were down-regulated (Analysis 1). In contrast, comparison between Q88 (ON) and Q88 (OFF) revealed that 240 genes were up-regulated, whereas 72 genes were down-regulated (Analysis 2). **Conclusion:** The findings support the functions of wild-type DRPLAp as a transcriptional co-regulator. The findings that a much larger number of genes were up-regulated in cells expressing mutant DRPLAp than that in cells not expressing mutant DRPLAp raises a possibility that mutant DRPLAp with expanded CAG repeats may lead to altered transcriptional regulation relevant to neurodegeneration in DRPLA. Further studies using neuronal cells will be needed to clarify the altered transcriptional regulations in DRPLA.

3039F

SMC1B is present in mammalian somatic cells and interacts with mitotic cohesin proteins. *A. Musio[1], L. Mannini[1], V. Quarantotti[1], C. Amato[1], F. Cucco[1,2], M. Tinti[1], L. Tana[3], A. Cohesin is an evolutionarily conserved protein complex that plays a role in many biological processes: it ensures faithful chromosome segregation upon cell division, regulates gene expression and preserves genome stability. Malfunctioning of cohesin has been linked to human multisystem developmental disorders such as Cornelia de Lange syndrome. In mammalian cells, the mitotic cohesin complex consists of two structural maintenance of chromosome proteins, SMC1A and SMC3, the kleisin protein RAD21 and a fourth subunit either STAG1 or STAG2. Meiotic paralogs in mammals were reported for SMC1A, RAD21 and STAG1/STAG2 and are called SMC1B, REC8 and STAG3 respectively. It is believed that SMC1B is only a meiotic-specific cohesin member, required for sister chromatid pairing and for preventing telomere shortening. Here, we show that SMC1B is also expressed in somatic mammalian cells, in addition to germinal cells. Genome-wide data indicates that cohesin-SMC1B binds to body genes, and in intergenic regions and SMC1B silencing leads to gene expression deregulation. Altogether, our data allows us to hypothesize that SMC1B takes part in transcription regulation.

Motif/Transcription factor prediction of brain expressed HERV-derived transcripts reveals enrichment of biological signature of transcriptional regulation. *G. Guffanti[1], S. Gaudi[2], J. Fallon[3], F. Macciardi[3].* 1) Department of Psychiatry, Harvard Medical School, Boston, MA; 2) Department of Infectious, Parasitic and Immune-Mediated Diseases, Italian National Institute of Health, Rome, Italy; 3) Department of Psychiatry and Human Behavior, University of California Irvine, Irvine, CA.

Background: Human Endogenous Retroviruses (HERVs) can be found embedded in the sequence of other genes, including introns and untranslated regions at either sides of a coding sequence. The vast majority of gene-embedded transposable elements (TE) appear to be harmless, but some of them are able to influence the transcription of their "host" genes. Although the precise mechanisms are yet to be elucidated, the prevailing theory is that gene-embedded TEs ultimately promote transcript diversity. **Objective:** Our aim is to identify biological processes influenced by dorsal-lateral prefrontal cortex (DLPFC) expressed genes containing HERVs within their sequence in a sample of 10 schizophrenia patients and 10 healthy controls. **Methods:** RNA samples were isolated from DLPFC, prepared for sequencing with Trueseq and sequenced on the Illumina HiSeq 2000. Transcripts were determined using Trinity de novo assembly and aligned to the reference genome for sequence homology using BLASTn and Repeatmasker for HERVs family and type assignment. We used iRegulon Cytoscape plugin to infer motif enrichment and prediction of Transcription Factors targeting enriched motifs of DLPFC expressed genes containing HERVs in their sequence (NES > 3). Then we used Reactome Cytoscape plugin to test biological processes enrichment in in each cluster of genes targeted by common transcription factors (TF) (FDR < 10-3). **Results:** Of the 59,258 transcripts with FDR < 1 and FC>2, 4,177 embedded HERVs in their sequence. Through sequence homology analysis, we were able to identify 13,985 genomic regions overlapping reference HERVs. Of these, 7,263 map to at least one protein-coding or RNA gene. iRegulon identified enrichment of three motifs in the 200 KB region at the TSS of the DLPFC expressed genes with HERV embedded in their sequence: ZNF193, LSM6 and MO1102, targeted by the predicted TFs ZSCAN9, SETDB1, TEAD1 and GATA3. Target genes enriched in the complex motif/TF LSM6/ZSCAN9 revealed enrichment of cell adhesion, synaptic transmission and GTPase signal transduction; those in the complex motif/TF ZNF193/SETDB1 revealed enrichment of DNA dependent regulation of transcription. **Conclusions:** Genes harboring HERVs in their non-coding and untranslated regions share common motifs in their promoter regions, which are in turn targeted by common Transcription Factors. Clustering of DLPFC expressed genes based on shared motif/TF allows identifying putative influence on common biological processes.

Post-GWAS identification of a *PRSS1* promoter variant protecting against pancreatitis. *A. Boulling[1,2,3], M. Sato[4], E. Masson[1,5], E. Génin[1], J. M. Chen[1,2,3], C. Férec[1,2,3,5].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U1078, Brest, France; 2) Faculté de Médecine et des Sciences de la Santé, Université de Bretagne Occidentale (UBO), Brest, France; 3) Etablissement Français du sang (EFS) - Bretagne, Brest, France; 4) Section of Gene Expression Regulation, Frontier Science Research Center, Kagoshima University, Kagoshima, Japan; 5) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Régional Universitaire (CHRU) Brest, Hôpital Morvan, Brest, France.

Introduction: Over the past two decades, genetic factors have been increasingly appreciated to play an important role in the etiology of chronic pancreatitis. Recently, a genome-wide association study (GWAS) found that the minor T allele of rs10273639, a common single nucleotide polymorphism (SNP) located 408 bp upstream of the translation initiation codon of the *PRSS1* gene (encoding cationic trypsinogen), was associated with protection against chronic pancreatitis. This protective effect is attributed to a decrease of *PRSS1* mRNA expression within pancreas. However, whether this allele is the causal variant or not remains unknown. **Methods:** The *PRSS1* promoter was sequenced in 287 French individuals of European ancestry to search for SNPs in linkage disequilibrium (LD) with rs10273639. Then, several luciferase reporter constructs were used to assess *PRSS1* promoter activity in AR42J cells treated with dexamethasone. The activity of the *PRSS1* promoter was also validated *in vivo* with a novel technic based on the intra-pancreatic parenchymal injection for gene transfer coupled to luciferase assay. **Results:** Here, we first showed that rs10273639 is in perfect LD with rs4726576, a SNP located 204 bp downstream of rs10273639, in French Caucasians. Employing promoter reporter gene assays in both AR42J cells treated with dexamethasone and in a mouse model, we showed that the proximal region of the *PRSS1* promoter is sufficient to drive basal expression. Then, the use of reporter constructs carrying variations corresponding to the different possible haplotypes provided evidence that only the minor A allele of rs4726576 is able to decrease *PRSS1* expression by altering its promoter activity. **Conclusion:** This result highlighted that it is the minor A allele of rs4726576 that was associated with reduced gene expression and therefore represents the causal variant underlying the GWAS-revealed protective effect. This finding also has implications for risk assessment in different populations, wherein the degree of LD between the two SNPs was found to vary significantly.

3042T

Understanding the regulatory network of chromosome 21 transcription factors. *A. Letourneau[1], G. Cobellis[2], E. Falconnet[1], P. Ribaux[1], C. Gehrig[1,3], M. Guipponi[1,3], C. Borel[1], S. E. Antonarakis[1,3,4].* 1) Genetic Medicine & Development, University of Geneva Medical School, Geneva, Switzerland; 2) Dpt of Biophysics, Biochemistry & General Pathology, Seconda Universita di Napoli, Italy; 3) University hospitals of Geneva, Switzerland; 4) iGE3, Institute of Genetics and Genomics of Geneva, Switzerland.

Down syndrome (DS or Trisomy 21) is most likely the result of a gene dosage alteration. However, uncovering the relationship between the DS phenotypes and the increased expression of candidate genes remains a challenge. We hypothesize that some of the DS-associated abnormalities are caused by the dosage imbalance of chromosome 21 (HSA21) transcription factors (TFs). We thus aimed to comprehensively investigate their potential role in the DS manifestations by revealing 1/ their binding sites and target genes, 2/ their underlying transcriptional regulatory networks and 3/ the complex interplay between them. To this end, we studied 12 relevant TFs encoded on HSA21 (Aire, Bach1, Erg, Ets2, Gabpa, Nrip1, Olig1, Olig2, Pknox1, Runx1, Sim2, 1810007M14Rik) as well as the Hmgn1 DNA binding protein. We used a unique cellular model of mouse embryonic stem (mES) cells overexpressing the Flag-tagged protein under the control of an inducible Tet-off system. For each TF, we combined ChIP-sequencing (3 replicates) and RNA-sequencing assays to identify the DNA binding sites and downstream targets. A pilot study on Sim2 (Letourneau *et al*, 2015) already revealed a list of 1229 high-confidence binding sites and confirmed the role of Sim2 in neuronal processes. More specifically, we will use the same system to investigate the role of Hmgn1 in the genome-wide gene expression dysregulation domains (GEDDs) recently described in trisomic cells (Letourneau *et al*, 2014). Given its role in chromatin modification, we hypothesized that the overexpression of the Hmgn1 DNA binding protein might contribute to the GEDDs pattern. Our preliminary RNA-sequencing analysis revealed that overexpression of Hmgn1 in mES cells induces GEDDs similar to those observed in the Ts65Dn mouse model. The analysis of the Hmgn1 binding profile provides the location of its preferential DNA binding sites and offers more insights into the molecular mechanisms contributing to the GEDDs. Altogether, these results will improve our comprehension of the transcriptional regulatory networks of HSA21 TFs and their role on cellular phenotypes associated with DS individuals.

Developmental expression patterns and alternate splicing of human transcription factors. *K. Siebenthall[1], E. Haugen[1], R. Sandstrom[1], A. Reynolds[1], M. Maurano[1], T. Canfield[1], K. Lee[1], R. Scott Hansen[1], E. Giste[1], S. Vong[1], P. Sabo[1], M. Diegel[1], D. Bates[1], A. Johnson[1], I. Glass[2], R. Kaul[1], J. Stamatoyannopoulos[1].* 1) Genome Sciences, University of Washington, Seattle, WA; 2) Genetics Division, Seattle Children's Hospital, Seattle, WA.

The ~1,600 transcription factors (TFs) encoded in the human genome orchestrate the progression of development, directing gene expression programs that establish the body plan, drive cellular differentiation and organize cellular communities into complex tissues. Most of the human TF repertoire remains functionally uncharacterized. In order to address this deficit, we performed RNA-seq of 15 organs spanning six weeks of human fetal development and examined TF expression patterns across these tissues. We find that 91% of human TFs are utilized during development. While we anticipated uncovering a large cohort of tissue-specific regulators, we instead found the majority of TFs expressed across all organ systems with elevated levels in one or two organs, suggesting that TF stoichiometry plays a role in tissue-specific gene expression programs. Strikingly, each organ uses at least one member of nearly every TF family. A broadly expressed TF may still adopt lineage-restricted roles through the tissue-selective use of alternate splicing. We find widespread alternate splicing among TFs that gives rise to thousands of distinct isoforms, with 14% of TFs expressing a transcript in a tissue-selective manner. Alternate splicing frequently modulates the structural configuration of TFs, including the wholesale removal of DNA-binding and protein-interaction domains. This behavior is especially prominent among the C2H2 zinc-finger family of TFs, which have expanded greatly in the primate lineage. We propose that TF isoforms lacking key structural domains generally serve a dominant-negative function, which can be especially potent in the case of TFs that must dimerize in order to bind DNA. We provide, to our knowledge, the most extensive study to date of TF expression patterns and alternate splicing during human development, resulting in a catalogue of 952 TFs with known or potentially novel roles in organogenesis.

Genetic and epigenetic signatures of gene regulation specific to type 2 diabetes-relevant tissues. *J. P. Didion[1], S. C. J. Parker[2,3], B. N. Wolford[1], J. R. Hyughe[4], R. Welch[2,3], M. R. Erdos[1], P. S. Chines[1], N. Narisu[1], L. J. Scott[4], M. Stitzel[5], M. Boehnke[4], F. S. Collins[1].* 1) NHGRI, Bethesda, MD. , USA; 2) Department of Computational Medicine & Bioinformatics, University of Michigan, Ann Arbor, MI, USA; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI, USA; 4) Deptment of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI, USA; 5) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA.

Multiple tissues are involved in glucose metabolism and the etiology of type 2 diabetes (T2D), including skeletal muscle, adipose, and pancreatic islets. Although hundreds of genetic variants have been associated with T2D and related traits, the tissue-specific effects of those variants are not well understood. To identify gene expression signatures in T2D-relevant tissues, the Finland United States Investigation of NIDDM Genetics (FUSION) Study obtained muscle and adipose biopsies from 278 Finnish individuals, and pancreatic islets from 78 unrelated cadaveric donors. We performed dense genotyping and deep mRNA sequencing on all muscle and islet samples; mRNA sequencing of adipose samples and whole-methylome sequencing of a subset of samples is in progress. In addition, we obtained genotype, RNA-seq and methylation data for T2D relevant tissues (including brain, liver, stomach, small intestine) from published studies and the Genotype-Tissue Expression (GTEx) project. We process all samples using a pipeline for imputation, transcriptome assembly, analysis of differential expression (including allele-specific expression) and splicing. We identify transcripts at the exon, gene, isoform and allelic levels that are enriched in each tissue, including hundreds of apparently novel transcripts. We also identify tissue-specific expression and splicing quantitative trait loci (e/sQTL), and we use reference chromatin state maps to quantify the proportion of e/sQTLs that occur in tissue-specific chromatin states. We have already found significant enrichment of SNPs associated with T2D and related traits in enhancer regions of skeletal muscle and islets. In addition, we will identify sites of differential methylation that are associated with e/sQTLs in a tissue-specific manner (mQTLs), which will suggest specific links between genetic and epigenetic variation in gene regulation. Because we have roughly equal numbers of male and female samples, we will also be able to identify sex-specific effects on expression and methylation. This resource will form the basis for further understanding the role of functional and regulatory variation in the contribution of each tissue to the etiology of T2D.

Polymorphic *Alu* insertions with functional consequences may be the causative variant identified in GWAS. *L. Horvath, J. Steranka, K. Burns.* Pathology, McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

Transposable elements make up the majority of our genome, with the most abundant form being *Alu* interspersed repeats. Ongoing retrotransposition results in polymorphic insertions. Functional consequences of these have not yet been dissected, but insertions can lead to misregulation of nearby genes and altered phenotypes. As a first step to evaluate functional effects of common insertion variants, we focused on *Alu* insertions occurring near regions identified in genome wide association studies (GWAS) as being associated with a disease (p<10-8). A total of 793 polymorphic *Alu* insertions map to regions that are in linkage disequilibrium (LD) with GWAS signals (r2<0. 8). Given that the responsible functional variant has not been identified at most of these loci, the large (>300 bp) *Alu* insertions are attractive candidates. For a GWAS to have successfully identified a causative *Alu*, the insertion should be in LD with the trait-associated SNP (TAS). To measure LD, we genotyped the presence or absence of the *Alu* in reference individuals with known SNP genotypes. To date, 100 have been assayed and 43 insertions are in LD with nearby TASs. We have prioritized functional evaluation to insertions in LD with a TAS and also those mapping to likely regulatory regions based on ENCODE annotations. The potential for *Alu* insertions to alter transcript levels is being evaluated using enhancer assays with luciferase reporters. Comparing *Alu*-containing alleles to alleles without the insertion for over 100 loci, revealed a continuum of effects with significant outliers that up- or down-regulate luciferase activity. To address the mechanism underlying *Alu* sequence directed changes in transcription levels, the isolated effects of *Alu* subfamily consensus sequences were evaluated in this system. Four (4) types of *Alu* sequences altered reporter expression, 3 by upregulating reporter activity and one by decreasing reporter expression. This demonstrates that some *Alu* sequences have the intrinsic ability to alter transcription regulation. Additional candidates are being evaluated, and the mechanism for misregulation will be dissected for the most significant outliers. *Alu* insertions that are in LD with TASs and have functional effects in the reporter assay are especially promising candidates for further study. Our results indicate that *Alu* sequences have strong potential to alter transcriptional regulation and we have genetic evidence that they could contribute to common disease risk.

3046T

Characterization of a Sjögren's syndrome-associated long non-coding RNA at 2p25. 1. *J. A. Ice[1], I. Adrianto[1], H. Li[1,2], A. Rasmussen[1], G. B. Wiley[1], D. U. Stone[2], B. M. Segal[3], N. L. Rhodus[4], L. Radfar[2], J. A. James[1,2], C. G. Montgomery[1], R. H. Scofield[1,2,5], P. M. Gaffney[1], L. F. Thompson[1], A. D. Farris[1], S. Kovats[1], J. D. Wren[1], K. L. Sivils[1,2], C. J. Lessard[1,2].* 1) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) University of Oklahoma Health Sciences Center, Oklahoma City, OK; 3) Hennepin County Medical Center, Minneapolis, MN; 4) University of Minnesota, Minneapolis, MN; 5) US Department of Veterans Affairs, Oklahoma City, OK.

Sjögren's syndrome (SS) [MIM: 270150] is a common autoimmune disorder characterized by immune-mediated exocrine gland destruction and systemic inflammation contributing to clinical heterogeneity. Complex regulatory mechanisms govern these responses, but are poorly understood. In a previous RNA-sequencing (RNA-seq) study, we identified >2,600 differentially expressed (DE) transcripts associated with SS. In this study, we sought to validate, replicate, and functionally characterize one upregulated long non-coding RNA (lncRNA) mapped to chromosome 2p25. 1 to better understand its role in SS pathogenesis. RNA-seq data showed significant upregulation of the 2p25. 1 lncRNA when comparing 27 healthy controls and 57 SS patients [*P*=8. 40x10-7; Fold Change (FC)=2. 54]. Of note, we observed a greater FC and stronger statistically significant DE in anti-Ro(-)/biopsy(+) patients (FC=2. 85, *P*=4. 21x10-6) compared to anti-Ro(+) patients (FC=2. 24, *P*=1. 62x10-4). Technical validation by qPCR confirmed upregulation of the 2p25. 1 lncRNA (*P*=0. 0096), and correlation with RNA-seq results was observed (*r*=0. 869). We next replicated these findings in an independent sample set of 36 SS patients and 21 controls (*P*=0. 0183). Using the bioinformatics tools GAMMA-seq, lncRNA2function, and GeneFriends, we identified co-expression of the 2p25. 1 lncRNA with transcripts in pathways related to T and NK cell signaling and activation. Using only RNA-seq data from anti-Ro(-)/biopsy(+) SS patients, we observed co-expression (*r*>|0. 7|) with >80 transcripts in pathways enriched for IL-12 and IL-2 signaling, immune response and regulation, and NK-T-cell lymphoma, among others. As lncRNAs can be cell-type specific, we assess 2p25. 1 lncRNA expression by qPCR in 9 FACS-isolated immune cell subsets from 2 patients and 2 healthy controls. We identified the strongest expression in CD8+ and CD4+ T cells as well as in CD56dim and CD56bright NK cells. Low expression was detected in CD1c+CD11c+ myeloid DCs, monocytes, and pDCs, but was not detectable in CD141+ myeloid DCs or B cells. We have identified, technically validated, and independently replicated the upregulation of a novel SS lncRNA at 2p25. 1. Furthermore, we have established the high expression of this transcript in CD4+ and CD8+ T cells and NK cells. This study establishes the 2p25. 1 lncRNA as the first associated with SS and lays the groundwork for further functional characterization in the pathogenesis of this complex disorder.

3047F

Using miRNA expression profiling and sparse machine learning methods for diagnostics of inflammatory bowel disease. *M. Huebenthal[1], G. Hemmrich-Stanisak[1], F. Degenhardt[1], S. Szymczak[1,2], Z. G. Du[1], A. Elsharawy[1], A. Keller[3], S. Schreiber[1,4], A. Franke[1].* 1) Institute of Clinical Molecular Biology, Christian-Albrechts-University of Kiel, Kiel, Germany; 2) Institute of Medical Informatics and Statistics, Christian-Albrechts-University of Kiel, Kiel, Germany; 3) Chair for Clinical Bioinformatics, Saarland University, Saarbruecken, Germany; 4) Department of Internal Medicine I, University Hospital Schleswig-Holstein, Kiel, Germany.

The diagnosis of inflammatory bowel disease (IBD) still remains a clinical challenge and the most accurate diagnostic procedure is a combination of clinical tests including invasive endoscopy. In this pilot study we evaluated whether systematic miRNA expression profiling, in conjunction with machine learning techniques, is suitable as a non-invasive diagnostic test for the major IBD phenotypes (Crohn's disease (CD) and Ulcerative colitis (UC)).

Based on microarray technology expression levels of 863 miRNAs were determined for whole blood samples from 40 CD and 36 UC patients and compared to data from 38 healthy controls (HC). To discriminate between disease-specific and general inflammation we included miRNA expression data from other inflammatory diseases (inflammation controls (IC): 24 chronic obstructive pulmonary disease, 23 multiple sclerosis, 38 pancreatitis and 45 sarcoidosis cases) as well as another 70 healthy controls from previous studies. Classification problems considering two, three or four groups were solved using different types of penalized support vector machines (SVMs). The resulting models were assessed regarding sparsity and performance and a subset was selected for further investigation. Measured by the area under the receiver operating characteristic (ROC) curve (AUC) the corresponding median holdout-validated accuracy was estimated as ranging from 0. 75 to 1. 00 (including IC) and 0. 89 to 0. 98 (excluding IC), respectively.

In combination the models provide highly accurate tools for solving different diagnostic problem such as the distinction of CD and UC as well as CD, UC and HC by incorporating not more than 16 distinct miRNAs. Experimentally validated target genes of these miRNAs have been previously described as being related to IBD and show significant enrichment for IBD susceptibility loci identified in earlier genome-wide association studies.

3048T

Identification of novel lincRNAs in human adipose and peripheral blood mononuclear cells. *C. Xue[1], X. Zhang[1], H. Zhang[1], J. Lin[1], J. Ferguson[2], M. Li[1], M. Reilly[1].* 1) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Medicine, Vanderbilt University.

LincRNAs are a class of RNAs involved in various molecular functions and processes. Recent studies have identified lincRNAs across multiple tissues using RNA-seq. The power of lincRNA discovery is often limited by sequencing depth due to low expression of lincRNAs. In the Genetics of Evoked-responses to Niacin and Endotoxemia study, we performed deep RNA-seq of human adipose from 25 subjects and peripheral blood mononuclear cells (PBMCs) from 15 subjects, achieving mean depth of ~350 million and ~220 million 101bp paired-end reads per sample in adipose and PBMCs, respectively. Using *de novo* transcriptome assembly and a stringent filtering pipeline, we identified 270 novel lincRNAs from adipose and 109 from PBMC that have not been annotated in Gencode, RefSeq or previous studies. Analyses of these novel lincRNAs suggest that they are much more tissue specific than coding genes. Some of the most abundant novel lincRNAs were replicated in public RNA-seq dataset in relevant tissues. 44% of adipose novel lincRNAs are syntenic in mouse but only 40% of them have annotated lincRNAs from Gencode M4 in syntenic regions. A similar pattern was observed in PBMC novel lincRNAs. 53% of adipose novel lincRNAs and 26% of PBMC novel lincRNAs overlap predicted enhancers from Roadmap Epigenomics datasets. 20% of adipose novel lincRNAs and 14% of PBMC novel lincRNAs overlap predicted TSS. The pattern of enhancer overlap is similar using the stringent set of lincRNAs from Cabili et al. but the extent of TSS overlap is smaller in our study, which can be explained by the overall low expression level of novel lincRNAs. To gain insight into potential clinical importance of novel lincRNAs, we overlapped these lincRNAs with SNPs associated with cardiometabolic traits (waist-hip ratio adjusted BMI, plasma levels of triglycerides, cholesterol, HDL-cholesterol and LDL-cholesterol, as well as type 2 diabetes and fasting glucose) GWAS public data. Seven novel lincRNAs harbor GWAS significant SNPs within +/- 2kb of the lincRNAs. In 3 cases the top signals are in the lincRNA, not in neighboring coding genes and there is no strong LD between the SNPs in lincRNAs and those in coding genes, suggesting potential roles of these lincRNAs in mediating trait associations. In summary, we have identified and characterized a set of novel lincRNAs in human adipose and PBMC that will facilitate the study of lincRNA functions and their role in cardiometabolic disease.

Differential expression of microRNAs in breast cancer tumors associated to lymph node metastasis. *E. Pérez-Moreno[1], V. Zavala[1], V. Cornejo[2], W. Fernández[2], J. Gamboa[3], M. Carvallo[1].* 1) Department of Cellular and Molecular Biology, Pontificia Universidad Católica de Chile, Santiago, Santiago, Chile; 2) Unidad de Anatomía Patológica, Hospital Clínico San Borja Arriarán, Santiago, Chile; 3) Unidad de Patología Mamaria, Hospital Clínico San Borja Arriarán, Santiago, Chile.

Breast cancer is the most common malignancy in women worldwide and it is responsible for the highest cancer-associated death rates. It is a heterogeneous disease and can be subclassified into several subtypes. Lymph nodes near to the primary breast tumor have an increased chance of developing a secondary tumor, representing one of the first signs of metastasis in breast cancer. The presence of axillary lymph node metastasis is a critical prognostic factor for the application of specific surgical and/or therapeutic strategies, and the amount of positive lymph nodes is known to have an inverse linear correlation with prognosis and survival. MicroRNAs are small non-coding RNAs that are involved in post-transcriptional regulation. Their expression has been frequently described to be altered in different cancer types, including breast cancer. MicroRNAs have emerged as candidate molecular biomarkers and novel therapeutic targets because of their stability, easy detection and ability to regulate a large set of genes that are involved in cancer growth and metastasis. In this work, we analyzed microarray based miRNA expression data to identify microRNAs differentially expressed in primary breast tumors with lymph node metastasis. We extracted total RNA from 31 fresh frozen breast tumors (Invasive Ductal Carcinomas) with different tumor grades (1 to 3). Patients did not receive neoadyuvant chemotherapy. Within the analyzed tumors, 16 were obtained from patients with a detectable lymph node metastasis. Microarray data analyzed using RankProd (R package) revealed 26 microRNAs downregulated in tumors associated with lymph node metastasis ($p<0.05$). Among the identified microRNAs 77% have been previously described to regulate early steps of metastasis in different cancer types, like members of the miR-200 family (miR-200c and miR-141), miR-205 and miR-30a. In addition we found other microRNAs not previously associated with metastasis, like miR-1202 and miR-199a-3p. Our results suggest that downregulation of an important proportion of the identified microRNAs, may lead to an over expression of their target genes in primary breast tumors, inducing a metastatic behavior of tumor cells, promoting invasion and colonization of lymph nodes. In this sense, the loss of expression of these microRNAs may serve as a new biomarker and/or indicator of prognosis in breast cancer patients. Supported by FONDECYT 1120200.

microRNA expression profiling in breast cancer tumors associated to BRCA1 expression. *V. A Zavala[1], P. Gajardo[1], C. Alvarez[1], W. Fernandez[2], V. Cornejo[2], J. Gamboa[3], P. Carvallo[1].* 1) Pontificia Universidad Catolica de Chile, Santiago, Region metropolitana, Chile; 2) Unidad de Anatomía Patológica, Hospital San Borja Arriarán, Santiago, Chile; 3) Unidad de Patología Mamaria, Hospital San Borja Arriarán, Santiago, Chile.

BRCA1 is a tumor suppressor gene which mutations confer high susceptibility to develop breast cancer. In addition, it has been described that 50% of hereditary breast cancer tumors with no germline mutation loss BRCA1 expression, as well as 30% of sporadic breast tumors. In this relation, different somatic events have been described that silence BRCA1 such as promoter hypermethylation and genomic deletions of BRCA1 locus. These mechanisms do not completely explain BRCA1 loss in breast tumors. miRNAs constitute a relevant mechanism in silencing gene expression, since they have been found deregulated in different cancer types. Our aim was to identify miRNAs differentially expressed in tumors with low/absent BRCA1 protein. We isolated total RNA from 36 fresh frozen breast cancer tumors, not selected for family history. miRNA profiling was performed using 8x15K Human miRNA Microarrays (Agilent Technologies). Raw data was background corrected, normalized using quantiles and log2 converted. We considered for analyses only probes with an intensity 10% over the brightness of negative controls. As reference, for expression levels we used a commercial RNA pool derived from normal mammary glands from 5 donors. Differentially expressed miRNAs among BRCA1 positive and BRCA1 negative tumors were detected using RankProd Package in R. Eighteen miRNAs were found upregulated in BRCA1-deficient tumors ($p<0.05$). Prediction analyses using mirWalk revealed eight miRNAs that could regulate BRCA1 expression. In addition, pathway analysis using mirPath showed that one overexpressed microRNA, miR-575, is implicated in the regulation of different cancer pathways such as MAPK and PI3K-AKT signaling and cell cycle pathways. Among the targets described for miR-575 we found: BRAF, E2F2, PIK3CB, FGF1 and MDM2 genes. Interestingly, it has been described that inhibition of PI3K-AKT pathway, through the silencing of PIK3CA or PIK3CB impairs BRCA1 expression and sensitizes breast cancer cell lines to PARP inhibitors. Our results suggest that miR-575 produce an indirect silencing of BRCA1, through the regulation of PIK3CB. In relation to the other miRNAs, mirPath analysis identified different targets associated to secondary metabolic pathways.

Genetic variations within microRNAs and microRNA binding sites influence the risk of Parkinson's disease. *M. Ghanbari[1,2], S. Darweesh[1], H. de Looper[3], A. Hofman[1], M. A Ikram[1], O. H Franco[1], S. J Erkeland[3], A. Dehghan[1].* 1) Department of Epidemiology, Erasmus University Medical Center, Rotterdam, Netherlands; 2) Department of Genetics, School of medicine, Mashhad University of Medical Sciences, Mashhad, Iran; 3) Department of Hematology, Erasmus University Medical Center, Rotterdam, Netherlands.

Recently, a large number of genetic variants and genomic loci contributing to Parkinson's disease (PD) have been identified by genome-wide association studies (GWAS). However, the vast majority of the identified variants are thought to be merely proxies of functional variants and their causal mechanisms remain to be elucidated. MicroRNAs (miRNAs) serve as key post-transcriptional regulators of gene expression and are involved in various biological processes. Here, we hypothesized that variants located in miRNAs and their binding sites could constitute a part of the functional variants associated with PD. First, we examined the association of miRNA-related polymorphisms with PD using data from the thus far largest GWAS on PD. We identified two single-nucleotide polymorphisms (SNPs) in miRNAs that are associated with PD, rs897984 in miR-4519 (*p*-value=1. 34×10-5 and OR=0. 93) and rs11651671 in miR-548at-5p (*p*-value=1. 06×10-6 and OR=1. 09). Second, in silico analysis showed that these variants may affect the processing of the pre-miRNAs. In full agreement, in vitro assays demonstrated reduced levels of the mature miRNAs from the mutant alleles. Third, we determined a number of miR-4519 and miR-548at-5p target genes that may mediate their effects on PD. In addition, we found 34 miRNA binding site-SNPs in the 3'UTR of 14 genes that are associated with PD and that have potential to affect miRNA-mediated regulation of their host genes. This includes rs356165 within the miR-658 target site that may disrupt miRNA-dependent regulation of *SNCA*. By implementing this approach, we further identified four new genes that are potentially associated with PD, including *CTSB*, *HSD3B7*, *IGSF9B* and *STX1B*. Taken together, these findings may improve our understanding of the role of miRNAs in the pathophysiology of PD.

Non-coding RNA dysregulation in schizophrenia patientsobserved in the amygdala region based on RNA-sequencing. *Y. Liu, X. Chang, P. Sleiman, H. Hakonarson.* Center for Applied Genomics CAG, The children's hospital of philadelphia CHOP, Philadelphia, PA.

Schizophrenia (SCZ) is a complex neuronal disease that involves complicated gene networks. The redundancy of the gene networks indicates that many gene combinations have the potentials to cause system dysfunction that manifest as related neuro-behavioral syndromes. Recent studies show that small non-coding microRNA (miRNA) and long non-coding RNA (lncRNA) are important factors shaping those networks that are dynamically regulated by neuronal activation. We selected amygdala brain tissues from 46 human individuals, including 22 SCZ patients and 24 healthy controls, performing RNA sequencing (RNA-seq) for lncRNA detections. 27 individuals (case=13, control=14) were further processed with small RNA-seq platform for microRNA detections. Many SCZ microRNAs have been found to be differentially expressed, including miR-132, miR-212 and miR-34a/miR-34c. A new miR-1307, which is the hot point of SCZ GWAS loci, has been observed to be highly differential expressed in cases and controls. Here we show that two lncRNAs, RP11-677M14. 2 and RP11-724N1. 1, both of which have been associated with SCZ GWAS SNPs and overlapping with SCZ related genes, are also differentially expressed in SCZ compared to control groups.

MicroRNAs signature in PBMCs from first-treated tuberculosis patients in western China and their potential diagnostic role. *M. Shang, X. Hu, Y. Ye, Y. Zhou, J. Zhou, X. Song, X. Lu, M. Kang, Y. Xie, D. Li, C. Tao, L. Wang, B. Ying.* Department of Laboratory Medicine, West China Hospital, Sichuan University, Chengdu, Sichuan, China.

Background: MicroRNAs (miRNAs) are a class of small non-coding RNAs regulated gene expression at the post-transcriptional level. Many studies have investigated role of miRNAs in the biological processes such as cellular differentiation, development, immunity and apoptosis. Methods: To evaluate role of miRNAs in immune responses during tuberculosis infection, we performedmiRNAprofiling inperipheral blood mononuclear cells isolated from first-treated tuberculosis patients and healthy controls via microarray analysis. Then the remarkably differential expressed miRNAs were chosen for further qRT-PCR validation. The receiver operating characteristic (ROC) curve and 95 % confidence intervals (CI) were calculated to evaluate the diagnostic value of the tuberculosis specific miRNAs. Results: 9 differential expressed miRNAs were chosen for qRT-PCR validation. Among these 9 miRNAs, 3 miRNAs (miR-218, miR-29a, and miR-29c) were down-regulated in the patients. In ROC plots, the area under the curve was 0. 756(95%CI: 0. 672, 0. 841) for miR-218, 0. 705(95%CI: 0. 610. 0. 799) for miR-29a and 0. 657(95%CI: 0. 558, 0. 757) for miR-29c. Conclusion: Our study suggests that a combination of 3 PBMCs miRNAs have great potential to serve as non-invasive biomarkers of tuberculosis.

Elucidating the role of miR-29a in fibroproliferative diseases. *T. J. Creamer[1,3], A. Lal[2], D. S. Warren[1].* 1) Surgery, Johns Hopkins University, Baltimore, MD; 2) Center for Cancer Research, National Cancer Institute, Bethesda, MD; 3) Institute of Genetic Medicine, Johns Hopkins University, Baltimore, MD.

MicroRNAs (miRNAs) are important regulators of gene expression that have the capacity to potently influence phenotypic outputs. Accordingly, therapeutic approaches that seek to normalize miRNA expression and function are being actively pursued for a number of human diseases. Fibrosis describes an abnormal accumulation of extracellular matrix (ECM) and is a central pathological component of diseases that affect the heart, liver, lungs and kidneys. Despite significant progress in our understanding of fibroproliferative pathways, organ fibrosis continues to account for a significant fraction of the morbidity and mortality in the developed world with few, if any, effective treatments. Members of the miR-29 family (miR-29a/b/c) are down-regulated in all fibrotic tissues examined to date and have been shown to inhibit the expression of numerous ECM proteins including several collagens, elastin and fibrillin. Consistent with a role for miR-29 as a critical regulator of organ fibrosis, we recently demonstrated that systemic administration of a miR-29 expressing adeno-associated virus (AAV) can prevent and even reverse hepatic fibrosis in vivo. In these studies, AAV transgene expression was limited to hepatocytes with no detectable expression in ECM producing hepatic stellate cells. These observations suggest that the therapeutic benefits of enforced miR-29 expression in fibrotic organs involve more than direct repression of ECM protein synthesis. Therefore, to better understand the miR-29 mediated changes in gene expression that occur within specific cellular compartments of fibrotic organs, we used an unbiased approach to identify miR-29 targets in both HuH-7 (hepatocyte) and LX-2 (hepatic stellate) cell lines. Following the method described by Lal et al. (2011), transfection and subsequent pull-down of a biotinylated miR-29a mimic identified 1644 and 2166 potential mRNA targets in HuH-7 and LX-2, respectively. The lists of enriched transcripts include both established and novel miR-29 targets that function across a variety of cellular pathways including apoptosis, histone modification, and signal transduction. In parallel, we also determined the changes in gene expression in HuH-7 and LX-2 cells exposed to the pro-fibrotic cytokine TGF-b. Together our data provide new insight into the normal and disease associated roles of miR-29 in both epithelial and mesenchymal cellular compartments and inform ongoing efforts to developed effective anti-fibrotic therapies.

Difference in plasma circulating free microRNAs between young and aged mice: A possible contribution of miR-1 on myogenic differentiation under a low temperature condition. *M. Fukuoka, H. Hohjoh.* Department of Molecular Pharmacology, National Institute of Nuroscience, National Center of Neurology and Phychiatry, Kodaira, Tokyo, Japan.

Aging is characterized by a progressive loss of physiological integrity and leads to functional declines in physiology such as a decrease in hearing, visual acuity, muscle strength and memory skills. To see such an aging at a molecular level, we investigated plasma-circulating free microRNAs (miRNAs) between young (6-week old) and aged (2-year old) C57BL6/J mice by means of an expression profile analysis in this study. MiRNAs, which are 21~23-nucleotide-long small non-coding RNAs, function as mediators in gene silencing, and play an essential role in gene regulation by inhibiting translation of messenger RNAs (mRNAs) and by digestion of mRNAs. Recently miRNAs have been found as well in various body fluids including plasma/serum other than inside cells, and such a part of miRNAs are enclosed in extracellular vesicles such as exosomes or associated with RNA-binding proteins, e. g. , Arugonaute2. Such cell-free (extracellular) miRNAs might be implicated in a cell-cell communication and capable of becoming useful biomarkers. From our current expression profiles of miRNAs that were prepared from plasma samples of young and aged mice, the level of miR-1 and miR-133, which are known to be myogenic miRNAs, appeared to be higher in the plasma of young mice than in that of aged mice. In addition, it is noteworthy that young plasma had the potential for inducing myogenic differentiation of mouse C2C12 cells (a myoblast cell line) even under a lower temperature condition (at 30°C). We further investigated the effects of miR-1 and miR-133 on myogenic differentiation of C2C12 cells under a low temperature condition, by examining the expression of *Myogenin* that is a key indicator gene for myogenic differentiation. The results indicated that miR-1 might have the potential for inducing the expression of *Myogenin* even under a low temperature condition. Accordingly, our findings suggested that cell-free miR-1 might contribute to peripheral myogenic differentiation (e. g. , limb muscles) which may occur at a low temperature relative to a core body temperature, and that the reduction of cell-free miR-1 in the plasma of aged mice might be implicated in a decreased muscle mass in aged mice.

3056T

Genomic variation of mouse microRNAs. *I. Hovatta[1,2,3], K. Trontti[1], J. Väänänen[1], K. Icay[3], T. Sipilä[3], D. Greco[4].* 1) Department of Biosciences, University of Helsinki, Helsinki, Finland; 2) Department of Health, National Institute for Health and Welfare, Helsinki, Finland; 3) Research Programs Unit, Molecular Neurology, Biomedicum Helsinki, University of Helsinki, Finland; 4) Unit of Systems Toxicology, Finnish Institute of Occupational Health, Helsinki, Finland.

MicroRNAs (miRNAs) are small non-coding RNAs that function in the post-transcriptional regulation of gene expression. A single miRNA can target hundreds of genes, often within the same biological pathway. Genetic variation within miRNA genes and their putative regulatory regions may affect either the expression level of miRNAs or target gene recognition, thus resulting in phenotypic differences. We investigated systematically genetic variation within the miRNA genes in the mouse genome. We used publicly available dataset of 28 inbred mouse strains, including the most common laboratory and wild-derived strains (http://www. sanger. ac. uk/resources/mouse/genomes/) that are used as models of various human diseases. We performed a genome-wide analysis of SNPs and structural variation within miRNA genes. We observed, as expected, genomic variation occurring less frequently within the miRNA loci compared to the rest of the genome. Furthemore, the seed region, important in the target recognition, harbored less polymorphisms than the rest of the mature miRNA sequence, the pre-miRNA sequence, and the putative promoter region. We next carried out miRNAseq in the hippocampus and frontal cortex tissue of six inbred mouse strains (129S1/SvImJ, A/J, C3H/HeJ, C57BL/6J, DBA/2J, and FVB/NJ). By comparing DNA variation data with miRNAseq data we found consistent RNA editing of three miRNAs. To investigate how RNA editing or SNPs in the miRNA seed region (N=29 seed region SNPs among the six inbred strains) affect their putative mRNA targets, we carried out bioinformatic target predictions using several algorithms with both alternative alleles. As expected, the target sets of the two alternative alleles had minimal overlap. Consequently, the biological processes and pathways potentially regulated by the two miRNA alleles were different asrevealed by theIngenuity Pathways Analysis or DAVID. In conclusion, although mouse miRNA genes are highly conserved, we found a number of seed region SNPs among inbred mouse strainsthat putatively affect which mRNAs the polymorphic miRNAs target. We are currently testing this hypothesis with brain miRNAseq data and in vitro models. This variation likely affect expression levels of numerous genes contributing to the phenotypic differences between the mouse strains. Therefore, inbred mouse strains provide a genetic model system for investigating the effect of genomic variation within the miRNA genes on various phenotypes.

Mitochondrial miRNA profile in mtDNA-less cells. *R. Li[1,4], Y. Peng[1], N. Dasgupta[1], Z. Tan[1], G. Ciraolo[2], D. Daren Wang[3].* 1) Human Genetics, Cincinnati Children's Hosp, Cincinnati, OH; 2) Division of Pathology, Cincinnati Children's Hospital Medical Center, 3333 Burnet Avenue, Cincinnati, OH 45229; 3) Maxillofacial Pathology and Radiology Department, Ohio State University College of Dentistry,304 W. 12th Avenue, Columbus, OH 43210; 4) Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH 45229.

In this report, we investigate the novel regulation mechanism in mtDNA-less 206 -o cells. Very low mtDNA copy in 206 -o cells was identified. But no 13 mitochondria-specific proteins were translated in 206 -o cells. Their mitochondrial respiration complex V, III, II were 86. 5%, 29. 4% and 49. 6% of 143B cells respectively. Complex I and IV were completely loss in 206 -o cells. 206 -o cells depend on non-mitochondrial respiration to generate ATP. Some mitochondrial RNAs including 12S rRNA, COX1, COX2, COX3, ND4 and ND5 were low expression. However, ND1, ND3 and Cyto b were not expressed in 206 -o cells. Unequal transcription of mitochondrial RNAs indicated the posttranscriptional cleavage and processing mechanisms in the regulation of mitochondrial gene expression in 206 -o cells. miRNAs may modulate these mitochondrial RNA expression in these cells. RNA-induced silencing complex (RISC) within 206 -o cell mitochondria indicated miRNAs in 206 -o cell mitochondria. miRNA profile in mtDNA-less 206 -o cells was studied by Next-generation sequencing of small RNAs (sRNAs). Several mitochondria-enriched miRNAs such as miR-181c-5p and miR-146a-5p were identified in 206 -o cell mitochondria. miR-181c-5p and miR-146a-5p had 23 and 19 potential targets on mitochondrial RNAs respectively, and these two miRNAs had multiple targets on mitochondria-associated mRNAs encoded by nuclear genes. These data provided the first direct evidence that that miRNAs were imported into mitochondria and regulated mitochondrial RNAs. Thus, our findings may provide new insights for study regulation mechanism of miRNAs on mitochondrial RNAs, particularly in mtDNA-less cells.

DASHR - Database of small human non-coding RNA. *Y. Y. Leung[1,2], P. P. Kuksa[1,2], A. Amlie-Wolf[3], O. Valladares[1], B. D. Gregory[3,4], L. -S. Wang[1,2,3].* 1) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Penn Institute for Biomedical Informatics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Genomics and Computational Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Biology, University of Pennsylvania, Philadelphia, PA.

Small non-coding RNAs (sncRNAs, <200nts) are key regulators of diverse cellular processes. Although thousands of them are known to be present in the human genome, studies continue to uncover new sncRNAs and many of them still have unknown functions. Recent advances in small RNA-sequencing (smRNA-seq) technology and computational tools allow for the unprecedented discovery and characterization of these sncRNAs in a genome-wide manner. However, it is still a great challenge to study the important and versatile roles of sncRNAs due to a lack of completeannotation and resources. Therefore it is invaluable to have a comprehensive human small non-coding RNA database containing the functions, structural features, and expression profile of these complex sncRNAs genome-wide across various human tissues and cell types. We present and analyze DASHR, the most complete and integrated human sncRNA database to date. We first built our own sncRNA annotation on eight different types of known processed sncRNAs (46,306 in total). We then collected smRNA-seq data from over 30 sources, representing 42 human tissues and cell types from 198 individuals. Using a novel smRNA-seq specific pipeline, we uniformly processed all these data to delineate the expression profiles of all sncRNAs. We catalogued expression profiles of the known sncRNAs and captured 70% of mature and primary miRNAs, 35% of piwi-RNAs, 50% of small cytoplasmic RNAs, 87% of small nucleolar RNAs, 21% of small nuclear RNAs, 86% of transfer RNAs derived sncRNAs, and 45% of transfer RNA fragments. We also found 2,912 novel sncRNAs not present in GENCODE or UCSC. 6%, 20%, 37% and 21% of these novel processed sncRNAs resided within promoters, exonic, intronic and intergenic regions respectively. DASHR represents a searchable comprehensive landscape of processed normal human sncRNAs. In addition to the annotation and sequence information of sncRNAs, we also included their expression profiles across all tissues, secondary structures, as well as statistics calculated to infer the specificity of sncRNA processing. This database is thus a unique resource on individual sncRNAs serving as a starting point for any large scale studies. The DASHR database provides a systematic characterization of human normal sncRNA biology, and informs future disease-related studies seeking to characterize the roles of tissue-specific sncRNAs and non-coding variants. All data is available for download and query atwanglab. pcbi. upenn. edu/DASHR. .

Non-coding transcriptome of the developing mammalian retinal photoreceptors. *L. Zelinger, G. Karakulah, J. W. Kim, H. J. Yang, M. Brooks, V. Chaitankar, A. Swaroop.* Neurobiology, Neurodegeneration & Repair Laborator, NIH-NEI, Bethesda, MD.

Purpose:Only about 2% of the genome encodes for protein-coding transcripts, yet over 80% is actively transcribed. The non-coding transcriptome includes several professional RNA species with wide range of cellular functions. The goals of this study are to identify key long non-coding (lnc) RNAs that are functionally relevant in retinal photoreceptors, the cells responsible for initiating the visual process. Methods:-Photoreceptors were purified from retina of *Nrlp*-GFP and *Nrl*-knock out (KO) *Nrlp*-GFP mice by fluorescence activated cell sorting. We carried out transcriptome analysis of developing and mature photoreceptors using RNA-seq. Data was mapped to GRCm38 and analyzed using the ENSMBL annotation. ChIP-seq experiments were performed using two key photoreceptor transcription factors (TF) NRL and CRX. Weighted correlation network analysis (WGCNA) was performed to predict participation in functioning pathways. High-resolution in-situ imaging was done using the RNAscope kit. Results:We identified 12,448 and 13,333 non-coding transcripts in rod and cone-like photoreceptors, respectively. About 3100 transcripts areprofessional non-coding RNA species, and approximately 40% of these are annotated as lncRNAs, the most abounded group in our data set. In order to identify the key lncRNA associated with photoreceptor function, we used NRL and CRX ChIP-seq data together with differential expression analysis. By implementing this approach, we identified 13 lncRNAs, which are potentially regulated by both NRL and CRX, 13 by CRX alone, and another 14 by NRL. To validate and further investigate these transcripts, we selected 12 lncRNAs for in-situ hybridization experiments. While all lncRNAs showed expression in the photoreceptor layer of the retina, 5 showed especially interesting subcellular localization, (such as near the connecting cilium, or perinuclear). Bioinformatics analysis revealed potential interaction of these lncRNAs with proteins and their participation in functional pathways that included, vision and light perception, chromatin modification and maintenance and establishment of RNA localization. Conclusion:Using a combination of experimental analysis and bioinformatic tools, we have discovered a subset of lncRNAs that appear to play key roles in retinal photoreceptors. Further studies are currently underway to identify the human orthologs of photoreceptor-specific lncRNAs and their relevance, if any, to disease.

Uncovering the mechanisms and the genetics of enhancer transcription activities via population-scale sequencing of nascent RNAs. *H. Kwak, H. M. Kang.* Department of Biostatistics, University of Michigan, Ann Arbor, Ann Arbor, MI.

Histone modification marks, chromatin accessibility, protein binding sites, and methylation profiles expand our understanding of genetic and epigenetic regulation of gene expression. Recently, nascent RNA sequencing implemented by Precision nuclear Run-On sequencing (PRO-seq/PRO-cap) revealed a precise map of enhancer transcription activities, suggesting strong relationship between promoters and enhancers. However, it is still unclear what the impact of genetic variation is on the transcription activity variations and subsequently on the gene expression levels. In addition, it is unclear how to interpret the raw data to precisely infer transcript start sites (TSSs). For example, recently suggested hypothesis of convergent transcription dramatically changes the algorithm to infer TSSs from PRO-cap sequence reads. Here we present a preliminary analysis of the genetic landscape of transcription activity, by sequencing nascent RNAs of lymphoblast cell lines of ~70 individuals with African ancestry. The main goal for our study is to understand the genetic variation of active enhancer transcription, and their relationship with gene expression levels. To infer active transcript start sites precisely without assuming either divergent or convergent transcription models, we developed a novel algorithm that hierarchically clusters the peaks of PRO-cap sequence reads and deconvolutes pairs of sense and antisense peaks using a bipartite graph matching algorithm. Our method allows to infer convergent and divergent transcription activities in an unbiased manner. By the time of the abstract presentation, we plan to perform 'tssQTL' analysis using the inferred interval of transcription site sites in population scale. If there are individual differences in the predicted transcription binding intervals caused by genetic variation, we will be able to identify association between genetic variations and the presence and absence of predicted transcription binding intervals. We will perform genome-wide tssQTL analysis and compare the difference between tssQTL and the landscape of dsQTLs and eQTLs.

3061F

The identification of Carboxy-terminal frameshift mutations and their role in human disease. *J. White[1], Z. Akdemir[1], S. Jhangiani[2], T. Gambin[3], E. Boerwinkle[2,4], R. A. Gibbs[1,2], J. R. Lupski[1,2,5,6], C. M. B. Carvalho[1], Baylor-Hopkins Center for Mendelian Genomics.* 1) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX; 3) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 4) Human Genetics Center, University of Texas Health Science Center at Houston, TX; 5) Texas Children's Hospital, Houston, TX; 6) Department of Pediatrics, Baylor College of Medicine, Houston, Texas.

Nonsense-mediated decay (NMD) is an RNA quality control process by which mutant transcripts containing a premature termination codon (PTC) are actively degraded. However, NMD is sometimes unable to recognize a PTC located at the portion of the transcript encoding the C-terminus of the protein, allowing for the production of a mutant protein product with a large C-terminal aberration. The notion that a proportion of variants escape NMD is important clinically, as some genes only display pathogenesic phenotypes due to a dominant-negative or gain-of-function mechanism and have been demonstrated to alter disease inheritance patterns (e. g. recessive loss-of-function disease resulting from a dominant mutation) and explain allelic affinity in genes with a known disease association. To investigate the frequency of these C-terminal mutational events we examined our in-house cohort of ~5000 exomes. We selected all frameshifting variants located in the final exon plus 200bp upstream in the penultimate exon according to the RefSeq transcripts. All candidates were filtered against exome data in publicly available databases, including the NHBLI Exome Sequencing Project and the Atherosclerosis Risk in Communities Study database. Of the resulting ~2000 unique variants we manually curated those predicted to escape NMD. Our list of variants includes genes where C-terminal truncation has previously demonstrated an altered pathogenesis and the disease state is not a result of haploinsufficiency including *AHDC1, FBN1, DMD* and *DVL1.* We have recently reported the variant alleles in *DVL1* escape NMD and all share an identical PTC within the last exon that creates a mutant DVL1 protein with a large atypical C-terminal peptide tail. This rare mutational mechanism was reported as a common cause of Robinow syndrome likely due to a gain-of-function and/or dominant-negative mechanism (PMID:25817016). Similar to the variants identified in *DVL1*, we have identified greater than 100 candidate variants in multiple affected patients with unsolved exomes that present with overlapping phenotypes, including cohorts of osteoporosis, Robinow syndrome, intellectual disability and multiple eye diseases. Our data show that variants that do not lead to haploinsufficiency contribute to human disease and should be carefully analyzed. We suggest that gain-of-function and dominant-negative mutations are highly under-recognized in genomic analyses and likely result in a wide variety of human disease.

3062T

Spatial and temporal dynamics of epitranscriptome in normal neurodevelopment and fragile X syndrome. *F. Zhang[1], Y. Kang[1], Y. Yue[2], C. He[2], P. Jin[1].* 1) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322; 2) Department of Chemistry, University of Chicago, Chicago, Illinois 60637.

*N*6-methyladenosine (m6A) is the most prevalent internal modification of mammalian messenger RNA (mRNA). This reversible modification can destabilize mRNA, increase translation efficiency, and regulate RNA-protein interactions. However, the role(s) of m6A in neurodevelopment remains unclear. We have found that m6A/A level changed significantly during neurodevelopment, and genes involved in m6A dynamics were differentially expressed during neuronal differentiation, insinuating a potential role for m6A in neurogenesis. To evaluate the spatial and temporal dynamics of m6A during neurodevelopment, we profiled genome-wide m6A sites of four brain regions (cerebellum, cerebrum cortex, hippocampus, and hypothalamus) during neurodevelopment in mouse using anti-m6A immunoprecipitation (MeRIP) followed by high-throughput sequencing. In the combination of four brainregions, 3081 genes (13% of total expressed genes) contain high-confidence (HC) m6A site(s) in their transcripts. In all four regions, the majority of HC m6A sites were near stop codonor in 3'-UTRs, andthemotif[GA]GAC was highly enriched within these sites. Nevertheless, each brain region contained an appreciable number of region-specific HC m6A sites. In cortex,86 transcripts with region-specific HC m6A sites showed 10-fold enrichment for postsynaptic genes ingene ontology analyses(Fisher's Exact test, p=3. 1E-5). Interestingly,one variantof themotif, AGACUG, was prominent only in cerebellum. Transcripts containing this variant displayed a strong correlation with macromolecule metabolic process (p=1. 1E-6). Intriguingly, overlapping analyses revealed that 40% of 842 mRNAs bound by Fragile X Mental Retardation Protein (FMRP) contained HC m6A sites in at least one brain region (3. 0-fold enrichment, p=4. 5E-88), many of which are involved in nervous system development (p=9. 3E-27). Furthermore, transcripts of 27% of 631 autism-related genes (such as NLGN1, NRXN1, BDNF, and UBE3A) contain HC m6A sites in at least one brain region (2. 0-fold enrichment, p=5. 4E-22). Biochemically we have found that FMRP is associated with m6A-binding proteins. Furthermore, using a fly model of fragile X syndrome, we have observed the genetic interaction between *FMR1* and the genes involved inthe m6A pathway. These results together suggest that m6A modification is widespread in the brain transcriptomes, displays spatial and temporal dynamics, and could contribute to the molecular pathogenesis of fragile X syndrome.

3063F

Identification and characterization of genetic determinants of RNA editing in humans. *Y. Z. Kurmangaliyev, S. V. Nuzhdin.* University of Southern California, Los Angeles, CA.

ADAR-mediated adenosine to inosine deamination (A-to-I) is the most common type of RNA editing in metazoans. Inosines form Watson-Crick base pairs with cytosines and can mimic guanosines. Such recoding events may result in alterations of encoded proteins. RNA editing usually affects only a portion of all expressed transcripts and the degree of editing may vary strongly among particular sites. The proper editing profiles are required for function of many human genes, and aberrant editing may result in deleterious phenotypes. Surprisingly, the degree of RNA editing of particular A-to-I sites has been never associated with underlying genetic determinants. In a recent study, we uncovered a novel type of functional genetic variation affecting the editing level of particular A-to-I sites in *Drosophila melanogaster* (Kurmangaliyev et al. , manuscript submitted). We were able to identify putative regulatory variants associated with changes in RNA editing levels (RNA-editing quantitative trait loci or edQTLs).

Here we studied genetic variation in editing of ADAR targets in transcriptomes of 462 individuals generated by the GEUVADIS project. The association analysis allowed us to detect dozens of *cis*-edQTLs associated with altered editing of human A-to-I sites. The analysis was performed separately in the European and African populations, and many of identified associations were replicated in both populations. The overall features of human edQTLs were consistent with observations in Drosophila. Associated variants were enriched near the regulated editing sites. Some of them were associated with editing of several colocalized sites. This is a first study of genetic variation in RNA editing in humans. We characterize a novel type of functional genetic variation affecting human transcriptomes. Similar to studies on expression and splicing QTLs, characterization of edQTLs will greatly expand our understanding of gene regulation. Another intriguing question raised by these findings is the contribution of a novel functional variation to human diseases and other phenotypic traits.

***MTO1* inhibition impairs mitochondrial and cellular function in human cell lines.** *C. Chen, ZW. Gao, Y. Chen, MX. Guan.* Institute of Genetics, Zhejiang University, Hangzhou, Zhejiang, China.

Mitochondria are essential organelles of cells considering their major function in ATP production through the process of oxidative phosphorylation. An efficiently functional mitochondrion requires active interplay between nuclear and mitochondrial genomes. Accumulating evidence suggests various types of posttranscriptional modifications are indispensable for the survival of cell. The human *MTO1* gene encodes a highly conserved protein which plays a key role in mitochondrial translation and further in mitochondrial respiration. Multiple mutations of *MTO1* have been reported to be associated with hypertrophic cardiomyopathy and lactic acidosis. To investigate the molecular mechanisms underlying the mitochondrial disorders associated gene, we established *MTO1* knocking down cell lines using lentiviral vectors conveying sequence-specific short hairpin RNA. A significant decrease of the mitochondrial protein level was observed in the knocking down cell lines when compared to the negative controls, suggesting impaired mitochondrial functions. In addition, we found that there was anapproximate20% decrease in mitochondrial ATP production relative to total ATP production, and the JC-10 assay revealed a marked decline in mitochondrial membrane potential. Furthermore, using a seahorse extracellular flux analyzer, we showed reduced oxygen consumption rates in the knocking down cells. These data highlight the cellular function of *MTO1* and provide new insights into further understanding of pathogenesis of *MTO1* related diseases.

3065F

Analysis of RNA editing in non-human primates. *M. Bozinoski[1,2], C. E. Mason[2].* 1) Pharmacology Dept , Weill Cornell Graduate School of Medical Sciences, New York, NY; 2) Physiology and Biophysics Dept , Weill Cornell Graduate School of Medical Sciences, New York, NY.

Adenosine deaminases acting on RNA (ADAR) enzyme mediated RNA editing is the prevalent form of post-transcriptional modification in higher organisms. Deamination of Adenosine creates Inosine, which is recognized as Guanosine by both ribosome and spliceosome thereby causing changes in the coding sequence, splicing and miRNA binding. RNA editing is mostly primate specific phenomenon and few studies of limited scope have shown that humans possess more editing sites than other primates. Here, we present the topology and extent of RNA editing throughout the transcriptome of 12 species of non-human primates from our Non-Human Primate Reference Transcriptome Resource (NHPRTR), including great apes, old world monkeys, new world monkeys and prosimians, spanning approximately 70 million years of primate evolution. Using a robust pipeline to resolve the bona fide RNA editing sites, we analyzed a dataset consisting of RNA-Seq data from 21 polled tissues for each of the 12 primate species/subspecies, supplanted by data from genomic DNA sequencing for all of the animals used to obtain theRNA-Seq data. Our results show that primates show less RNA editing than humans, with baboon, gorilla and chimp showing 19. 7% 13. 4% and 12. 1% less editing sites respectfully, perfectly fitting within the phylogenetic tree. Since RNA editing is a tissue-specific phenomenon, we extended our analysis of RNA editing in tissue specific manner, using data from 14 separate sequenced tissues from 10 primate species. By expanding the analysis in tissue-specific manner, we identify most of the RNA editing events to be within the central nervous system. Additionally, we observe distinct conservation of RNA editing sites throughout the different brain regions, with primate species phylogenetically closest to human showing more human-like distributions. Assessment of the topology of identified RNA editing sites in non-human primates, revealed a surprising portion of the edited sites (up to 20%) being in non-coding transcripts, thereby implicating a broad regulatory role for RNA editing. Further analysis of the editing sites in the coding regions of the transcripts show that edited codons are much more likely to be non-synonymous than synonymous (4:1 ratio), further more stressing the importance of RNA editing as a transcriptome (and, subsequently, proteome) diversification mechanism.

Alternative promoter usage in *STK39* leads to distinct transcripts with human-specific 5'UTRs but identical protein isoforms as in mice. *Y. Chang, C. Mercado, X. Wang.* School of Medicine, University of Maryland, Baltimore, MD 21201, USA.

STK39 encodes a serine threonine kinase, SPAK, that plays a crucial role in maintaining blood pressure through the strict regulation of salt reabsorption along the distal convoluted tubule (DCT) and the thick ascending limb (TAL). SPAK is part of a network of kinases (including WNKs and OSR1) and bumetenide- and thiazide-sensitive ion cotransporters (NKCC2 and NCC, respectively). Environmental stressors such as hypovolemia activate WNK kinases to phosphorylate SPAK and OSR1, which in turn phosphorylate NKCC2 and NCC to allow for the influx of extracellular Na+ and Cl- into renal epithelial cells. In mice, *STK39* undergoes alternative promoter usage and splicing, which results in numerous functionally distinct protein isoforms that have been well characterized. These include the full-length protein (63 kDa) and two shorter isoforms that are both kidney specific; a 50 kDa isoform known as SPAK2 (start codon in exon 2) that lacks part of the kinase domain, and a 38 kDa isoform known as KS-SPAK (start codon in exon 6) that lacks the entire kinase domain. Both isoforms are more abundant within the mouse TAL, whereas full-length SPAK is highly expressed within the DCT, and they both function to inhibit phosphorylation of NCC and NKCC2 by full-length SPAK. However, the existence of orthologous SPAK isoforms (SPAK2 and KS-SPAK) in human kidney, and the role of SPAK in nephron-segment-specific regulation of NCC and NKCC2, still have not been determined. In this study, we performed RNA-seq and 5'RACE to analyze the human and mouse kidney transcriptomes. This approach has led to the discovery of several human-specific *STK39* alternative transcripts, including those with novel alternative start sites and splicing of exon 13, all of which have been confirmed by RT-PCR. Interestingly, while the human and mouse transcript homologs have distinct transcription start sites and 5'UTRs, the resulting human protein isoforms are nearly identical to what was found in mice. In contrast to mouse SPAK homologs, the respective human SPAK isoforms are not kidney specific, yet they exhibit differential expression across tissues. Examining promoter signatures and functional significance of these isoforms will provide a deeper understanding of how *STK39* may have evolved differently between mice and humans, and how human SPAK isoforms may achieve effective blood pressure control.

Exploration of RNA editing sites in human retina and retinal pigment epithelium-choroid-sclera. *D. Cho[1], K. Kazmierkiewicz[1,2], M. Li[3], D. Stambolian[1].* 1) Department of Ophthalmology, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA; 2) Bioinformatics Core, Memorial Sloan Kettering Cancer Center, New York, NY, 10065, USA; 3) Department of Biostatistics and Epidemiology, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104, USA.

RNA editing is the post-transcriptional modification that involves the alteration of a nucleotide. The most common form of RNA editing is adenosine-to-inosine (A-to-I) where the inosine is translated as guanine by ribosomes. Recent studies have shown that diseases are correlated with A-to-I RNA editing such as glaucoma, diabetes, psychiatric disorders, and neurological disorders. In this study, RNAseq was performed on eight human post-mortem eyes to look for known and novel A-to-I RNA editing sites. REDItools was used to computationally predict significant editing sites using Fisher Exact Test and FDR correction ($p < 0.05$). Known single nucleotide polymorphisms from dbSNP, 1000Genomes, and SeattleSeq were removed to lower the possibility of finding a false positive editing site. After a preliminary list of predicted A-to-I editing sites was produced, BLAT was used to confirm the original GSNAP alignment that further filtered the predicted editing sites. After processing, the RNA editing sites were annotated and quantified between locations (macular versus peripheral) and tissues (retina versus RPE-choroid-sclera). 1,327 editing sites were found in the macular retina and 682 editing sites were found in the macular RPE-choroid-sclera while 1,174 editing sites were found in the peripheral retina and 885 editing sites were found in the peripheral RPE-choroid-sclera. For each tissue-location, 6-15% of the predicted editing sites were known from the DARNED database and 20-31% of the editing sites were located within protein coding genes. At least one editing site was found within genes associated with age-related macular degeneration, refractive error, and primary open angle glaucoma. From the analysis, our pipeline was successful in confirming previously known A-I editing sites while discovering possible novel A-I editing sites. Validation of these novel RNA editing sites will also be presented.

Global binding map of the splicing regulatory factor SRSF5. *G. H. Bruun[1], T. K. Doktor[1], A. Masuda[2], A. R. Krainer[3], K. Ohno[2], B. S. Andresen[1].* 1) Biochemistry and Molecular Biology (BMB), University of Southern Denmark, Odense, Denmark; 2) Division of Neurogenetics, Center for Neurological Diseases and Cancer, Nagoya University Graduate School of Medicine, Nagoya, Japan; 3) Cold Spring Harbor Laboratory, PO Box 100, Cold Spring Harbor, NY 11724, USA.

mRNA splicing is a fundamental process required for correct gene expression of most protein coding genes. One prominent group of splicing regulatory proteins, the SR proteins, binds splicing regulatory elements (SREs) in a sequence-specific way to enhance exon inclusion. Thus, SNPs and mutations that affect SREs may disrupt splicing, and an increasing number of human diseases are now known to be caused by aberrant splicing. However, the specific binding motifs are not precisely defined for most splicing regulatory proteins, and maps of their location, as part of SREs in human disease genes, are missing or sparse. To unravel the regulatory landscape of splicing and to predict potential pathogenic consequences of disease-associated sequence variations it is important to precisely identify the binding sites of splicing regulatory factors. We used iCLIP (Individual nucleotide-resolution Crosslinking and Immunoprecipitation) to identify the transcriptome-wide binding sites and derive *in vivo* binding motifs of the SR protein SRSF5. We used HeLa cells expressing T7-tagged SRSF5 and performed UV-crosslinking to induce covalent bonds between SRSF5 and RNA. After immunoprecipitation and removal of the crosslinked protein by proteinase treatment, the RNA was eventually used as a template for cDNA synthesis and PCR. The amplified products were then subjected to next-generation sequencing and analyzed. We identify approximately 20,000 SRSF5 binding sites across the transcriptome, and their distribution correlates with the predicted roles of SRSF5 in mRNA splicing. As an example, we find that a previously reported pathogenic mutation, shown to cause skipping of *IVD* exon 2, disrupts SRSF5 binding, suggesting that this may be the cause of exon skipping. To further elucidate the roles of SRSF5 in mRNA splicing, we performed siRNA-mediated knockdown in HeLa cells followed by RNA-seq analysis. This suggested that SRSF5 regulates splicing of other splicing regulatory proteins, such as *MBNL1* exon 5 and *PTBP2* exon 10, and thus that SRSF5 may both directly and indirectly affect mRNA splicing. Generation of the *in vivo* SRSF5 binding map will enable identification of *in vivo* targets, and in combination with the *in vivo* binding motifs, this will help pinpoint genetic variants that may cause aberrant splicing.

Sex Chromosome Dosage and the Human Transcriptome: A Study of XO, XX, XXX, XY, XXY, XYY and XXYY Karyotypes. *A. Raznahan[1], N. Parikshak[2], V. Chandran[2], F. Gao[2], J. Blumenthal[1], L. Clasen[1], A. Alexander-Bloch[1], A. Zinn[3], D. Wangsa[4], D. Murphy[5], P. Bolton[5], T. Ried[4], G. Coppola[2], J. Ross[7], J. N Giedd[6], D. H. Geschwind[2].* 1) Developmental Neurogenomics Unit, Child Psychiatry Branch, NIMH Intramural Research Program, NIH, Bethesda, MD; 2) Neurogenetics Program, Department of Neurology and Center for Autism Research and Treatment, Semel Institute, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA, USA; 3) McDermott Center for Human Growth and Development and Department of Internal Medicine, University of Texas Southwestern Medical School, TX, USA; 4) Genetics Branch, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD, USA; 5) Institute of Psychiatry, Psychology and Neuroscience, King's College London, University of London, UK; 6) Department of Psychiatry, UC San Diego, La Jolla, CA, USA; 7) Department of Pediatrics, Thomas Jefferson University, Philadelphia, PA, USA.

A key question in the basic biology of sex-differences has received little direct empirical study in humans: how does sex chromosome dosage (SCD) influence the expression of sex chromosome and autosomal genes? Here, we address this question using oligonucleotide microarrays to profile gene-expression in lymphoblastoid cell lines from 68 participants across 7 SCD groups: XO, XX, XXX, XY, XXY, XYY, and XXYY. First, we show that agnostic clustering of X- and Y-chromosome genes based on their expression change across groups recovers four gene clusters with differing dosage sensitivity: pseudoautosomal region (PAR) genes, Y-linked genes, X-linked genes that escape X-inactivation (XCIE) and X-linked genes that undergo full inactivation (XCI). However, contrary to expectations, expression of the XCI cluster reduces with increasing X-chromosome count. We validate these findings by bioinformatic comparison with prior evolutionary and epigenetic data, and qtPCR measures of gene expression in an independent sample of ~400 individuals. Second, by surveying expression changes across the genome we show that the total number of differentially-expressed genes is greatest with the lack of an X-chromosome in females (>2000), intermediate with additional copies of an X in males (>200), and smallest with additional copies of an X in females or a Y in males (>20) – reflecting that fact that gonadal sex and/or Y-chromosome status can modify the impact of altered X-chromosome dosage on autosomal gene expression. However, lack of an X in females, and presence of an additional Y in males, induce highly correlated expression changes in autosomal genes – suggesting that X-Y homologous genes and/or epigenetic mechanisms may mediate SCD effects on autosomal gene expression. Finally, Weighted Gene Co-Expression Network Analyses identify two anti-correlated sets of gene modules that show opposing relationships with X-chromosome dosage:(i) DNA replication and cell-cycle control modules enriched for XCIE genes (greater module expression with greater X-chromosome count), (ii) apoptosis and oxidative phosphorylation modules enriched for XCI genes (reduced expression with increasing X count). Strikingly, these two sets of counterpoised SCD-sensitive gene networks both show binding site enrichment for the dosage sensitive X-linked zinc-finger protein transcription factor gene ZFX. Our findings shed new light on basic sex chromosome biology, and clinical aspects of sex chromosome aneuploidy.

Transcriptional consequences of 2q23. 1 deletion syndrome in iPSC-derived neural progenitor cells provide insight into neurodevelopmental disorders and autism. S. V. Mullegama1, S. R. Williams2, J. T. Alaimo1, L. Chen1,3, F. J. Probst1, C. Haldeman-Englert4, J. W. Innis5, P. Stankiewicz1, S. W. Cheung1, T. Ezashi6, S. H. Elsea1. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, One Baylor Plaza, Houston, TX, 77030, USA; 2) Center for Public Health Genomics, University of Virginia, Charlottesville, VA 22902, USA; 3) Department of Cellular and Genetic Medicine, School of Basic Medical Sciences, Fudan University, Shanghai 200032, China; 4) Fullerton Genetics Center, Asheville, NC 28803; 5) Departments of Human Genetics and Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI 48109, USA; 6) Division of Animal Sciences, University of Missouri, Columbia, Missouri 65211, USA.

2q23. 1 deletion syndrome (2q23. 1 del) is a neurodevelopmental disorder in which haploinsufficiency of *MBD5* is responsible for the core phenotype, which includes intellectual disability (ID), autism spectrum disorder (ASD), seizures, speech impairment, motor delay, and sleep and behavioral problems. To comprehensively understand the molecular role of *MBD5* in early neuronal development, the 2q23. 1 del phenotype, and ASD, we generated neural progenitor cells (NPCs) derived from induced pluripotent stem cells (iPSCs) that originated from 2q23. 1 del and age/sex-matched control fibroblasts and performed transcriptome profiling by RNA-sequencing. Overall, 300 transcripts were differentially expressed as a consequence of reduced *MBD5* dosage using Benjamini-Hochberg FDR (q<0. 05) analysis. Our transcriptome profile through DAVID was enriched for neuronal development (P=0. 0002), neuronal migration (P=0. 0001), and neurogenesis (P=0. 00001). IPA identified a strong statistical enrichment for pathways, including PTEN (P=0. 0003) and WNT signaling (P= 0. 003), which are critical contributors to neural stem cell and nervous system development. We identified genes within our profile that are implicated in phenotypes present in 2q23. 1 del patients including ID (*FMR1*), seizures (*SEZ6*), speech impairment (*FOXP2*), motor delay (*NR4A2*), and behavioral problems (*ARTNL, HTR1B*). Interestingly, 30% of our differentially expressed genes are associated with ASD as defined by the Simons Foundation and AutismKB and are involved in essential cellular processes crucial in ASD pathogenesis including transcriptional regulation (*MEF2C*, *FOXG1, NFIA*), chromatin modification (*CDH8, SIX1*, *MEOX1*), and neuronal function (*NTNG1*, *GRIK2, LAMC3*). In addition, when *MBD5* is haploinsufficient, genes involved in phenotypically similar ASDs such as 5q14. 3 deletion syndrome (*MEF2C*) and congenital variant of Rett syndrome (*FOXG1*) were dysregulated, suggesting that these genes function in a transcriptional cascade of common biological networks that result in overlapping phenotypes. To identify possible novel deletion disorders, we queried our top 50 MBD5-down regulated genes, which were not linked to ASD or OMIM disorders, through genome-wide aCGH databases and identified 17 candidate genes as possible disease causing genes. Overall, we demonstrate the multifactorial role of MBD5 in the regulation of genes and pathways known to contribute to the genetic architecture of neurodevelopment and disease phenotypes.

Gene expression analysis of chitinase-like protein, YKL-40, with mammalian chitinases using qPCR in normal human tissues. *M. Ohno[1,2], Y. Kida[1], M. Sakaguchi[1], Y. Sugahara[1], F. Oyama[1].* 1) Department of Chemistry and Life Science, Kogakuin Univ, Hachioji, Tokyo, Japan; 2) Research Fellow of Japan Society for the Promotion of Science (DC2), Chiyoda-ku, Tokyo, Japan.

Humans express two active chitinases, chitotriosidase (Chit1) and acidic mammalian chitinases (AMCase) and also express chitinase-like proteins (CLPs), which are structurally homologous to chitinases but lack the ability to degrade chitin. Humans produce primarily YKL-40 (CHI3L1 or human cartilage glycoprotein-39). YKL-40 levels have been reported elevated in patients with asthma, cystic fibrosis, rheumatoid arthritis and malignant tumors. However, expression levels of YKL-40 have not been compared with those of chitinases and housekeeping genes in normal human tissues. Recently, we established a quantitative real-time PCR (qPCR) system using a single standard DNA molecule to quantify multiple genes. Here, we quantified the YKL-40 mRNA levels and compared them with two chitinases, Chit1 and AMCase, and housekeeping genes in normal human tissues using qPCR system with the standard DNA. We found that YKL-40 mRNA was widely expressed in human tissues. The highest levels of YKL-40 mRNA were detected in human liver, followed by the kidney. In the kidney and liver, YKL-40 levels were more than 100-times higher than Chit1, while being lower than the levels of GAPDH and β-actin. The data presented here can be considered as fundamentals for understanding the biological roles of YKL-40 and mammalian chitinases upon pathological human tissues changes.

3072T

Positional coding and noncoding transcriptomes of synovial fibroblasts in joint specific patterns of arthritis. *G. Russo[1], M. Frank-Bertoncelj[2], M. Trenkmann[2], M. Armaka[3], A. Bratus[1], C. Kolling[4], B. A. Michel[2], R. E. Gay[2], C. D. Buckley[5], G. Kollias[3], S. Gay[2], C. Ospelt[2].* 1) Functional Genomics Center Zurich - ETH/UZH, Zurich, Switzerland; 2) Center of Experimental Rheumatology, University Hospital Zurich, Switzerland; 3) Institute of Immunology, Biomedical Sciences Research Center Alexander Fleming, Vari, Greece; 4) Schulthess Clinic Zurich, Switzerland; 5) Center for Translational Inflammation Research, University of Birmingham, UK.

BackgroundMolecular mechanisms underlying differential topographic susceptibility of the joints to rheumatoid arthritis (RA) are unknown. Positional expression of Hox genes along body axes regulates limb development. Adult skin fibroblasts retain the positional embryonic Hox code and exhibit major differences in transcriptome, defining their unique positional identities. **Objectives**We hypothesize that synovial fibroblasts (SF), which locally drive joint destruction in RA, show positional gene expression patterns predisposing joints to certain pathologies. **Methods**SF were isolated from RA and osteoarthritis metacarpophalangeal (MCP), shoulder and knee joints, healthy human knees, and front paws, ankles and knees of wild type and TNFα transgenic arthritic C57BL/6 mice. RNA was extracted from the human samples (n=21)and sequenced. Hierarchical clustering, pathway analysis and qPCR analysis followed. Positional epigenetic regulation and function of HOTAIR were studied in SF treated with TNFα or silenced for HOTAIR by chromatin immunoprecipitation, qPCR and ELISA. **Results**Clustering of the transcript abundances for human SFreflectedthe location rather than disease groups. Small noncoding RNA conferred the strongest positional identity by clustering 21 out of 21 SF into groups accurately reflecting their joints of origin. Conversely, clustering based on the expression of long noncoding RNA and mRNA suggests that, at least in SF, these transcripts are less joint-specific during the course of the arthritis. Several arthritis-relevant pathways, such as chemotaxis, cell adhesion and the Jak-Stat inflammatory pathway were enriched in a joint-specific manner. In particular, matrix-degrading pathways were enriched in MCP compared to knee SF. Hox-residing RNA exhibited strict positional pattern in human and mouse. TNFα significantly repressed HOTAIR levels in SF. Repression of HOTAIR in anterior and TNF treated SF coincided with enrichment of H3K27me3 repressive histone mark at the HOTAIR promoter. Basal and TNFα-induced production of matrix metalloproteinases 1, 3, 13 and 14 was significantly enhanced in HOTAIR-silenced SF. **Conclusion**Large positional differences in the transcriptome of SF suggest that functionally unique SF subsets populate different joints. The existence of an epigenetically imprinted positional “risk” signatures of SF, like positional HOTAIR expression, may confer certain jointsgreater susceptibility to develop destructive arthritis, such as RA.

Systematic identification of cancer-testis genes in 20 cancer types: a source of epi-driver genes. *Z. Hu, C. Wang, Y. Gu, K. Zhang, K. Xie, M. Zhu.* Department of Epidemiology and Biostatistics, School of Public Health, Nanjing Medical University, Nanjing, Jiangsu, China.

Cancer-testis (CT) genes represent similarity between the process of spermatogenesis and tumorigenesis, and are conventionally considered as targets of anticancer vaccines. We integrated transcriptomics data from several large databases (e. g. , GTEx, TCGA, HPM, FANTOM, ENCODE etc.) and systematically identified 881 novel CT genes in 20 cancer types and explored their relation with testis-specific regulatory elements. We proposed extremely highly expressed CT genes (EECTGs) as potential epi-drivers and found mutually exclusive associations between EECTGs and somatic mutations in significantly mutated genes, such as *PIK3CA* in breast cancer. We also provide evidence that promoter de-methylation and close non-coding RNAs (namely, CT-ncRNAs) may be two reactivation mechanisms of EECTGs. In vitro or In vivo experiments further proved that two newly identified EECTGs (*LIN28B* and *MEIOB*) and their nearby CT-ncRNAs played a crucial role in tumorigenesis. Therefore, our findings provide new perspectives for identifying epi-driver genes of cancer.

Genome specific transcriptional signatures predict differentiation biases in Human ES/IPS cells. *G. Stein-O'Brien[1,2], A. Jaishankar[1], S. Suel-Kee Kim[1], S. Seo[1], J. Heon Shin[1], D. Hoeppner[1], J. Chenoweth[1], T. Hyde[1], J. Kleinman[1], D. Weinberger[1], E. Fertig[3], C. Colantuoni[1], R. McKay[1].* 1) McKusick-Nathans Inst of Genetic Medicine, JHMI Baltimore, MD; 2) Lieber Inst For Brain Development, Baltimore, MD; 3) Oncology Dept, Biostatistics and Bioinformatics Div, JHMI, Baltimore, MD.

Predicting the effect of an individuals genetic background is key to advancing personalized medicine. To capture the mechanisms by which these effects emerge, time-course data of the transcriptome in human ES/IPS cells during pluripotency and differentiation conditions from numerous backgrounds was collected. Novel whole-genome Coordinated Gene Activity in Pattern Sets (CoGAPS) analysis of this RNA-seq data clearly separated shared developmental trajectories from unique transcriptional signatures for each individual's genome. These signatures were able to identify their respective donors in data from multiple tissues and across technical platforms, including RNA-seq of port-mortem brain, micro arrayed embryoid bodies, and publicly available datasets. Further analysis of these signatures found they were predictive of lineage biases during neuronal differentiation. Individuals whose signatures had high rankings of OTX2 and SOX21 also had enhanced induction of markers of telecephallic precursors (i. e. PAX6, WNT1). Conversely, signatures with enrichment of retinoic acid responsive genes (p<1E-5) corresponded to enhanced induction of hindbrain markers including HOXB1 and HOXB4 as well as OLIG2 positive cells. Further, lineage biases were consistent with early differences in morphogenetic phenotypes within monolayer culture, thus, linking transcriptional genomic signatures to stable quantifiable cellular phenotypes. Interestingly, matched single nucleotide polymorphisms (SNP) and RNA-seq from the Lieber Post-mortem Brain Collection indicate that relatedness of any two individuals transcriptional signature is independent of the race of the individuals. As many complex diseases are often attributed to the 70-90 percent of human variation found within race, the identification of signatures that define the functional rather than physical background of an individual's genome has the potential to profoundly influence understanding of human disease. For example, the relationship between pathway enrichment in these transcriptional signatures and drug response differences between individuals IPS cells may prove powerful for optimal patient stratification in clinical trials. .

RNAseq based microRNA and transcriptome profiles of the rat hippocampus. *A. Matos[1], A. Vieira[1], A. Canto[1], K. Brumatti[1], C. Rocha[1], B. Carvalho[1], V. Pascoal[2], R. Glioli[1], I. Lopes-Cendes[1].* 1) UNICAMP, Campinas, Brazil; 2) UFF, Nova Friburgo, RJ, Brazil.

Gene expression can be regulated by microRNAs and they are important in many key biological functions. It has been demonstrated that different microRNAs may have different expression pattern in different brain regions. The hippocampus is functionally highly heterogeneous and it is likely to present different pattern of gene expression in different subfields. RNAseq-based transcriptome analyzes offers the possibility of accurate profiling global gene expression. The aim of this study was to analyze and correlate microRNA and transcriptome profiles in different regions of the hippocampus: Dentate Gyrus (DG), CA1, CA2 and CA3 subfields. Five male Wistar rats were euthanized and the brains were processed for laser microdissection using Zeiss PALM LCM. DG, CA1, CA2 and CA3 were collected from each rat, total RNA was extracted, and libraries were prepared for total RNA and small-RNA sequencing in an Illumina Hiseq platform. Sequences were aligned and quantified with the TopHat/DESeq2 pipeline for total RNA and bowtie/DESeq2 for small-RNA. Gene Onthologies, molecular networks and gene interactions were analyzed with the MetaCore® software. The miRNA target was analyzed by miRWalk® software. A total of 63 miRNAs and 4693 genes were found to be differentially expressed (p<0,05) when comparing CA1 with DG. In CA2, 131 miRNAs and 5819 genes were differentially expressed in comparison with DG. In CA3, 96 miRNAs and 6331 genes were found to be differently expressed. Furthermore, when comparing CA2 to CA1, 54 miRNAs and 2645 genes; CA3 to CA1, 48 miRNAs and 4096; and CA3 to CA2, 38 miRNAs and 1744. Enriched gene ontology categories identified miRNAs involved in p53 signaling, immune response IL-10 signaling pathway, microRNA-dependent inhibition of epithelial to mesenchymal transition. For transcriptome data, the networks were involved in receptor-mediated axon growth repulsion, epidermal growth factor receptor signaling pathway, synaptic vesicle fusion and recycling in nerve terminals. Overall, the most activated genes were regulated by miR- 204, 205, 652, 187, 204, 532-3p, 873, 652, 34b and 375. The present data indicates a large spatial heterogeneity in gene and microRNA expression in the rat hippocampus subfields. A better understanding of such variability may improve our interpretation of the molecular mechanisms involved in normal and pathological conditions related to the hippocampus, such as epilepsy and Alzheimer´s disease. Supported by CEPID-BRAINN, FAPESP.

Integrative analysis of RNA, translation and protein levels reveals distinct regulatory variation across humans. *C. Cenik[1], E. Sarinay Cenik[1], G. W. Byeon[1], F. Grubert[1], S. I Candille[1], D. Spacek[1], H. Tilgner[1], C. L. Araya[1], H. Tang[1], E. Ricci[2], M. P. Snyder[1].* 1) Department of Genetics, Stanford University School of Medicine, Stanford, CA; 2) Université de Lyon, Lyon, France.

Elucidating the consequences of genetic differences between humans is essential for understanding phenotypic diversity and personalized medicine. Although variation in RNA levels, transcription factor binding and chromatin have been explored, little is known about global variation in translation and its genetic determinants. We used ribosome profiling, RNA sequencing, and mass spectrometry to perform an integrated analysis in lymphoblastoid cell lines from a diverse group of individuals. We find significant differences in RNA, translation, and protein levels suggesting diverse mechanisms of personalized gene expression control. Combined analysis of RNA expression and ribosome occupancy improves the identification of individual protein level differences. Finally, we identify genetic differences that specifically modulate ribosome occupancy - many of these differences lie close to start codons and upstream ORFs. Our results reveal a new level of gene expression variation among humans and indicate that genetic variants can cause changes in protein levels through effects on translation.

Comparison of gene expression biomarker classifiers developed for use as an Alopecia Areata Disease Activity Index (ALADIN). *J. E. Cerise[1], A. Jabbari[1], M. Duvic[3], M. Hordinsky[4], D. Norris[5], V. Price[6], J. Mackay-Wiggan[1], R. Clynes[1], A. M. Christiano[1,2].* 1) Dept of Dermatology, Columbia University, New York, NY; 2) Dept of Genetics and Development, Columbia University, New York, NY; 3) Dept of Dermatology, MD Anderson Cancer Center, Houston, TX; 4) Dept of Dermatology, University of Minnesota, Minneapolis, MN; 5) Dept of Dermatology, University of Colorado, Denver, CO; 6) Dept of Dermatology, UCSF, San Francisco, CA.

Alopecia areata (AA) is a common autoimmune disease manifesting with hair loss ranging from spontaneously resolving patches to lifelong total body involvement. Accessibility of the target organ within skin biopsies has provided the opportunity to develop a novel disease activity score based on quantitative composite gene expression signatures. Using both Affymetrix microarrays and RNA-Seq data, we previously identified three striking gene expression signatures in total skin from both human AA and the C3H-HeJ mouse, namely, an IFN-γ response (IFN) signature, a cytotoxic T cell (CTL) signature, and a hair keratin (KRT) signature. To generate a functional biomarker from the AA transcriptome, we developed the Alopecia Areata Disease Activity Index (ALADIN), a three-dimensional quantitative composite score. ALADIN, derived from expression levels of representative genes from the IFN, CTL and KRT signatures provides a measure of the distance of AA transcriptional levels from a baseline obtained from the scalp skin of healthy individuals. In our earlier studies of mouse AA, we demonstrated that ALADIN scores provide a quantitative measure of pharmacologic prevention and treatment of disease. Here, using Affymetrix microarray data from RNA obtained from scalp biopsies from a multi-center cross-sectional study, we identify single-gene features that differentiate patients with varying levels of disease severity, as well as "meta-genes" comprised of genes whose expression is highly correlated across samples. We develop biomarker classifiers from the single-gene features as well as from composite features, i. e. , ALADIN signatures and co-expression meta-genes using several methods including diagonal linear discriminant analysis, k-nearest neighbors, logistic regression, and support vector machines. We perform both internal cross-validation and external validation of the classifiers' ability to discriminate patients' disease severity in a second cross-sectional study and examine the classifiers' performance using data from a longitudinal study in which we tracked patients enrolled in an interventional clinical study of AA. Our findings demonstrate the potential utility of ALADIN and these classifiers as a dynamic functional biomarker to stratify and longitudinally track patients enrolled in observational and interventional clinical studies of AA.

Method to Delineate and Confirm Genetically Distinct Cell Populations from Mosaic Individual Shows Differential Expression Related to Disease Pathway. *C. M. Grochowski[1], E. A. Tsai[5], H. C. Lin[2,3], K. M. Loomes[2,3], N. B. Spinner[1,4].* 1) Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Pediatric Gastroenterology, Hepatology, and Nutrition. The Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perlman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Pathology and Laboratory Medicine, Perlman School of Medicine, University of Pennsylvania, Philadelphia, PA; 5) Genomics and Computational Biology Graduate Group, Perlman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Human mosaicism is a unique genetic phenomenon that occurs when two genetically distinct cell populations arise from a single fertilized egg. We studied a proband with Alagille syndrome and a chromosome 20p deletion including *JAG1*, and her clinically unaffected mother, who is mosaic for the deletion. We developed a method to separate the deletion and normal cells from the mosaic mother, and test the resulting lines for purity. Our goal was to then use the purified cells to analyze differential gene expression associated with the *JAG1* deletion, by comparison to the isogenic normal cell line. Normal and *JAG1*-deleted cell lines were created from a fibroblast cell line from the mosaic individual, by clonal expansion. Induced pluripotent stem cells (iPSC's) were generated from each of the lines and genotyped on the HumanHap 610 Quad BeadArray. The B Allele Frequency of heterozygous SNPs contained in the deleted 20p region was used to determine the percent mosaicism of each derived iPSC line. In order to determine the precise breakpoints of the deletion, we used a high-density array followed by long-range polymerase chain reaction (PCR) to obtain a nucleotide-level resolution surrounding the breakpoint region. Subsequent Sanger sequencing revealed the exact breakpoint architecture, which included 7 bases of microhomology. To efficiently identify the presence of the deleted chromosome in our cell lines, we designed a primer set that would only amplify a 600bp PCR product in the presence of the *JAG1*-deleted line. To rule out low-level mosaicism, primers were designed to amplify a SNP (rs2273061) in intron 3 of *JAG1,* which would be heterozygous only in a non-deleted line. Viewing the presence and relative ratio of the SNP on the chromatogram allowed for a rapid and precise assay to determine clone purity. Subsequent microarray analysis on the cloned deleted and normal cell lines showed many genes to be differentially expressed between the two populations. Decreased expression levels of the known deleted gene *JAG1* was used as a positive control within the experimental model. Several differentially expressed genes implicated in the Notch signaling pathway identified, included the following: *EDN1,* an inhibitor of *JAG1*, *HEY2*, a downstream target of Notch genes, and *CNTN1*, a less common Notch ligand all show overexpression in deleted lines. Future analysis will help to delineate how the expression differences in these genes could be related to the disease phenotype.

Proteomic profile of dorsal and ventral dentate gyrus of a rat epilepsy model induced by electrical stimulation and displaying classical hippocampal sclerosis. *A. Morato do Canto[1, 2], A. Hilario Berenguer Matos[1, 2], A. Schwambach Vieira[1, 2], R. Glioli[3], I. Lopes-Cendes[1, 2].* 1) Medical Genetics, School of Medical Science - UNICAMP, Campinas, Brazil; 2) Brazilian Institute for Neuroscience and Neurotechnology - BRAINN, Campinas, Brazil; 3) Multidisciplinary Center for Biological Investigation of Laboratory Animals (CEMIB), Campinas, Brazil.

PurposeProteomic analysis is a promising tool for the identification of key biological processes leading to epilepsy. However, the power of such "omic" approach is dependent on the preparation of homogeneous cell populations. In this context, laser-capture microdissection presents the ability to select specific cell populations that would give the most informative data in proteomic studies. The aim of this study is to identify differentially expressed proteins in the dorsal and ventral Dentate Gyrus (dDG and vDG) from epileptic rats. In these animals epilepsy was induced by a perforant pathway stimulation protocol which leads to classical hippocampal sclerosis, similar to what is seem in patients with mesial temporal epilepsy. **Methods** Rats were induced as described by Norwood et al. , 2010. Frozen sections were prepared and the dDG and vDG were laser microdissected (Zeiss PALM). Total proteins were obtained from using 8M urea and analyzed by LC-MS/MS using an LQT-Orbitrap (Waters) and the quantitative data were obtained using the software Scaffold 4. 0. **Results**We identified a total of 1271 proteins in samples of dDG and vDG combined. Of these, 42 proteins were found to be differentially expressed in dDG and 50 in vDG. Although there was some overlap between proteins that were differently expressed in dDG and vDG, we found that 76% of proteins differently expressed in dDG and 80% in vDG were unique to these sub-fields. Most of the differentially expressed proteins are involved in neuronal pathways such as GABA-receptor recycling, neurofilaments remodeling and constitutive AMPA receptor pathway, as indicated by gene ontology analysis employing the Metacore® software (Thomson Reuters). **Conclusion**The proteins identified in the present study can indicate new pathways involved in epileptogenesis. Furthermore, we found that additional molecular complexities could be elicited as hippocampal subfields were analyzed separately. We believe that the further integration of proteomic data with other "omics" approaches could generate even more informative data about the neuronal processes involved in epilepsy. Supported by BRAINN-CEPID/FAPESP, BRAZIL.

RNAseq reveals distinct transcriptomic profiles of diverse cell populations within human skin. *R. Ahn, K. Taravati, K. Lai, K. Lee, J. Nititham, R. Gupta, M. Rosenblum, W. Liao.* Dermatology, University of California, San Francisco, San Francisco, CA.

Human skin consists of multiple cell types, including epithelial, immune, and stromal cells. Transcriptomic analyses have previously been performed from bulk skin samples or from epithelial and immune cells expanded in cell culture. However, transcriptomic analysis of bulk skin tends to drown out expression signals from relatively rare cells while cell culture methods may significantly alter cellular phenotypes and gene expression profiles. To identify distinct transcriptomic profiles of multiple cell populations without substantially altering cell phenotypes, we employed a novel fluorescence activated cell sorting method to isolate keratinocytes, myeloid dendritic cells, CD8+ T effector cells, CD4+ T effector cells, and CD4+ Treg cells from healthy skin samples, followed by RNAseq of each cell population. Principal components analysis revealed distinct clustering of cell types across samples, while gene expression and pathway analyses revealed transcriptional profiles of individual cell populations distinct from bulk skin. Our work provides a high resolution view of cutaneous cellular gene expression and suggests that transcriptomic profiling of bulk skin may inadequately capture the contribution of rarer cell types.

NGS Library Preparation Method for Transcriptome Profiling With Enhanced Sensitivity of Transcript Detection. *D. Rodriguez, E. Yigit, M. Karaca, D. Munafo, P. Liu, L. Apone, V. Panchapakesa, C. Sumner, C. Chater, L. Mazzola, J. Bybee, D. Rivizzigno, F. Stewart, E. Dimalanta, T. Davis.* New England Biolabs, Ipswich, MA.

Transcriptome profiling by Next Generation Sequencing (RNA-seq) is a powerful technique for large-scale genome-wide expression analysis, including mRNA, non-coding RNA, and miRNA profiling. RNA-seq is beginning to have multiple applications in clinical diagnostics; providing better insights into how altered RNA expression impacts the biological pathways and the molecular mechanisms associated with disease progression. The successful adoption of NGS into the clinical laboratory will depend on the library preparation techniques that can capture the entire molecular repertoire within a sample without any sequence bias. Here, we present a method for directional or strand-specific RNA-seq that retains information about which strand of DNA is expressed. Determining the polarity of RNA transcripts is important for the correct annotation of novel genes, identification of antisense transcripts with potential regulatory roles, and for correct determination of gene expression levels in the presence of antisense transcripts. This method is based on the labeling and excision of the second strand cDNA, and it is compatible with both poly A-tail enriched and ribosome-depleted RNA. We will provide a comprehensive analysis of different eukaryotic and prokaryotic RNA libraries including library performance, library complexity, duplication rate, and continuity of gene coverage and strand specificity. Our results show this improved method generates high library yields that allow use of low amount of input RNA with reduced PCR duplicates, delivering high quality strand-specific RNA-seq data. This streamlined protocol is also amenable to large-scale library construction and automation.

Longevity and the transcriptome: Identifying gene expression changes in long-lived individuals. *K. A. Mather[1], A. Thalamuthu[1], B. J. Chen[2], M. Janitz[2], N. J. Armstrong[3], P. S. Sachdev[1, 4], Sydney Centenarian Study and the Sydney Memory and Ageing Study teams.* 1) Centre for Healthy Brain Ageing, UNSW Australia, Sydney, NSW, Australia; 2) School of Biotechnology and Biomolecular Sciences, UNSW Australia, Sydney, NSW, Australia; 3) Mathematics and Statistics, Murdoch University, Perth, Australia; 4) Neuropsychiatric Institute, Prince of Wales Hospital, Sydney, Australia.

Background: Our population is ageing and will place a significant burden on the health system. Long-lived individuals are examples of successful ageing, many of whom have avoided age-related disease until very late in their lives or escape them altogether. Age-related changes in gene expression have been reported, however, few studies have examined the transcriptome comprehensively in long-lived individuals. This study aims to assess transcriptomic differences between long-lived and younger individuals using RNA sequencing. **Method:** Total RNA was extracted from whole blood collected in PAXgene tubes from 24 long-lived (mean age = 97. 8 years) non-demented participants from the Sydney Centenarian Study (Sachdev et al. 2010) aged 95 and over and 24 younger cognitively normal controls (mean age = 78. 8 years) from the Sydney Memory and Ageing Study (Sachdev et al. , 2010). The two groups were matched for sex and there were equal numbers of men and women. After ribosomal RNA depletion, poly A+ RNA libraries were prepared. Paired-end (101 bp) sequencing was performed using Illumina HiSeq. Sequenced reads were processed using TopHat and Cufflinks. Transcriptome profiles of the two groups were compared using three popular methods, DESeq, edgeR and baySeq. **Results:** Using the overlap between the results (FDR-corrected p-value<. 05) from three commonly used methods of analysis, a subset of genes that were differentially expressed was identified (N=4,116). These genes included many genes that have been previously associated with longevity such as *ATM*, *WRN*, *SIRT1* and *MTOR*. **Conclusions:** Using RNA sequencing, differentially expressed genes were observed in long-lived individuals compared to younger controls. This work will provide insights into the genes and pathways underlying exceptional longevity and suggest avenues for future research that will inform us about the molecular mechanisms involved in successful ageing.

RNA-sequencing reveals novel candidate genes for Ring chromosome 20 syndrome. *D. A. McEldrew[1], R. Rajagopalan[1], C. M. Grochowski[1], A. M. Falsey[1], L. K. Conlin[1,2,3], J. A. Mills[1], N. B. Spinner[1,2,3].* 1) Dept. Of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Genomic Diagnostics, The Children's Hospital of Philadelphia, PA; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Ring chromosomes are a rare chromosome abnormality caused by fusion of the short and long arms of a chromosome. All human chromosomes have been identified with ring structures and the overall frequency of constitutional ring chromosomes isestimated to be 1 in 30,000 to 1 in 60,000 births. Ring chromosomesare often associated with clinical features which can vary depending on the chromosome, but refractory seizures, microcephaly, behavioral abnormalities and mild to severe cognitive impairment are common to a number of rings. Ring chromosome 20 is one of the more common rings, and we previously showed that some rings are present in all cells of a patient and these rings always contain deletions of one or more arms; while other rings are mosaic, with normal and ring containing cells and in all cases studied, these mosaic cases have no demonstrable deletions or duplications. Skin samples were collected were collected from two mosaic R(20) patients, cultured into fibroblast cell lines and the normal and ring cells were cloned out to separate the cell types. We established cell lines containing pure r(20) cells and pure normal from these two patient samples. Cell proliferation assays were performed showing a decreased growth potential in R(20) fibroblast compared to isogenic controls (P < 0. 05). We performed RNA-sequencing to characterize gene expression profiles of these samples and to potentially identify genes associated with decreased growth in R(20) fibroblast cells. We used STAR aligner to align fastq sequences to the human transcriptome and used multiple computational tools such as DESeq2 and the CuffLinks pipeline to estimate differential gene expression. We found a total of 987genes differentially expressed between ring and normal samples. Of the 987 differentially expressed genes, 861 were up-regulatedand 126 were down-regulated in thering sample. PLCB1 was the top hit on chromosome 20 for differential expression, and this gene has been shown to be involved in cell proliferation, differentiation, and cellular maintenance. We also found several other differentially expressed genes (TGM2, SALL4, CASS4, DNMT3B etc.) on chromosome 20 that may be candidates for altered growth potential. To our knowledge, this isthe first report of differential gene expression analysis of ring chromosomes and we believe this will enhance our understanding of the molecularmechanisms of Ring Chromosome 20 syndrome.

Global Gene Expression Profiling during Pregnancy. *A. Mittal[1], L. Pachter[2], M. Smed[3], H. Kjaergaard[3], V. Zoffmann[3], I. Hallgrimsdottir[2], D. Jawaheer[1].* 1) Children's Hospital Oakland Research Institute, Oakland, CA 94609; 2) University of California, Berkeley, CA 94720; 3) Juliane Marie Center, Rigshospitalet, Copenhagen, Denmark.

Introduction: Little is known about systemic changes in the maternal transcriptome duringnormal human pregnancy since previous studies focused mostly on the maternal-fetal interface. The gene expression profiles specific to different trimesters of pregnancy are also poorly understood. We have examinedglobal transcriptome changes that occur in the bloodstream of healthy women from pre-conception topostpartum to identify genes that are involved in different stages of pregnancy. Methods:Using a longitudinal study design, blood was drawn from 5 healthy women before conception, once each trimester and at 3 intervals postpartum. Total RNA was extracted and used to prepare cDNA libraries which were sequenced on Illumina HiSeq2500 instrument to generate on average 60 million paired-end reads (100bp). The raw RNA sequencing (RNA-seq) data was preprocessed and aligned to the reference Human transcriptome using Bowtie2. Gene expression levels were quantified using eXpress. The edgeR package was used to perform differential gene expression analysis across different time points. The enrichment of specific biological processes and pathways among differentially expressed genes were analyzed using DAVID bioinformatics resource. Results: A total of 790 genes showed at least 2-fold differential expression (p*<0. 05) during pregnancy with respect to the pre-pregnancy baseline, while their post-partum expression profiles reverted back to the pre-pregnancy levels. Among these were genes having common expression patterns across all three trimesters as well as genes with profiles specific to the stage of gestation. Specifically, we identified genes that were a) upregulated in all three trimesters (enriched in processes involved in inflammatory response, translational elongation and ribosomal biogenesis and assembly), b) upregulated in second and third trimesters (enriched in defense response, homeostasis, erythrocyte differentiation and negative regulation of immune system process), c) downregulated in all three trimesters (genes involved in metal ion binding), d) downregulated in first trimester (including ALOX15, IL5RA, NR4A1 (p*<0. 01)), and e) downregulated in third trimester (including ENPP3, HDC, CPA3 (p*<3x10-5)). *FDR correctedConclusions: These gestation-specific gene signatures can lead to a better understanding of what systemic changes occur in the mother during healthy pregnancy, and may provide molecular insights into disorders that are influenced by pregnancy.

Transcriptome analysis of CD4+ T cells in coeliac disease. *C. Coleman, E. M. Quinn, B. Molloy, P. Dominguez Castro, V. Trimble, N. Mahmud, R. McManus.* Clinical Medicine, Trinity College Dublin, Dublin, Ireland.

Genetic studies have to date identified 43 genome wide significant coeliac diseasesusceptibility (CD) loci comprising over 70 candidate genes. However, how alteredregulation of such disease associated genes contributes to CD pathogenesis remainsto be elucidated. Recently there has been considerable emphasis on characterisingcell type specific and stimulus dependent genetic variants. Therefore in this study weused RNA sequencing to profile over 70 transcriptomes of CD4+ T cells, a cell typecrucial for CD pathogenesis, in both stimulated and resting samples from individualswith CD and unaffected controls. We identified extensive transcriptional changesacross all conditions, with the previously established CD gene IFNy the most stronglyup-regulated gene (log2 fold change 4. 6; Padjusted=2. 40x10-11) in CD4+ T cells fromCD patients compared to controls. We show a significant correlation of differentiallyexpressed genes with genetic studies of the disease to date (Padjusted=0. 002), and 21CD candidate susceptibility genes are differentially expressed under one or more of theconditions used in this study. Pathway analysis revealed significant enrichment ofimmune related processes. Co-expression network analysis identified several modulesof coordinately expressed CD genes. Two modules were particularly highly enrichedfor differentially expressed genes (P<2. 2x10-16) and highlighted IFNy and othergenetically associated transcription factors which showed significantly reducedexpression in coeliac samples as key regulatory genes in CD.

Transcriptomic analyses reveal sex-dependent expression differences in hundreds of genes and show an upregulation of immune response genes in women. *A. Joensuu[1,2], ML. Nuotio[1,2], E. Raitoharju[3], M. Kähönen[4], T. Lehtimäki[3], V. Salomaa[2], O. Raitakari[5,6], M. Perola[1,2,7], J. Kettunen[2,8,9].* 1) National Institute for Health and Welfare, Helsinki, Finland; 2) Dept of Health, National Institute for Health and Welfare, Helsinki, Finland; 3) Dept of Clinical Chemistry, Fimlab Laboratories and School of Medicine, University of Tampere, Tampere, Finland; 4) Dept of Clinical Physiology, Tampere University Hospital and School of Medicine, University of Tampere; 5) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Turku, Finland; 6) Turku University Hospital, Turku, Finland; 7) University of Tartu, Tartu, Estonia; 8) Computational Medicine, Institute of Health Sciences, University of Oulu, Oulu, Finland; 9) NMR Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, Kuopio, Finland.

Background: The expression of genes regulates biological pathways and processes and thus gives rise to differences in observed phenotypes. Identifying common sex-dependent differences in transcription levels in a large cohort with sufficient power is important for better interpretation of smaller studies focusing on specific diseases. **Methods:** We studied differences in autosomal gene expression between males and females in two Finnish population cohorts, the Young Finns Study (575 males and 680 females aged 34-49) and DILGOM (240 males and 278 females aged 25-74). Both cohorts have genome-wide transcriptional coverage (>30,000 transcripts) from whole blood measured with Illumina HumanHT-12 BeadChips. The effect of sex on quantile-normalized expression levels corrected for age, BMI and smoking was analyzed separately in the cohorts with linear regression and combined with random-effects meta-analysis. Women using contraceptive pills or pregnant were excluded. Functional annotations were studied with DAVID using significantly expressed genes as input and all genes in the meta-analysis as the background reference gene set. **Results:** Expression of 512 transcripts in 491 (2. 6%) autosomal genes showed higher expression in males whereas levels of 480 transcripts in 460 (2. 4%) genes were higher in females. Interestingly, in the transcripts more expressed in females a 3. 1-fold enrichment of genes related to Immune response Gene Ontology (GO) processes was seen (FDR=2. 5*10-8). Supporting this, the most strongly elevated transcript in females (b=0. 61; 95% CI:0. 51-0. 70; p-value 7. 5e-37) was seen in the gene *Lymphotoxin beta* (*LTB*), an inducer of the inflammatory response system. Genes more expressed in females also showed enrichment in the GO processes Apoptosis and Programmed cell death as well as in the Cytokine-cytokine receptor interaction KEGG pathway. In contrast no enriched GO processes or KEGG pathways passed the FDR<0. 05 criterion in males. **Conclusions:** We could detect significant sex-dependent enrichment of transcription in 5% of the genes studied. Genes related to immune response are more expressed in females, which could reflect the higher female prevalence of most autoimmune diseases. Next we will use Weighted Gene Co-expression Network Analysis to identify sex-dependent transcription modules which can be tested against further phenotypes. Similar studies may help to gain insight into some of the sex-dependent susceptibility rates observed in various diseases.

Gene expression of *PTK2B* in peripheral blood is associated with cortical thickness in Alzheimer's disease. *K. Nho[1,2,3], S. Kim[1,2,3], S. L. Risacher[1,3], H. D. Soares[4], P. Singh[4], L. Wang[4], Z. Qi[4], A. He[4], I. Neuhaus[4], V. Patel[4], T. Foroud[1,2,3,5,6], K. M. Faber[6], L. Apostolova[7], M. W. Weiner[8,9], A. J. Saykin[1,2,3,5], Alzheimer's Disease Neuroimaging Initiative.* 1) Radiology and Imaging Sciences, Indiana University School of Medicine, Indianapolis, IN; 2) Indiana Alzheimer Disease Center, Indiana University School of Medicine, Indianapolis, IN; 3) Center for Computational Biology and Bioinformatics, Indiana University School of Medicine, Indianapolis, IN; 4) Bristol-Meyers Squibb, Wallingford, CT; 5) Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN; 6) National Cell Repository for Alzheimer's Disease, IN; 7) Department of Neurology, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA; 8) Departments of Radiology, Medicine, and Psychiatry, University of California-San Francisco, San Francisco, CA; 9) Department of Veterans Affairs Medical Center, San Francisco, CA.

Background: Human brain function depends on the precise regulation of gene expression. Transcriptome profiling has become a major focus of neurodegenerative disease research. Prior studies suggest that abnormal gene expression patterns may contribute to the onset and progression of late-onset Alzheimer's disease (LOAD). We performed transcriptome and whole-brain cortical thickness analyses of 22 LOAD susceptibility genes identified from recent large-scale GWAS using gene expression profiles from the Alzheimer's Disease Neuroimaging Initiative (ADNI). **Methods**: 661 ADNI non-Hispanic Caucasian participants with Affymetrix Human Genome U219 Array data from peripheral blood samples (PaxGene RNA tubes) were included. Raw expression values were pre-processed using the Robust Multi-chip Average normalization followed by standard quality control (QC) procedures on samples and probe sets. Statistical analysis of microarray data was performed using the regularized t-test to evaluate differences in gene expression between LOAD and cognitively normal controls (HC). Data were adjusted for age, gender, plate, and RIN score (RNA integrity number). Multivariate whole-brain analysis was performed to identify highly correlated brain regions with gene expression levels. Statistical maps using SurfStat were thresholded with random field theory correction for multiple testing. **Results**: Of the 19 genes represented on the array after QC, one gene (*ABCA7*) was significantly up-regulated in LOAD (corrected p=0. 034). Whole-brain analysis of cortical thickness identified brain regions, especially entorhinal cortex, significantly associated with blood expression of *ABCA7* and *PTK2B*. Individuals with lower expression showed greater cortical thickness (corrected p<0. 05). *cis*-eQTL mapping analyses of *ABCA7* and *PTK2B* detected 63 and 16 significant associations with $p < 2.5 \times 10^{-12}$, respectively. *cis*-eQTL of rs6987305 (*PTK2B*) in healthy human brains yielded a p=0. 000096 for the temporal cortex tissue (BRAINEAC). **Conclusions**: This is the first study to show that *ABCA7* and *PTK2B* gene expressions in blood are associated with reduced cortical thickness, especially in entorhinal cortex. These data illustrate the potential of combining transcriptome profiles with neuroimaging to understand the genetics and pathobiology of AD, an approach that may be useful for novel therapeutic target identification for AD.

3088T

Dissection of Gene Expression Signatures of Recurrent Acute Pancreatitis Risk in Extreme Hypertriglyceridemia. *K. Tremblay, D. Gaudet.* Université de Montréal Community Genomic Medicine Centre and ECOGENE-21, Chicoutimi, PQ, Canada.

Background: Recurrent acute pancreatitis (RAP) is defined as more than two attacks of acute pancreatitis (AP) without any evidence of underlying chronic pancreatitis. Extreme hypertriglyceridemia (fasting triglycerides >10 mmol/L) is associated with chylomicronemia (CM) and increased risk of RAP. The number of pancreatitis episodes varies significantly between patients with CM. **Aim:** To investigate the gene expression profiles of AP and RAP in patients with extreme hypertriglyceridemia and CM. **Methods:** A total of 62 consenting subjects participated in this study. Prior to the analyses, patients with CM were divided into three groups covering a wide spectrum of recurrence of AP: 0 episode (n=21), 1-3 (n=10) and ≥ 4 (range 4 to 40, n=16) episodes. The gene expression profile of the three CM groups was compared to the profile of 15 healthy controls. AP was defined according to the revised Atlanta classification. RNA samples were extracted from whole blood PAXgene and hybridized on Affymetrix Human Gene 2. 0 ST Array according to manufacturer procedures. Robust Multi-Array normalization has been applied on the probe raw intensities. Differential expression moderated T-tests between studied groups were performed using a linear model of the Bioconductor package Limma. False discovery rate (FDR) estimation was carried out using the Benjamini-Hochberg method. **Results:** The studied groups allowed conducting six differential analyses on a total of 48,226 detected probes. At a p-value < 0. 01, a FDR of 5% and a >2-fold down-expression (down) or over-expression (over) significance levels, a set of 41 probes have been found differentially expressed in CM subjects with no pancreatitis, 106 in the CM group with 1 to 3 pancreatitis, and 90 in the group with ≥ 4 pancreatitis compared to healthy controls. Of the identified probes, 33 are shared by all CM groups; 6 are specific to CM with no pancreatitis [3 down (2 annotated;1 non-annotated) and 3 over (2 annotated;1 non-annotated)]; 41 are specific to CM with 1 to 3 pancreatitis [30 down (15 annotated;15 non-annotated) and 11 over (7 annotated;4 non-annotated)], and finally 27 are specific to CM with ≥ 4 pancreatitis [24 down (11 annotated;13 non-annotated) and 3 over (2 annotated;1 non-annotated)]. Most of the annotated genes are involved in inflammatory, immune or signaling biological pathways. **Conclusion:** Using extreme hypertriglyceridemia as a model, these results reveal gene expression signatures of RAP.

3089F

Impact of Genetic Variation on upstream Open Reading Frame (uORF) Translation and Differential Gene Expression in Human Populations. *Y. Wang[1], T. Chun[2], R. Mills[1,2].* 1) Human Genetics, University of Michigan, Ann Arbor, MI; 2) Computational Medicine & Bioinformatics, University of Michigan, Ann Arbor, MI.

Upstream open reading frames (uORFs) are regions of protein coding potential that begin in the 5' untranslated region (UTR) of an mRNA and end either before or after the start codon of the canonical gene. Previous studies have demonstrated that the existence of uORFs in the 5'-UTR of genes is associated with lower expression level of these genes at both the mRNA and protein levels by multiple possible mechanisms, and recent work has combined DNA and RNA sequencing data with ribosomal profiling and proteomics to investigate the extent to which this occurs. Here, we explore this further by applying a novel method for identifying actively translating regions using ribosomal profiling data to identify differentially translated uORFs due to genetic polymorphisms that create or destroy the open reading frame across human populations. We present an analysis of these regions within the context of local gene expression, translation, protein abundance, and conservation in other primate species. We further examine the effect of such variation on putative ORFs in noncoding regions throughout the genome and compare with previously reported sets of expression quantitative trait loci in order to discover potential regulatory regions.

PennDiff: Detecting differential alternative splicing from RNA-Seq data. *Y. Hu[1], C. Xue[2], M. Reilly[2], M. Li[1].* 1) Department of Biostatistics and Epidemiology, University of Pennsylvania Perelman School of Medicine Philadelphia, PA; 2) Cardiovascular Institute, University of Pennsylvania Perelman School of Medicine Philadelphia, PA.

Alternative splicing is a regulated process and a major mechanism for generating protein diversity. Detecting differential alternative splicing (DAS) between two groups of samples (e. g. , cases vs. controls, before vs. after drug treatment) could provide an effective way to discover disease susceptibility genes. To detect DAS from RNA-Seq data, we developed a novel statistical method PennDiff, which makes use of information on known gene structures and pre-estimated isoform relative abundances. For each alternatively spliced exon of a gene, PennDiff divides isoforms into two categories depending on whether the exon is included or not. The inclusion level of the alternatively spliced exon is then estimated as the total relative abundances of all isoforms with the exon included. PennDiff has several advantages. First, grouping exons avoids multiple testing for “exons” originated from the same isoform. Second, it utilizes all available sequencing reads in exon-inclusion level estimation, which is in sharp contrast to DEXSeq and rMATS that only use exon+junction reads. Third, collapsing isoforms sharing the same alternatively spliced exons reduces the impact of isoform expression estimation uncertainty and yields more accurate estimate of exon-inclusion level. To detect DAS, we assume the exon-inclusion levels follow a beta distribution, and the correlation between alternatively spliced exons within the same gene is modeled through the use of Gaussian copula. Through this Gaussian copula framework, PennDiff is able to perform both exon-based and gene-based tests, thus offering much more flexibility than existing methods. To evaluate the performance of PennDiff, we analyzed both simulated data and a real RNA-Seq dataset from peripheral blood mononuclear cells (PBMCs) collected before and after experimental human endotoxemia. We compared PennDiff with several existing methods, including Cuffdiff, DEXSeq, rMATS, IUTA and SplicingCompass. Our results indicate that PennDiff has well-controlled type I error rate, and is more powerful than existing methods, especially when sequencing depth is low. In contrast, Cuffdiff and rMATS suffer from substantial loss of sensitivity. We are performing experimental validations of DAS genes that were detected by PennDiff but were missed by all other tests in the PBMC dataset. As the use of RNA-Seq continues to grow exponentially, we expect PennDiff will be useful for studies of alternative splicing in diverse RNA-Seq projects.

Mesenchymal stem cells of patients with multiple myeloma have different epigenetic characteristics compared to normal bone marrow stem cells. *m. noruzinia[1,2], m. Mashadikhan[1, 2], A. saremi[2, 3], M. ahmadvand[1, 2], A. dehghani[1, 2], O. bashti[1, 2].* 1) tarbiat Modares University of Medical Sciences, Tehran, Tehran , Iran; 2) Sarem Cell Research Center, Tehran, Iran; 3) Sarem Women Hospital, Tehran, Iran.

Epigenetic aberrations are reported to contribute in pathogenesis of multiple myeloma. Histone modifications and DNA methylation are two major epigenetic modifications. Epigenetic differences are detected between patients with multiple myeloma and normal. These differences are reported in gene specific methylation as well as global hypomethylation. Bone marrow Mesenchymal stem cells in patients have been involved in the pathogenesis of multiple myeloma. Osteoblastogenesis is impaired in MM and it has been shown that abnormalities in bone marrow mesenchymal stem cells are involved. We sought to search the role of epigenetics in the difference between normal bone marrow stem cells and multiple myeloma bone marrow stem cells. Materials and methods:BM nucleated cells (BMNC) from 6 normal donors and 6 MM patients were plated, cultured inα-MEM medium. After passage 3 the cell were put through flowcytometry RT PCR and invitro differentiation to confirm the authenticity of mesenchymal stem cells. RT PCR for transcripts of genes involved in epigenetic programing and DNMTs, were performed to compare the two patients and normal. Resuts:Mesenchyal stem cells of MM patients had slower growth. Immunophenotyping confirmed absence of myeloma cells. ALPL expression was significantly lower in MM MSCs compared to normal MSCs. DNMT1 DNM3A and DNM3B are differentially expressed in MM MSCs compared to Normal MSCs. Discussion:Recent investigations show that Mesenchymal stem cells in patients with myeloma might be important in the pathogenesis of this disease. Current treatments do not show satisfying efficacy in the treatment of this malignancy of plasma cells. On the other hand epidrug therapy has shown to be promising in the treatment of many cancers as well as multiple myeloma. We sought to find whether there is a difference between some epigenetic characteristics of MSCs of MM patients and Normal persons. MM MSCs seem to be different from normal MSCs as DNA methyl transferases are differentially expressed. ALPL show a diminished expression too. Taken together these result might show a potential for epidrug therapy of MM Mesenchymal stem cell which would help to treat patients who are resistant to current treatments.

Transcriptome profiling of hypoxia tolerant heterozygous *EdnrB* mice reveals genes associated with cardiac contractility. *T. Stobdan[1], D. Zhou[1], E. Ao-Ieong[2], D. Ortiz[2], R. Ronen[3], I. Hartley[1], Z. Gan[2], A. D. McCulloch[2], V. Bafna[4], P. Cabrales[2], G. H. Haddad[1,5,6].* 1) Pediatrics, Univ. California San Diego, San Diego; 2) Bioengineering, Univ. California San Diego, San Diego; 3) Bioinformatics & Systems Biology Graduate Program, Univ. California San Diego, San Diego; 4) Computer Science and Engineering, Univ. California San Diego, San Diego; 5) Neurosciences, Univ. California San Diego, San Diego; 6) Rady Children's Hospital, San Diego, California, USA.

The Ethiopians highlanders are considered one of the best adapted to high altitude environment but the genetic basis for the adaptation has never been understood. Candidate genes were identified through unbiased whole genome sequencing of adapted individuals and we focused on one of them for deeper analysis. A heterozygote knockout mouse of one of the candidate genes, *Endothelin Receptor B* (*EdnrB*-/+), could tolerate various levels of hypoxia, even extreme hypoxia (5% O2). To understand the molecular mechanisms, we compared the transcriptomic profile of left ventricles of *EdnrB*-/+ to their littermate controls, both under normoxia and hypoxia and used a bayesian approach, conditioning the criteria for mining specific genes and pathways. For within group comparisons i. e. , *EdnrB*+/+ and *EdnrB*-/+ respectively, of normoxia vs hypoxia, we obtained 3870 differentially expressed genes of which 1547 genes were common. Interestingly there were 3 genes, *Nppa*, *Sln* and *Myl4* (q<0. 05) that were oppositely expressed in *EdnrB*+/+ and *EdnrB*-/+ with an average FPKM of >100. They were subsequently validated by RT-PCR. The composite network analysis of these 3 genes were primarily related to Ca2+ homeostasis, regulation of ATPase activity, and regulation of the cardiac contractility, consistent with a better cardiac performance. We conclude that *EDNRB* plays a key role in hypoxia tolerance and the 3 atria-specific genes *Nppa*, *Sln* and *Myl4*, likely play a role in the improved cardiac performance during hypoxia in the heterozygote mice.

The microbiota and interleukin-10 modulate the chromatin landscape and transcription in lamina propria macrophages and experimental colitis. *J. M. Simon[1], J. P. Davis[1], M. Weiser[1], S. E. Lee[1], G. R. Gipson[1], J. Whitley[1], V. B. Iyer[1], A. G. Robinson[1], R. B. Sartor[1], H. H. Herfarth[1], R. Rahbar[1], T. S. Sadiq[1], M. J. Koruda[1], D. P. McGovern[2], J. D. Lieb[3], K. L. Mohlke[1], T. S. Furey[1], S. Z. Sheikh[1].* 1) University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Inflammatory Bowel Disease Center, Cedars-Sinai Medical Center, Los Angeles, CA; 3) University of Chicago, Chicago, IL.

Chromatin accessibility is dynamic in response to certain stimuli or through cellular differentiation. However, how the underlying genotype contributes to the cellular response to a given stimulus, potentially by altering the chromatin landscape, is not well understood. In this study, we use Crohn's Disease (CD), a chronic inflammatory disease of the intestine, as a model wherein intestinal microbes, environmental triggers, the immune system, and underlying genotype all contribute to disease onset. Macrophages in particular are one key immune cell type that responds inappropriately to intestinal microbes due to underlying genetic variation, resulting in chronic inflammation. To address how macrophages respond to bacteria at the level of chromatin and gene expression, and how this response is altered based on underlying genetics, we performed Formaldehyde-Assisted Isolation of Regulatory Elements (FAIRE-seq) in conjunction with RNA-seq on two types of macrophages in wild-type and colitis prone (*Il10*-/-) mice. We identified ~4,700 regions, mainly near pro-inflammatory cytokine genes, with altered chromatin accessibility associated with genotype that poise intestinal macrophages for an aberrant response to microbes. In order to test whether human CD patients exhibited chromatin alterations consistent with this experimental model, we performed FAIRE-seq on genotyped colonic mucosal biopsies from two CD and two control patients. We identified ~300 regions of accessible chromatin associated with disease status that are syntenic to the genetically driven baseline chromatin alterations seen in murine macrophages. We also tested whether *in vitro* immunotherapy could revert the pro-inflammatory chromatin landscape in macrophages established through genetic susceptibility. We found this therapy affected <5% of the 2,883 accessible chromatin sites, possibly explaining the lack of success of these treatments, and concluded that genetics may irreversibly predispose macrophages during differentiation for aberrant responses to intestinal microbes in CD. Our study provides the first insights into how genetics and the environment may irreversibly shape chromatin and alters the macrophage response to microbes, and extends these findings to human disease. .

3094T

Single-cell RNA-seq on pancreatic islets of Langerhans reveals different heterogeneity between non-diabetic and diabetic individuals. *M. Garieri[1,2], C. Borel[1], T. Stoger[3], F. Santoni[1], C. Howald[1,2], P. Ribaux[1], L. Pelkmans[3], P. A. Halban[1], S. E. Antonarakis[1], E. T. Dermitzakis[1,2].* 1) Department of Genetic Medicine and Development, University of Geneva, Geneva, Geneve, Switzerland; 2) Swiss Institute of Bioinformatics (SIB), Geneva, Switzerland; 3) Institute of Molecular Life Sciences, University of Zurich, Zurich, Switzerland.

Pancreatic islets of Langerhans consist of several endocrine cell types. We investigate the cellular heterogeneity in non-diabetic (ND) and diabetic (D) donors using single cell (SC) RNA-seq. Dissociated islet cells of 3 ND donors (n=216) and 2 type 2 diabetes (T2D) donors (n=120) were analyzed. We also sequenced 93 sorted-beta SCs from the same individuals (57 ND and 36 D). On average we obtained 36. 6 million 100-bp-reads per SC after quality filtering. Clustering analysis on islet SCs identified a first population expressing high levels of insulin (INS) with a significant (p=4. 58e-12) difference between ND and T2D (62% ND SCs, mean 35924 RPKM vs. 24% T2D SCs 14297 RPKM). A second population expressed high levels of glucagon (GCG) (p=8. 064e-05; 8% ND 119263 RPKM vs. 30% T2D 29983 RPKM). Interestingly the mutually exclusive expression of *INS* and *GCG* in beta and alpha cells was not observed in a third population of SCs co-expressing high levels of *INS* and *GCG*: 7% ND islet SCs (0% ND sorted-beta SCs) vs. 23% T2D islets SCs (20% T2D sorted-beta SCs). Furthermore other bi-hormonal SCs are present: 11 INS-SST (10 ND SCs which represent 3. 6% of all ND SCs, and 1 D SC which correspond to 0. 6% D SCs), 22 INS-PPY SCs (17 - 6. 2% ND, 5 - 3. 2% D), 8 GCG-PPY SCs (0 - 0% ND, 8 - 5% D) and 3 GCG-SST (1 - 0. 4% ND, 2 - 1. 3% D). Differential expression analyses reveals enrichment in RNA splicing in D SCs. Beta ND SCS are enriched in growth factor binding pathway, while D alpha SCs for RNA binding. Correlation analysis with INS allows us identify enrichment in peptide hormone processing in ND SCs, while in D SCs there is an enrichment in cell differentiation and cellular developmental process. Allelic specific expression analysis is compatible with the expression of both INS and GCG in one cell, and convincingly excluded the possibility of erroneous analysis of two cells. We controlled for the absence of transcript contamination by sequencing 11 empty chambers. We are verifying dual hormone gene expressing SCs using another technology (branched-DNA single-molecule FISH) allowing for quantification and cellular localization of transcripts. SC transcriptome analysis provides an unprecedented opportunity to explore the heterogeneity of islet cells and compare this in cells from type2 diabetic vs. non-diabetic subjects. M. G and C. B. contributed equally to the work.

Ultraconserved elements populate genomic regions disrupted in both cancers and neurodevelopmental disorders. *R. B. McCole[1], C. Y. Fonseka[1], B. Harrison[2], R. L. Collins[2], S. Erdin[2], C. Redin[2], M. E. Talkowski[2], C. -T Wu[1].* 1) Genetics, Harvard Medical School, Boston, MA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA.

The ultraconserved elements (UCEs) are regions of the human genome possessing extremely high levels of DNA sequence conservation between related species. The question of why UCEs show such extraordinary conservation and their relationship to disease is widely debated. We have demonstrated that UCE-containing genomic regions are significantly depleted from 43,727 copy number variable (CNV) regions pooled from 8 separate studies in healthy human subjects (P=1. 7 × 10-12, obs/exp ratio=0. 8), and in contrast, that UCEs are enriched within 177 genomic regions demonstrating recurrent copy number alteration specifically in cancerous tissues from 17 studies covering 52 different human cancers (P=1. 2×10-4, obs/exp=1. 1). In a small pilot study, we also found that UCEs were enriched within CNVs found in subjects with neurodevelopmental disorders (NDDs), prompting the hypothesis that UCE enrichment in these datasets could be explained by high occurrence of UCEs within critical genes and pathways implicated in cancer formation and NDDs. From analyses of 557 cancer-associated genes listed in the COSMIC cancer gene census, we discovered that UCEs are almost two-fold over-represented against a background of all genes (P=3. 8×10-7, obs/ex =1. 9). With respect to germline variation contributing to NDDs, as expected UCEs were highly enriched among the 1000 most constrained genes in the genome (P=7. 8×10-5, obs/exp=4. 8), and were significantly over-represented within three different lists of autism and NDD associated genes (168 AutismKB genes, 126 DAWN genes, and 605 SFARI genes, P=5. 1×10-9, 2. 7×10-3, and 0. 004 respectively). When we considered loci disrupted by *de novo* inversions and translocations associated with NDDs, we found the genomic regions flanking 135 balanced rearrangement breakpoints were as enriched for UCEs as the cancer-associated loci (P=8. 0×10-6, obs/exp=2. 5). By contrast, UCEs were not significantly enriched within 418 genes associated with schizophrenia by common variant GWAS. Our findings suggest that UCEs may arise and be maintained specifically in disease-relevant genomic regions where multiple and pervasive deleterious effects occur as a result of mutation, perhaps depending on context, such that NDDs arise from mutations present during development, but cancer results when similar mutations occur somatically. UCEs may also provide a new map to the landscape of deleterious genetic variations that manifest in humans as diseases even beyond cancer and NDD.

Human umbilical vein endothelial cells Response to shRNA-mediated knock down of ITPA gene in presence of Nitric Oxide. *z. Abedi, a. ahmadi, m. behmanesh.* tarbiat modares, tehran, Iran.

Reactive oxygen species (ROS) can increase the production of non-canonical nucleotides. ITPA gene encodes an enzyme which removes the non-canonical inosine triphosphate (ITP) nucleotide from the nucleotide pool. Since ITP can incorporate into the DNA and increase the rate of mutations, ITPA play critical role in maintenance of genome integrity. ITPA deficiency can result in ITP accumulation and DNA lesions. Deamination of DNA bases can lead to mutagenesis through use of deamination products by DNA polymerase and misrepair, or no repair. Nitric oxide reacts with oxygen, it can react with amines, thiols, and other nucleophiles. N2O3, acts on DNA bases and leading to direct DNA damage via deamination. Deamination of cytosine, adenine, guanine, and 5-methylcytosine forms uracil, hypoxanthine, xanthine, and thymine, respectively. The aim of the present study is to find if ITPA gene deficiency and Nitric Oxide treatment may increase the susceptibility of HUVEC cells to ROS. HUVEC cell were cultured in a medium containing doxorubicin as a ROS inducing agent. shRNAs against the ITPA gene was designed and used to knock down of ITPA gene. The efficiency of designed shRNAs was evaluated by real time polymerase chain reaction (qPCR) and western blot. The viability of shRNA transfected cell was evaluated by MTT assay. Results showed that our shRNA could knock down of ITPA effectively. Furthermore, we found that Nitric Oxide induce cell death in HUVEC cells. All together our shRNA worked properly and it is useful to evaluate if knockdown of ITPA enhances apoptosis and decreases the viability in HUVEC cells. Keywords: Inosine triphosphatase, short hairpin RNA, Reactive oxygen species, Human umbilical vein endothelial cell.

Stimulating human CD4+ memory T cells uncovers cell state-dependent allelic expression enriched in risk genes for rheumatoid arthritis. *M. Gutierrez-Arcelus[1,2], N. Teslovich[1,2], HJ. Westra[1,2], K. Slowikowski[1,2], DA. Rao[3], J. Ermann[3], MB. Brenner[3], S. Raychaudhuri[1,2,4].* 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Division of Rheumatology, Immunology, and Allergy, Brigham and Women's Hospital, Smith Building, 1 Jimmy Fund Way, Boston, MA, USA; 4) 4. Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

In the last decade, investigators have made important advances in understanding the pathogenesis and genetics of autoimmune diseases. However, many questions remain, particularly in understanding how genetic factors act in the specific cell-types and physiological states most relevant for each disease. Our group and others have previously implicated in rheumatoid arthritis and type I diabetes a role for CD4+ memory T cells, essential players in the adaptive immune system. In order to better understand the genetic regulatory variation active in varying cell states in this cell population, we have subjected CD4+ memory T cells from one individual to a physiologically relevant stimulus and have assayed the transcriptome with RNA-seq at six different time-points following stimulation. We have called heterozygous variants from the RNA-seq data. From this high-resolution time course experiment, we have identified many time and stimulus condition specific (TASC) allelic effects, which reflect the activation or inactivation of genetic regulatory effects upon stimulation. We tested these associations with logistic regression after removing PCR duplicates, but we weighted duplicates to preserve allelic information. In a single individual we have tested 3,815 heterozygous sites for which we have sufficient read depth in all time points. At 10% FDR, we have identified 23 heterozygote SNPs with TASC allelic expression, overlapping 15 protein coding genes (pi1=0. 08; estimate of the proportion of true positives in a P-value distribution). The effect size (beta) of the driving time points in these statistically significant events are concordant with other heterozygous variants within the same exon (r=0. 41, P = 0. 03). Noticeably, we find a 3. 7 fold increase in enrichment of low P-values for genes in RA risk loci associated with super enhancers in human CD4+ T cells (pi1=0. 30, N=57), a 4. 2 fold increase for candidate biological RA risk genes (pi1=0. 34, N=56), and none if we take all genes within risk loci for RA with no prioritization (pi1=0, N=125). We are expanding the experiment to 20 densely genotyped individuals. Additionally, we will evaluate which disease-associated pathways are most affected by genetic regulatory variation during T cell activation. This study will yield novel insights into the genetic variation influencing gene regulation in cell-types and cell-states with important roles in autoimmunity.

Elucidating the gene regulatory mechanisms that control the acute phase response using comparative genomics. *M. Liang[1,2], A. Alizada[1,2], A. Medina-Rivera[1,3], P. Mazrooei[4,5], M. Lupien[4,5], M. Wilson[1,2].* 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, The University of Toronto, Toronto, Ontario, Canada; 3) International Laboratory for Research in Human Genomics, Universidad Nacional Autónoma de México, Juriquilla, Querétaro, México; 4) Department of Medical Biophysics, The University of Toronto, Toronto, Ontario, Canada; 5) Princess Margaret Cancer Centre, University Health Network, Toronto, Ontario, Canada.

The acute phase response (APR) is a highly conserved response to noxious stimuli that is triggered by inflammatory cytokines, resulting in the rapid reprogramming of liver gene expression. There are over 60 secreted APR proteins in humans, defined clinically as any protein whose serum concentration changes by > 25% following inflammation. These "classic" APR proteins participate in several homeostatic processes including blood coagulation, innate immunity, and lipid metabolism and are often used as clinical markers of health and disease. However, relatively little is known about how transcription factors coordinate this extraordinary transcriptional response. To identify gene regulatory mechanisms that drive APR gene expression, we first defined co-regulated modules using mouse liver gene expression datasets obtained from over 30 TF knockout studies. We found modules of APR genes that were regulated by distinct sets of TFs. These APR modules were enriched for specific biological functions and allowed us to make predictions for additional TFs involved in the APR. For example, genes involved in blood clotting and complement were enriched for motifs of canonical liver transcription factors includingHNF1A and ONECUT1 whereas immune response genes were enriched for STAT2 and IRF motifs. Given that the APR is highly conserved in vertebrates, we performed cross-species (human, macaque, dog, mouse rat) analysis of liver enriched TFs to identify shared and species-specific APR gene regulatory regions. We found common and rare genetic variants within conserved APR regulatory regions that are predicted to affect TF binding. We looked for variants representing cross-species genetic differences whose predicted effects were concordant with observed gain or loss of TF binding in other species. One such variant, rs72842444, is predicted to disrupt ONECUT1 binding and resides in a conserved regulatory region in the 3'UTR of *C2*and upstream of*CFB*, both of which are APR genes associated with reduced risk of age-related macular degeneration (ARMD14 [MIM 615489]). This variant is an ancestral macaque allele and corresponds with a loss of macaque ONECUT1 binding. Overall, our findings show that APR genes can be grouped into biologically meaningful clusters that are controlled by specific sets of liver expressed TFs. We propose that variants within conserved APR regulatory regions are important places to look for determinants of variability in the acute phase response.

3099F

Transcriptional and genetic regulatory response to anti-IL-6 treatment in system lupus erythematosus. *E. E. Davenport[1,2], M. Gutierrez-Arcelus[1,2], K. Slowikowski[1,2], J. S. Beebe[3], B. Zhang[3], M. Vincent[3], S. Raychaudhuri[1,2,4].* 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Pfizer Inc. , Cambridge, MA, USA; 4) Faculty of Medical and Human Sciences, University of Manchester, Manchester, UK.

IL-6 is a pleiotropic cytokine and has a range of roles in immune regulation and inflammation. A dose-ranging study conducted in patients with systemic lupus erythematosus (SLE) has provided a unique opportunity to address the questions of response to therapy and identification of genetic variants underlying variation in this response. SLE is a systemic autoimmune disease characterized by the production of autoantibodies, which bind to host tissues. The joints, skin, lungs, blood vessels, kidneys and nervous system are frequently affected but the severity of disease, spectrum of clinical features and response to therapy varies widely between patients. In SLE, IL-6 is thought to play a role in B cell hyperactivity, maintenance of the auto-inflammatory loop and mediating tissue damage. Blocking the effect of IL-6 may improve SLE by reducing the amount of immunoglobulin, produced by hyperactive B cells, and reducing anti-dsDNA antibodies. 180 SLE patients were recruited to evaluate the efficacy and safety of an IL-6 monoclonal antibody, which binds and neutralizes IL-6. The phase II clinical trial randomized patients to placebo or three different doses of study drug (Wallace, D et al. Arth Rheum 66(12) 3529-3540, Dec 2014). The assigned dose of study drug was administered three times during the course of the study. Whole blood was collected at baseline and then at two further time points. Following globin depletion we generated high-depth RNA-seq data (up to 200M mapped reads) for a total of 480 samples. We have aligned data to the reference genome and quantified gene expression using Subread and featureCounts respectively. Following quality control, we will determine the response to drug through differential gene expression analysis using Limma. In addition, genotyping data are available for the individuals, which will allow the mapping of gene expression as a quantitative trait (eQTL). Comparing DNA variants with evidence of an association with gene expression before and after treatment will allow us to identify context specific regulatory variants. Determining the transcriptional response to anti-IL-6 will increase our understanding of the mechanism of action of IL-6 signaling. Integrating these results with the extensive clinical data collected, including outcome measures such as the SLE Disease Activity Index (SLEDAI)-2K score, will yield new insights into the subgroups of patients most likely to benefit from such treatment.

Aminoglycosides stress together with the mitochondria 12S rRNA 1494C>T mutation leads to mitophagy. *J. Yu[1], J. Zheng[1], P. Jiang[1], M. Guan[1,2].* 1) School of medical, institution of genetics, Zhejiang University, Hangzhou, Zhejiang Province, China; 2) Cincinnati Children's Hospital Medical Center, Human Genetics.

Aminoglycosides as modifying factors, modulated the phenotypic manifestation of mitochondrial rRNA mutations and the incomplete penetrance of hearing loss. In this report, using cybrids harboring the m. 1494C>T mutation as cell model, we showed that gentamycin aggravated mitochondrial dysfunction in a combination of the m. 1494C>T mutation. The m. 1494C>T mutation was responsible for the dramatic reduction in the mtDNA encoded proteins of H-strand, except for the MTND6 protein, accompanied with mild reduction of ATP production and increase in mitochondrial reactive oxygen species, compared with those of control cybrids. After exposure to gentamycin, further reduction of mitochondrial ATP production was observed in mutant cybrids with a marked decrease of the mitochondrial membrane potential. More excessive cellular reactive oxygen species was detected with stimulus of gentamycin than those in mutant cells. With gentamycin and m. 1494C>T stress together, more dysfunctional mitochondria were forced to fuse and exhibited mitophagy via up-regulated LC3-B, as a compensatory protective response to try to optimize mitochondrial function, rather than undergo apoptosis. These findings may provide valuable information to further understand of mechanistic link between mitochondrial rRNA mutation, toxicity of aminoglycosides and hearing loss.

RNA-sequencing in the DLPFC of schizophrenia patients and controls identifies novel differentially expressed transcripts originated in transposons. *F. Macciardi[1], G. Guffanti[2], S. Gaudi[3], J. Fallon[1].* 1) Psychiatry & Human Behavior, Univ California, Irvine, Irvine, CA; 2) Department of Psychiatry, Harvard Medical School, Boston, MA; 3) Department of Infectious, Parasitic and Immune-Mediated Diseases, Italian National Institute of Health, Rome, Italy.

Background: Genome-wide association analyses identified several genetic variants mapping to non-coding RNAs as risk factors of neuropsychiatric disorders, including schizophrenia (SZ). Functional studies focused on dysregulation of long-intergenic non-coding RNAs in neuro-developmental and neuro-degenerative disorders leading to evidence supporting a critical role of non-coding RNAs in brain transcriptome functional regulation. Recently, evidence is accumulating on the identification of brain-specific non-coding RNAs originated in transposons with potential cis-regulatory functions. **Methods:** We used RNA-sequencing to identify differentially expressed (DE) transcripts in 10 SZ patients and 10 healthy controls. RNA samples were isolated from Dorsal-Lateral Prefrontal Cortex, prepared for sequencing with Trueseq and sequenced on the Illumina HiSeq 2000. Raw FASTQ files were aligned to the human genome (hg19) using TOPHAT. Transcripts were determined using Trinity de novo assembly, aligned to the reference genome for sequence homology using BLASTn and functionally annotated using Trinotate. DE was determined using EdgeR with a false discovery rate (FDR) q-value of 0. 05 and a fold change (FC) of >2. **Results:** More than 790,000 transcripts were identified, of which 59,258 had FC>2 and 10 were also statistically significant after FDR correction. We initially focused on the characterization of transcripts that present sequence homology with mobile elements of type HERV. First, we identified a putative novel transcript that has sequence homology and protein homology with Zinc Finger 259 (ZNF259) as well as sequence homology with MSTA, the LTR of type ERVL-MaLR (Mammalian apparent LTR retrotransposon). The analysis of the sequence of ZNF259 did not reveal sequence homology with MSTA, which led to the hypothesis that our transcript is a novel chimaeric transcript derived from the fusion of HERV and Zinc finger protein. Second, we identified a lincRNA, whose second exon is derived from the sequence of ORF of HERVL-E. Interestingly, this transcript revealed sequence homology with additional 43 LTR copies with different genomic locations. **Conclusions:** We present here preliminary evidence of differential expression of HERV-derived chimaeric transcripts and non-coding RNAs in the postmortem dorsal-lateral-prefrontal cortex of schizophrenia patients and controls. Further analyses on the structure of these transcripts and their functional consequences are warranted.

Cabrales 2 , Roy Ronen 3, Dan Zhou 1, Orit Poulsen 1, Otto Appenzeller 5, Yu Hsin Hsiao 1, Vineet Bafna 4 and Gabriel G Haddad 1,6,7. 1Division of Respiratory Medicine, Department of Pediatrics, University of California, San Diego, La Jolla, CA 92093, USA2Department of Bioengineering University of California, San Diego La Jolla, CA 92093 USA. 3Bioinformatics and Systems Biology Graduate Program, University of California, San Diego, La Jolla, CA 92093, USA4Department of Computer Science and Engineering, University of California, San Diego, La Jolla, CA 92093, USA5 Department of Neurology, New Mexico Health Enhancement and Marathon Clinics Research Foundation, Albuquerque, NM 87122, USA6Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093, USA7Rady Children's Hospital, San Diego, CA 92123, USACorresponding author:Gabriel G. Haddad: ghaddad@ucsd. edu**Since Polycythemia is a predominant trait in some high altitude dwellers but not others living at the same altitude in the Andes, we took advantage of this human experiment in nature and studied both populations (with and without Chronic Mountain Sickness or CMS). We generated a disease in-the dish-model of polycythemia by re-programming fibroblasts from CMS and non-CMS subjects. As compared to sea level controls and non-CMS subjects who respond to hypoxia by increasing their RBCs modestly or not at all, CMS cells increase theirs remarkably (up to 60 fold) with a dose-dependent response to hypoxia (1. 5, 5, 10% O2). Based on our previous whole genome sequencing of CMS and non-CMS subjects6, we knocked down SENP1 (a desumoylase) in CMS cells using lentiviral constructs and observed a striking reduction (>90%) of the CMS exuberant erythropoietic response to low O2. Furthermore, VEGF, GATA1 and BclXL increase in gene expression in the CMS RBCs, in contrast to the other two populations. By utilizing a SUMO-GATA1 fused construct, we show that GATA1 desumoylation, a target of SENP1, is critical for the CMS phenotype. We conclude that the increased erythropoietic sensitivity in CMS subjects is at least partly due to a gain of function of SENP1 which leads to the activation of GATA1.** .

Effects of hematopoietic stem cell transplant (HSCT) on the oral microbiome of patients with severe aplastic anemia. *N. Ames[1], J. Barb[2], H. Kim[3], A. Oler[4], N. Chalmers[5], A. Ranucci[1], R. Childs[6], A. Cashion[3], G. Wallen[1].* 1) Clinical Center Nursing Department, National Institutes of Health, Bethesda, MD; 2) Mathematical and Statistical Computing Lab, Center for Information Technology, National Institutes of Health, Bethesda, MD; 3) National Institute of Nursing Research, National Institutes of Health Bethesda, MD; 4) National Institute of Allergy and Infectious Diseases, Bioinformatics and Computational Biosciences Branch, Office of Cyber Infrastructure and Computational Biology, Bethesda, MD; 5) National Institute of Dental and Craniofacial Research, National Institutes of Health Bethesda, MD; 6) National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD.

The human microbiome, especially the oral microbiota, might be the key to understanding infections and other perturbations that assault the human body. Patients with severe aplastic anemia undergoing hematopoietic stem cell transplant (HSCT) experience substantial immune system changes as a result of conditioning for HSCT and reconstituting a new immune system. To investigate the role of the oral microbiome during this process, we collected tongue brushings at baseline prior to HSCT, at engraftment and 100 days post-transplant from 4 severe aplastic anemia patients. We hypothesized that modulation of the immune system, the effects of HSCT with its inherent use of obligate antibiotics, would impact bacterial diversity. Bacterial DNA was subjected to next-generation sequencing using Ion Torrent Personal Genome Machine 400-bp kit and 316 v2 chip and the new Ion 16S Metagenomic Kit ™ (Life Technologies) targeting multiple variable regions of the 16S rRNA gene, specifically variable (V) regions, V2, V3, V4, V67, V8 and V9. We developed a novel analytical pipeline and then applied a published processing pipeline specific to Ion Torrent data to compare results across the 6 different regions, using a combination of tools from Mothur, UPARSE and QIIME. Of the 12 samples, two appeared to be outliers and were excluded from further analysis. Proportions of oral bacteria differed based on the variable region. The tongue microbiome during engraftment demonstrated a striking lack of diversity in 3 out of 4 patients. Indicators of microbial diversity demonstrated a trend where diversity decreased at engraftment from baseline and then increased 100 days post-transplant for all 5 variable regions. The genus *Rothia* was found in large proportions in the engraftment samples in most variable regions but markedly less in V3. In all 10 samples, the number of operational taxonomic units (OTUs) present across the 3 groups differed significantly. The post-transplant 100 day samples had fewer OTUs than at baseline but more than in the engraftment samples. With this novel analytical approach, we were able to separate reads into their respective regions without knowing primer sequences and thus were able to show distinctive changes in the oral microbiome before and after HSCT over 5 different hypervariable regions. Our next goal is to use this approach to correlate interventions during HSCT with the changes identified in the oral microbiome.

Crohn's disease (CD) results from an inappropriate immune response to the resident intestinal microbiota. We hypothesize that there exist unique microbial communities in the intestine of patient with CD compared to non-IBD controls. Previous studies have focused on examining the intestinal microbiota using fecal samples, but it is unclear how well these reflect the more physiologically relevant microbial population of mucosally-adherent intestinal bacteria. For our study, we collected mucosal samples from macroscopically non-inflamed and inflamed sections of resected colon and small intestine (ileum) from CD and non-CD patients. For each sample, we performed 16S sequencing of the V1 and V2 regions of the ribosomal RNA of intestinal bacteria, a primary component of the microbiota. Using QIIME, we determined operational taxonomic units (OTU) to classify the bacteria compositions for each sample, and compared the mean bacterial species diversity (α-diversity) between disease phenotypes and between individuals from the same disease phenotype (β-diversity). Overall, we found the α-diversity was significantly decreased in both the ileum and colon in CD patients compared to non-IBD controls. There was no significant change in α-diversity in the ileum due to inflammation within CD patients. We clustered a subset of our CD patients, where we had samples both from inflamed and non-inflamed regions, based on the β-diversity using weighted Unifrac metric. We found that the matched non-inflamed and inflamed samples from the same CD patients clustered with themselves as opposed to by inflammation. This suggests that merely the presence of disease appears to alter microbial compositions across the region as opposed to localizing where the inflammation exists. While the α-diversity exhibited no significant change across inflammation status, we did note changes in the genus of bacteria seen in inflamed versus non-inflamed ileum such as an increase of bacteria in the *Enterococcus* and *Clostridium* genus.

Role of Environment and Diet on Microbiome Composition in Diverse Rural Africans. *M. A. Rubel[1], M. E. B. Hansen[2], A. Bailey[3], K. Bittinger[3], A. Laughlin[3], W. Beggs[2], A. Ranciaro[2], S. Thompson[2], F. D. Bushman[3], S. A. Tishkoff[2].* 1) Department of Anthropology, University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 3) Department of Microbiology, University of Pennsylvania, Philadelphia, PA.

Given their antiquity, African populations may harbor unique physiological adaptations to their environments and diets, including diverse gut microbiomes. To address fundamental questions about sources of variation that can influence the microbial composition of understudied Africans, fecal DNA was extracted from sixty Tanzanians practicing a range of subsistence strategies (Hadza hunter-gatherers, Burunge agriculturalists, Maasai pastoralists, and recently settled Sandawe hunter-gatherers). The bacterial 16S rRNA V1-V2 amplicons were sequenced on the Illumina MiSeq platform. Bacterial communities were characterized by presence, absence, and changes in relative abundance of bacterial taxa. This data was paired with nutritional and ethnographic surveys as well as genetic data from an Illumina 5M Omni SNP Array. Bacterial compositional analysis between and within our populations revealed that the Hadza have a lower within-group diversity than the other populations. Principal coordinate analysis of abundant bacterial families showed that Tanzanians had two predominant gradients of bacteria associated with broad global enterotypes: A strong Prevotellaceae to Ruminococcaceae gradient and a separate, weak Bacteroidales to Ruminococcaceae gradient. Bacteroidales is associated with diets high in protein and fats, whereas Prevotellaceae and Ruminococcaceae are associated with diets rich in plants and fiber. This result is consistent with what we would expect from populations with rural, nonwestern diets. Mantel tests indicated that the presence or absence of bacteria in our populations has a stronger geographic correlation than bacterial abundance, consistent with low abundance taxa having strong regional variation. This represents one of the largest microbiome studies to date of ethnically diverse Africans with a wide range of subsistence strategies living indigenous lifestyles and provides novel microbiome data from sparsely characterized African groups.

3106T

ABO antigen and secretor status are not associated with gut microbiota composition. *E. R. Davenport[1], J. K. Goodrich[1,2], J. T. Bell[3], T. D. Spector[3], R. E. Ley[1,2], A. G. Clark[1].* 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, USA; 2) Department of Microbiology, Cornell University, Ithaca, NY, USA; 3) Department of Twin Research and Genetic Epidemiology, King's College London, UK.

Microbes in the gut interact with their host through mechanisms that may include cell surface and secreted human antigens. One such potential antigen is encoded by the *ABO* gene and is classically known as the major red blood cell histo-incompatibility molecule for blood transfusions. This antigen is not only found on the surface of red blood cells, but is also secreted from epithelial and endothelial cells in individuals with an intact *FUT2* gene ("secretors"). In addition to transfusion medicine, ABO and secretor status play important roles in several diseases, including inflammatory bowel, cardiovascular, and infectious disease risks. It is unclear, however, whether inter-individual variation in the expression of these antigens in the gut affects the microbiota, and in turn, whether the microbiota mediates risk for diseases known to be associated with ABO or secretor status. In this study, we examined the relationship between ABO, secretor status, and the composition of the gut microbiome in a cohort of >900 individuals from the United Kingdom Adult Twin Registry (TwinsUK). 16S rRNA gene sequencing was used to characterize microbial composition in stool for each individual, utilizing Illumina MiSeq technology. First, we sought to identify broad trends in the microbiome with ABO status, secretor status, and the interaction of ABO by secretor status by performing principal components analysis, discriminant analysis of principal components, and principal coordinates analysis of Bray-Curtis and Unifrac indices. These methods applied to both presence/absence data and bacterial abundance measurements of the common operational taxonomic units (OTUs) failed to identify clustering by ABO or secretor status. Next, we applied linear mixed models with terms to account for the relatedness among twins to identify bacterial OTU or taxa abundances that were associated with ABO status or secretor status. After correcting for multiple tests using *q*-values, zero associations were identified even at a lenient $q <= 0.1$ significance threshold. Finally, we applied a random forests classification scheme to attempt to classify ABO or secretor status in individuals using the abundances of common bacterial taxa. The resulting classification error rates for each model were high (>50% error). These results from a large cohort demonstrate that despite previous reports, the taxonomic composition of the microbiota does not appear to be associated with ABO or secretor status.

Rapid growth between birth and two years is associated with lower diversity in oral and gut microbiomes. *S. J. C. Craig[1,2], D. Blankenberg[3], D. Bouvier[3], M. E. Marini[4], J. S. Beiler[5], N. Verdiglione[5], J. S. Williams[4,6], L. L. Birch[7], F. Chiaromonte[2,8], A. Nekrutenko[3], I. M. Paul[2,9], K. D. Makova[1,2].* 1) Department of Biology, Penn State University, University Park, PA; 2) Center for Medical Genomics, Penn State University, University Park, PA; 3) Department of Biochemistry and Molecular Biology, Penn State University, University Park, PA; 4) Center for Childhood Obesity Research, Penn State University, University Park, PA; 5) Pediatrics Support Services, Penn State University, Milton S. Hershey Medical Center, Hershey, PA; 6) Department of Nutritional Sciences, Penn State University, University Park, PA; 7) Department of Foods and Nutrition, University of Georgia, Athens, GA; 8) Department of Statistics, Penn State University, University Park, PA; 9) Department of Pediatrics, Penn State College of Medicine, Hershey, PA.

Rapid infant growth, commonly defined as upward crossing of two major centile lines on pediatric weight-for-length growth charts, has emerged as one of the strongest risk factors for childhood obesity. The human microbiome, a collection of organisms that form distinct communities on different areas of the human body, is also emerging as a causative and predictive environmental factor to the development of obesity. The initial composition of these microbial communities reflects various perinatal factors and changes drastically over the first years of life. Therefore, the characterization of these communities and their development is essential for a more complete understanding of the etiology of childhood obesity. Changes in the gut microbiome in early life are influenced by diet, mode of delivery, and medication use. However, these differences have not been demonstrated using an unbiased technology in a large and phenotypically well-characterized study cohort. Furthermore, no studies have investigated the oral microbiome in conjunction with the gut microbiome as an additional potential influence on childhood obesity, or the relationship between the gut and oral microbiomes. In this study, we have used 16S sequencing to survey the gut and oral microbiomes of 125 two-year-old children for whom extensive social, behavioral, and phenotypic data were collected. We found that children with rapid weight growth within the first two years after birth have a lower diversity in both their oral and gut microbiomes than those children who do not have rapid weight growth. This indicates that there is a relationship between rapid weight growth rate in the first two years and the establishment of a perturbed microbiome, which is likely influenced by developed lifestyle and behavioral patterns.

3D-NOME: an integrated **3-D**imensional **N**ucle**O**me **M**odeling **E**ngine for data-driven simulation of spatial genome organization. D. Plewczynski1,2,3, P. Szalaj3,4, Z. Tang2, P. Michalski2, M. Pi-tal1, O. Luo2, X. Li2, Y. Ruan2. 1) Centre of New Technologies, University of Warsaw, 00-927 Warsaw, Poland; 2) The Jackson Laboratory for Genomic Medicine, Farmington, CT, USA; 3) Centre for Innovative Research, Medical University of Bialystok, Bialystok, Poland; 4) I-BioStat, Hasselt University, Belgium.

Background: Chromosomal folding are important features of genome organization, which play critical roles in genome functions, including transcriptional regulation. Using 3C-based mapping technologies to render long-range chromatin interactions has started to reveal some basic principles of spatial genome organization. Among 3D genome mapping technologies, ChIA-PET is unique in its ability to generate multiple datasets (in a single experiment), including binding sites, enriched chromatin interactions (mediated by specific protein factors), as well as non-enriched interactions that reflect topological neighborhoods of higher-order associations. The multifarious nature of ChIA-PET data represents an important advantage in capturing multi-layer structural-functional information, but also imposes new challenges in multi-scale modeling of 3D genome. **Results:** We report the development of 3D-NOME (*3-Dimensional* **N***ucle***O***me* **M***odeling* **E***ngine*), for processing ChIA-PET data, which includes four components: 1) identifying interactions from ChIA-PET reads, 2) multidimensional scaling on proximity graph distances for rapid low-resolution structural inference, 3) multiscale Monte Carlo algorithm for high-resolution simulations, and 4) web-based visualizing tool. Using ChIA-PET data of human B-lymphocytes (GM12878 cell line), we demonstrate the effectiveness of 3D-NOME in building 3D genome models at multiple levels, including the entire nucleome, individual chromosomes, specific segments at megabase (Mb) and kilobase (kb) resolutions. We also consider CTCF-motif orientations and looping patterns in order to achieve more reliable structures. **Conclusions:** 3D-NOME is an integrative computational pipeline that is effective in processing the multifaceted ChIA-PET data for simulation of 3D genome from higher-order chromosome folding to detailed functional interactions mediated by protein factors. Further refinement of 3D-NOME and application to additional ChIA-PET and other types of 3D genome mapping data will help to advance our understanding of genome structures and functions.

***In vitro* and *in vivo* exploration of regulatory variation in melanocytes.** *M. B. Baker[1], D. U. Gorkin[1], D. Lee[1], M. A. Beer[1,2], A. S. McCallion[1].* 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University, Baltimore, Maryland, United States of America; 2) Department of Biomedical Engineering, Johns Hopkins University, Baltimore, Maryland, United States of America.

Recent studies have highlighted the importance of non-coding variation in disease, with conservative estimates suggesting that at least 40% of SNPs implicated in disease by GWAS fall into haplotype blocks devoid of coding sequence. Predicting the impact of genetic variation in the non-coding space of the genome has remained elusive. To that end, we developed a computational classifier to estimate the impact of variation on regulatory sequences (presented by Dongwon Lee). The classifier was trained on a set of putative melanocyte enhancers defined by the intersection of EP300 and H3K4me1 ChIP-seq signals in melanocytes. To validate the classifier, we initially selected two well-characterized melanocyte enhancers for our analyses, using the classifier to predict the functional consequences of all possible nucleotide substitutions at every site along their length. We then selected a subset of variants predicted to have positive, negative, or no effect to test functionally *in vitro* using a luciferase reporter. We observed a high correlation of the reporter expression with our classifier's predictions. We recognize that *in vitro* assays are inherently synthetic, removing candidate sequences from their endogenous context and evaluating them in mini-gene constructs that we introduce into cells. To begin to address this limitation, we have started to employ circularized chromatin conformation capture followed by sequencing (4C-seq), which allows us to infer physical proximity of sequences *in vivo*. Enhancers are thought to be brought into looping structures with the promoters they regulate; with 4C-seq, we capture putative enhancer sequences that physically interact with promoters of interest. We have generated a 4C-seq profile using the promoter of melanocyte-critical *Sox10* and are in the process of validating the contacts identified. To further explore the relationship of putative regulatory sequences to one another and gene expression in hopes of better understanding the role of non-coding variation in disease, we are employing CRISPR/Cas9 to selectively delete candidate sequences and assess the effect of their loss on looping and transcriptional output. .

Massive parallel sequencing revealed the conformational dynamics of the non-B form DNA at the promoter. *H. Inagaki[1], H. Miyamura[2], M. Tsutsumi[1], T. Kato[1], H. Nishizawa[2], H. Kurahashi[1].* 1) Div Mol Genet, ICMS, Fujita Health University, Toyoake, Aichi, Japan; 2) Dpt Obstet Gynecol, Fujita Health University School of Medicine, Toyoake, Aichi, Japan.

Alternate DNA structures such as non-B form DNAs cause the chromosome structural aberrations and change the gene expression. The connection between the polymorphisms within the annexin A5 gene (*ANXA5*) promoter and the obstetric complications including the recurrent pregnancy loss is highlighted in recent reports, although its mechanism is still unknown. Previously, we have reported that the polymorphisms in the *ANXA5* promoter affected the gene expression possibly through the predisposition for G-quadruplex (G4) structure. *In vivo* G4 formation can be detected by the sodium bisulfite treatment of the genomic DNA, which converts the cytosine to thymine specifically at the single-stranded region. In the present study, we analyzed the pattern of nucleotide changes in each strand to elucidate the G4 formation pattern in a single cell level. The genomic DNA from the placenta was treated with sodium bisulfite in a mild condition, not to dissociate the DNA strand during the treatment. This DNA was used for the PCR template and the *ANXA5* promoter region was amplified with the specific primers adding the adaptor sequences for the massive parallel sequencing at the 5' ends. About one to ten thousands sequences per sample was obtained by Illumina MiSeq sequencer. After the quality control, these sequences were assigned to each strand, i. e. upper strand or lower strand, according to the conversion of the nucleotides (C>T or G>A). The sequences were then clustered into groups according to the conversion pattern by using the MAFFT and other programs. The results indicated that the small amount (5-10%) of the molecules indeed formed the single-stranded form that is shown by the clusters of the converted nucleotides extended across the region ranging from 30 to 100 bp. We found two conversion patterns: one cluster at the complementary position of the G4 consensus region of the promoter indicating the G4 *in vivo*, and the other cluster extending to the downstream from the promoter indicating the signature of mRNA transcription initiation. These patterns were slightly different between normal allele and decreased expression allele (M2), suggesting the G4 formation may contribute the upregulation of the gene expression. The overall patterns of the single-stranded region may represent the temporal change of the DNA structure *in vivo*, and this technique combined with the NGS technology will shed light on the dynamics of DNA conformation in the cell.

3111F

Translational correlation of MeCP2 binding dynamics and clinical presentation of male patients with missense mutations. *T. I. Sheikh[1,2,7], J. Ausio[3], H. Faghfoury[4], J. Silver[4], A. Percy[5], J. B. Lane[5], P. MacLeod[6], J. B. Vincent[1,2,7].* 1) Molecular Neuropsychiatry & Development (MiND) Lab, Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 2) Institute of Medical Sciences, University of Toronto, Toronto, ON, Canada; 3) Department of Biochemistry and Microbiology, University of Victoria, BC, Canada; 4) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network and Mount Sinai Hospital, Toronto, ON, Canada; 5) Civitan International Research Center, University of Alabama at Birmingham, AL, USA; 6) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 7) Department of Psychiatry, University of Toronto, Toronto, ON, Canada.

The Methyl CpG Binding Protein 2 (MeCP2) binds to methylated DNA through its methyl binding domain (MBD) to regulate gene expression. Mutations in the*MECP2*gene are the main cause of Rett syndrome (RTT). In heterozygous females the variable severity of phenotypic conditions is modulated by non-random X inactivation, thus making phenotype/genotype comparisons unreliable. However phenotype/genotype correlations in males with hemizygous*MECP2*mutations may provide more accurate insights into the true biological effect of specific mutations. The functional effects of different MeCP2 mutants have been studied extensively, but reports of direct correlation of functional effects of missense mutations in the hemizygous males are extremely rare. Here, we present a rational comparison of 1) the effect on binding properties of various common and rare MeCP2 MBD mutants and their consequences on overall chromatin organization; 2) the distinct mobility dynamics and binding patterns of the mutant MeCP2 proteins; and 3) phenotypic comparison for MeCP2-variant hemizygous males. We found a complete absence of MeCP2-DNA interaction for mutations on or close to the MBD-methylated DNA binding interface such as Arg111Gly, Arg133Leu, Thr158Met, and Arg106Trp which is present on the β-sheet site directing towards the MBD-DNA binding interface. On the other hand, Pro152Arg and two novel mutations in male Pro152His and Asn126Ile showed chromatin clustering defects. Furthermore, binding and mobility dynamics of Arg111G, Thr158Met, Pro152Arg, Pro152His and Pro152A show a gradient of impairment (severe to mild), depending on the physical and chemical properties of the substituting amino acid. All these changes are strictly site specific in the tertiary structure of MeCP2. Interestingly, a similar wide range of phenotype/clinical severity, ranging from neonatal encephalopathy to mild psychiatric abnormalities, consistent with the functional severity were observed, i. e. Thr158Met> Phe157Ile > Asn126Ile>Arg-133Cys> Pro152His > Arg167Trp> Pro152Ala >wild type, which show a direct phenotype genotype correlation in the MeCP2 hemizygous male patients.

Wilson[1,3].* 1) Genetics and Genome Biology Program, SickKids Research Institute, Toronto, ON, Canada; 2) Department of Gene Technology, Tallinn University of Technology, Tallinn, Estonia; 3) Department of Molecular Genetics, University of Toronto, Canada; 4) Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, ON, Canada; 5) Research Department of Cancer Biology, Cancer Institute, University College London, London, UK; 6) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Trust Genome Campus, Hinxton, Cambridge, United Kingdom; 7) The Donnelly Centre, University of Toronto, Toronto, ON, Canada; 8) Present address: The Babraham Institute, Cambridge, United Kingdom; 9) Present address: Syncona Partners LLP, London, United Kingdom; 10) Present address: Laboratory of Systems Biology and Genetics, Lausanne, Switzerland; 11) Present address: International Laboratory for Research in Human Genomics, Universidad Nacional Autónoma de México, Juriquilla, Querétaro, México; 12) Cancer Research UK, Cambridge Institute, University of Cambridge, Cambridge, United Kingdom.

Type II DNA topoisomerases are critical enzymes that regulate DNA topology by generating double stranded DNA breaks. Topoisomerase II beta (Top2b) is required for vertebrate development and has been implicated in treatment related cancers and chemotherapeutic side effects. Characterizing the protein interaction networks of TOP2B and genome-wide occupancy is required for understanding its role in vertebrate development and the mechanisms behind off-target effects in chemotherapy. Using proteomic analysis (BioID), chromatin immunoprecipitation (ChIP), and high-throughput chromosome conformation capture (Hi-C) we detect proximal TOP2B protein interactions *in vitro* and characterize the genomic landscape of Top2b binding *in vivo*. We find that TOP2B interacts with various chromatin regulators and localizes to active chromatin regions that show hallmarks of function including DNAse I hypersensitivity and conserved transcription factor binding. Specifically, TOP2B interacts with CTCF and several members of the cohesin complex. Top2b/Ctcf/cohesin proteins bind chromatin with a distinct spatial organization and are enriched at the boundaries of chromosomal domains. Our findings show that TOP2B is robustly positioned to resolve topological constraints at critical points of genome control and suggest a novel mechanism by which Top2b-mediated double strand breaks could impact human disease and treatment related phenotypes.

Reconstructing A/B compartments as revealed by Hi-C using long-range correlations in epigenetic data. *K. D. Hansen[1,2], J. P. Fortin[1].* 1) Dept. of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA; 2) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins School of Medicine, Baltimore, MD, USA.

Introduction: Analysis of Hi-C data has shown that the genome can be divided into two compartments called A/B compartments. These compartments are cell-type specific and are associated with open and closed chromatin. Existing Hi-C experiments have largely been performed in cell lines or for samples where unlimited input material is available. Here we show that A/B compartments can be reliable estimated using epigenetic data from several different platforms: the Illumina 450k DNA methylation microarray, DNase hypersensitivity sequencing, single-cell ATAC sequencing and single-cell whole-genome bisulfite sequencing. This work makes A/B compartments readily available in a wide variety of cell types, including many human cancers. Results: We first estimated A/B compartments from two Illumina 450k Methylation array datasets (Fibroblasts and EBV-transformed lymphoblastoid cell lines) by exploiting the fact that correlations of methylation levels between two regions located in the closed compartment are substantially higher than between other regions. At resolution 100kb, we showed good correlation with A/B compartments estimated from public Hi-C experiments performed on the GM12878 and IMR90 cell lines. Next, we showed that A/B compartments can be estimated similarly from DNase hypersensitivity sequencing by using two publicly available datasets: 70 HapMap samples and 4 replicates of the IMR90 cell line. Remarkably, our method can be further applied to single-cell epigenetic data to study within-individual genome compartmentation by using a publicly available single-cell ATAC sequencing experiment and a single-cell whole-genome bisulfite sequencing experiment. As an valuable application, we estimated A/B compartments for 11 cancer types from The Cancer Genome Atlas (TCGA) by using the publicly available 450k methylation datasets. We emphasize that TCGA does not included assays measuring chromatin accessibility such as DNase or various histone modifications, therefore making our estimated compartments a valuable data source for the community. Conclusion: This work makes A/B compartments readily available in a wide variety of cell types, including many human cancers. Our reliable estimation of the genome compartmentation from single-cell epigenetic data potentially allows our method to be used on rare types of cells.

3114T

High Quality Next-Generation Sequencing Libraries for Sub-Nanogram Amounts of ChIP DNA. *C. Couture[1], J. Irish[1], A. McUsic[1], J. Laliberte[1], L. Kurihara[1], R. Spurbeck[1], C. Schumacher[1], V. Makarov[1], D. Langlais[2], G. D. Gilfillan[3].* 1) Swift Biosciences, Ann Arbor, USA; 2) McGill University, Montreal, Canada; 3) Norwegian High Throughput Sequencing Centre, Oslo, Norway.

ChIP-Seq is widely used to produce genome-wide profiles for chromatin proteins and transcription factors. However, ChIP DNA samples are inefficiently converted into next-generation sequencing (NGS) libraries due to the limited quantity and quality of DNA samples following de-crosslinking, especially when only low cell numbers are available (patient samples, biopsies). To overcome these limitations, we developed a library preparation method that utilizes as little as 100 pg of ChIP DNA to generate highly complex NGS libraries with exceptional coverage of GC-rich regions, thus reducing the sequencing depth requirements. To validate the range of input levels required for comprehensive detection of precipitated regions using our method, we generated libraries from two ChIP DNA amounts using different master ChIP samples made with antibodies against the interferon response regulator IRF8, the hematopoietic transcription factor PU. 1, or the histone modification H3K4me3. ChIP DNA was quantified by Bioanalyzer and 1 ng or 100 pg were used to prepare a series of NGS libraries that were sequenced on the Illumina®platforms. In all three ChIP samples, when correcting for sequencing depth, we observed the same number of binding sites for samples prepared from 1 ng or 100 pg with about 90% overlapping peaks between the two different inputs suggesting that 100 pg of starting material provides the same profile as 1 ng. The peaks that were exclusive to one or the other input had low quality peak scores suggesting low confidence peaks just above the background threshold. To further analyze PU. 1, we performed deep sequencing and analyzed the number of peaks as a function of the number of reads. The 1 ng and 100 pg rarefaction curves were similar and reached the maximum at the same depth of sequencing indicating preserved complexity even at low input. Our new library preparation method pushes the limits for low input ChIP samples. Our highly efficient method, coupled with the high complexity of the resulting libraries, generates high quality sequencing data and eliminates the need for deep sequencing or additional replicates to obtain confident peak calls. Our proven library preparation method also supports inputs as low as 10 pg for whole genome sequencing and doesn't require precise input quantification (a limitation of other library preparation protocols). We are currently working to further reduce our ChIP input requirement to 10 pg.

Whole Genome Sequencing (WGS) provides a more complete ascertainment of de novo mutation compared to microarrays or target sequencing. An exhaustive investigation of structural variation in a large ASD cohort has not yet been reported. We investigated the contributions of de novo structural variants including copy number variants (CNVs), transposable elements, and complex structural rearrangements to autism spectrum disorder (ASD) by WGS and custom mutation detection in 235 subjects, including 71 with ASD, 26 sibling controls and their parents. Deletions, Duplications, Inversions and a variety of complex structural rearrangements were detected using a custom SV calling pipeline, and de novo mutations were detected using a Gaussian Mixture Model-based SV genotyper. A high rate of de novo copy number variation was observed in controls (15% of subjects), revising previous estimates. CNVs in ASD cases were enriched for genes that are mutated in independent studies of neurodevelopmental disorders. Recurrent mutations detected here and in independent studies implicate specific genes in ASD, including of CDH8, TMEM185A and CACNG2. WGS captures a wide spectrum of human mutation and promises to accelerate genetic discovery in ASD.

3116T

The copy number variation (CNV) database for autism spectrum disorder (ASD). *X. Liu[1], J. Nomura[1,2], Y. Yamaguchi[3], T. Takumi[1].* 1) Mental Biology Team, RIKEN Brain Science Institute , Wako, Saitama , Japan; 2) Graduate School of Biomedical Science, Hiroshima University, Hiroshima, Japan; 3) Neuroinformatics Japan Center (NIJC), RIKEN Brain Science Institute, Wako, Saitama, Japan.

Copy number variations (CNVs) are defined as duplication or deletion of a section of DNA with a length usually from 1 kb to several Mb. They are widespread in the human genome and account for a substantial proportion of genetic variation. Recent studies have demonstrated that CNVs are critical pathogenetic factors to autism spectrum disorder (ASD) - a severe early onset nerurodevelopmental disorder characterized by social impairments and communication difficulties. With the accumulating CNV data, it becomes urgent to build an up-to-date and comprehensive, accurate and well-annotated, flexible, yet easy to use database for both research and clinical settings. Here, we present an ASD CNV database based on manually curated information from literatures and Japanese data from our own study. In addition, we adopt a novel approach to visualize complex CNV data and also provide human to mouse synteny maps for all CNVs, which is particularly relevant to animal studies. In summary, this database is a useful resource to tackle the genetic complexity of ASD and also may help clinicians for better diagnoses and care for ASD individuals.

3117F

Building a dosage map of the genome to assist in CNV interpretation. *A. E. Hare[1], B. R. King[2], E. L. Easse[2], D. H. Ledbetter[1], C. L. Martin[1].* 1) Autism & Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA; 2) Computer Science Dept. , Bucknell University, Lewisburg, PA.

In order to assess the pathogenicity of copy number variants (CNVs) in developmental brain disorders (DBD), we constructed dosage maps of CNVs (>1 kb) and compared shared and unique regions of variation in the genome between cases and controls. While previous similar maps have been constructed by merging overlapping CNVs, we employed a different approach utilizing CNV frequency to identify regions of variation. Each map was constructed by quantifying the number of dels/dups at each basepair along a chromosome and joining adjacent nucleotides that have the same number of variants (+/-5) into variant blocks. In controls, we created maps of 1,075,110 deletions (dels) and 130,487 duplications (dups) from 23,842 controls in the Database of Genomic Variants (DGV; October 16, 2014 release date). In a control population, blocks with a high number of CNVs are predicted to be dosage tolerant (DT) and not likely to confer risk for disease, while blocks with little to no CNVs are potentially dosage sensitive (DS). For the control deletion map, we defined the DS cut-off as <150 dels (corresponding to a population frequency threshold of <0. 01% in DGV) and DT as ≥150 dels by using a ROC curve analysis based on known haploinsufficient regions or genes curated as part of the ClinGen project. In controls, 0. 89% of the genome is DT and dels in these regions (avg size = 16. 7 kb) are predicted to be benign. Similarly, using triplosensitivity data from ClinGen for our control duplication map we found that 0. 97% of the genome is DT and dups in these regions (avg size = 55 kb) are also predicted to be benign. For cases, we constructed maps of 10,987 CNVs from 13 studies of DBD cases in dbVar with clinical assertions of uncertain or likely pathogenic/pathogenic. Genomic regions with a high number of CNVs in cases and not in controls are predicted to be DS. In cases, pathogenic dels encompass 11. 0% of the genome, while pathogenic dups span 24. 7% of the genome. Uncertain dels cover 3. 61% of the genome and uncertain dups span 0. 99% of the genome. For dels and dups in the pathogenic and uncertain maps, there was <1. 0% overlap with DT regions defined in the control maps; therefore we were able to determine that these regions are DS. By comparing the overlap of novel CNVs to DT regions in controls and DS regions in cases, the dosage maps presented here can assist in the assessment of variant pathogenicity to inform clinical interpretations.

Mapping the "Dark Matter" of the Genome – Complex Structural Variations and Towards True Contiguity of *de novo* Assembly with NanoChannel Technology. *H. Cao[1], A. Hastie[1], E. T. Lam[1], A. Pang[1], W. Andrews[1], T. Anantharaman[1], T. Chan[1], X. Zhou[1], J. Reifenberger[1], H. Saghbini[1], M. Austin[1], P. Sheth[1], Z. Y. Zyu[1], Z. Dzakula[1], X. Xun[2], P. Kwok[3].* 1) BioNano Genomics Inc. , San Diego, CA; 2) BGI, Shenzhen, China; 3) UCSF, San Francisco, CA.

Large genomic structural variations (SV, >1 kb) known to be associated with complex traits and diseases are found to be more prevalent than previously thought. In spite of the advancements made in high-throughput short read next-generation sequencing, a fair portion of the human genome architecture is unresolved or ambiguously characterized as gaps and unknown structural or heterozygous information, also known as the "dark matter" of the genome. Rapid whole genome mapping using NanoChannel Arrays represents a new standard of single-molecule platform independent and yet complementary to DNA sequencing for accurate genome assembly and structural variation analysis. Extremely long intact DNA molecules of hundreds to thousands of kilobases fluorescently labeled at sequence motifs and linearized in true nanofluidic channels enable direct image interrogation of the genome's architecture at a high resolution. *De novo* assembly of these single molecules yields long contiguous genome maps, spanning highly repetitive regions and complex structures in their native form. Here we present results from analysis on human diploid and cancer genomes, non-model and large complex genomes. Two methods were employed either by the *de novo* genome mapping process or direct alignment of long raw molecules against a digitally digested and "barcoded" reference genome yielding detection of chromosomal abnormalities such as translocations, arm breakpoints or other lesions. Using ultra long molecules and the Irys® System, unknown SV events, such as chromothripsis, that often incorporate fragmented chromosome arms shattered during cancer transformation can be bridged. In these genomes, we detected haplotype differences and hundreds of large SVs revealing the locations, orientations, and copy numbers of complex SVs that are biologically and clinically relevant; and precisely mapped viral component integration sites within the human genome believed to be linked to genome instability and oncogenesis. Now, a population scale comparative whole genome study to identify comprehensive genomic SV on a single platform with a large patient cohort is feasible due to the standardized high quality data and automated efficiency of data generation enabled by NanoChannel technology.

Characterization of Common Maternal Copy Number Variations observed in Non-Invasive Prenatal Testing. *Y. Sun, E. Almasri, Y. Wu, A. R. Mazloom, M. Ehrich, T. Burcham, S. Kim.* Sequenom, Inc. , San Diego, CA.

Low coverage genome wide sequencing is a common method for non-invasive prenatal testing to detect fetal aneuploidies. Our method uses normalized sequencing reads to determine the local over- or under-representation of sequence counts, to infer fetal copy number variations (CNV). However, because circulating cell free DNA (ccfDNA) in maternal plasma is a mixture of maternal and fetal DNA, maternal CNVs can be detected by the same principle. Here, we present the population-level characterization of maternal CNVs identified within a research-consented de-identified cohort of over 51,000 samples. More than 40% of the samples in the cohort have at least one putative maternal CNV, with an average size of 145 Kb. These CNVs have significant overlap (p<0. 01, Fisher's exact test) with the regions reported in the Database of Genomic Variants (DGV, http://dgv. tcag. ca/) despite the latter involving a wide range of experimental methodologies, such as qPCR, aCGH, MassSpec and FISH for CNV identification across worldwide populations and with varying resolution. Specifically, we have identified 28 samples within our cohort that share the largest most frequent 2. 3 Mb CNV event on chromosome 8p23 which is consistent with the regions reported in DGV. Additionally, we have identified a total of 8 samples, in which copy number variations were located in regions of known cancer genes (EGFR, RB1 and SMARCB1). Furthermore, it is observed that deletion events are significantly lower in Guanine-Cytosine (GC) rich regions than in GC poor regions (p<0. 01, Wilcoxon rank sum test). As gene-rich regions are correlated to regions of high Guanine-Cytosine base composition, these results are suggestive of selective pressures against detrimental deletions. Overall, we analyzed the frequency and genomic distribution of maternal CNVs in a large cohort of pregnant women, and found many CNVs that are associated with various pathologies.

3120T

Copy Number Variation Associated With Bronchopulmonary Dysplasia. *A. Ahmad[1], S. Bhattacharya[1], T. J. Mariani[1], A. M. Iqbal[2].* 1) Department of Pediatrics, University of Rochester Medical Center, 601 Elmwood Ave. , Rochester - NY, 14642; 2) Department of Pathology and Laboratory Medicine, University of Rochester Medical Center, 601 Elmwood Ave. , Rochester- NY 14642.

Bronchopulmonary Dysplasia (BPD) is common in premature babies born before 29 weeks of gestational age and weighing <2. 2 lb. Variability in the incidence and severity of BPD among premature infants with similar risk factors suggests that genetic susceptibility plays a significant role in its pathogenesis. The goal of this study is to leverage existing clinical DNA microarray data repositories to identify CNV that are either predictive of, or associated with, BPD. We conducted a retrospective analysis of clinical DNA microarray data (n=2800) from our institution. We identified 19 subjects diagnosed with BPD, and two controls groups with no lung-related disease; full-term (n=41) and pre-term (n=23). DNA microarray experiments were previously performed on 4x44K Agilent platform and data were re-analyzed using Feature Extraction v10. 10 and Genomic Workbench v7. 0 software (Agilent Technologies, USA). To test for differences in the frequency of individual CNV between BPD and control groups, we used Fisher's Exact test. To test for development-associated changes in expression for genes residing in the CNV regions, we interrogated a previously published normal human lung development expression dataset. To test for pathways and processes represented by genes residing within CNV regions, we used Ingenuity pathways analysis tools. Among 19 subjects with confirmed diagnosis of BPD, three loci, at 11q13. 2, 16p13. 3. and 22q11. 23-q12. 1, were affected in more than one subject. The frequency of all three recurrent loci were significantly higher (p<0. 05) in BPD subjects as compared with at least one control group. We found fifteen of 21 genes (71. 4%) within the recurrent CNV loci demonstrated significant changes (p<0. 05) in expression between the pseudoglandular and canalicular stages of human lung development, approximately at the time of preterm birth for subjects with the greatest risk of BPD. Genes within the recurrent CNV loci were involved in various development- and disease-related processes. We also identified canonical pathways represented by the 21 genes, which included AHR signaling, xenobiotic metabolism signaling and glutathione-mediated detoxification. We have identified regions in the genome that are recurrently affected in subjects with BPD. Our data should be useful to aid in the identification of genetic factors associated with increased risk for chronic lung disease in preterm infants.

3121F

SMN2 copy number frequency in a sample of the Brazilian Population. *M. Goncalves, P. G. COUTO, L. B. ALVIM, T. SANTOS, N. P. LOPES, A. G. ASSINI, E. L. CONCENTINO, G. C. LOPES, N. REGINA, A. M. CASTRO.* INSTITUTO HERMES PARDINI, VESPASIANO, MG. , BRASIL.

INTRODUCTION: Spinal Muscular Atrophy (SMA) is one of the most common autosomal recessive neuromuscular disease and is usually caused by deletions of the survival motor neuron 1 (*SMN1*) gene. A closely related gene, *SMN2*, modifies the disease severity. Due to a single nucleotide polymorphism (840C>T), *SMN2* produces less full-length transcript than *SMN1* and cannot entirely prevent neuronal cell death at physiologic gene dosages. Determination of SMN2 copy number frequency have not been reliably estimated in Brazilians and is important to define, along with the age of onset and the severity of symptoms, the type of SMA (I, II, III or IV) when the individual do not present any copy of SMN1. **METHODS:** Genomic DNA was isolated from peripheral blood cells from 162 Brazilian individuals using Gentra Puregene Blood Kit (Qiagen). The DNA was quantified using Nano-View and the ratio 260/280 nm was measured to obtain the purity of DNA. The Multiplex ligation-dependent probe amplification (MLPA) for genetic testing of SMA was based on the commercially available SALSA MLPA kit P021 to determine *SMN1* and *SMN2* copy numbers. The electrophoresis capillary was carried out in an ABI3730 DNA analyzer. The 36cm capillary was used with POP7 polymer and the GeneScan 500 ROX dye Size Standard. **RESULTS:** Our sample consisted of 79 men (48. 8%) and 83 women (51. 2%). Of all 162 samples tested we found that 6/162 (3,7%) had 0 copies of *SMN2*, 15/162 (9,26%) had 1 copie of SMN2, 56/162 (34,57%) had 2 copies of *SMN2*, 54/162 (33,33%) had 3 copies os *SMN2*, 24/162 (14,81%) had 4 copies of *SMN2*, 6/162 (3,7%) had 5 copies of *SMN2* and 1/162 (0,62%) had 6 copies of *SMN2*. **CONCLUSIONS:** According to the literature, the *SMN2* copy number distribution in Brazilians were similar to Europeans that are more likely to harbor 2 copies of *SMN2* but its different from sub-Saharan Africans that are more likely to harbor 1 copies of the gene. This finding is important to consider in SMA genetic diagnostic in individuals with zero copies of *SMN1*, to determine the severity of the disease.

3122T

Characterization of NAHR-mediated type-1 *NF1* deletions with breakpoints within the PRS2 hotspot. *H. Kehrer-Sawatzki[1], M. Hillmer[1], D. Wagner[1], M. Daiber[1], V. -F. Mautner[2], D. N. Cooper[3], L. Messiaen[4].* 1) Institute of Human Genetics, University of Ulm, Ulm, Germany; 2) Department of Neurology, University Medical Centre, Hamburg-Eppendorf, Germany; 3) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, UK; 4) Medical Genomics Laboratory, Department of Genetics, University of Alabama at Birmingham, USA.

NF1 microdeletions are observed in 5% of neurofibromatosis type 1 (NF1) patients. The majority of *NF1* microdeletions span 1. 4-Mb as determined by MLPA, the most commonly used detection technique. Most of the 1. 4-Mb deletions exhibit breakpoints located within the low-copy-repeats, NF1-REPa and NF1-REPc, which exhibit 97. 5% sequence homology within 51-kb. The 1. 4-Mb deletions with breakpoints in the NF1-REPs are designated “type-1 *NF1* deletions” and have been considered to be caused by non-allelic homologous recombination (NAHR). However, owing to the wide spacing of the MLPA probes, it is impossible to distinguish between type-1 *NF1* deletions mediated by NAHR and atypical *NF1* deletions not mediated by NAHR. In this study, we analysed 67 independent type-1 *NF1* deletions initially identified by MLPA. We performed SNP genotyping as well as breakpoint-spanning PCRs and found that 95% of *NF1* deletions designated type-1 according to MLPA were mediated by NAHR and hence are indeed type-1. Our study also confirms that PRS2, spanning 4-kb, is a very strong NAHR hotspot since it harbours 78% of all type-1 deletion breakpoints. We sequenced the breakpoint-spanning PCR products of 48 *NF1* deletions with breakpoints in PRS2 and noted considerable differences in terms of the location of the regions of strand exchange (ERs) between NF1-REPa and NF1-REPc. The ERs are flanked by sequence variants that allow NF1-REPa and NF1-REPc to be distinguished. Within the ERs (ranging in size from 50-bp to 975-bp), NF1-REPa and NF1-REPc exhibit complete sequence identity. In total, 13 different ERs were noted within a 4-kb region. This heterogeneity in ER position may be explicable in terms of the predicted positions of PRDM9 binding which in turn direct the location of the recombination-initiating DSB as well as the extent of the 5’ to 3’-resection and the branch migration of the double Holliday junction. Notwithstanding the heterogeneity of ER locations, we observed 3 recurrent ERs that harboured the breakpoints of 38 independent *NF1* deletions. Further, 44 (92%) of the 48 ERs were located within 1-kb of the PRDM9-binding sites in both directions. If 1. 4-kb regions flanking the PRDM9-binding sites are considered, all 48 ERs were located within these regions. These findings imply that the current model of PRDM9-induced chromatin reorganization at recombination hotspots, which was established in the mouse, is also applicable to the NAHR events underlying type-1 *NF1* deletions.

3123F

Whole-exome sequencing identifies a novel 2. 5 kb duplication in *INSR* in a patient with Donohue syndrome. *M. Schotik[1,2], F. Beleggia[1], F. Percin[3], J. Altmueller[1,4], H. Thiele[4], P. Nuernberg[4], B. Wollnik[1].* 1) Institute for Human Genetics, University Hospital of Cologne, Cologne, NRW, Germany; 2) Cologne Graduate School of Ageing Research, University of Cologne, Cologne; 3) Department of Medical Genetics, Faculty of Medicine, Gazi University, Ankara, Turkey; 4) Cologne Center for Genomics, University of Cologne, Cologne, Germany.

Identification of structural variations in the genome by whole-exome sequencing (WES) constitutes a major challenge. Here we use three different software programs for copy-number variation (CNV) analysis to identify a two-exons duplication in the *INSR* gene in a patient with Donohue syndrome. Donohue syndrome (OMIM 246200) or Leprechaunism is a rare, autosomal, recessively inherited congenital disorder. It is characterized by severe insulin resistance, pre- and postnatal growth retardation, and typical physical features such as acanthosis nigricans, lack of adipose and muscular tissues, and an enlarged abdomen. We studied a Turkish girl affected by Donohue syndrome, born to consanguineous parents. After excluding point mutations in *INSR* by Sanger sequencing, we performed WES and CNV analysis. Using the programs CODEX, XHMM, and FishingCNV, we successfully identified a homozygous duplication of two exons, with an approximate size of 2. 5 kb spanning exons 10 and 11 of *INSR* (NM_000208). This duplication was confirmed to be in the homozygous state in the patient and in the heterozygous state in the parents by qPCR analysis. Moreover, using a nested-PCR approach, we could characterize the duplication as a tandem event, thereby resolving the genetic organization of the mutation. Sequencing of fibroblast *INSR* mRNA from the parents showed that the mutated allele is nearly absent and is thus likely to undergo nonsense-mediated decay, consistent with the predicted generation of a premature stop codon. To our knowledge, tandem duplications have not been described as a mutational mechanism in Donohue syndrome, indicating that a comprehensive molecular diagnostic approach might be necessary to identify all mutations in *INSR*. Additionally, our study provides evidence that WES can be successfully used to identify duplications in the lower kilobase range, below the resolution of standard array-based technologies. Therefore, WES is a rational first choice as a diagnostic tool to detect a wide range of different mutational mechanisms.

3124T

Copy number variation in early-onset Alzheimer's disease. *M. N. Bamne[1], E. McDade[2], X. Wang[1], F. Y. Demirci[1], E. Feingold[1], W. E. Klunk[3], M. I. Kamboh[1].* 1) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA; 2) Department of Neurology, University of Pittsburgh, Pittsburgh, PA; 3) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA.

Early-onset Alzheimer's disease (EOAD) accounts for about 2% of all Alzheimer's disease cases. Mutations in three genes – APP, PS1 and PS2 – are associated with EOAD; however, mutations in these genes explain only about 50% of EOAD cases, indicating the existence of additional genetic factors. Recent studies have identified rare copy number variants (CNVs) in familial and sporadic EOAD. In this study, we performed a genome wide screen for CNVs using a high-resolution oligonucleotide array-based comparative genomic hybridization (a-CGH) (Agilent SurePrint G3 Human 1M platform) in 10 sporadic EOAD subjects having *APOE* 3/3 genotype (4 males and 6 females of Caucasian descent; age-of-onset range= 41-58 years). After filtering out CNVs reported in dbVAR (http://www. ncbi. nlm. nih. gov/dbvar) and DGVa (http://www. ebi. ac. uk/dgva) databases, we identified a total of 61 CNVs that have not been reported previously. Of these, 8 were shared between more than one EOAD subjects included in this study. Of the 61 novel CNVs, 20 were duplications and 41 were deletions. Further characterization of these CNVs and investigation in additional EOAD samples is in progress.

3125F

Copy number variant frequency and genomic diversity in the Danish population. *M. Bertalan[1], W. Mazin[1], S. Weinsheimer[1], T. Sparsø[1], M. Hollegaard[2], A. Ingason[3], T. Werge[1], BROAD Institute, iPSYCH.* 1) Mental Health Centre, Sct. Hans and Institute of Biological Psychiatry, Psychiatric Center Sct. Hans, Roskilde, Denmark; 2) Section of Neonatal Genetics and the Danish Neonatal Screening Biobank, Statens Serum Institute. Copenhagen, Denmark; 3) deCODE.

Introduction and findings: Copy number variant (CNV) frequencies are typically estimated in association studies from case-control samples subjected to ascertainment bias. Here we present, for the first time near unbiased population estimates of CNV frequencies in the Danish population.

The majority of the predicted CNVs are found in specific regions of the genome (hotspots) that are not randomly distributed over the genome. We observed that some chromosomes are enriched for CNV hotspots, including chromosomes 15, 16, 17, and 22, while other chromosomes seem depletedby such structural alterations, for example chromosomes 8 and 13.

Some hotspots are from genomic regions that have been previously associated with mental diseases, such as 1q21. 1, 15q13. 3, 16p13. 11, and 22q11. 2. However, many hotspots have not been previously associated with or studied in relation to disease. The large number of hotspots demonstrates that CNVs may account for a substantial amount of genetic variation in the Danish population.

We report diagnoses among CNV carriers in this large, random population sample as recorded in the near complete, nationwide Danish health registers, thus setting the scene for subsequent CNV association and survival analysis studies at the population level.

The study offers the first compilation of CNV frequencies and hotspots in a large population. These results improve our understanding of genomic variants and diseases, revealing genomic diversity and its evolution.

Methods: Dried blood spots (DBS) have been collected in Denmark since 1981, creating one of the largest and near complete population-based biobanks [Danish Neonatal Screening Biobank; DNSB] with samples from more than 2 mio. individual born in Denmark. Clinical phenotypic information on all DNSB subjects are retrieved from the comprehensive Danish health registers, allowing the application of epidemiology study designs in disease genetics.

A random sample were drawn from DNSB of more than 30,000 subjects born 1981-to-2006 corresponding to approx 2% of subjects born in the period. DNA was extracted from DBS, and subsequently whole-genome amplified and genotyped on PsychChip BeadChip array(Illumina) and CNVs were predicted using three complementary methods: *i*PsychCNV, PennCNV and iPattern. In this study we target CNVs tagged by more than 20 SNPs on the array, which are all considerable larger than the classical CNV size-definition of 1 kb.

3126T

DNA replication dynamics and its role in CNV instability. *L. Chen[1], W. Zhou[1], C. Zhang[2], Y. Chen[1], L. Jin[1], F. Zhang[1].* 1) School of Life Sciences, Fudan University, Shanghai, China; 2) Boston Children's Hospital, Boston, MA.

The fidelity of DNA replication is the guarantee of all activities in organisms. Many efforts have been made on discovering the overall dynamics of this complex and ultimate event. Copy number variation (CNV) in the human genome is of vital importance to human health and evolution. However, much of the molecular basis of CNV mutagenesis remains to be elucidated. Considering the DNA replicative mechanism of 'fork stalling and template switching' for CNV formation, we hypothesized that replication fork progression could be important for CNV mutagenesis. However, molecular assays of replication fork progression at the genome level are technically challenging. We therefore conducted an algorithm defining a statistic R for the estimation of DNA replication dynamics based on the available data of DNA replication timing. After comparing the R values of the CNV breakpoint regions to those of genome-wide average level in the genomes of human, mouse and *Drosophila*, a significant association of DNA dynamics and CNV instability is observed. Notably, the homology-mediated and VNTR-mediated CNVs contribute the most to the correlation, suggesting repeat-induced DNA replication error and consequent CNV formation. Our concordant observations suggest an important role for DNA replicative mechanisms in CNV mutagenesis and genome instability. Recently, the variance of DNA replication timing between individuals has been reported. Therefore, we further investigated the variance of replication timing between individuals in the Chinese populations. We hypothesize that human genetic variants may be responsible for variances of DNA replication timing and dynamics, which further suggests the interaction between CNV mutagenesis and DNA replication dynamics.

3127F

Identification of Copy Number Variation in the genome of Japanese population. *I. Danjoh[1], K. Tsuda[1,2], N. Konno[1], R. Saito[1,2], J. Yasuda[1].* 1) Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Life Science Analytics Center, Toshiba Corporation Healthcare Company, Sendai, Miyagi, Japan.

Eastern part of Japan was suffered from a big earthquake 4 years ago. The victims have a larger risk of acquiring diseases in the devastating environment. Advanced, genome-based precision medicine based on the precise genomic information of Japanese will be an ideal solution to restore the medical services in the damaged area. Copy number variations (CNVs) are critical factors for our mission: they are associated with various diseases, in addition to causing SNP miscalling. Therefore, we have analyzed CNVs in the genome of Japanese population to figure out the aspect of the Japanese population. The genomic DNAs from 1450 Japanese healthy volunteersin ToMMo cohort, 683 males and 767 females, who passed the standard quality control (QC) procedures for SNPs and samples including the estimation of "cryptic relatedness", were genotyped with Omni 2. 5 microarray (Illumina Inc.) on which approx. 2. 5 million SNPs are arrayed. Then the genotype data were used for further CNV analysis. CNVpartition, which is one of the module installed in GenomeStudio software and it called CNVs by likelihood-based algorithm, and PennCNV were used for CNV calling. As a result of CNV calling, we identified 3075 CNV region (CNVRs). We will report the details on CNVR region and the comparison with other Asian populations in this meeting.

3128T

Copy Number Variation in Cynomolgus monkeys linked to tissue specific gene expression. *A. R. Gschwind[1,2], T. Heckel[3], U. Certa[3], A. Reymond[1].* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) SIB Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) Roche Pharmaceutical Research and Early Development, Pharmaceutical Sciences, Roche Innovation Center Basel, F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Macaque monkeys are key model species for various fields of biomedical research such as simian immunodeficiency virus pathogenesis, transplantation biology, drug development and safety testing. Cynomolgus monkeys (*Macaca fascicularis*) are the most widely used non-human primate species for drug safety testing in pharmaceutical companies and naturally experimental results might be influenced by variation in biological processes among the individuals sampled. Knowledge of genetic factors contributing to variability with respect to biological drug responses could help to design better experimental approaches, which in turn would help to reduce, refine or even replace animal experiments. We attempt to investigate the importance and implications of genetic variation on cellular processes by combining genome-wide information on copy number variation (CNV) and gene expression data from 24 Cynomolgus monkeys originating from four different populations used in pharmaceutical research (Mauritius, Vietnam, China and the Philippines). Using array comparative genome hybridization (aCGH) data and a CNV calling pipeline combining three different methods, we assess copy number variation among our cohorts. These results are then combined with gene expression data from five different tissues (heart, kidney, liver, lung and spleen) to map expression quantitative trait loci (eQTLs) in proximity of the detected CNVs. We discover eQTLs in all tissues, acting mostly in a tissue specific manner. Of interest many of these loci are found in the kidney, a key organ for drug excretion. Using further downstream analyses, we attempt to get information on cellular processes possibly affected by these gene regulatory changes and to make statements on potential implications for drug safety testing.

High-Throughput Screening for Rare Copy Number Variants across a ~45,000 Subject Pediatric Biobank by qPCR. *C. Kao, R. Pellegrino, J. Garifallou, F. -X. Wang, J. Snyder, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Many rare copy number variations (CNVs) are known to be causative for a number of human syndromes and disorders. However, these CNVs often were discovered in the context of the most extreme phenotypes, with the assumption that the variation is pathognomonic because subsequent encounters in the clinic arise from genetic screening following clinical presentation. This ascertainment bias can thus mask the true phenotypic variability in presentation for these syndromic CNVs. We performed a non-biased screen across a large pediatric cohort of ~45,000 subjects in the biobank at the Children's Hospital of Philadelphia at five known pathogenic loci: the 22q11. 21, 16p11. 2, 15q13. 3 regions and the NRXN1 and MYT1L genes. A method was developed using quantitative, real-time PCR that enabled high-throughput screening across ~45,000 subjects in an efficient and accurate manner at a fraction of the cost compared to an array-based format. We present here the technical parameters for establishing and optimizing this workflow, including the key variables needed to assess for proper quality control. Sample quality of the DNA, the tolerance of the "master-mix" reagent, and the PCR cycling conditions are critical for consistent and reliable performance across different samples and with different primer/probe sets. In particular, different commercial "master mix" reagents have different tolerances for variations in DNA quality, primer/probe sequences, and storage at ambient temperature. For problematic samples of poor quality, we find that clean up improves performance for a large proportion of samples, despite neglible improvement of A260/280 and A260/230 ratios in many instances. For QC, the comparison of performance across different loci is critical for assessing the accuracy of an apparent copy number change at any single loci. Importantly, we found that a commonly used RNAse P reference exhibits copy number variability in ~1% of cases, which confounds the screening for rare CNVs occuring at similar or lower frequencies. The CNVs found by our qPCR-based workflow were validated by array-based approaches with high concordance (>95%). Thus, the CNV dataset generated here is robust and highly accurate, which can be used to estimate population frequencies/prevalence. Additionally, the detailed phenotyping available through electronic health records linked to each subject/sample will enable us to broadly assess phenotypic variability presented by each CNV.

3130T

Phenome-wide Copy Number Burden Association on a Range of Phenotypes in 10,000 Participants from the eMERGE Network. *D. Kim[1], J. Glessner[2], A. Lucas[1], Y. Bradford[1], S. S. Verma[1], J. H. Haines[3], P. Peissig[4], J. Denny[5], M. Basford[5], D. Crosslin[6], J. Harley[7], L. Rasmussen-Torvik[8], I. Kullo[9], E. Larson[10], P. Avillach[13,14], M. Brilliant[4], J. Connolly[2], G. Ritchie[1,11].* 1) The Pennsylvania State University, University Park, PA; 2) Children's Hospital of Philadelphia, Philadelphia, PA; 3) Case Western Reserve University, Cleveland, OH; 4) Marshfield Clinic, Marshfield, WI; 5) Vanderbilt University, Nashville, TN; 6) University of Washington, Seattle, WA; 7) Cincinnati Children's Hospital, Cincinnati, OH; 8) Northwestern University, Evanston, IL; 9) Mayo Clinic, Rochester, MN; 10) Group Health, Seattle, WA; 11) Geisinger Health System, Danville, PA; 12) Essential Institute of Rural Health, Duluth, MN; 13) Boston Children Hospital, Boston, MA; 14) Center of Biomedical informatics, Harvard Medical School, Boston, MA.

Recent studies on copy number variations (CNV) have suggested that an increasing burden of CNVs is associated with susceptibility or resistance to disease. A large number of genes or genomic loci contribute to complex diseases such as autism. CNV burden as - measured by the total number of base pairs deleted or duplicated in an individual - can be used as a measure of genomic instability to identify the association between global genetic effects and phenotypes of interest. However, no systematic CNV burden association analysis has been done on a wide range of phenotypes. We performed a phenome-wide CNV burden association analysis to explore global CNV burden effects associated with multiple phenotypes in subjects from the electronic Medical Records and Genomics (eMERGE) Network, a multi-ethnic cohort with electronic medical records linked to DNA biobanks. We tested for significant associations between CNV burden, measured as base pairs of duplication, deletion, or total copy number change, in 10,538 samples and 21 phenotypes based on ICD9 diagnosis and Lab values from five eMERGE sites. Logistic regression models were fit to the data to evaluate the associations between CNV burden and case/control phenotypes. Linear regression models were used to examine associations for continuous phenotypes, adjusting for age, sex, the first three principal components of ancestry, genotyping centers, and eMERGE sites. We found several statistically significant associations between blood-related phenotypes and CNV burden including duplication burden – erythrocyte sedimentation rate (P= 4. 4x10-5), total CNV burden – erythrocyte sedimentation rate (P= 3. 6x10-5), duplication burden – LDL (P= 1. 7x10-2), total CNV burden – LDL (P= 4. 0x10-2), deletion burden – red blood cell count (P= 1. 1x10-2), and deletion burden – glycosylated hemoglobin measurement (P= 4. 8x10-2). These findings indicate that blood-related phenotypes might be more associated than other traits with global CNV burden. This is interesting given the nature of blood cells constant process of developing new cells, erythropoiesis and warrants further phenotype exploration.

Structural variation at the glycophorin locus from genome sequencing of Gambian trios. *E. M. Leffler[1], Q. S. Le[1], G. Band[1], K. Kivinen[2], G. B. J. Busby[1], M. Jallow[3], F. Sisay-Joof[3], J. Stalker[2], K. A. Rockett[1,2], D. P. Kwiatkowski[1,2], C. C. A. Spencer[1], The Gambia Genome Diversity Project.* 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Wellcome Trust Sanger Institute, Wellcome Trust Genome Campus, Hinxton, Cambridgeshire, United Kingdom; 3) MRC Unit, Atlantic Boulevard, Fajara, The Gambia.

Characterising variation in complex regions of the genome remains difficult despite medical and evolutionary importance. One such challenging region is the glycophorin gene cluster on chromosome 4 encoding the putatively non-translated *GYPE* as well as *GYPA* and *GYPB*, which underlie the MNS blood group system and serve as red blood cell surface receptors for*Plasmodium falciparum*. This locus has been suggested to be under balancing selection reflecting a continued evolutionary battle between host and parasites. However, further interpretation and study is complicated by the high similarity among the three homologous copies, each about 100 kb, which makes assembly, mapping and variant calling problematic. Here, we develop a method to infer large copy number variants that are robust to the homology of the region using a hidden Markov model and sequence coverage data. We apply the method to trios from four ethnic groups in the Gambia and identify three common events, including two deletions that involve complete removal of*GYPB*, with 20% of Gambian individuals carrying non-diploid copy number in the region. We then call structural variants in worldwide 1000 Genomes populations, observing individuals with*GYPB*copy number ranging from 0 to 3 and additional duplications and deletions encompassing*GYPA*or*GYPE*. Finally, we integrate this variation into analyses of association with malaria and signatures of selection.

3132T

Effects of copy number variable regions on the transcriptome and phenotypic variation in Finnish population-based cohorts. *H. Mattsson[1,2], A. Joensuu[1,2], V. Salomaa[3], T. Lehtimäki[4], O. Raitakari[5,6], J. Kettunen[1,7,8], M. Perola[1,2,9].* 1) Dept of Health, Unit of Genomics and Biomarkers, National Institute for Health and Welfare, Helsinki, Finland; 2) University of Helsinki, Institute for Molecular Medicine Finland (FIMM), Helsinki, Finland; 3) Dept of Health, Unit of Health Monitoring, National Institute for Health and Welfare, Helsinki, Finland; 4) Dept of Clinical Chemistry, Fimlab Laboratories and School of Medicine, University of Tampere, Tampere, Finland; 5) Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, Turku, Finland; 6) Dept of Clinical Physiology and Nuclear Medicine, Turku University Hospital, Turku, Finland; 7) Computational Medicine, Institute of Health Sciences, University of Oulu, Oulu, Finland; 8) NMR Metabolomics Laboratory, School of Pharmacy, University of Eastern Finland, Kuopio, Finland; 9) University of Tartu, Estonian Genome Center, Tartu, Estonia.

Copy number variants (CNVs) represent a significant source of genetic diversity and an important evolutionary force. There is also growing evidence linking copy number variation to complex disease susceptibility. The pathogenic effects of CNVs on human health are not fully understood but may be explained by various ways including modifications in gene dosage and gene expression. We conducted an association analysis of 4258 copy number variable regions (CNVRs) with peripheral blood leucocyte transcriptome in order to determine the effect of common variants on gene expression in *cis* in a Finnish population cohort the Young Finns Study (YFS, N=3596). A linear regression model adjusted for potential confounders was used to examine the associations between CNVRs and expression levels of 37,022 transcripts. A comparable model was used to evaluate phenotypic consequences of CNVRs that showed significant association with gene expression. For replication we used a *cis* window of +/-1Mb around each CNVR considering the differences in CNV breakpoints produced by various genotyping platforms. After taking multiple testing into account, associations of 216 CNVRs with transcript levels were observed (p<4. 9e-07) in the YFS. The CNVR on chromosome 10q11. 22 associated with expression of *ANXA8* in the YFS and showed further association with diastolic blood pressure in women (p=0. 038). We replicated these associations in an independent cohort DILGOM (N=278) with p-values 2. 3e-06 and 4. 2e-02 respectively. In conclusion, the present study highlights the importance of integrative analyses of genome-wide copy number data and gene expression profiles in identification of common disease variants which may offer more in-depth awareness on genotype-phenotype associations. Our results also suggest possible differences between sexes in CNVR contribution to complex traits through intermediate phenotypes.

Detecting copy number variations by analyzing whole exome sequencing data using the eXome Hidden Markov Model. *S. Miyatake[1], E. Koshimizu[1], A. Fujita[1], R. Fukai[1], E. Imagawa[1], C. Ohba[1], I. Kuki[2], A. Araki[3], Y. Makita[4], T. Ogata[5], M. Nakashima[1], Y. Tsurusaki[1], N. Miyake[1], H. Saitsu[1], N. Matsumoto[1].* 1) Department of Human Genetics, Yokohama City University, Yokohama, Japan; 2) Department of Pediatric Neurology, Pediatric Medical Care Center, Osaka City General Hospital, Osaka, Japan; 3) Department of Pediatrics, Kansai Medical University, Hirakata, Japan; 4) Education Center, Asahikawa Medical University, Asahikawa, Japan; 5) Department of Pediatrics, Hamamatsu University School of Medicine, Hamamatsu, Japan.

Whole exome sequencing (WES) is becoming a standard tool for detecting nucleotide changes, and is now known as a possible method to detect copy number variations (CNVs). To date, several algorithms have been developed for such analyses, although verification is needed to establish if they fit well for the appropriate purpose, depending on the characteristics of each algorithm. Here, we performed WES CNV analysis using the eXome Hidden Markov Model (XHMM). We validated its performance using 27 rare CNVs previously identified by microarray as positive controls, finding that the overall detection rate for known CNVs was as high as 59%, and even higher (89%) with three or more targets. Larger CNV size increases the detection rate, and in general, CNVs > 200 kb are likely to be detected. Overall, XHMM tended to call smaller CNVs than microarrays. In this study, 22. 2% of total calls were < 10 kb, and 71. 7% < 100 kb, indicating it may be possible to detect exonic deletions. However, we found that about half of these calls were false-positives, regardless of the quality score. It may be important to minimize conditional experimental differences for higher true positive rates. Although adjacent read information is usually limited, XHMM data can be useful for identifying CNV breakpoints. We were able to successfully determine breakpoints of 7- and 22-kb deletions, which are usually difficult to detect by microarrays. Identifying breakpoints can provide precise information, including in-frame gene fusions. Next we applied XHMM to genetically unsolved patients, demonstrating successful identification of pathogenic CNVs: 1. 5–1. 9-Mb deletions involving *NSD1* in patients with unknown overgrowth syndrome leading to the diagnosis of Sotos syndrome, and 6. 4-Mb duplication involving *MECP2* in affected brothers with late-onset spasm and progressive cerebral/cerebellar atrophy confirming the clinical suspect of *MECP2* duplication syndrome. As it is not known if a nucleotide variant or gross CNV is the culprit before analysis, an “exome-first” approach may save time and cost of unnecessary microarray analysis. This approach is even more effective with target CNVs > 200 kb.

3134T

Understanding the genetic structure of FCGR genes region for Kawasaki disease using sequence capture of target fragments for long reads sequencing. *E. Png[1], P. F. De Sessions[1], L. Low[1], H. Liany[2], V. Kumar[2], C. E. Tacke[3], S. Nagelkerke[4], J. Geissler[4], S. Davila[2], T. W. Kuijpers[3,4], M. Hibberd[1].* 1) Infectious Diseases, Genome Institute of Singapore, 60 Biopolis Street, Singapore 138672; 2) Human Genetics, Genome Institute of Singapore, 60 Biopolis Street, Singapore 138672; 3) Pediatric Hematology, Immunology and Infectious Diseases, Emma Children’s Hospital, Academic Medical Center (AMC), Amsterdam, The Netherlands; 4) Department of Blood Cell Research, Sanquin Research and Landsteiner Laboratory, Academic Medical Center, Amsterdam, The Netherlands.

Kawasaki disease (KD) is an acute inflammatory disorder associated with vasculitis, usually affecting the coronary arteries. In recent genome wide association studies (GWAS), we identified a non-synonymous single nucleotide variant (SNV) (rs1801274, P= 7. 35x10-11, OR 1. 32, 95% C. I. 1. 22-1. 44) in the *FCGR2A* gene to be significantly associated with KD susceptibility. The *FCGR2A* gene is situated among the *FCGR2/3* locus, which contains highly homologous genes encoding the five major Fc-gamma receptors (*FCGR*) for immunoglobulin G (IgG). Incidentally, the infusion of intravenous IgG is the standard effective treatment for KD. Yet, genotype variations in the *FCGR* genes have been demonstrated to influence IgG response in certain KD patients. Because of the immunologically importance of this locus in susceptibility and managing KD, we need a better understanding of the genetic mechanism underlying the *FCGR* genes associations. However, the coverage of probes in the GWAS array is sparse over this *FCGR2/3* locus, due to the presence of a large segmental duplication and copy number variations (CNV). Thus, GWAS SNPs alone are unlikely to help decipher the full spectrum of genetic variations that are significant to KD. In order to identify potentially functional variants, we performed targeted re-sequencing of the entire *FCGR2/3* locus in 6 sets of trio families with individuals affected or not affected by KD. We synthesized NimbleGen SeqCap EZ library baits, which is estimated to cover 92% of the target region of interest (ROI) (chr1:161,500,415-161,683,654), to pull down fragments in the ROI for sequencing using the PacBio System. The sequenced data is aligned to the human reference using BWA and GraphMap software. SNV is identified using GATK Unified Genotyper. Larger structural variations are called using PBHoney and cnvSeqCap for confirmation. On average we have 12500 circular consensus sequences per library, with a mean read quality of insert of >99%. More than 4Mb of sequences from each library mapped to the ROI allowing each target base to be covered >20x. The genotype of variants identified through sequencing will be analyzed for concordance with those called independently using a multiplex ligation-dependent probe amplification (MLPA) assay. Haplotypes analysis and imputation will be used to infer the genotype of variants identified through sequencing, to the entire KD cohorts that have subset of variants genotyped using the MLPA assay.

3135F

Genic intolerance to copy number variation in 60,000 individuals and applications to identifying risk genes in schizophrenia. *D. Ruderfer[1], M. Fromer[1], T. Hamamsy[1], M. Lek[2,3], K. Samocha[2,3], K. Karczewski[2,3], J. Moran[3], S. McCarroll[3], C. Hultman[4], P. Sullivan[5], P. Sklar[1], M. Daly[2,3], D. MacArthur[2,3], S. Purcell[1,2,3], Exome Aggregation Consortium.* 1) Icahn School of Medicine at Mount Sinai, New York, NY; 2) Massachusetts General Hospital, Boston, MA; 3) Broad Institute, Cambridge, MA; 4) Karolinska Institutet, Solna, Sweden; 5) University of North Carolina at Chapel Hill, Chapel Hill, NC.

Copy number variation (CNV), in particular a gain or loss of coding sequence, is known to contribute to phenotypic diversity and risk of diseases including schizophrenia (SCZ). Here we characterize genic intolerance to CNV – defined as observing fewer CNVs in a gene than expected – using data from nearly 60,000 individuals from the Exome Aggregation Consortium (ExAC). We hypothesized that CNVs in intolerant genes would be more likely to have deleterious effects. We further show how this resource and the derived genic intolerance values can be used to relate CNV burden to risk of SCZ. We calculated genic likelihoods of CN per individual, allowing us to distinguish between a diploid state for the extent of a gene, versus a high likelihood of partial or complete gene CNV, versus the absence of a confident call. Individuals averaged 0. 81 deleted and 1. 75 duplicated genes although 63% and 46% of individuals did not have any deleted or duplicated genes, respectively. A single gene was involved in 34% of CNVs and 62% of single gene CNVs are likely to disrupt (partial deletion or duplication) the gene. Genes with fewer CNVs than expected were defined as more intolerant. In the absence of accurate models of CNV mutation rates across the genome, we calculated genic intolerance from the residuals of a logistic regression of CNV frequency on gene length, read depth, GC content, sequence complexity and presence between pairs of segmental duplications. CNV intolerance was significantly correlated with a haplo-insufficiency constraint score based on loss-of-function variants in the same sample (deletions r=0. 23, duplications r=0. 11). Genes highly expressed in the brain were the most intolerant to CNVs (p=7. 66x10-16); similarly, the mostly highly intolerant genes (n=157) were involved in neuronal and axon development. In a subset of individuals with SCZ and matched controls, cases were more likely to have a CNV in an intolerant gene (22% versus 18%). Over and above the increased burden, genes hit by CNV in cases were also more intolerant compared to controls (p=0. 007). Although directly using ExAC CNV data as a convenience control sample runs a high risk of bias, here we also demonstrate improved power to detect SCZ loci when considered along with an appropriate matched control sample.

Complex structural variation in the MHC locusinfluences schizophrenia risk by shaping expression of *complement component 4*. *A. Sekar[1,2], A. R. Bialas[3,4], H. de Rivera[1,2], T. R. Hammond[3], A. Davis[1,2], J. Presumey[4], N. Kamitaki[1,2], K. Tooley[1,2], G. Genovese[1,2], M. Baum[1,2,3], V. Van Doren[1], S. Rose[2], R. E. Handsaker[1,2], M. J. Daly[2,5], M. C. Carroll[4], B. Stevens[2,3], S. A. McCcarroll[1,2], Schizophrenia Working Group of the Psychiatric Genomics Consortium.* 1) Department of Genetics, Harvard Medical School, Boston, MA, USA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Department of Neurology, F. M. Kirby Neurobiology Center, Boston Children's Hospital, Harvard Medical School, Boston, MA, USA; 4) Program in Cellular and Molecular Medicine, Children's Hospital Boston, MA, USA; 5) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA.

Complex forms of structural variation affect hundreds of human genes, but their biological significance is largely unknown. We found that schizophrenia's strong but previously unexplained association with common genetic variation in the Major Histocompatibility Complex (MHC) locus arises in part from diverse structural alleles of the complement component 4 (*C4*) gene. These *C4* structural alleles promoted widely varying levels of *C4A* and *C4B* expression in different individuals' brains. Among 28,799 cases with schizophrenia and 35,986 controls, alleles of *C4* associated with schizophrenia in proportion to their tendency to promote higher brain expression of *C4A*. We found human C4 protein localized at dendrites, axons, neuronal cell bodies, and synapses. In mice, C4 mediated synapse elimination during postnatal development. These results implicate excessive complement activity in schizophrenia and may help explain the reduced numbers of synapses in the brains of affected individuals. The implication of the complement pathway suggests novel strategies for treating schizophrenia.

3137F

Copy number variant conferred risk of mental disorders in the Danish population. *T. Sparsø[1], SM. Weinsheimer1[1], M. Bertalan[1], W. Mazin[1], M. Hollegaard[2], T. Werge[1], SSI, BROAD & iPSYCH investigators.* 1) INSTITUTE OF BIOLOGICAL PSYCHIATRY, Mental Health Services of Copenhagen, Copenhagen, Denmark; 2) Section of Neonatal Genetics and the Danish Neonatal Screening Biobank, Statens Serum Institut, Copenhagen, Denmark.

Introduction and findings: It is well established that copy number variants (CNV) confer risk of both somatic and mental disorders. Risk of disease is typically estimated from case-control studies subjected to ascertainment bias among others. Here we present, for the first time near unbiased population estimates of CNV conferred risk of mental disorders in the Danish population. We here report the study of a population-based sample of more than 80. 000 subjects born 1981-to-2006, corresponding to approx. 5% of the individuals born in this period, and including all subjects with autism, ADHD, schizophrenia, bipolar disorder and major depression, and healthy controls. We identified more than 100 hotspots in the genome where CNVs are shared in the Danish population with frequencies ranging from 0. 01% to 5%, and for each we estimate the conferred risk for the five target disorders and combinations thereof. The initial association analyses are complemented by survival analysis to provide estimates of risk corrected for sex, age, calendar time, place of birth, maternal and paternal age, parental origin and family history of psychiatric disorders. The study offers the first compilation of population-based risk estimates of CNVs for mental disorders. These results improve our understanding of structural variants in the genome that cause mental disorders and prompt studies of the underlying biology. *Methods:* Dried blood spots (DBS) have been collected in Denmark since 1981, creating one of the largest and near complete population-based biobanks [Danish Neonatal Screening Biobank; DNSB] with samples from more than 2 mio. individuals born in Denmark. Clinical phenotypic information on all DNSB subjects are retrieved from the comprehensive Danish health registers, allowing the application of epidemiology study designs in disease genetics. A random sample were drawn from DNSB of more than 25,000 subjects born 1981-to-2005 corresponding to approx 2% of subjects born in the period. Furthermore, all subjects born in this period and assigned a clinical diagnosis of autism (n=12,735), ADHD (n=13,004), schizophrenia (n=2,311), bipolar disorder (1,121), affective disorders (n=14,985) or anorexia (2,012) recorded in the Danish health registers were selected for analysis. CNVs were predicted using data obtained from the Infinium PsychArray BeadChip (Illumina) using three complementary methods: *i*PsychCNV, PennCNV and iPattern.

3138T

Comprehensive comparative performance analysis of high-resolution array platforms for genome-wide CNV detection in humans. *A. Urban, R. R. Haraksingh.* Psychiatry and Genetics, Stanford University, Palo Alto, CA.

High-resolution microarray technology can comprehensively and efficiently detect copy number variants (CNVs) in the human genome. It is routinely used for fundamental applications in basic and translational research as well as in clinical practice – namely in clinical cytogenetics, large association studies, the tracking of genome stability in stem cell culture, and the orthogonal confirmation of CNVs detected by sequencing methods. A new generation of array designs from several manufacturers (Affymetrix, Agilent, and Illumina) has recently become available. These designs combine high probe densities (interrogating hundreds of thousands and up to almost 5 million loci on a single array) with optimized probe placement strategies and experimental workflows, with the expectation of providing an essential workhorse for CNV-level genome analysis for the coming years. We carried out a comprehensive comparative analysis of the relative detection and resolving power of the 16 currently available array platforms for genome-wide CNV analysis. We achieved unbiased comparison by hybridizing DNA from the well-characterized genome of HapMap/1000 Genomes Project subject CEU-NA12878 to all arrays and performing data analysis using both manufacturer-recommended and platform-independent software for each array. These are the same study design features that we used in [Haraksingh et al. , 2011] now applied to the all the currently and newly available array designs and platforms. Our results confirm some general expectations e. g. regarding the benefits of increasing probe numbers, while providing quantitative measures of power of detection. Furthermore we also show that array design specifics can have striking and unexpected effects on array performance, which could only be revealed through direct benchmarking using a previously well-characterized genome and direct comparison of array designs. For example adding probes specific to the exonic regions of the genome to an already high-powered genome-wide design only somewhat increases the power of detection of a given array design and may lead to a considerable increase in false positive CNV calls. These results will help to inform appropriate platform selection for a given individual project or application (e. g. clinical diagnostics vs. association study vs. cell line monitoring), and also enable the genomics community to gauge the CNV-analytical power of already existing and ongoing array-based genomics studies.

3139F

A single rearrangement event resulting in two concomitant genomic disorders: the *PMP22-RAI1* contiguous gene duplication syndrome. *B. Yuan[1], T. Harel[1], S. Gu[1], P. Liu[1], A. Coe[2], M. Wright[3], L. Burglen[4], S. Chantot-Bastaraud[4], V. Gelowani[1,5], C. R. Beck[1], C. M. B. Carvalho[1], S. W. Cheung[1], A. Munnich[6], P. L. Magoulas[1], L. Potocki[1], J. R. Lupski[1,5,7,8].* 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA; 2) University Hospitals, Coventry and Warwickshire NHS Trust, University Hospital, Coventry, UK; 3) Institute of Human Genetics, Newcastle University, Newcastle, UK; 4) APHP, Service de Génétique et embryologie Médicales, CHU Paris Est - Hôpital d'Enfants Armand-Trousseau, Paris, France; 5) Human Genome Sequencing Center, Baylor College of Medicine, Houston, Texas, USA; 6) Service de Génétique, INSERM U781, Hôpital Necker-Enfants Malades, Institut Imagine, University Sorbonne-Paris-Cité, Paris, France; 7) Department of Pediatrics, Baylor College of Medicine, Houston, Texas, USA; 8) Texas Children's Hospital, Houston, Texas, USA.

The genomic duplication associated with Potocki-Lupski syndrome (PTLS) maps in close proximity to the duplication associated with Charcot-Marie-Tooth disease type 1A (CMT1A) on chromosome 17p11. 2-17p12. PTLS is characterized by hypotonia, failure to thrive, reduced body weight, intellectual disability, and autistic features. CMT1A is a common autosomal dominant distal symmetric peripheral neuropathy. The key dosage sensitive genes *RAI1* and *PMP22* are associated with PTLS and CMT1A, respectively. Recurrent duplications accounting for the majority of subjects with these conditions are mediated by nonallelic homologous recombination between low copy repeats (LCRs). The LCR pairs flanking *RAI1* and *PMP22* do not share extensive homology with each other; thus, duplications encompassing both loci are rare and potentially generated by a different mutational mechanism. We characterized genomic rearrangements duplicating both *PMP22* and *RAI1*, including nine potential complex genomic rearrangements, in twenty-two subjects by high-resolution array comparative genomic hybridization and breakpoint junction sequencing. Insertions and microhomologies were found at the breakpoint junctions, suggesting potential replicative mechanisms for rearrangement formation. At the breakpoint junctions of these nonrecurrent rearrangements, enrichment of repetitive DNA sequences was observed, indicating that they might predispose to genomic instability and lead to rearrangement. Clinical evaluation revealed blended CMT1A and PTLS phenotypes with a potential earlier onset of neuropathy. Moreover, additional clinical findings may be found due to the extra duplicated material included in the rearrangements. Our genomic analysis suggests replicative mechanisms as a predominant mechanism underlying *PMP22-RAI1* contiguous gene duplications and provides further evidence supporting the role of complex genomic architecture in genomic instability.

Comprehensive breakpoint analyses for genomic disorders reveal the correlation of CNV size and complexity with clinical severity at the *PLP1* locus. *L. Zhang[1], J. Wang[2], C. Zhang[1], D. Li[2], J. Xiao[1], W. Zhou[1], C. Carvalho[3], C. Liu[4], Y. Luo[5], L. Jin[1], J. Lupski[3], F. Zhang[1], Y. Jiang[2].* 1) Fudan university, Shanghai, China; 2) Department of Pediatrics, Peking University First Hospital, Beijing, China; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 4) Institute of Medicinal Plant Development, Chinese Academy of Medical Sciences, Beijing, China; 5) The Research Center for Medical Genomics, MOE Key Laboratory of Medical Cell Biology, College of Basic Medical Science, China Medical University, Shenyang, China.

Human genomic copy-number variation (CNV) can be responsible for many human diseases, especially genomic disorders. The molecular mechanisms of genomic disorders include dosage effect, position effect, and etc. Pelizaeus-Merzbacher disease (PMD, MIM#312080) is a classic genomic disorders that can be caused by the nonrecurrent CNVs at the *PLP1* locus. However, it is technically challenging to get the exact breakpoints of the PMD-associated CNVs. Here we reported 49 cases with *PLP1* gene CNVs, 19 cases of which have complex CNVs. In addition to using previously reported methods of traditional long-range PCR and target-DNA capture sequencing, we also newly developed Asymmetry Primers PCR (APP), which is a high-efficiency method of CNV breakpoint analysis. Therefore, we successfully obtain the CNV breakpoints in more than 90% of the PMD cases. Intriguingly, the CNV sizes are associated with the severity of the clinical features in PMD patients (P<0. 05). Additionally, complex CNV structures, especially the inverted duplications, tends to induce more severe clinical features (P<0. 05). In conclusion, we found the size and the genomic orientation of the pathogenic CNVs at *PLP1* affected the phenotype of genomic disorders. We also showed that the APP method can be used for analyzing CNV breakpoint sequences, especially for the challenging cases with complex CNVs in the genomic regions with complex genome architecture.

3141F

Correlations between *AMY1* copy number, diet and BMI in ethnically diverse African populations. *K. E. Johnson[1], C. C. Elbers[1,2], S. R. Thompson[1,2], A. Ranciaro[1,2], D. W. Meskel[3], A. L. Mandel[4], G. Belay[3], S. A. Tishkoff[1,2].* 1) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Biology, School of Arts and Sciences, University of Pennsylvania, Philadelphia, PA; 3) Department of Biology, Addis Ababa University, Addis Ababa, Ethiopia; 4) Monell Chemical Senses Center, Philadelphia, PA.

Amylase 1 (*AMY1*) is expressed in human saliva and is the first step in digestion of starches. Previous research has shown that *AMY1* copy number varies significantly between human populations, and that higher copy number may have been selected in populations with a starchy diet (Perry *et al,Nature Genetics*, 2007). To further investigate the relationship between subsistence methods and *AMY1* copy number, we estimated copy number using qPCR in a diverse data set of 1390 individuals from 20 populations in Tanzania and Ethiopia. Pastoralist populations, which consume a low-starch diet, are associated with significantly lower copy number compared to other subsistence methods (P = 3. 99x10-7). Agriculturalism is also associated with a decrease in copy number (P = 0. 0003), while hunter gathering and agropastoralism had no significant effect on copy number. *AMY1* copy number has also been associated with obesity and BMI (Falchi *et al, Nature Genetics*, 2014), with increased copy number leading to decreased risk of obesity. We tested for association between *AMY1* copy number and BMI in our diverse sample, and found no association in any of the populations alone nor in the combined sample (P = 0. 347). However, these populations contain no individuals that would be classified as obese by BMI. In conclusion, we found significant differences in copy number between African populations practicing different subsistence methods, but were unable to replicate the association between *AMY1* copy number and BMI.

3142T

Customizable exon-centric target enrichment for copy number and targeted mutation detection. *K. Jeong, A. Vadapalli, B. Peter, A. Ashutosh, D. Joshi, J. Ghosh, D. Roberts.* Agilent Technologies, Santa Clara, CA.

Structural variations in the genome can be determined from NGS data with either whole genome sequencing (WGS) or targeted enrichment using exome or gene panels. WGS has the potential to provide a single platform solution for detecting copy number variations (CNVs). However, it is prohibitively expensive in identifying mutations such as single nucleotide polymorphisms (SNPs), and insertions and deletions (INDELs) that require high sequencing read depths. Although whole (WES) or targeted exome sequencing is a cost-effective method for identifying mutations in exons, high read depths from several neighboring exonsare often required to provide confident copy number determination. WES also does not provide accurate aberration boundaries in potentially important regulatory regions outside of exons such as in introns or promoters. To enable higher resolution copy number calls in and around genes/exons of interest, we have augmented exonic tiling with custom target enrichment probes designed specifically to improve copy number (CN) resolution in these regions while maintaining exonic coverage of SNPs/INDELs. OneSeq is an NGS target enrichment solution providing simultaneous detection of genome-wide CNVs and copy neutral loss of heterozygosity (cnLOH) in addition to SNPs and INDELs at desired loci. Herein we describe custom OneSeq, enabling higher resolution, exon-centric CN determination in any genes of interest. To this end, we have created a library of high resolution target enrichment probes targeting exon-proximal regions. When deployed in conjunction with existing exonic probes, they improve detection of biologically relevant CNVs in and near exons, while simultaneously detecting exonic SNPs and INDELs. The targeted CN regions can be customized to address only a subset of genes, thus maximizing sequencing efficiency. To demonstrate the efficacy of custom OneSeq, we compare customized OneSeq panels to targeted exonic sequencing alone. Custom OneSeq improves detection of copy number changes with resolution often spanning just a few exons. Additionally, we identify aberrations in samples with either SNP/INDEL or CNV at a particular locus, and in some cases, compound heterozygotes with different aberrations in both alleles of the same locus. The addition of customizable, exon centric OneSeq probes provides a means to detect exonic, intronic and intergenic CNVs, together with SNPs/INDELs in a single assay.

Modifying DNA extraction protocol alters human brain copy number estimation. *C. Proukakis[1], K. Gancheva[2], A. Soenmez[1], C. Grace[2], R. Valli[3], D. Pease[1], A. Ejaz[1], H. Houlden[4], A. Pittman[4], S. Vattathil[5], E. Maserati[3], J. W. Taanman[1], A. H. Schapira[1], E. Nacheva[2].* 1) Clinical Neuroscience, UCL Institute of Neurology, London, England, United Kingdom; 2) Academic Haematology, Royal Free Campus, UCL, London, UK; 3) Genetica Umana e Medica, Dipartimento di Medicina Clinica e Sperimentale, Université dell'Insubria, Varese, Italy; 4) Molecular Neuroscience, UCL Institute of Neurology, London, England, United Kingdom; 5) Department of Epidemiology, The University of Texas MD Anderson Cancer Center, Houston, Texas, USA.

Background Mosaicism may be relatively common, including in the brain, and a role in common sporadic diseases such as Parkinson disease (PD) has been proposed. Sub-integer copy number (CN) changes could indicate mosaicism, but potential confounding influences of DNA extraction methods on CN estimates remain largely unexplored. **Methods and results**We analysed brain DNA extracted using spin columns from the cerebellum and frontal cortex (FC) of 4 PD cases and 4 controls, initially using a custom aCGH design focused on PD genes. We did not detect aberrations in PD genes. Further review suggested possible widespread subtle CN changes, mostly losses in cerebellum, predominantly in GC rich regions, even when using matched FC DNA as reference. CN determination of 2 genes (TSC2, EIF2C1) by droplet digital PCR (ddPCR) was consistent with mosaic losses, despite normal results in peripheral monocyte DNA. SNP array did not, however, detect any B-allele frequency (BAF) deviations. We therefore considered the possibility that we were incompletely extracting certain genomic regions, leading to falsely low CN estimates. Varying the protocol by using overnight protease digestion, lower starting tissue amount, and a non-spin column method (Puregene), radically altered results. ddPCR showed almost complete normalization. When DNA from cerebellum and FC of the same brain extracted with Puregene was hybridized together on aCGH, the losses previously seen were no longer evident. Losses were, however, still seen in direct hybridizations of certain combinations of DNA extracted differently from the same cerebellum. Increasing the proteinase K amount in Puregene extraction affected aCGH results in a cerebellar sample, but had no clear effect on the FC. **Discussion and conclusions** As apparent losses were present in both aCGH and ddPCR, mosaicism was a plausible explanation. The clear influence of DNA extraction method on the result, however, is consistent with a previous report of systematic bias introduced during DNA extraction from rat tissues. GC rich regions in particular may be inadequately recovered from spin columns, particularly if large amounts of starting material are used, or with any protocol, if protein digestion is incomplete. The reason for the clearer appearance of this phenomenon in the cerebellum may be the higher cell density. CN estimation using any technique may be misleading after suboptimal DNA extraction.

***De Novo* Copy Number Variation in Taiwanese Trios Affected by Schizophrenia.** *T. Poterba[1], J. Maller[1], D. Howrigan[1], K. Chambert[1], J. Moran[1], H. Hwu[6], W. J. Chen[6], S. V. Faraone[5], S. J. Glatt[5], M. Tsuang[4], S. McCarroll[1, 3], B. M. Neale[1, 2].* 1) Stanley Center, Broad Institute of Harvard and MIT, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Harvard University School of Medicine, Boston, MA; 4) University of California San Diego, La Jolla, CA; 5) SUNY Upstate Medical University, Syracuse, NY; 6) National Taiwan University, Taipei, Taiwan.

Schizophrenia is a highly heritable psychiatric disorder, but the collective understanding of the genetic mechanisms behind its pathology is incomplete. Both common SNP variants and large rare copy number variants (CNVs) have been shown to harbor substantial risk for schizophrenia. However, the contribution of *de novo* CNVs to schizophrenia risk is not well characterized, with previous reports of ~600 trios with schizophrenia. This work demonstrated a role for recurrent *de novo* events in schizophrenia (Kirov et al, 2012). Therefore, we performed a large-scale genome-wide experiment to identify CNVs, both*de novo*and inherited, associated with risk for schizophrenia. We collected 1121 parent-child trios from Taiwan, generally with only the child affected with Schizophrenia. This cohort is double the size of the largest schizophrenia trio cohort reported in the literature (Kirov et al, 2012). All trios were genotyped on PsychChip, a custom Illumina array with 588k total SNPs, 255k of which are common (minor allele frequency > 0. 05) in East Asian populations. We called CNVs on samples passing initial QC using PennCNV (Wang et al, 2007), and these calls were filtered based on size and quality. We compiled and compared calls within trios to generate one list of inherited CNVs and one of de novo events found in the probands. Initial results are largely consistent with the literature, with about 4% of our probands possessing a*de novo*large CNV, many of which localized to known disease regions like 22q11 deletions, 16p11 duplications, and 3q29 deletions. We also observed an enrichment of extremely large (greater than 2 MB) CNVs, occurring in roughly 1% of probands.

3145F

Sequence analysis and characterization of active human Alu subfamilies. *M. K. Konkel[1], J. A. Walker[1], A. B. Howes[1], M. C. Ranck[1], C. C. Fontenot[1], J. Storer[1,2], D. Kural[3,4], M. P. Strömberg[3], C. Stewart[3,5], G. T. Marth[3,6], M. A. Batzer[1], the 1000 Genomes Consortium.* 1) Department of Biological Sciences, Louisiana State University, Baton Rouge, LA; 2) Department of Molecular, Cellular and Developmental Biology, The Ohio State University, Columbus, OH; 3) Department of Biology, Boston College, Chestnut Hill, MA; 4) Seven Bridges Genomics, Inc. , Cambridge, MA; 5) The Broad Institute of MIT and Harvard, Cancer Genome Computational Analysis, Cambridge, MA; 6) Eccles Institute of Human Genetics, University of Utah, Salt Lake City, UT.

Structural variations (SV), such as deletions, duplications, and insertions, are common within humans. Insertions are commonly caused by transposons also referred to as, mobile element insertions (MEIs). Alu elements are one type of MEI, and are major contributors to genome variation among humans. In recent years, MEI detection from short-read sequencing data has become a way to identify MEIs on a large scale. Subfamily assignment for Alu insertions from short-read data has also been performed. However, comprehensive wet-bench validations are often limited. To better understand the properties of MEIs validated by PCR and toward a gold standard for MEIs, we performed Sanger sequencing for 322 previously PCR validated polymorphic Alu insertions. For each element, we determined features associated with target-primed reverse transcription (TPRT), the mechanism by which MEIs are typically inserted into the genome. These hallmark features include target site duplications, an Adenosine-rich (A)-tail, and an endonuclease cleavage site. Moreover, we determined the precise genomic breakpoint coordinates, subfamily assignment, and divergence from the respective subfamily consensus sequence. More than 98% of the sequenced MEIs contained the expected features as well as a breakpoint indicative of insertion through the TPRT mechanism. Five of six events previously identified as insertions, were in fact deletions roughly the size of an Alu element (about 300 bp). These events were distinguished from traditional MEIs because the breakpoint resided within an Alu element and/or within the flanking sequence, further supported by an alignment to the orthologous region of the chimpanzee genome (and presumably the ancestral genomic state). The remaining locus, represented an Alu insertion, fixed in the human population with an A-tail of varying length due to the expansion of a microsatellite sequence. All of the sequenced Alu loci were members of the AluY lineage. AluYa5 is the most active Alu subfamily in human populations, followed by AluYb8 and AluY. In addition, we identified several other subfamilies, including three previously uncharacterized groups that we have termed AluYb7a3, AluYb8b1, and AluYa4a1. In summary, many Alu subfamilies are currently active within human populations, including a surprising level of AluY retrotransposition. Human Alu subfamilies exhibit continuous evolution with potential drivers generating a succession of new Alu lineages.

3146T

Biochemical analysis of chimeric human and mouse AMCase proteins expressed in *Escherichia coli*. *K. Okawa[1], M. Ohno[1,2], A. kashimura[1], Y. Kobayashi[1], M. Sakaguchi[1], Y. Sugahara[1], F. Fumitaka[1].* 1) Department of Chemistry and Life Science, Faculty of Engineering, Kogakuin University, Hachioji, tokyo, Japan; 2) Research Fellow of Japan Society for the Promotion of Science (DC2), Chiyoda-ku, Tokyo, Japan.

Chitinases are enzymes that digest chitin. Acidic mammalian chitinase (AMCase) is implicated in asthma, allergic inflammation and food processing. Human and mouse AMCase share 82% sequence identity and 86% sequence similarity. Despite these structural similarities, these two homologues significantly differ with respect to their enzymatic characters at enzymatic activities. The chitinolytic activity of the recombinant human AMCase was less than that of the mouse counterpart. To determine regions responsible for the reduced chitinolytic activity in human AMCase, we constructed chimeric human-mouse AMCase proteins and expressed in *E. coli.* We successfully expressed chimeric AMCase proteins in *E. coli* and measured the chitinolytic activity of the proteins. We found that the N-terminal region of human AMCase containing conserved active site residues significantly reduced the chitinolytic activity among the chimeric enzymes. Thus, the N-terminal region of human AMCase impairs the chitinolytic activity of the enzyme.

Whole Genome Reference Panel of One Thousand Japanese Individuals and Bioinformatics in ToMMo. *M. Nagasaki.* Tohoku Medical Megabank Organization, Tohoku University, Tokyo, Japan.

Tohoku University Tohoku Medical Megabank Organization (ToMMo) located at the north-eastern Japan is now developing a biobank (the final goal is 150,000 volunteers with millions samples) that combines medical and genome information during the process of rebuilding the community medical system and supporting health to foster the reconstruction from the Great East Japan Earthquake on Mar/11/2011. One of the missions of ToMMo is to reveal a fine genetic architecture of Japanese population to tackle the further genome wide associate study analysis by combining the knowledge, which is daily accumulated in the ToMMo prospective genome cohort project, e. g. questionnaire data, physiological data, medical treatment records and other omics data from serum, plasma and immortalized lymphocytes. The first goal is to sequence one thousand samples to cover MAF > 0. 5% variants including short insertion, deletion, and large structural variants in Japanese for constructing the Japanese whole-genome reference panel (1KJPN). In our experimental design, to minimize the biases caused by the different equipment, protocol and bioinformatics analysis, we performed whole genome sequencing of one thousand samples with 30x high coverage using the HiSeq 2500 rapid run mode and analyzed by the same bioinformatics pipeline. This talk presents our bioinformatics analyses and preliminary findings while constructing 1KJPN.

EyeSeq - Toward a Comprehensive Genomic Research and Diagnosis Resource for Inherited Retinal Degenerations. *L. Shen, D. Navarro-Gomez, M. Maher, E. M. Place, M. B. Consugar, J. Comander, J. L. Wiggs, E. A. Pierce, X. Gai.* Ocular Genomics Institute, Dept. Ophthalmology, Massachusetts Eye and Ear Infirmary and Harvard Medical School, Boston, Massachusetts, USA.

Inherited retinal degenerations (IRDs) are a large family of highly heterogeneous blinding diseases characterized by progressive death and dysfunction of rod and cone photoreceptor cells. Existing resources of IRD-associated variants include the commercially available HGMD, RetinoGenetics (http://www.retinogenetics.org/) with data on 194 genes derived from 943 publications, Retina international (http://www.retina-international.org/) with data on 78 IRD genes, and single disease databases like USHbase with 20 genes only but richer annotations. These resources are limited in data and analytical capabilities. This has presented a significant hurdle for genetic diagnosis of IRDs, especially with the emergence of NGS technologies and associated techniques such as whole-exome sequencing. The Ocular Genomic Institute (OGI) at Massachusetts Eye and Ear Infirmary conducts both research and CLIA certified diagnostic service for genetic eye diseases including IRDs, early-onset glaucoma and optic atrophy. We established a comprehensive DNA variant resource EyeSeq that focuses on these diseases and enables phenotype and genotype integration. The disease portal organizes diseases in MESH hierarchical tree and links to curated phenotype and genomic data in a single place. EyeSeq interlinks eye diseases and phenotype dictionaries from internal symptom dictionary, OMIM, RetNet, ClinGen, CTD Base, and HPO. The pathogenic variants are compiled from ClinVar, HGMD, Ensmebl phenotype, and the community sources, and supplemented with in-house pathogenic variant data, as well as control data sets for easier interpretation. They include over 17,000 variants, including 7,000 open to the general public, in 888 genes that are currently associated with 446 diseases as defined by all related clinical terms. A web-based diagnosis tool is developed to aid such interpretation by extracting data from the EyeSeq resource, while capturing newly identified pathogenic variants from diagnostic lab in return. Additionally, web-based annotation tools are created to collect community expert input, including ClinVar compatible pathogenicity data submission tools. Together, EyeSeq aims to be the community genomic resource to aid in both genetic eye disease research and diagnosis.

3149F

Significance ranking of sequence variants in Parkinson Disease variant database. *J. Vance[1], K. Nuytemans[1], L. Wang[1], G. W. Beecham[1], C. Van Broeckhoven[2].* 1) John P. Hussman Institute for Human Genomics, Miami Morris K. Udall Parkinson Disease Research Center of Excellence (UPDRCE), University of Miami, Miller School of Medicine, Miami, FL; 2) Department of Molecular Genetics, VIB and Laboratory of Neurogenetics, Institute Born-Bunge, University of Antwerp, Universiteitsplein 1, B-2610 Antwerp, Belgium.

Next generation sequencing (NGS) has significantly increased the rate of rare sequence variants (RVs) reported in PD patients. Interpretation of the functional significance of RVs in PD development can be difficult however, due to the vast amounts of data and disparate data sources. Current available databases do not address the contribution of variants to PD pathogenesis and/or do not accommodate NGS data. We designed the PD variant database to address these needs. Variants are extracted from the literature (known and candidate genes) and existing NGS datasets (public databases or through collaboration). The variants are evaluated in each of three evidential categories by using predefined criteria that will be manually curated: 1) “Population Genetic evidence” (e. g. population frequency, family segregation) and 2) “Functional Genetic evidence” (e. g. binding specificity, RNA expression) extracted from literature and data repositories and 3) “*in-silico* evidence” (e. g. PolyPhen2 for missense, ESEfinder for splice, RegulomeDB and GWAVA for non-coding variants, conservation measures). Each variant will then be placed in one of six ranks, based on the strength of evidence from the three categories [Table 1]. For each variant, summary data across the available datasets will be included rather than individual level data. Currently, data on all variants reported in all known PD genes in literature or identified in the WES at Miami UPDRCE have been imported in the database (~674k variants). All ranks and supporting data will be available to the user through the website (launch mid2015, online by ASHG meeting 2015). Additional summary data for each dataset and variant (e. g. QC, frequency) will be linked to the contributing lab’s info or publication to facilitate collaborative efforts. This database will allow users to quickly evaluate variants when interpreting sequence data, leading to a more focused follow-up in a research or clinical setting. The summary data format avoids the presence of individual identifiers, facilitating rapid availability of NGS data to the PD research community and thus potential collaborative efforts.

Table 1. Rankings for variants

	Rank 1	Rank 2	Rank 3
Genetic support	Highest	High	High
In-silico support	High	High or Intermediate	High or Intermediate
Functional support	Any	High	Intermediate or Low
	Rank 4	Rank 5	Rank 6
Genetic support	Intermediate	Low	Low
In-silico support	Any	High	Intermediate or Low
Functional support	Any	Intermediate or Low	Low

3150T

Distribution and clinical impact of functional variants in 31,000 whole exome sequences from the DiscovEHR study. *F. Dewey[1], D. J. Carey[2], L. Habegger[1], S. Balasubramanian[1], J. B. Leader[2], S. N. Fetterolf[2], C. Van Hout[1], C. O'Dushlaine[1], S. A. Pendergrass[2], H. L. Kirchner[2], O. Gottesman[1], J. Staples[1], J. Packer[1], C. Gonzaga-Jauregui[1], A. Lopez[1], J. D. Overton[1], S. Mellis[1], A. Murphy[1], A. Economides[1], R. Phillips[1], N. Stahl[1], G. D. Yancopolous[1], F. D. Davis[2], W. A. Faucett[2], J. G. Reid[1], M. D. Ritchie[2], M. F. Murray[2], A. R. Shuldiner[1], A. Baras[1], D. H. Ledbetter[2].* 1) Regeneron Pharmaceuticals, Inc. , Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

The DiscovEHR collaborative project between the Regeneron Genetics Center and Geisinger Health System MyCode community health initiative aims to catalyze genomic discovery and genomic medicine by coupling high throughput sequencing to a large, integrated healthcare population utilizing longitudinal electronic health records (EHR). All participants are consented for re-contact phenotyping and return of clinically-actionable results. Here we describe initial insights from deep whole-exome sequencing of over 31,000 participants. We sequenced the exons of 18,951 protein-coding genes in 31,058 participants of predominantly European ancestry with clinical phenotypes described in the EHR. The median duration of EHR data in these participants was 14 years, during which a median of 87 clinical encounters, 687 laboratory tests and 7 procedures were captured. In these participants we found ~5. 8 million single nucleotide variants, ~700,000 insertion deletion events, and ~180,000 putative loss of function (LoF) variants in the protein coding regions of the genome. The overwhelming majority of these genetic variants were rare (MAF < 1%) and over half were singletons. At this sample size, over 90% of genes, including genes encoding existing drug targets and a list of 76 genes (56 designated by ACMG plus 20 additional) conferring risk for actionable, highly penetrant genetic diseases, harbor rare heterozygous putative LoFs. Over 15% of genes contain rare homozygous putative LoFs. Each participant harbored a median of 31 rare putative LoFs. Linking these data to EHR-derived clinical phenotypes, we highlight examples of protective and harmful clinical associations that support or invalidate therapeutic targets. In individuals harboring deleterious variants in the clinically actionable gene list, we highlight examples of clinical phenotypes derived from the electronic health record that reflect this genetic disease predisposition, and outline plans to return and act clinically on these findings. In a large collection of exome-sequenced participants with longitudinal EHRs, we identified hundreds of thousands of protein-disrupting alleles and provide concrete examples of the use of this data for genetic association discovery, identification and genetic validation of therapeutic targets, and use of sequencing data in clinical care. This collaboration will serve as a blueprint for large-scale genomic medicine initiatives such as the Precision Medicine Initiative.

3151F

Analysis of structural variants in 2,200 whole-genome sequenced myocardial infarction cases and controls. *E. M. Schmidt[1], J. Chen[2], O. L. Holmen[3], K. Hveem[3], R. E. Mills[1], H. M. Kang[1,4], C. J. Willer[1,2].* 1) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 2) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, MI; 3) HUNT Research Centre, Department of Public Health and General Practice, Norwegian University of Science and Technology, Levanger, Norway; 4) Department of Biostatistics and Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, MI.

Myocardial infarction (MI) is a major cause of death throughout the world, with both common and rare single genetic mutations contributing to early-onset risk. Discovery of large structural variants (SVs) will give a more complete understanding of the genetic etiology of this complex disease. We perform whole-genome sequencing at 5x coverage of 2,200 individuals from Nord-Trøndelag, Norway as part of the population-based HUNT study. Cohort participants include cases with early-onset MI, and 1:1 age- and sex- matched healthy controls. We hypothesize that there are different frequencies of large structural variants in MI cases compared to controls and apply established and complementary SV detection algorithms to identify deletions, duplications, inversions, and translocations. Using the non-redundant union set of calls, we test for differences in both the prevalence and distribution of large structural variation among individuals with MI compared to their matched controls. In addition to analyzing association of genotypes with MI status, we examine the relationship between SVs and single nucleotide variants associated with coronary artery disease (CAD) and related traits identified by genome wide association studies. A top association shows a 505bp deletion near a CAD-associated collagen locus, which is a known structural component of the inner surface of blood vessels. We also investigate novel or Norwegian-specific SVs not present in the 1000 Genomes Project. Structural variants identified here will be imputed into a larger HUNT cohort of 30,000 samples for further study. This research provides broader insight into the genetic architecture underlying myocardial infarction and other heart disease-related clinical phenotypes.

3152T

Structural variants and obesity: Analysis of *FTO* intron 1 enhancer. *S. S. Sundseth[1], M. W. Lutz[2], R. Saul[3], R. McPherson[4], R. Dent[4], A. D. Roses[1,2].* 1) Cabernet Pharmaceuticals, Chapel Hill, NC, USA; 2) Deptartment of Neurology, Duke University Medical Center, Durham, NC, USA; 3) Polymorphic DNA Technologies, Alameda, CA, USA; 4) University of Ottawa Heart Institute, Ottawa, ON, Canada.

Over the last decade, genome wide association studies (GWAS) identified many loci associated with obesity, however the precise causal variants and the molecular mechanisms underlying those genetic associations remain largely unknown. In the post-GWAS era, we have concentrated on the identification of causal genetic factors. There is now evidence that many important causal variants for human traits are caused by structural variants (SVs) rather than SNPs, and that SVs are located in non-coding intronic and intergenic regions that affect gene regulation. Our strategy is to (1) use bioinformatic tools to identify non-coding regulatory genomic regions likely to be involved with obesity, (2) create and annotate our database of SVs from which to compile lists of SV targets within such regions, (3) apply proprietary scoring methods to identify those SVs most likely to have a biological effect, (4) analyze the top-scoring SVs in DNA samples from obese case and lean control subjects, (5) use phase-defined DNA sequencing and phylogenetic analysis to characterize the inheritance patterns of the variants. The approach has been successful for neurodegenerative diseases (Alzheimer's Disease, Lewy Body Variant-AD and Parkinson's Disease), but this is our first application to a "non-neurological" disease. We focused on the 47kb enhancer region within intron 1 of *FTO* that contains several SNPs previously associated with BMI and fat mass in multiple GWAS. We examined the 47kb *FTO* enhancer for SVs, scored them for putative function, and then sequenced the 4kb CUX1 element within the 47kb enhancer in Caucasian obese case/lean control subjects. To test for interactions between variants that may have an association with phenotype, recursive partitioning and statistical modeling was done. The analysis was done twice: (1) using case/control status as the dependent variable and (2) using the BMI measurements as an interval dependent variable. In this study one SNP, but no SVs were associated with BMI in the CUX1 region. We are currently analyzing additional SVs in the 47kb *FTO* enhancer for association with BMI and related phenotypes (waist circumference, fat mass, hyperlipidemia, T2D.) Identifying functional genetic variants involved in obesity and related phenotypes can lead to clinically relevant applications including earlier diagnosis, accurate prognosis, enhanced understanding of mechanism(s) of action and new therapeutic strategies.

3153F

***COL4A3* Mutations Cause Focal Segmental Glomerulosclerosis.** *L. Hu[2], J. Xie[1], X. Wu[2], H. Ren[1], W. Wang[1], Z. Wang[1], X. Pan[1], X. Hao[1], J. Tong[1], J. Ma[1], Z. Ye[3], G. Meng[4], Y. Zhu[2], K. Kiryluk[5], X. Kong[2], N. Chen[1].* 1) State Key Lab of MedicalGenomics, Ruijin Hospital, Shanghai, China; 2) State Key Laboratory for Medical Genomics, Institute of Health Sciences, Shanghai Jiao Tong University School of Medicine (SJTUSM) and Shanghai Institutes for Biological Sciences (SIBS), Chinese Academy of Sciences (CAS), Shanghai, China; 3) Nephrology Department, Huadong Hospital Affiliated to Fudan University, Shanghai, China; 4) State Key Laboratory for Medical Genomics, Shanghai Institute of Hematology, Rui Jin Hospital Affiliated to Shanghai Jiao Tong University School of Medicine, Shanghai, China; 5) Division of Nephrology, Department of Medicine, College of Physicians and Surgeons, Columbia University, New York, USA.

Focal segmental glomerulosclerosis (FSGS) is a histologically identifiable glomerular injury often leading to proteinuria and renal failure. To identify its causal genes, whole-exome sequencing and Sanger sequencing were performed on a large Chinese cohort that comprised 40 FSGS families, 50 sporadic FSGS patients, 9 independent autosomal recessive Alport's syndrome (ARAS) patients, and 190 ethnically matched healthy controls. Patients with extrarenal manifestations, indicating systemic diseases or other known hereditary renal diseases, were excluded. Heterozygous *COL4A3* mutations were identified in five (12. 5 %) FSGS families and one (2 %) sporadic FSGS patient. All identified mutations disrupted highly conserved protein sequences and none of them was found in either public databases or the 190 healthy controls. Of the FSGS patients with heterozygous *COL4A3* mutations, segmental thinning of the glomerular base membrane (GBM) was only detected in the patient with electronic microscopy examination results available. Five ARAS patients (55. 6 %) had homozygous or compound-heterozygous mutations in *COL4A3* or *COL4A4*. Serious changes in the GBM, hearing loss, and ocular abnormalities were found in 100 %, 80 %, and 40 % of the ARAS patients, respectively. Overall, a new subgroup of FSGS patients resulting from heterozygous *COL4A3* mutations was identified. The mutations are relatively frequent in families diagnosed with inherited forms of FSGS. Thus, we suggest screening for *COL4A3* mutations in familial FSGS patients.

3154T

Long single-molecule RNA sequencing detects novel variants in humans. *H. Yang[1], S. Mangul[1], F. Hormozdiari[1], E. Tseng[2], A. Zelikovsky[3], E. Eskin[1].* 1) Department of Computer Science, UCLA, Los Angeles, CA; 2) Pacific Biosciences, Menlo Park, CA; 3) Department of Computer Science, Georgia State University.

RNA sequencing is essential for understanding biological processes but current method such as short-read sequencing is not able to fully describe an entire RNA molecules. Previously long-read sequencing was infeasible due to high error rate which disables identification of genetic variants. However, single-molecule long-read RNA sequencing allows to sequence complete haplotype isoforms, which allows parental haplotype identifications. As short-read sequencing relies on statistical analysis on the covered regions, it introduces a significant bias toward higher mapping rates for of the reference allele at the heterozygous loci and disregards the variants in minor alleles that are expressed in low level. HapIso (Haplotype-specific Isoform reconstruction) tolerates high error-rate of long-read sequencing and identifies partition the isoform reads into parental alleles. Phasing the reads according to the allele of origin allows our method to efficiently distinguish between read errors and the true biological mutation. HapIso uses a k-means clustering algorithm to group the reads into two meaningful clusters, maximizing the similarity of the reads within cluster, and minimizing the similarity of the reads from different clusters. Each cluster corresponds to a parental haplotype. We use family pedigree information to evaluate the approach. Furthermore, single-molecule sequencing was able to find novel variants that were not able to be identified in short-read sequencing. 2755 variants were identified through single-molecule sequencing that were not identified by short-read sequencing, while 1323 variants were identified in both single-molecule sequencing and short-read sequencing; the newly identified variants were confirmed by family based validation using trio family data.

3155F

Survey of Human Cytomegalovirus Gene Polymorphism in Infants Infected Congenitally or Postnatally from Gunagzhou, China. *H. Li[1], B. WANG[1], Z. DENG[1,2], T. ZHOU[1].* 1) Dept. Biotechnology, Jinan University, Guangzhou, Guangdong, China; 2) Psychiatry and Behavioral Sciences Keck School of MedicineUniversity of Southern California, 1501 San Pablo Street, Los Angeles,CA.

Human cytomegalovirus (HCMV) is the leading cause of intrauterine viral infection, affecting 0. 3–0. 7% of live births in industrialized countries and 1–5% in developing countries. CMV may cause pregnancy complications such as intrauterine growth restriction and birth defects. Congenital CMV (cCMV) infection may result in spontaneous abortion, stillbirth, microcephaly, hepatosplenomegaly, jaundice, petechiae, or chorioretinitis Approximately 10% of newborns infected congenitally are symptomatic at birth; if symptoms of CMV infection are present, they are frequently non-specific for CMV infection. When disabilities, such as hearing loss, mental retardation, or visual impairment, become apparent in next months or years, it is generally too late to identify cCMV infection as the culprit. Both host and viral factors may affect the outcome of infection. CMV virulence may depend on genetic variability in several regions of the genome. The CMV genome, the largest of all human herpesviruses, is a linear 235–240 kbp double- stranded DNA and contains more than 200 open reading frames (ORFs). In this study, we collected the urine samples of 62 newborn infants with congenital or postnatal CMV infection, who represented disease outcome and were born in Guangzhou, China. Four low passage HCMV clinical strains, D3, D2, D52, C30, were successfully isolated and identified from these urine samples. CMV polymorphisms were studied in UL133-UL148 genes from these clinical strains. Genotyping was performed by a sequencing analysis of PCR-amplified fragments. The results demonstrated that (1) there are abundant polymophism in UL133-UL148 genes from D3, D2, D52, C30, comparing with other HCMV clinical isolates; (2) UL136-UL148 genes are not essential for viral reproductivity and infection in vitro. Further more, we will establish which genotypes in several genes associated with immunodeficiency might play a role in congenital and postnatal CMV infections in infants, and attempted to explore the relationship among genetic variations, disease outcome and viral gene polymorphisms.

STR-Seq: a next generation technology for massively parallel microsatellite sequencing and genotyping. *G. Shin[1], S. Grimes[2], B. Lau[2], H. Lee[1], E. Hopmans[2], H. P. Ji[1,2].* 1) Division of Oncology, Stanford University School of Medicine, Stanford, CA; 2) Stanford Genome Technology Center, Stanford University, Palo Alto, CA.

Short tandem repeats (STR), otherwise known as microsatellites, are multiallelic in terms of germline variation. As a result, STR genotyping is highly informative for genetic applications such as forensics DNA fingerprinting. In addition, STRs are prone to accumulating somatic mutations in cancers that lack DNA mismatch repair mechanism and are informative for clonal analysis. Despite their wide application in a variety of fields, the analysis of STRs with next generation sequencing-based (NGS) methods is limited by several major issues including: i) Only the reads which encompass an entire STR locus are informative; ii) PCR amplification during library preparation can introduce artifactual "stutter" mutations that confound accurate genotyping. Consequently, analysis on STRs requires more sequencing depth with finely controlled target selection, but current target enrichment methods such as bait-hybridization are of limited utility. In this study, we developed a novel targeted sequencing technology, short tandem repeat sequencing (STR-Seq), by which a novel sequencing technology can generate STR-spanning reads for thousands of microsatellites. This technology is highly scalable and eliminates traditional sequence alignment. This technology involves programming an Illumina sequencing flowcell to select STR / microsatellite loci targets in a massively parallel fashion. Unlike conventional traditional bait hybridization or PCR amplification methods, targeting primer-probes are engineered into a flowcell, which maximize the efficiency and specificity of target selection. We demonstrate simultaneous analysis of approximately 2,500 STR loci in a single lane with individual reads cover the entire STR. We also developed a targeted fragmentation process to improve target selection and coverage. In addition, to eliminate stutter noise, sequencing libraries were prepared by an amplification-free method, thus each read corresponds to a single DNA molecule. Finally, we developed a novel bioinformatics pipeline for quantitation of STR repeat motifs and associated variants in phase with the STR. The process has two internal validation steps for high-confidence genotype calling, which use the target capture sequence and flanking sequences of the repeat regions as the validation targets. We demonstrate that this technology has concordance with conventional methods with dramatically higher throughput.

3157F

The importance of heterozygous protein truncating variants in the human genome. *A. Telenti[1], I. Bartha[2], A. Rausell[3], P. McLaren[2], P. Mohammadi[4], M. Tardaguila[3], N. Chaturvedi[2], J. Fellay[2].* 1) J Craig Venter Institute, La Jolla, CA; 2) École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 3) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 4) Computational Biology Group, ETH Zurich, Switzerland.

Sequencing projects have identified large numbers of rare stop-gain and frameshift variants in the human genome. As most of these are observed in the heterozygous state, they test a gene's tolerance to haploinsufficiency and dominant loss of function. We analyzed the distribution of truncating variants across 16,260 protein coding autosomal genes in 11,546 individuals. We observed 39,893 stop-gain and frame-shift variants affecting 12,062 genes, which significantly differed from an expectation of 12,916 genes under a model of neutral *de novo* mutation ($p<10-4$). This suggests that there is a set of genes in the human genome that cannot tolerate heterozygous protein truncating variants (PTVs) because of early life lethality. Genes lacking any PTVs have fewer paralogs, are more likely to be part of protein complexes and are more connected in protein-protein interaction networks than the rest of the genes. Furthermore, they have characteristics of essentiality and a higher probability of CRISPR-Cas9 editing compromising cell viability. The set of genes not carrying stop-gain or frameshift variants is enriched in OMIM genes annotated with 'haploinsufficient' or 'dominant negative' keywords and are overrepresented in functional categories such as transcription regulation, developmental processes, cell cycle, and nucleic acid metabolism. Assuming that a fraction *f* of genes do not carry *de novo* PTVs while the remaining genes do so according to their neutral mutation rates, *f* can be estimated by fitting a model to the observed distribution of PTVs. By doing so we estimated that at least 10. 8% of human genes do not tolerate heterozygous PTVs. The study of PTVs delineates the essential genome and, more generally, identifies rare heterozygous variants as an unexplored source of diversity of phenotypic traits and diseases.

3158T

Whole genome sequencing of six baboon species reveals high levels of polymorphism including extensive functional variation. *M. Raveendran[1], R. A. Harris[1], M. Dahdouli[1], D. Rio Deiros[1], C. J. Jolly[2], J. Phillips-Conroy[3], L. Cox[4], D. Muzny[1], K. Worley[1], R. A. Gibbs[1], J. Rogers[1].* 1) Baylor College of Medicine , Houston, TX; 2) New York University, New York, NY; 3) Washington University School of Medicine, St. Louis, MO; 4) Texas Biomedical Research Institute, San Antonio, TX.

Baboons, genus *Papio*, are a commonly used research model for studies of various human diseases and health-related phenotypes. One baboon species, the olive baboon (*Papio anubis*) is widely used in research related to obesity, diabetes, cardiovascular disease, atherosclerosis, neuroimaging and epilepsy. To facilitate genetic analyses of risk factors for disease, we generated a de novo reference assembly for the olive baboon genome, and sequenced four additional *P . anubis* individuals. The Illumina HiSeq 100bp reads were mapped to the baboon reference, Panu_2. 0 (http://www. ncbi. nlm. nih. gov) and the single nucleotide variants (SNVs) called using both Atlas2 and GATK. Among these five individuals, we identified 5,840,388 SNVs and using the Ensembl variant effect predictor tools found 27,743 mis-sense variants, 299 de novo stop codons and 5,738 splice site variants. There are five other recognized species of *Papio* baboons, some of which are also used in biomedical research studies: *P. hamadryas* (osteoporosis), *P. cynocephalus* (atherosclerosis, cardiovascular disease, infectious disease), *P. ursinus* (bone formation) and *P. papio* (epilepsy). Although closely related and known to form hybrids in the wild, the species within this genus differ in social behavior, ecology, body size and other fundamental characteristics. To investigate genetic differences among species, as part of the baboon genome analysis consortium, we sequenced (~25x Illumina whole genome coverage) two individuals representing *P. hamadryas* (Ethiopian wild caught), two *P. papio* (Guinea), two wild-caught *P. cynocephalus* (Yellow), two *P. ursinus* (Chacma) and three wild-caught *P. kindae* (Kinda) baboons. Again the intersection of SNVs calls (16,524,065) from Atlas2 and GATK were used for subsequent analyses. We identified 4. 5M SNVsin *P. hamadryas*, 6. 5M in *P. cynocephalus*, 3. 2M in *P. papio*, 4. 8M in *P. ursinus* and 8. 2M in *P. kindae*. The average SNVs per individual ranges from 2. 8M (Guinea baboons) to 5. 2M (kinda baboons). We identified 51,188 missense, 551 stop gained, and 9,212 splice region variants. Overall, 7,453 variants were scored by Polyphen2 as probably damaging and SIFT as deleterious. The extensive genetic variation, much of which is expected to have functional consequences, can be used to extend baboon models of human health and disease by more extensively incorporating genetic variation into research study design and analysis.

3159F

Calling mitochondrial DNA (mtDNA) variants from whole exome sequencing data. *P. Zhang[1], H. Ling[1], K. Hetrick[1], E. Pugh[1], D. Witmer[1], J. Ding[2], N. Sobreira[3], D. Valle[3], K. Doheny[1].* 1) Center for Inherited Disease Research, (CIDR), Johns Hopkins University, Baltimore, MD; 2) Laboratory of Genetics, National Institute on Aging, NIH, Baltimore, MD; 3) Institute of Genetic Medicine, Johns Hopkins University School of Medicine.

As part of the Baylor Hopkins Center for Mendelian Genomics (CMG) (http://www. mendelian. org/), CIDR has performed whole exome sequencing (WES) for over 900 samples to discover the genetic basis for Mendelian conditions. When potential causal variants are not identified from coding regions in the WES data we need to look beyond the exome. In this project, we examine whether the off-target reads of mitochondrial DNA (mtDNA) generated by WES can be used to study mtDNA variation. As many large-scale genetic studies are collecting WES data, the method and protocol developed by us could have wide application. We extracted off-target mtDNA reads from our WES data and tried to identify homoplasmies (positions with all the same non-reference alleles) and heteroplasmies (positions with a mixture of two or more alleles) using MitoCaller [Ding et al. PLoS Genetics (2015), in press], a software designed to call both homoplasmies and heteroplasmies from next-generation sequencing data. We observed a mtDNA median depth of coverage (DOC) ranging from 3x to 500x in the 767 samples, out of which 21. 5 % had a median DOC >100x. The DOC varied significantly by DNA source. We used Agilent SureSelect HumanAllExonV4 capture and sequenced on Illumina HiSeq2500 platform. The mean on-target (exonic) DNA coverage in these samples ranged from 50x to 322x with a median DOC of 93x (percentage DOC on target at least 10x ranges from 85. 9% to 99. 6%). After applying MitoCaller to our WES data, we called 0 to 8 (median 1) heteroplasmies per sample for individuals with a median mtDNA DOC > 100x, using a 10% minor allele fraction threshold. As expected, analyses using trios showed high maternal and low paternal inheritance of homoplasmy. We also annotated the called mtDNA variants with ANNOVAR to assess their functional implications with the phenotype of interest. We will further evaluate how the DOC and DNA sources affect the quality of homoplasmy and heteroplasmy calls, and continue to search for variants that are associated with the Mendelian traits combining the other information available.

Sequencing and typing of HLA class I genes by using a single-molecule, real-time sequencing technology. *Y. Kuroki[1,2], N. Nariai[1], A. Ono[1], K. Tateno[1], N. Inagaki[1], S. Saito[1], M. Nagasaki[1], J. Yasuda[1], M. Yamamoto[1].* 1) Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Miyagi, Japan; 2) Genome Medicine, National Center for Child Health and Development, Tokyo, Japan.

Human leukocyte antigen (HLA) is the human version of the major histocompatibility complex (MHC), which has important functions in cellular interactions and immune reactions. The human HLA region consists of more than 250 genes, which are arranged as duplicated and clustered structures spanning of 3. 78 Mb genomic region on the chromosome 6p21. The genes located in this region are known as the susceptibility genes for various diseases, such as the common diseases and the autoimmune disorders. HLA genes play a critical role in the occurrence and the development of these diseases; however the molecular basis and the detailed relationship between the genes and HLA-related disorders have not been fully explained. One of the reasons for this is the complexity of the genome structures–in other words, the diverse sequences and different structures known as the polymorphisms within the population. To reveal the polymorphisms and the types of each allele, here we have sequenced the HLA class I genes (HLA-A, HLA-B, and HLA-C) by using single-molecule, real-time (SMRT) sequencing technology. The sequence data obtained by SMRT sequencing were subjected to computational typing for each allele. We analyzed more than 200 Japanese samples belonging to the 'ToMMo reference sequence panel', which form part of the sequence data from the prospective genome cohort study by Tohoku Medical Megabank Organization (ToMMo). Currently, we have identified several candidates for novel sequences that do not match the sequences already deposited in the IMGT/HLA database. We will present an overview of this project and report its current status at the meeting.

Linking Protein Annotation and Genome Variation in ClinGen Knowledge Base. *P. McGarvey[1], M. Harris[1], S. Rao[1], X. Feng[2], R. Patel[2], A. Milosavljevic[2], S. Madhavan[1].* 1) Innovation Center for Biomedical Informatics, Georgetown University Medical Center, Washington DC; 2) Bioinformatics Research Laboratory, Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, Texas.

Gene variants may cause deleterious effects via many mechanisms including: gene transcription & splicing; protein translation; and disruption of protein structure & function. Understanding the effects of polymorphisms on protein function is a key component of gene & variant curation but much of this information is not readily available. UniProtKB contains decades of literature-based and semi-automated curation describing protein function including variation. Standard NGS annotation tools identify simple effects like translation stops & missense mutations, but more subtle effects like disruption of an enzyme active site, protein-binding site or post-translational modifications are often not included. There is a need to make this valuable functional information available to the genomic community to connect DNA variation to the protein and the biological consequence. To integrate UniProtKB, information needs to be mapped from the multi-dimensional space of protein structural features into the coordinate space of transcripts and genomic sequences. We map protein features to the genome using software developed to integrate information from UniProtKB and RefSeq. Each UniProt sequence is mapped to a Refseq protein entry. The corresponding RefSeq RNA location on the genome including the intron/exon boundaries and transcription start site is used to map the amino acid sequence to the genome. Splicing introduces complexity as functional domains on an amino acid sequence and even individual codons may have multiple locations on the genome due to intron splicing. The software outputs protein to genome coordinates in tabular, and JSON formats. The JSON output is used to load the data into ClinGen Knowledge Base via APIs using a document model created for protein sequence features. Annotated protein variations are loaded as simple allele documents and linked to related documents on gene, reference sequences, protein features and evidence to be used in the ClinGen Pathogenicity Calculator. Results from a test set of genes will be presented and illustrated by examples where genomic variants are aligned with UniProt features such as Active Sites, Domains and other features that could explain a variant's pathogenicity. Also shown are novel disease associated protein variations with published evidence not currently in ClinVar. The results suggest that this integration can help the classification of pathogenic variants that ultimately will support decisions on actionability.

Somatic mutation analysis in a healthy adult's blood and sperm. *C. Zeng[1], Y. Hong[1], W. Chen[1], D. Zhang[1], Y. Fu[2].* 1) Laboratory of Genomic and Precision Medicine, Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing, China; 2) Human Genetics Center and Division of Biostatistics, School of Public Health, University of Texas, Houston, TX.

Somatic mutations commonly occurred in cells during the DNA replication and DNA repair process. Although studies on somatic mutations were focused on their association with diseases, this type of mutations was continually generated in our bodies and most of them were neutral as inferred by current research without exact test. Studying somatic mutations in normal tissues will give us insight into the mutation hot spots, the accumulation of mutations and their impacts in cell development. However, a big challenge to study somatic mutations is their very low frequency that are hardly to be distinguished from the background noise of next generation sequencing. Here we developed a method by estimating the error probability to detect low frequency somatic mutations. With this approach we also analyzed the dynamics of mutation distributions in blood and sperm sampled from an adult. To filter the errors produced in the process of whole exome sequencing, a probability based error estimating model was constructed using a priori error distribution generated by control sequences with no mutation. The probability of a call as to be a mutation or an error was then calculated accordingly. Applying this model, hundreds of probably true mutations were found in each tissue. Similar mutation numbers were seen in two tissues, whereas the distributions of the mutation frequency spectrums between blood and sperm appear to be different. Greater number of high frequency mutations were detected in blood, perhaps because of large effective cell population size in early stage of development and higher number of cell divisions in blood than that in sperm. Interestingly, the observed spectrums in both tissues showed significant bias towards low frequency mutations in comparison with the simulation of mutation generation starting from one cell. One possibility for this phenomenon is the change in mutation rate during the process of cell development. Moreover, in five time-point samples, three from blood and two from sperm with the 12 month interval for each tissue, only the very high frequency somatic mutations were shared among samples. However, for the hundreds of low frequency mutations, only one or two were overlapped in either blood or sperm. This is most likely due to the different lineages of active hemopoietic stem cells sampled in time points, or a relatively large population size in sperm.

The Korean Reference Genome project: construction of the reference panel for imputation analysis. *Y. Kim, B. Kim, B. Han.* Center for Genome Science, National Institute of Health, Heungdeok-gu, Chungcheongbuk-do, South Korea.

Next Generation Sequencing (NGS) technology is becoming powerful tool for discovery of genetic variants across entire chromosomes in genomic study. However, NGS is not yet feasible to apply in a large scale population based genome study due to its relatively high cost and required high computing power. In this context, imputation analysis gathered much attention as an alternative tool for comprehensive analysis of all genetic variants that are estimated using sequencing data as the reference panel. The 1,000 Genomes project data is widely used as a public reference panel. There are about 2,500 samples from 20 populations in the phase 3 dataset. Among them, 504 samples with East Asian ancestry were included. However, Korean samples were not included in the 1,000 Genomes project. Geographically, the Republic of Korea is located between China and Japan in North-East Asia. In this study, we describe the Korean Reference Genome (KRG) project which was initiated in 2012. We sequenced 400 Korean samples (10-30x) and constructed the study specific reference panel containing about 20 million single-nucleotide variants. We demonstrated that the KRG reference panel increased imputation performance over the 1,000 Genomes reference panel. The KRG reference panel will be valuable resource and would be great aid for imputation based association analysis in the Korean population.

Association study of *TAF2* with aspirin exacerbated respiratory disease and FEV1 decline. *J. Kim[1], C. Park[2], H. Shin[1,3].* 1) Research Institute for Basic Science, Sogang University, Seoul, South Korea; 2) Division of Allergy and Respiratory Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, South Korea; 3) Department of Life Science, Sogang University, Seoul, South Korea.

Aspirin exacerbated respiratory disease (AERD) is a clinical syndrome characterized by a severe decline in forced expiratory volume in one second (FEV1) when taken with non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin. Our previous genome-wide association study (GWAS) has identified several variants, including a nonsynonymous variant, of *RNA polymerase II, TATA box binding protein (TBP)-associated factor* (*TAF2*, a cofactor for TFIID-dependent RNA polymerase II-mediated transcription) as potential susceptible loci for AERD. To validate the potential association between *TAF2* and AERD, we performed an extended study using additional single nucleotide polymorphisms (SNPs), different genetic models, and haplotype analysis in a larger cohort. In the logistic analysis, *TAF2* polymorphisms showed potential association signals for the development of AERD ($P < 0.05$). In addition, regression analysis showed significant associations between *TAF2* polymorphisms and FEV1 decline after aspirin provocation in asthmatics ($P < 0.05$). Despite the needs for replications in other populations and further functional evaluations, our findings suggest that *TAF2* polymorphisms might be associated with AERD and FEV1 decline, or its related symptoms.

3165F

An integrative computational workflow for eQTL analysis. *N. Prodduturi, C. Wang, H. Sicotte, JP. Kocher.* Department of Health Sciences Research,Mayo Clinic, 200 first street SW, Rochester, MN 55905 Rochester, MN.

Background: Genome-wide association studies (GWAS) have led to the discovery of many variants associated with risk, prognosis, outcome, and pharmacogenomics drug response. Even after the functional variant is identified by fine mapping, the functional mechanism of action of this variant remains to be elucidated. Currently, only 20% of variant-phenotype associations can be explained by amino acid changes. The remaining association involve variants located in non-coding regions that could be functional by affecting transcripts regulation. If this assumption is correct, an association between genotype and gene expression could be established using expression quantitative trait loci analysis(eQTL). This analysis can either detect cis-eQTLs, that have direct influence on regulatory elements affecting genes near the DNA variant, or trans-eQTLs that affect distal genes or genes on a different chromosome. Integrative eQTL analysis can therefore help explain the functional role of clinically relevant SNPs. Despite the availability of tools to perform eQTL computation, a comprehensive workflow is still lacking. **Results:**We developed an easy to use workflow consisting of powerful tools in public domain, such as MatrixEQTL, plink, and ANNOVAR. In addition, we designed additional components to reduce false positives and facilitate results interpretation. This workflow is portable and can be used on single machines or computer clusters, using the Sun Grid Engine (SGE) cluster management software. Genotyping and expression data with the genomic coordinates and strand information are the required input files for the workflow. The package provides multiple options to customize eQTL analysis: choosing different statistical methods, running permutation based hypothesis-testing, and retrieving flexible forms of annotation tables. Moreover, the workflow provides users with additional reports, which include input data QC reports, eQTL results with FDR corrected p-values, annotations, fold changes, and information about correlated SNPs in blocks of linkage-disequilibrium (LD). Collectively, this versatile workflow is helpful to facilitate interpretation of genomic variants and formulation of mechanistic hypothesis.

3166T

Fine-mapping red blood cell traits using eQTL in erythroblasts differentiated *ex vivo* from CD34+ hematopoietic stem cells. *S. Lessard[1,2], G. Lettre[1,2].* 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Université de Montréal, Montreal, Quebec, Canada.

INTRODUCTION: A challenge arising from genome-wide association studies (GWAS) is the identification of causal relationships between variants and specific genes, since most associated variants fall outside coding regions. A powerful approach to circumvent this problem is expression quantitative trait loci (eQTL) mapping, but this requires access to relevant human tissues or cells. Red blood cell (RBC) traits are ideal for testing the eQTL method: (1) they are highly heritable (h2~0. 4-0. 8), (2) they are clinically relevant, being implicated in cancers, hemoglobin disorders and malaria resistance, and (3) RBC progenitors are accessible and amenable to *in vitro* culture. **METHODS & RESULTS:** Erythroblasts differentiated *ex vivo* from CD34+ hematopoietic stem cells obtained from 24 anonymous human donors were genotyped on the HumanOmniExpress array (Illumina). We imputed genotypes using the 1000 genomes phase 3 reference haplotypes. We measured gene expression levels by RNA-sequencing (>40M reads per sample), mapping reads and evaluating expression values using Tophat2 and Cufflinks2. We first identified genes displaying allelic imbalance (AI). For each sample at heterozygous sites, we tested if the reads alternative-to-reference allele ratio deviated from an expected ratio corrected for mapping bias using a binomial test. For each gene with AI P<5x10-8 (N=355), we mapped candidate eQTLs. First, we tested if surrounding SNPs (±100kb) were associated with the gene's expression by linear regression. Second, we tested if the candidate eQTL SNP was concordant with AI using a *t*-test, based on the hypothesis that heterozygotes should display AI, whereas homozygotes should display the expected ~50:50 ratio. We determined that both statistics are poorly correlated (R2 = 0. 01) and can thus be combined using Fisher's method to increase confidence in the results. With this approach and despite our small sample size, we identified at least one potential eQTL with false discovery rate (FDR) <0. 05 for 159 genes. We found several promising loci, including the SNPs rs1541252 and rs10900585, which are respectively associated with mean corspuscular hemoglobin concentration and malaria resistance, and are eQTLs for the *ATP2B4* gene. **CONCLUSION:** We identified several candidate eQTLs in erythroblasts, which provides a framework to fine-map RBC traits-associated variants. We aim to validate these eQTLs by engineering deletions of potential regulatory regions using the CRISPR/Cas9 system.

3167F

Identification of rare and common variants associated with gene expression in a complex Amish pedigree. *C. Brown[1], Y. Park[1], R. Kember[1], B. Emert[1], S. Elwyn[1], D. Craig[2], B. Engelhardt[3], D. Rader[1], M. Bucan[1].* 1) Genetics, University of Pennsylvania, Philadelphia, PA; 2) The Translational Genomics Research Institute, Phoenix, AZ; 3) Department of Computer Science and Center for Statistics and Machine Learning, Princeton University, Princeton, NJ.

The majority of heritability of complex traits in humans is associated with non-coding variants of modest effect size. In an effort to characterize the mechanisms by which non-coding variants contribute to phenotypic variation, numerous studies have identified genetic variation associated with gene expression (eQTLs) in a variety of tissues. While eQTLs have provided tremendous insight into genome wide association studies (GWAS) of disease, they suffer from limited statistical power because their sample sizes are often several orders of magnitude smaller than the corresponding GWAS. As a result, existing eQTL studies tend to identify genetic variants of large effect, which may miss many alleles relevant for disease. In population-based samples, power limitations become increasingly problematic with less frequent alleles. Recently, several groups have developed haplotype-based approaches that jointly model allele specific expression (ASE) and eQTL effects that increase power to detect genetic effects on expression. However, such approaches require accurate phasing between causal regulatory SNPs and coding SNPs and therefore have less benefit when these SNPs are near linkage equilibrium. To address these limitations, we have performed an eQTL and ASE study in a large (n=497), complex (9 generation) Old Order Amish pedigree, combining whole genome and RNA sequencing. We demonstrate that this study design has a number of advantages for the ascertainment of genetic variants associated with gene expression. High quality, long-range haplotypes improve the ability to jointly model QTL and ASE effects at distal regulatory elements and improve detection of allele specific transcript isoform usage. Moreover, by studying a large family from a founder population, we are able to detect associations with large effect genetic variants that are rare in European population cohorts. Finally, we use the unique pedigree structure of this family to estimate heritability components for gene expression and splicing.

3168T

Characterizing regulatory variation using a panel of induced pluripotent stem cells. *NE. Banovich[1], YI. Li[2], SM. Thomas[1], MC. Ward[1], PY. Tung[1], JE. Burnett[1], MD. Myrthil[1], CL. Kagan[1], I. Gallego Romero[1], BJ. Pavlovic[1], JK. Pritchard[2,3], Y. Gilad[1].* 1) Human Genetics, University of Chicago, Chicago, IL; 2) Departments of Genetics and Biology, Stanford University, Stanford, CA; 3) Howard Hughes Medical Institute, Stanford University, Stanford, CA.

Human induced pluripotent stem cells (iPSCs) provide unprecedented potential to study gene regulation in multiple differentiated cell types from a single individual. This tool also allows researchers to perform experimental perturbations in disease relevant tissues. A first step for the study of gene regulation in iPSCs is to generate a panel large enough to study the effects of genetic variation on gene regulation. To this end, we reprogrammed lymphoblastoid cell lines (LCLs) from 70 individuals into iPSCs. These individuals have been used extensively in previous work, making them attractive for further studies on gene regulation. In this study, we characterized regulatory variation, by collecting gene expression data and identifying expression quantitative trait loci (eQTLs). In our hands, the number of eQTLs identified in iPSCs are comparable to those identified in somatic cell types with similar sample sizes. This result was surprising given our observation that gene expression in iPSCs is highly homogeneous among individuals. Interestingly, we found that eQTL effect sizes are smaller on average in iPSCs compared to their counterparts in somatic cells. This however may be explained by standard errors of our estimated effect sizes in that are an order of magnitude lower on average in iPSCs. To further improve our understanding of regulatory variation in these lines, we measured DNA methylation and chromatin accessibility (ATAC-seq). Finally, to demonstrate the broad utility of iPSCs, we differentiated iPSCs from ten individuals into cardiomyocytes and collected RNA-seq data. Altogether we have generated a panel of iPSCs of sufficient size to identify QTLs associated with multiple regulatory phenotypes. Our initial analyses have identified eQTLs and highlighted differences between the effect of genetic variation on gene expression in iPSCs and somatic tissues. This panel will be a valuable resource in the study of gene regulation for our group and others.

"Buffet-Style" eQTL Discovery – Assessing the Impact of PEER Adjustment on Replicability of Cis and Trans eQTL Associations in Whole Blood. *P. J. Castaldi[1,2], M. Obeidat[3], M. H. Cho[1,4], E. K. Silverman[1,4], P. D. Pare[3], D. D. Sin[3], . C. P Hersh[1,4].* 1) Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA; 2) Division of General Medicine and Primary Care, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA; 3) University of British Columbia Centre for Heart and Lung Innovation, St Paul's Hospital, BC Canada; 4) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA 02115, USA.

Background: It is common practice to adjust for probabilistic estimation of expression residuals (PEER) factors in eQTL analyses, based on the rationale that this eliminates systematic noise and increases power. However, PEER factors also capture biologic signal. Thus, PEER adjustment could be beneficial or detrimental to eQTL discovery, and this could vary for *cis* and *trans* eQTLs. Using two blood eQTL datasets of 130 and 490 subjects with chronic obstructive pulmonary disease (COPD), we systematically evaluated the impact of adjustment for a range of PEER factors on eQTL yield, replicability, and retention of baseline (i. e. non PEER-adjusted) eQTL. **Methods:** Gene expression data were generated for 130 subjects with COPD from the ECLIPSE Study using the HG-U133 Plus 2. 0 GeneChip (the ECLIPSE 1 sample), and additional expression data were generated for 490 non-overlapping subjects with COPD from ECLIPSE using the HumanGene ST 1. 0 chip (ECLIPSE 2 sample). In each sample, up to 80 PEER factors were generated from RMA-normalized and rank transformed expression data. ECLIPSE 2 data were analyzed both at the gene and exon levels. A series of 1,440 *cis* and *trans* eQTL analyses were performed for chromosomes 15 and 22, using MatrixeQTL with a 1MB cis window, adjusting for 0 through up to 80 PEER factors, and the impact of PEER adjustment on *cis* and *trans* eQTL discovery and replication was assessed. **Results:** PEER adjustment increased the yield of cis eQTLs, though in ECLIPSE 1 there were diminishing returns after adjustment for >15 PEER factors. ECLIPSE 1 cis eQTL associations replicated in ECLIPSE 2 at a rate ranging from 55-78% and 33-54% at the gene and SNP-gene level, respectively. Notably, 20-30% of significant non-PEER adjusted eQTLs were no longer significant after PEER adjustment, though these eQTLs replicated at a similar rate to PEER-identified eQTLs. For *cis* eQTL analysis, collecting all significant results across PEER-adjusted analyses increased eQTL yield without sacrificing replicability, after adjusting for the increased number of tests. For *trans* eQTL discovery, PEER adjustment often decreases yield. **Conclusions:** PEER factor adjustment aids *cis* eQTL discovery, but often impairs *trans* eQTL discovery. Concatenating significant *cis* eQTL results across non-PEER and PEER-adjusted analyses, i. e. "buffet-style" eQTL discovery, is a more powerful approach than the traditional method of selecting a single number of PEER factors to use for adjustment.

Local epistasis between regulatory and coding variants contributes to disease in diverse human tissues. *S. E. Castel[1,2], T. Lappalainen[1,2].* 1) New York Genome Center, New York, NY; 2) Department of Systems Biology, Columbia University, New York, NY.

Genetic variants that affect gene expression (expression quantitative trait loci, eQTL) are common in human populations and it is well known that they canassociate to disease. Interactionbetween these common regulatory variants and rare putatively deleterious protein coding variants may explain some of this association, but has not been extensively studied. Such interaction, termedepistasis, could result in the increased penetrance of acoding variant if it finds itself on the more highly expressed haplotype as a resultof acis-eQTL. In this work, we put forward a novel population genetics basedmodel that describes theepistatic risk resulting from interaction between regulatory and deleterious codingvariants within a gene. We use the model to predict eQTL frequency spectra thatwould lead to epistatic interactions within heterozygous individuals. Using datafrom the Genotype Tissue Expression (GTEx) and 1000 Genomes projects wefind a both a reduction in strength and number of eQTLs in the allele frequencyspectra where we predict negative interactions would occur, suggestive ofpurifying selection acting against negative epistasis. By integrating epistaticsignatures with gene and variant level annotations we identify a set of genes thatare at high risk for negative interactions that could result in disease. Finally, weuse the transcriptome as a molecular phenotype to illustrate the effect of thisphenomenon within individuals. Our results suggest thatlocal epistatic interactionbetween cis-eQTLs and coding variants is common, and plays arole in disease.

Induced pluripotent stem cells retain patient-specific gene expression patterns largely driven by cis-regulatory variation. *G. E. Hoffman[1], I. Carcamo-Orive[2], P. Cundiff[3], J. W. Knowles[2], N. D. Beckmann[1], S. D'Souza[3], S. Whalen[4], D. Papatsenko[1], A. Patel[3], F. Abbasi[2], G. M. Reaven[2], M. Shahbazi[2], R. Chang[1], G. Pandey[1], I. Lemischka[3], T. Quertermous[2], E. E. Schadt[1].* 1) Department of Genetics and Genomic Sciences, Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Stanford School of Medicine, Cardiovascular Institute, Palo Alto, CA; 3) Department of Developmental and Regenerative Biology, Black Family Stem Cell Institute, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Gladstone Institutes, University of California, San Francisco, CA.

Patient-derived induced pluripotent stem cells (iPSC) are a powerful *in vitro* model of human disease owing to their ability to self-renew and differentiate into other cell lineages. iPSC's can be derived from adult somatic cells and it is well established that the reprogramming process overrides the gene expression pattern of the originating cell type. Yet the degree to which iPSC's retain a patient-specific expression pattern or converge to a more homogeneous iPSC pattern remains poorly understood. Moreover, the degree to which any retained patient-specific expression pattern is driven by genetic compared to epigenetic factors remains unknown. Here we characterize the drivers of variation in gene expression in the largest study of iPSC heterogeneity to date comprising 317 RNA-Seq experiments from 101 individuals (50 insulin resistant, 51 insulin sensitive) and ~3 iPSC clones per individuals derived through a non-integrative Sendai virus methodology. Applying a novel linear mixed model approach to quantify the contribution of multiple drivers of variation in expression, we observe that cross-individual variation is the major driver of gene expression variability, while other factors such as originating cell type and reprogramming batch have only a minor effect. Thus iPSC's demonstrate strong retention of patient-specific gene expression patterns. Across all genes, a median of ~50% of expression variability is driven by cross-individual variation, yet many genes have substantially higher or lower percentages of cross-individual variation. We observe that highly variable genes are enriched for cis-eQTL's detected in this dataset, while stable genes are depleted for cis-eQTL's. This relationship is highly significant (p-value < 1x10-75 by logistic regression test) and demonstrates that much of the cross-individual variation in gene expression is driven by detectable cis-regulatory variation rather than retained epigenetic factors. This analysis represents a step towards validating iPSC's as a robust system to study disease biology and regulation of gene expression in a patient-specific genetic background. We further interpret our analysis of eQTL's and the divers of gene expression variation in iPSC's in the context of insulin biology, genome-wide association studies, GTEX and the Roadmap Epigenomics Project.

Background and statement of purpose: Genetics of gene expression (eQTLs or expression QTLs) has proved an indispensable tool for understanding biological pathways and pathomechanisms of trait associated SNPs. However, power of most genome-wide eQTL studies is still limited. Therefore, our aim was to performed a large eQTL study in peripheral blood mononuclear cells of 2,112 individuals increasing the power to detect trans-effects genome-wide. Furthermore, going beyond univariate SNP-transcript associations, we aimed to investigate relations of eQTLs to biological pathways, polygenetic effects of expression regulation, trans-clusters, and enrichment of co-localised functional elements. **Methods:**We used Illumina HT-12 v4 Expression BeadChips and Affymetrix Axiom CEU SNP-chips Illumina-HT12-v4 expression chips imputed to HapMap2 CEU. After thorough pre-processing, 2,625,374 autosomal SNPs and 18,738 probes corresponding to 13,338 genes were included in the analysis, which was done primarily in the R language. **Summary of results:**We found eQTLs for about 85% of analysed genes, 18% of genes were trans-regulated. Local eSNPs were enriched up to a distance of 5 Mb to the transcript challenging typically implemented ranges of cis-regulations. Pathway enrichment within regulated genes of GWAS-related eSNPs supported functional relevance of identified eQTLs. We demonstrate that nearest genes of GWAS-SNPs might frequently be misleading functional candidates. We identified novel trans-clusters of potential functional relevance for GWAS-SNPs of several phenotypes including obesity-related traits, HDL-cholesterol levels, and haematological phenotypes. We used chromatin immunoprecipitation data for demonstrating biological effects. Yet, we show for strongly heritable transcripts that still little trans-chromosomal heritability is explained by all identified trans-eSNPs, however, our data suggests that most cis-heritability of these transcripts seems explained. Dissection of co-localised functional elements indicated a prominent role of SNPs in loci of pseudogenes and non-coding RNAs for the regulation of coding genes. **Conclusion:**In summary, our study substantially increases the catalogue of human eQTLs and improves our understanding of the complex genetic regulation of gene-expression, pathways and disease-related processes.

The effects of human genetic variation on the gene regulatory cascade. *Y. Li[1], B. van de Geijn[2], A. Petti[3], A. Raj[1], D. Knowles[4], J. Blischak[2], Y. Gilad[2], J. Pritchard[1,5,6].* 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Human Genetics, University of Chicago, Chicago, IL; 3) Genome Institute, Washington University in St. Louis, MO; 4) Department of Computer Science, Stanford University, Stanford, CA; 5) Department of Biology, Stanford University, Stanford, CA; 6) Howard Hughes Medical Institute, Stanford University, CA.

Understanding the mechanisms through whichgenetic variation impacts gene regulation and complex traits such as disease risk is central to the growth of genomics in medicine. Noncoding, in particularregulatory, variation is thought to play acentral role in disease, however it is as yet unclear what are the most important mechanisms affected. Here, we answer this question by quantifying the impact of genetic variation on gene regulation and diseases by jointly mapping genetic variants that affect the levels of histone modifications, DNA methylation, transcription rate, stable mRNA levels, ribosome occupancy and protein in lymphoblastoid cell lines.

We report two major bottlenecks that reduce the effects of genetic variation on the gene regulatory cascade, which limit their functional importance: (1) up to half of all genetic variants that affect histone modification levels do not appear to affect mRNA transcription rates and (2) although the vast majority of variants that affect mRNA transcription also affect protein expression levels, their effect sizes are often partially buffered. We also found that as many as 30% of all QTLs that affect protein expression levels do not appear to affect chromatin-level traits. Instead, they tend to modulate gene expression levels directly by affecting splicing and/or RNA decay. Lastly, using a polygenic model to partition heritability between different classes of QTLs across several common immune-related diseases, we estimate that variants that percolate through the regulatory cascade tend to have larger effects on disease than SNPs that appear to be buffered.

Quantifying tolerance of genes to *cis*-regulatory variation from allelic expression data. *P. Mohammadi[1,2], S. E. Castel[1,2], T. Lappalainen[1,2].* 1) New York Genome Center, New York, NY; 2) Department of Systems Biology, Columbia University, New York, NY.

Several approaches have been presented to assess the tolerance of coding genes against functional impact of genetic variation. However, noncoding variants are also likely to play a significant role in genetic predisposition to disease, as exemplified by the overrepresentation of disease-associated genetic variants among expression quantitative trait loci (eQTL). Yet, the extent to which individual genes tolerate common and rare regulatory variation remains largely elusive, which complicates the interpretation of putative disease-causing variants discovered in growing whole genome sequencing data sets. Allelic expression analysis is an elegant integrative approach for capturing functional impact of *cis*-regulatory variation over the expressed genome and is minimally obscured by other confounding regulatory mechanisms. Here we present a generative probabilistic model to describe allelic expression data as net outcome of one or more unobserved regulatory variants. We apply the method to derive a model-based clustering for identifying intrinsic patterns of allelic expression within a given dataset. Using simulation studies, we demonstrate that the model is able to robustly capture the expected spread of gene expression within population, a quantity we use to assess total regulatory tolerance of each gene. Application of this method to allelic expression data from GEUVADIS and GTEx consortia allowed us to estimate regulatory tolerance of most coding genes. We show that our results are in high concordance with equivalent scores calculated from eQTL data ($R=.66$, $p<10\text{-}110$). While eQTL data is inherently limited to loci with common genetic variant, our approach using allelic expression data is able to capture low-frequency regulatory variants as well. We observed that genes with higher tolerance to *cis*-regulatory variation tend to have higher tolerance to coding mutation as assessed by Residual Variation Intolerance Score ($p<10\text{-}74$), and are also less likely to be haploinsufficient ($p<10\text{-}40$). We further investigate the distribution of the scores between different classes of genes. We conclude that the presented regulatory intolerance score can be useful in interpretation and follow up analysis of disease-associated variants, including prioritization of rare variants observed in whole genome sequencing data.

Characterizing and mitigating winner's curse in expression quantitative trait loci (eQTL) studies. *G. Darnell[1], J. Tung[2], C. Brown[3], S. Mukherjee[4,5], B. E. Engelhardt[6].* 1) Lewis-Sigler Institute, Princeton University, Princeton, NJ; 2) Department of Evolutionary Anthropology, Duke University, Durham, NC; 3) Department of Genetics, University of Pennsylvania, Philadelphia, PA; 4) Departments of Statistical Science, Mathematics, and Computer Science, Duke University, Durham, NC; 5) Institute for Genome Sciences and Policy, Duke University, Durham, NC; 6) Computer Science Department, Princeton University, Princeton, NJ.

In quantitative genomic studies, effect sizes are often overestimated in low-power situations, leading to ascertainment bias referred to as Winner's curse [Zöllner et al. , 2007]. Indeed, this phenomenon may explain the correlation that is often observed between minor allele frequency and effect size in both genome-wide association studies (GWAS) and quantitative trait loci (QTL) studies. In particular, statistically significant single nucleotide polymorphisms (SNPs) are enriched for low minor allele frequency SNPs and a high effect size. Yet, our ability to verify this claim via detection of *truly* causal variants remains questionable. In this work, we illustrate the prevalence of Winner's curse in eQTL studies, and we describe a simple variation on the common statistical test for association to mitigate the effects of Winner's curse in these studies. First, through extensive simulations using data from the Genotype-Tissue Expression (GTEx) v6 project data, we assess whether or not current methods commonly identify truly causal variants, and the extent to which these studies are victims of Winner's curse. With this study design, our simulations capture the LD structure present in the human genome and imputed variants as in real genomic study data. Then, we developed a Bayesian statistical framework that incorporates the expected relationship between minor allele frequency and effect size by explicitly accounting for the error inherent in estimating variant effect sizes in limited-power situations (i. e. , for low minor allele frequency SNPs). Simulations show that our method mitigates the effect of Winner's curse by correcting for the ascertainment bias that results from assessing significance using a standard t-statistic. Applied to real eQTL study data, we find that we recover different allele frequency spectrum and power spectrum results across our eQTLs, and that our eQTLs show greater enrichment with respect to cis-regulatory elements, validating our approach.

3176T

Predicting tissue-specific gene expression by leveraging the genotype-tissue expression (GTEx) datasets. *Z. Qi[1,2], Y. Guan[1,2,3].* 1) Department of Pediatrics, Baylor College of Medicine, Houston, TX; 2) USDA/ARS Children's Nutrition Research Center, Houston, TX; 3) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

Tissue-specific gene expressions have direct relevance to disease phenotypes, and knowing gene expression in disease-relevant tissues is advantageous in both detecting novel associations and dissecting known genetic associations. Unfortunately, many genome-wide association study (GWAS) datasets have no companion gene expression essay, let alone tissue-specific ones. This project aims to develop novel methods that can impute tissue-specific gene expression into GWAS data by leveraging expression quantitative trait loci (eQTL) from genotype-tissue expression (GTEx) datasets. Using a full Bayesian approach, we first reproduce SNP-eQTLs by performing the single-SNP association analysis between gene-expression and genotypes in cis. Our SNP-eQTL results will be compared against those in the GTEx database. Then we perform haplotype analysis to detect hap-eQTLs, using a method that can integrate out phase uncertainty. The hap-eQTLs is complementary to SNP-eQTLs in that hap-eQTLs are often detected in regions that harbor allelic heterogeneity. For those loci that have significant hap-eQTLs but insignificant snp-eQTLs, we investigate, using RNA-seq data, whether the gene have multiple isoforms expressed. This knowledge is useful in defining gene expression unit. For each unit of gene expression, be it a gene or an isoform, we use a Bayesian variable selection procedure to combine SNP-eQTLs and hap-eQTLs. This variable selection procedure produces a posterior weighted predictive model that is more powerful than penalized regression methods such as LASSO and Elastic-Net. We produce one predictive model for each tissue-specific expression unit, and apply the model to impute tissue-specific gene expression of a GWAS dataset. We have a whole blood gene expression array data on a cohort that is similar in size with GTEx, and this cohort will be used to test our predictive models. Both our SNP-eQTL and hap-eQTL can jointly analyze multiple correlated phenotypes. Correlation of multiple measurements of the same gene will increase the power in predicting tissue-specific gene expression. The predicted gene expression, in disease-relevant tissues, can be used as a surrogate genotype to test for disease associations.

Fine mapping of QTLs with heterogeneous subgroups, as illustrated in cross-tissue and cross-population eQTL analysis. *X. Wen[1], Y. Lee[1], R. Pique-Regi[2], F. Luca[2].* 1) Dept Biostatistics, Univ. of Michigan, Ann Arbor, MI; 2) Center for Molecular Medicine and Genetics, Wayne State University, Detroit, MI, USA.

Recently, QTL studies have been extended to incorporate data from multiple potentially heterogeneous subgroups. The subgroups may represent different tissue environments, cellular conditions, population groups in different application contexts. For example, the GEUVADIS project analyzes expression-genotype data from 5 population groups;the GTEx project collects eQTL data from > 30 human tissues. In this presentation, we present an elegant integrative analysis approach that leverages QTL data collected from multiple potentially heterogeneous subgroups, and demonstrate its power using two applications of eQTL fine mapping analysis. In the first application, we analyze the GEUVADIS data aiming toidentify multiple independent cis-eQTL signals that are consistent across populations, accounting for population heterogeneity in allele frequencies and linkage disequilibrium patterns. We find that joint analysis across population groups greatly improves the power of eQTL discovery and the resolution of fine mapping of causal eQTL. We also find convincing evidence that many genes (7% of all interrogated protein coding genes and linc-RNAs) harbor multiple independent eQTLs in their cis regions. In addition, we find that many seemingly population specific eQTL signals from single SNP analysis can be explained by multiple consistent eQTLs and varying LD patterns across populations. In the second application, we showcase some interesting examples in multi-SNP fine mapping analysis of cross-tissue eQTLs using the pilot release of the GTEx data. In particular, we will highlight some interesting discoveries of multiple tissue-specific eQTLs which otherwise could be mis-interpreted by single SNP analysis. Finally, we illustrate that our analysis framework enables high-resolution functional analysis of eQTLs by integrating genomic annotations.

3178T

Partitioning of genetic variation influencing gene expressoin by chromosome. *J. Hall, W. Bush.* Institute for Computational Biology, Case Western Reserve University, Cleveland, OH.

Neither the structure of the genome nor how it's expressed are fully understood -- many factors affect gene expression, including temporal factors, epigenetic marks, genetic mutations/variation, and chromatin conformation. Gene expression is often influenced by cis regulatory elements, such as promoters and enhancers, which are located nearby or within a respective gene. Trans regulation is less understood and thought to be less frequent but is likely mediated through chromatin looping or proximity due to chromatin conformation. We systematically explored differences of variation in gene expression explained by cis and trans regions on the resident chromosome of the gene, as well as all other chromosomes, separately, for 10,343 genes. Using 210 HapMap samples (and corresponding lymphoblastoid cell lines) we partitioned genetic variation separately for each gene then calculated genetic relationship matrices (GRMs) for each region, representing genomic sharing of additive genetic effects within the respective region. We then fit those GMRs in mixed linear models, estimating the proportion of variation in gene expression explained by each region, for all respective genes. From these data we calculated, for each gene, the amount of gene expression explained overall by local and distant genomic regions. Initial results show that, unsurprisingly, the largest proportion of variance explained was due to variation on the resident chromosome. However, in our initial results we observed that some chromosomes have more overall trans influence than others and that expression of some genes can be explained more by trans variation than cis variation. We hypothesize that this trend may be due to certain chromosomes being more accessible (i. e. physically close to more chromosomes), due to conformation, which we plan to investigate more in the future.

3179F

Functional partitioning of local and distal gene expression regulation in multiple human tissues. *X. Liu[1], H. K. Funucane[1,2], A. Gusev[1], G. Bhatia[1], B. Bulik-Sullivan[3,4], F. A. Wright[5], P. F. Sullivan[6], B. M. Neale[3,4], A. L. Price[1,7].* 1) Department of Epidemiology, Harvard T. H. Chan School of Public Health, Boston, Massachusetts, USA; 2) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, Massachusetts, USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 5) Bioinformatics Research Center, North Carolina State University, Raleigh, North Carolina, USA; 6) Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, North Carolina, USA; 7) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Studies of the genetics of gene expression have served as a key tool for linking genetic variants to phenotypes. Large-scale eQTL mapping studies have identified a large number of local eQTLs, but the molecular mechanism of how genetic variants regulate expression is still unclear, particularly for distal eQTLs, which these studies are not well-powered to detect. In this study, we instead use a heritability partitioning approach to dissect the functional architecture of gene regulation. We utilize a method, stratified LD score regression (Finucane et al. biorxiv) that leverages all variants (not just those that pass stringent significance thresholds) to partition heritability by functional category, and adapt this method to analyze gene expression data. For both local (within 1Mb of TSS) and distal gene regulation, we estimate the proportion of SNP-heritability explained by SNPs in each functional category and define enrichment as this proportion divided by the proportion of SNPs in each category. We compute standard errors by jackknifing the set of regression SNPs. We first analyzed a large data set of gene expression in peripheral blood (Wright et al. 2014 Nat Genet). Our results included local functional enrichment of FANTOM5 enhancers (4. 17x), 5' UTR (4. 17x) and TSS (4. 00x), and distal functional enrichment of conserved elements (4. 38x), weak enhancer (4. 37x), and broadly defined DHS (1. 57x). All of these results were highly statistically significant (P < 10-12); the distal enrichments would not be detected from the limited number of significant distal eQTLs in this data. We next analyzed a large data set of gene expression in adipose, skin and LCLs (Grundberg et al. 2012 Nat Genet). Our results show that local functional enrichment is highly consistent across different tissues with average pairwise correlation of 0. 86, whereas enrichments of distal functional elements tend to vary across different tissues (average pairwise correlation = -0. 10). For example, distal enrichment of DHS is significantly different (P = 0. 0007) between adipose (2. 76x) and skin (1. 71x), and distal enrichment of coding regions is significant in blood (4. 31x enriched, P=1. 1x10-6) but not in adipose or skin. Our study identified enriched functional categories for both local and distal gene expression regulation, and revealed variation in functional enrichment among different tissues.

3180T

Characterizing the role of STRs in gene regulation. *D. Zielinski[1], M. Gymrek[2], S. Zaaijer[1], Y. Erlich[1].* 1) New York Genome Center, New York, NY; 2) Broad Institute, Cambridge, MA.

Most variants associated with complex traits reside in noncoding DNA, suggesting an important role for*cis*-regulatory elements. Efforts to discover*cis*eQTLs (expression Quantitative Trait Loci) have mainly focused on the contribution of SNPs to gene expression. However, several candidate gene studies in human and model organisms suggest that Short Tandem Repeat (STR) variations can modulate expression levels and splicing of nearby transcripts. After identifying significant associations between STR variations and expression profiles across hundreds of samples from the 1000 Genomes Project, we are experimentally validating the effects of these candidate STRs on expression levels in human cell lines. Specifically, we are using the CRISPR/Cas genome engineering system to edit STR allele lengths at several loci and measuring the associated gene expression levels. In parallel, we are also conducting dual fluorescent reporter assays to compare intensity levels for varying STR alleles. In addition to validating our*in silico*findings, these approaches will allow us to fine map individual eQTL signals and determine whether the STR is the true causal signal at these candidate loci. .

3181F

Rare non-coding variation in a population isolate from Sardinia. *M. Pala[1,2], Z. Zappala[2], M. Marongiu[1], X. Li[2], J. Davis[2], A. Mulas[1], R. Cusano[3], F. Crobu[1], K. Kukurba[2], K. S. Smith[2], F. Reinier[3], R. Berutti[3], M. G. Piras[1], M. Zoledziewska[1], F. Busonero[1], A. Maschio[1], M. Steri[1], G. Pistis[1], E. Porcu[1], F. Danjou[1], S. Sanna[1], C. Sidore[1], A. Battle[4], A. Angius[1], D. Schlessinger[5], G. Abecasis[6], F. Cucca[1,7], S. B. Montgomery[2].* 1) IRGB, CNR, Monserrato, Cagliari, Italy; 2) Dept. of Pathology, Stanford University School of Medicine; 3) CRS4, Advanced Genomic Computing Technology, Pula, Italy; 4) Center for Computational Biology, John Hopkins University; 5) Laboratory of Genetics, NIA, Baltimore, Maryland; 6) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 7) Dipartimento di Scienze Biomediche, Université di Sassari, Sassari, Italy.

Focused on a cohort from the founder population of Sardinia, the SardiNIA project has benefited from an excellent representation of European genetic variation with a shift toward higher frequencies for biologically relevant variants that are rare elsewhere and minimal admixture that enable high-powered studies of both rare and common genetic variants. We use whole genomes and peripheral blood transcriptomes of 624 individuals to identify genetic variants that contribute to both population and individual phenotypic differences. We identify 20,353 independent expression quantitative trait loci (eQTLs) and 11,152 independent splicing quantitative trait loci (sQTLs). We find that over half of all protein-coding and lncRNA genes are influenced by two or more independent *cis*-eQTLs (46. 7% and 46. 8% respectively) whereas pri-miRNA genes are most often influenced by only one *cis*-eQTL. In extreme cases, we find more than 10 independent *cis*-eQTLs for six protein-coding genes and four lncRNA genes. We compare eQTLs to those previously reported in two mainland European-descendent cohorts; after assessing for high reproducibility (>72%), we identify properties of highly-differentiated eQTLs in Sardinia reflective of its population history. We identify an enrichment of high frequency, large effect eQTLs in Sardinia. Considering trait loci identified in published GWAS studies, we find that eQTLs with large frequency difference between Sardinia and Europe are most enriched in SNPs associated with multiple sclerosis (p=1. 17x10-8), a disease with high prevalence on the island. In addition to the classical detection of common eQTLs, we developed a likelihood method that combines total gene expression and family relationship to detect gene expression outliers. It has been demonstrated that outlier gene expression can be driven by rare regulatory variants. Leveraging the familial relatedness of our experimental design (61 families), we identify 802 genes as expression outliers. The outliers show a significant increase in allelic imbalance with respect to non-outlier genes and contain an enrichment of shared rare variants within 1 MB of the TSS. We rank these variants by conservation and deleteriousness, and test their impact on traits measured in Sardinia. Our work provides insight into how studies of gene expression in isolated populations can inform population history, epidemiology and genetic risk factors across the genome.

3182T

Combining whole genome and RNA sequence data from multiple tissues to map causal eQTL using resampling methods. *A. Brown[1,2,3,4], O. Delaneau[1,3,4], E. Dermitzakis[1,3,4].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) NORMENT, K. G Jebsen Centre for Psychosis Research, University of Oslo, Norway; 3) Institute of Genetics and Genomics in Geneva, University of Geneva, Geneva, Switzerland; 4) Swiss Institute of Bioinformatics, Geneva, Switzerland.

GWAS studies have revealed many genetic regions associated with disease, but for the vast majority the precise causal variant acting remains unknown. Whole genome sequence (WGS) data gives full ascertainment of all variants in the population, crucial to identifying causal variants. As a first step, gene expression studies are ideal for investigating the potential of sequence data to identify causal variants: large expression effect sizes mean sufficient power with only hundreds of samples, and available ChIP-seq experiments can validate putative causal variants. Once causal eQTL are identified, we hope to observe downstream consequences on whole organism traits. Here, we combine 522 whole genome sequences produced by the UK10K project with RNA-seq quantified expression from 4 tissues from the Eurobats consortium (blood, fat, skin and LCLs) to map causal variants affecting expression in disease relevant tissues. A cis-eQTL analysis using sequence based genotype calls did not map many more eQTL (3613-8238 depending on tissue) than array genotype data imputed into 1000 Genomes (3676-8204 , FDR=0. 05). However, using GM12878 ChiP-seq ENCODE experiments, we observed more peak sequence genotype eQTL in transcription factor binding sites and open chromatin regions compared to array genotype eQTL (odds ratio>1 for enrichment in 80/83 experiments, FDR<0. 05 for 66/83). The implication is that eQTL identified using sequence data are more likely functional. When calling eQTLs, the specific peak significance variant depends on factors including variability in phenotype measurements and regional linkage structure. To produce a set of "candidate causal eQTL" (cc-eQTL), we applied bootstrap resampling methods. We call cc-eQTL the SNPs which were peak eQTL most frequently across bootstrap samples. These cc-eQTL are more enriched in GM12878 experiments than peak significance eQTL (OR>1 for 82/83 experiments, FDR<0. 05 for 57/83). We also saw more indels (11. 1% vs 8. 8%) and multiallelic SNPs (9. 3% vs 4. 4%) among cc-eQTL. We identify 663 genes where the same variant was chosen in >95% of the bootstrap samples, strong candidates for experimental validation. Current work is looking at tissue specificity of cc-eQTL, using relevant ChiP-seq experiments, and integration of these causal variants with GWAS signals. We will apply this methodology to the GTEx dataset, which has RNA-seq and WGS for 47 tissues, including ones central to the pathogenesis of a very wide spectrum of diseases.

Genomic modulators of gene expression in human neutrophils. *V. Naranbhai, B. P. Fairfax, S. Makino, P. Humburg, . D Wong, E. Ng, A. V. S. Hill, J. C. Knight.* Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom.

Neutrophils form the most abundant leukocyte subset and are central to many disease processes. Technical challenges in transcriptomic profiling have prohibited genetical genomic approaches to date. Here we report efforts to map expression quantitative trait loci (eQTL) in peripheral blood CD16+neutrophils from 101 healthy European adults. We identify cis-eQTL for 3281 neutrophil-expressed genes including many implicated in neutrophil function and Mendelian primary immunodeficiency syndromes, with 450 of these not previously observed in myeloid or lymphoid cells. We show extensive analyses to delineate those that are not present in other cell types. Paired comparison with monocyte eQTL demonstrates nuanced conditioning of genetic regulation of gene expression by cellular context. We describe underlying histone features, DNA methylation, microRNA binding site and transcription factor binding site variation as it relates to cell-type constraint of eQTL. Neutrophil eQTL are markedly enriched for trait-associated variants particularly autoimmune, allergy and infectious disease and find several novel examples of these. We further demonstrate how eQTL in PADI4 and NOD2 delineate risk variant function in rheumatoid arthritis, leprosy and Crohn's disease. Finally, we define eQTL present in neutrophils and under apparent selection suggesting possible operative forces for variant selection. Taken together, these data help advance understanding of the genetics of gene expression, neutrophil biology and immune-related diseases. .

Genetic variants affect expression of nearly all genes, but only in a specific context. *P. Deelen, The BIOS consortium.* University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, the Netherlands.

The expression of nearly all genes is subject to genetic regulation. This is a first conclusion from the largest population-based RNA-sequencing project executed so far, including 4,000 total blood mRNA samples from five Dutch biobanks. The large sample size, unprecedented resolution of this study and the comparison with other large population-based studies revealed that SNPs affecting expression (eQTLs) act in a context-dependent manner. Whereas microarray-identified blood eQTLs (Westra *et al.* , Nature Genetics, 2013) replicated well in our study (87%, including 6. 8% with opposite allelic direction), eQTLs identified by RNA-seq in lymphocyte cell lines (LCL) (Lappalainen *et al.* , Nature, 2013) replicated less well (78%, including 12% with opposite allelic direction). This was not due to differences in data processing as we analyzed all RNA-sequencing data using exactly the same pipeline, but was partly due to differences in cell-types. We inferred cell-type-specific eQTLs (Westra *et al.* , PLOS Genetics, 2015), and observed that lymphocyte-specific eQTLs replicated well in LCLs. Neutrophil-specific eQTLs on the other hand showed lower replications rates and more often show opposite effects when comparing to LCLs. We also observed that higher order effects that induce, abrogate, or inverse eQTLs. Using gene-expression levels as a proxy for stimulations, we were able to identify eQTLs affected by different conditions and stimulations. This allowed us to detect, among others, erythrocyte and regulatory T cell-specific eQTLs. We also replicated known eQTL modifiers, for instance the previously identified rhinovirus dependent eQTLs (Çaliskan, *et al.* , PLOS Genetics, 2013). Additionally, we find eQTLs affected by core cellular processes such as metabolism and cell cycle. In conclusion, we observed several examples where genetic risk factors affect gene expression only in a specific context. Since it is not feasible to collect eQTL data for all tissues and cell-types in combinations with all potential stimulations and cellular states, approaches that can untangle the effects of different stimulations are essential to properly interpret the effect of regulatory genetic variation. The BIOS project is funded by the BBMRI-NL, a research infrastructure financed by the Netherlands Organization for Scientific Research (NWO project 184. 021. 007).

Identifying the effects of postmortem sample collection parameters on RNA-sequencing results across 1,640 samples. *D. S. DeLuca[1], S. Ayellet[1], T. Sullivan[1], F. Aguet[1], E. Gelfand[1], A. Roa[2], H. M. Moore[2], K. Ardlie[1].* 1) The Broad Institute, Cambridge, MA, MA; 2) Biorepositories and Biospecimen Research Branch, National Cancer Institute, Rockville, MD.
In order to study the interaction of genomics and transcriptomics across individuals and tissue types, collection of a wide panel of tissue biopsies is required. For humans, this is only possible in a postmortem setting. Projects of this format, such as the National Institutes of Health Genotype-Tissue Expression (GTEx) Project , must optimize their collection protocols to ensure the highest RNA integrity possible to best facilitate downstream analytical applications such as RNA-sequencing. When effects of postmortem interval or preservation method are unavoidable, it is essential to elucidate the impact of these factors on downstream analyses.

To this end, the Biospecimen Methodological Study (BMS) was initiated by the National Cancer Institute's Biorepositories and Biospecimen Research Branch. The experimental design is based on the collection of six tissues (adrenal gland, artery, muscle, skin, pancreas, thyroid) from 32 individuals across 4 time points ranging from 1 to 15 hours postmortem. Each tissue biopsy was subdivided and preserved in each of three preservation methods: liquid nitrogen, dry ice, and PAXgene Tissue (Qiagen). Following RNA extraction, RNA Integrity Number (RIN) values were determined and Illumina RNA-seq with polyA-selected libraries was performed on a total of 1,640 samples.

Analysis of RNA quality showed that RIN was only modestly negatively correlated with postmortem time course, with a strong influence of tissue type. There was a significant effect of preservation method on RNA integrity. For tissue types prone to rapid degradation, samples preserved with PAXgene Tissue produced RNA with higher RINs. Initial quality control of the RNA-seq results indicated almost no observable effect of preservation method or postmortem interval on the technical success of sequencing when input material had a RIN of 4. 0 or higher. In contrast, gene expression was significantly impacted by the postmortem interval. Between 800 and 3000 genes were differentially impacted by postmortem interval. Correcting for these effects is essential for avoiding spurious associations and for increasing statistical power. The results of this study have important practical methodological implications, not only for GTEx, but for all projects using post-mortem, variable ischemic time, or otherwise degraded samples for analyses of the transcriptome.

Rare regulatory variants cause cross-tissue extreme gene expression. *X. Li[1], Y. Kim[2], Z. Zappala[3], J. Davis[3], E. Tsang[3], F. Damani[2], A. Battle[2], S. Montgomery[1,3], GTEx Consortium.* 1) Department of Pathology, Stanford University, Stanford, CA; 2) Department of Computer Science, Johns Hopkins University, Baltimore, MD; 3) Department of Genetics, Stanford University, Stanford, CA.

The discovery that most GWAS variants fall in non-coding regions suggests that an individual's genetic burden of disease risk is deeply related to regulatory variants (measured as expression quantitative trait loci; eQTLs). However existing eQTL discoveries have been limited to common variants while the roles of rare variants, abundant in human populations, remain challenging to detect. We use diverse GTEx human tissue samples (8555 RNA-Seq samples from 54 tissues of 522 donors, 157 also with sequenced genome, from the v6 release) to investigate the impact of rare variants on expression and, ultimately, disease. We identify that rare variants can lead to outlier expression levels far above or below the population mean and that outlier expression effects can exhibit across multiple tissues. We first discover the degree to which outlier expression identified in a single tissue and individual can be shared across other tissues. The degree of sharing is reflected by the closeness of tissues and such a gradient is concordant between over-expression and under-expression outliers. Next, we observe a continuous enrichment of rare variants at those outliers given increased number of shared outlier tissues. This enrichment of rare non-coding variants suggests increased selection pressure for variation which influences multiple tissues. Last, we observe that rare regulatory variants associated to outlier expression influence essential genes and genes involved in complex disease, and demonstrate that such effects increase an individual's risk for diverse diseases including diabetes and hypertension.

Genetic regulation of whole blood gene expression quantified in large families pedigrees. *A. Viñuela[1,2,3], A. Martinez-Perez[4], A. Brown[1,2,3,5], A. Ziyatdinov[4], H. Brunel[4], J. C. Souto[5], M. Sabater-Lleal[6], A. Hamsten[6], A. Buil[1,2,3], J. M. Soria[4], E. T. Dermitzakis[1,2,3].* 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Geneva, Switzerland; 2) Swiss Institute of Bioinformatics, Geneva, Switzerland; 3) Institute of Genetics and Genomics in Geneva, University of Geneva, Geneva, Switzerland;; 4) Instituto de Investigaciones Biomedicas Sant Pau (IIB-Sant Pau). Barcelona; 5) NORMENT, K. G Jebsen Centre for Psychosis Research, University of Oslo, Norway; 6) Atherosclerosis Research Unit, Center for Molecular Medicine, Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

Discovering rare variants affecting gene expression is challenging without very large sample sizes; however, a variant which is rare in the population can be seen more commonly within a particular pedigree. Therefore, methods based on linkage are well placed to discover these variants. Moreover, familial information allows for parent-of-origin studies, where the effect of a variant depends on whether it was inherited from the maternal or paternal line. Here, we describe de analysis of 935 individuals grouped in 35 pedigrees, with an average of 27 individuals per pedigree and a total of 8654 related pairs. All families have at least 10 living individuals in three or more generations, and were recruited and selected as part of a study on idiopathic thrombophilia with an age range of 3 to 101 years (mean 40). Hundreds of quantitative phenotypes were measured at time of recruitment, including anthropometric measurements, hemogram, hemostasis traits, as well as phenotypes related with platelets, platelet activity, homocysteine metabolism, inflammation, and flow cytometry of leukocytes and microparticles. We sequenced the mRNA transcriptome from whole blood for all the individuals, at the time of collection not medicated for thrombophilia, using 49 bp paired end reads. Reads were mapped onto the human genome reference using GEM, obtaining 16. 2M well mapped exonic reads per sample on average. Genotypes obtained from a mix of Illumina 1M and Illumina 500K chips were imputed into a 1000 genomes reference panel. We are performing eQTL mapping on this data, both standard association mapping using variance components to consider the familial structure in the data, and linkage analysis to discover rare variants, which co-segregate in familial individuals. In addition, by treating allelic specific expression (ASE) in family members as a quantitative phenotype, we are aiming to discover particular haplotypes which co-segregate within individuals showing ASE, which will demonstrate the presence of causal eQTL, possibly rare in the population. Furthermore, using the available cell count measures and other phenotypes, we will investigate cell type specific eQTL in this heterogeneous tissue as well as eQTL with specific effects in individuals with idiopathic thrombophilia. Finally, exploiting the many trios within the pedigrees, we will investigate particular parent-of-origin effects on gene expression.

RNA:DNA hybrids and genome instability in post-mitotic neurons. *V. Bhatia, M. Sanchez, L. Quintanilla, F. Ledesma, A. Aguilera, S. S. Bhattacharya.* Centro Andaluz de Biología Molecular y Medicina Regenerativ, CABIMER, Sevilla, Sevilla, Spain.

R-loops can impair transcription and replication and lead to genomic instability. However, not much is known about the molecular events associated with the formation and processing of R-loops in non-replicating cells and their physiological relevance. Our goals in this study have been to explore the existence and possible role of RNA-DNA hybrids in non-replicating postmitotic neurons. Nascent RNA can reinvade the negatively supercoiled DNA behind moving RNA polymerase and form a structure termed R-loops, where a ssDNA is accompanied by an RNA:DNA hybrid. mRNP biogenesis and export factors work in tandem to prevent R-loop accumulation and to warrant the maintenance of genome integrity. It has previously been shown that R-loops accumulate in absence of factors involved in mRNP biogenesis and export in human cells. Cells depleted of BRCA1 and BRCA2 double-strand break repair factors accumulate RNA-DNA hybrids and that the genomic instability in R-loop dependent manner. R-loops are considered a major threat to incoming replication fork (RF), but they are also detected in non-replicating cells. Here, we wondered whether R-loops are also a threat to genomic instability in non-replicating post-mitotic cells. Using post-mitotic neurons from mice brain and retina we have found that R-loops do accumulate in specific light sensor retinal cells called Photoreceptors. The results suggest a relationship between oxidative stress-associated DNA damage and R-loop accumulation in post-mitotic neurons. R-loops are frequently formed in cells and have been proposed to be a major source of replication stress and cancer-associated genomic instability. We show here that R-loops also accumulate in post-mitotic photoreceptor cells and affect cell survival and apoptosis signaling.

Complex multiple-nucleotide substitution mutations causing human inherited disease reveal novel insights into the action of translesion synthesis DNA polymerases. *J. M Chen[1,2,3], C. Férec[1,2,3,4], D. N. Cooper[5].* 1) Institut National de la Santé et de la Recherche Médicale (INSERM), U1078, Brest, France; 2) Etablissement Français du Sang (EFS) - Bretagne, Brest, France; 3) Faculté de Médecine et des Sciences de la Santé, Université de Bretagne Occidentale (UBO), Brest, France; 4) Laboratoire de Génétique Moléculaire et d'Histocompatibilité, Centre Hospitalier Universitaire (CHU) Brest, Hôpital Morvan, Brest, France; 5) Institute of Medical Genetics, School of Medicine, Cardiff University, Cardiff, United Kingdom.

Translesion synthesis (TLS) DNA polymerases potentiate the bypass of unrepaired lesions during DNA replication. Based upon mutational signatures of a subtype (N = 477) of multiple-nucleotide substitution (MNS) mutations causing human inherited disease, we postulated two properties of TLS DNA polymerases in DNA repair: namely, the generation of *neo*-microhomologies for strand-misalignment and additional micro-lesions within the templated inserts when recruited to stalled replication forks. To provide further support for this postulate, we analyzed the mutational signatures of a new and complex subtype of pathogenic MNS mutation. Several mutations containing long templated inserts (8-19 bp), that are highly informative with regard to their underlying mutational mechanisms, harbor imprints of TLS DNA polymerase action. Dissecting the mechanism underlying the generation of the 19 bp-insert implicates repeated participation of TLS DNA polymerases in the conversion of a damaged base into a complex MNS lesion through a process of successive template switching and bypass repair.

Breakpoint analysis of 43 patients with complex genomic rearrangements and their mechanisms for formation. *G. M. Novo-Filho[1], M. M Montenegro[1], E. A. Zanardo[1], A. M. Nascimento[1], F. A. R Madia[1], T. V. M. M. Costa[1], F. B Piazzon[1], A. T. Dias[1], C. P. Barbosa[3], B. Bianco[3], C. P. Christofolini[3], C. A. Kim[2], L. D. Kulikowski[1,3].* 1) Department of Pathology, Cytogenomics Laboratory , Universidade de Sao Paulo-HC-FMUSP, Sao Paulo, Sao Paulo , Brazil; 2) Genetics Unity, Department of Pediatrics, Children Institute, Universidade de São Paulo -HC-FMUSP Paulo, Brazil; 3) Human Reproduction and Genetics Center - Department of Collective Health, FMABC, Santo André, Brazil.

Genomic rearrangements have been shown to play an important role in pathogenesis of congenital or developmental defects in human diseases. Breakpointanalysis can help define genomic location, sequence structure, genetic content and also could improve understanding of the mechanisms for formation. In this sense, we studied a cohort of 63 patients with congenital malformation and ADNPM previously identified by MLPA with distinct kits (MCR- Holland) with at least one genomic rearrangement. Subsequently, we performed high-resolution array analysis using the Infinium CytoSNP-850K BeadChip (*Illumina Inc*. , San Diego, CA), Genome-Wide Human SNP Array 6. 0®(*Affymetrix, Inc. , Santa Clara, CA*), CytoScan HD and Human Genome CGH Microarray 2x105K® (*Agilent Technologies, Santa Clara, CA*), in order to breakpoint delineation. The results were entered into the *UCSC Genome Browser* using annotation GRCh37/hg19 and confirmed by the *NCBI Map Viewer*. The analysis revealed 43 patients with complex genomic rearrangements and several different breakpoints. Between them ten patients presented breakpoints surrounded by low-copy repeats (LCRs) suggesting non-alellic homologue recombination (NAHR) as a possible accountable mechanism. Whereas microhomology-mediated break induced replication (MMBIR) and fork stalling and template switching (FoSTeS) could be associated with the cause of complex rearrangements in other 29 patients. In four of patients, who presented more than five breakpoints, a chromoanasynthesis event, mediated by MMBRI or FoSTeS, could be the cause of complex genomic rearrangement. The breakpoint analysis is essential to understanding the etiology of complex genomic rearrangements and their association with pathogenic phenotypes. Financial support: CNPq and FAPESP.

Development of a quantitative targeted RNA-Seq methodology for use in differential gene expression analysis. *M. A. Hussong, M. D. Fosbrink, E. Lader.* Biological Research Content, New Product Development, QIAGEN Sciences, LLC, Frederick, MD.

RNA Sequencing (RNA-Seq) uses the capabilities of Next Generation high-throughput sequencing (NGS) methods to provide insight into the transcriptome of a cell as it generates millions of reads. Whole transcriptome sequencing can be used to quantify gene expression on a transcriptome-wide scale, identify splice variants, quantify allele specific expression, and characterize fusion transcripts. Development of a highly reproducible and sensitive targeted quantitative sequencing method would aid in facilitating a deeper understanding and characterization of the roles of a specific set of genes, while enabling much higher sample throughput and significant cost savings relative to whole-transcriptome sequencing. In this study, we report a targeted RNA-Seq technology, GeneRead RNA Counter (GRRC), which makes use of several methodologies to deliver an extremely flexible, highly precise tool for characterizing gene expression. GRRC incorporates 12-base random molecular barcodes into each unique target strand which benefits quantifying gene expression in a given multiplexed sample. Counting the number of molecular tags allows one to determine the sequence coverage per target and adjust experimental conditions to use the read budget of any sequencing platform most efficiently. Using either the Illumina or Ion Torrent platforms, users can choose to multiplex up to 96 RNA samples from 12 to 1000-plex expression panels. No mRNA selection or rRNA removal or blocking is required. The entire protocol, from cDNA synthesis to finished library, which is ready for sequencing, can be accomplished in under one day. Custom assays for a specific target site can add the ability to distinguish between isoforms or identify allele specific expression. We explore the capabilities of this system by profiling large numbers of genes in a cell model system's response to small molecule treatment. Changes in gene expression by these treatments were measured by GRRC NGS, and fold-changes in gene expression due to chemical perturbation were characterized. Complex gene relationships in perturbed pathways were mapped using QIAGEN's Ingenuity Pathway Analysis (IPA) tool. The IPA tool also facilitated the elucidation of the impact of gene expression changes in the context of biological processes, molecular interactions, cellular phenotypes and disease. This article will provide application data for GRRC including a discussion of technical challenges faced when profiling large numbers of genes in a large cohort.

A Microfluidic System for Generating Massively Partitioned and Barcoded DNA Sequencing Libraries. *M. Schnall-Levin.* 10X Genomics, Pleasanton, CA.

10X Genomics has developed a reagent-delivery system that transforms short-read sequencers into high throughput and accurate long-read systems with single molecule sensitivity. The GemCode system partitions long molecules of DNA, then prepares sequencing libraries in parallel such that all molecules produced within a partition share the same barcode. Custom software maps short-read data to original long molecules, creating Linked-Reads that span many 10's of kilobases. This enables many applications inaccessible with short-read data including phasing SNPs and indels, and calling and phasing of large-scale structural variants. The fundamental building block of this system is a picoliter droplet that encapsulates DNA, reagents, and a single gelbead to which barcode-containing oligos are covalently attached. A plastic microfluidic consumable creates hundreds of thousands of partitions within minutes. After partitioning, the gelbeads dissolve, releasing barcode-containing oligos and activate a custom library construction reaction. The system has numerous powerful characteristics: (1) generation of long-range (10s to 100s of kilobases) information, (2) compatibility with hybrid capture, and (3) creation of high-quality sequencing libraries from 1ng of DNA. Due to current limitations of short-read data, phasing generally requires statistical methods relying on trio data and/or linkage disequilibrium. These methods are problematic when trio information is unavailable or an individual is not part of a well-studied population. We demonstrate the use of Linked-Read data to phase SNPs and indels from a diverse set of ancestries including multiple European trios, as well as Gujarati Indian, African, and Mexican samples. Results were similar regardless of origin. Whole genome sequencing generated megabase-scale N50 phase blocks, with > 95% of SNPs phased and long switch error rates < 0. 05%. For exome sequencing, we achieved > 95% of genes phased <100kb with long switch error rates < 0. 05%. We also called and phased long-range (>50KB) deletions and inversions in multiple samples and confirmed the accuracy of these calls with multiple orthogonal methods.

3193F

The dynamics of meiotic recombination initiation in laboratory mouse strains. *K. Brick[1], F. Smagulova[2,3], Y. Pu[2], R. D. Camerini-Otero[1], G. Petukhova[2].* 1) Genetics & Biochemistry Branch, NIDDK, National Institutes of Health, Bethesda, MD; 2) Department of Biochemistry and Molecular Biology, USUHS, Bethesda, MD, USA; 3) Inserm UMR1085-Irset, 263 ave du Général Leclerc, 35042, Rennes, France.

Genetic recombination is a key mechanism by which genetic diversity is generated in sexually reproducing species. In mice, humans and most other mammals, the DNA double strand breaks (DSBs) that initiate meiotic recombination are directed to a subset of genomic loci by sequence-specific DNA binding of the PRDM9 protein. This sequence specificity is conferred by a long array of C-terminal zinc fingers (ZFs) that each recognize a preferred DNA sequence. Genome-wide maps of DSB hotspots have been generated for a limited repertoire of *Prdm9* alleles in congenic mice, however to understand the interplay between *Prdm9* and genetic background, we identified and analyzed DSB hotspots in mice with different *Prdm9* alleles representing all four *Mus musculus* subspecies and in their F1 hybrids. As expected, in the six mice homozygous for *Prdm9*, almost all DSB hotspot loci differ and are defined by the *Prdm9* allele. Alleles with common ZF combinations define some shared hotspot loci yet despite this, even a single extra ZF with little predicted effect on DNA binding is sufficient to globally alter the hotspot landscape. In addition to clear dominance of some PRDM9 alleles over others, a striking finding in F1 mice is that of the appearance of "novel" DSB hotspots, not present in either parental genome. To this end, although most hotspots in hybrids coincide with parental hotspots - with no evidence of imprinting - up to 35% of hybrid hotspots are absent from the parental genomes. Gene conversion will destroy highly active PRDM9 binding sites, however these PRDM9 binding sites remain untouched in mice with different *Prdm9* alleles. Thus, in hybrids, with one copy of each parental genome and of each parental *Prdm9* allele, DSB formation can once again occur at these "eroded" binding sites. We will also discuss curiously frequent instances of DSB hotspots that coincide with the sites where DSBs form in the absence of PRDM9 as the use of such hotspots may impede meiotic recombination.
