**Background:** Next generation sequencing enables exome sequencing rapidly become a common molecular diagnostic test for individuals with genetic disorders. Whole exome sequencing (WES) captures all coding regions in the genome, namely ~20,000 genes which may or may not have a disease association. To better facilitate clinical utility of the technology, clinical exome sequencing (CES) was created which captures genes associated with human diseases (~5,000 genes). The advantages for CES are easier interpretation of variants found in known disease-associated genes and better sequencing coverage. However gene discovery happens at a rapid pace and new genes are associated with diseases on monthly basis if not weekly. Therefore only whole exome sequencing make analyzing these newly discovered genes possible. **Methods and materials:** A hundred consecutive cases of each CES and WES were investigated. The following items were compared: diagnostic yield, testing indication, patient age and gender, number of reported variants. Diagnostic finding was defined as one pathogenic (P) or likely pathogenic (LP) variant identified in phenotype match autosomal dominant disease or two P/LP variants identified in phenotype match autosomal recessive disease. In addition, we examined if the gene is in CES gene list when diagnostic finding was identified in WES test. **Results:** There is no age and gender difference of patients tested for CES or WES. As literature reported, the main testing indications for both CES and WES are intellectual disability, developmental delay, epilepsy, neuromuscular symptoms, dysmorphic features, etc. The diagnostic yields for CES and WES are similar with CES being 28% and WES being 25%. The numbers of reported variants are also similar. For WES cases with diagnostic finding, 84% (21/25) of cases have the genes in CES capture set meaning these cases could be diagnosed by CES as well. There are 4 WES cases that genes with diagnostic findings are only in WES capture set. These genes have been associated to diseases within the last three years. **Conclusion:** Both CES and WES are effective genetic testing approaches for individuals with symptoms that suggest extreme heterogeneity. Analyzing more genes in cases of WES may not necessarily lead to higher diagnostic yield. However, WES has the benefit of capturing newly disease-associated genes that are missed by CES.

**Familial interstitial deletion 1(q43q44) due to maternal complex balanced insertional translocation (IT) and inversion in 3p.** Y. Hadid, Z. Leibovitz, H. Shapira, M. Ziv, J. Levitaz, C. Furman, R. Broneshter, R. Nabwani, S. Atalla, H. Bar El, A. Pavlenko, A. Shalata. Bnai Zion, Haifa, Israel.

Balanced interchromosomal insertional translocation (IT) is a rare chromosomal rearrangement that occurs when a part of one chromosome inserts into a non-homologous chromosome. A 41 year old mother was examined at 24<sup>th</sup> week of her ninth pregnancy. The examination demonstrated: small fetal head circumference, enlarged colpocephalic lateral ventricles and narrowed, widely separated vertically oriented frontal horns, and near complete agenesis of the corpus callosum. The hemispheres were small with widening of the subarachnoid space. Otherwise, the fetal anatomical scan and growth were normal. Sonographic evaluation after one week demonstrates the same pathologic finding and the pregnancy was terminated. The family history reports a normal large inbreeding family compound of healthy parents of Jewish origin with seven healthy siblings and one affected child with a 1q43q44 8.1Mb deletion (arr[hg19] 1q43q44(240,676,914-248,844,657)x1). Using a SNP Microarray from TOP fetal blood, the same deletion was detected as previously reported in their affected daughter. G-banding karyotyping and FISH studies (using ASI analysis software), revealed a maternal balanced insertion of the band 1q43q44 into the band 3p11 and a paracentric inversion between band 3p11 and 3p23. In conclusion when a CNV is detected in a patient and is not found by array in parental genomes, the deletion or gain is considered to be De-novo. However, to rule out a balanced IT/ cryptic changes in the parents a further investigation (e.g. G-banding karyotype and FISH) are crucial, especially when the finding is repeated in the family.

**Investigating complex structural variants using third generation genome sequencing and mapping technologies.** R. Rajagopalan<sup>1,2,3</sup>, D.A. McEldrew<sup>1</sup>, P. Vaidiswaran<sup>4</sup>, M. Zaykaner<sup>1</sup>, V. Jayaraman<sup>1</sup>, J. McCaffrey<sup>2</sup>, J. Sibert<sup>2</sup>, E. Young<sup>2</sup>, S.J. Pastor<sup>2</sup>, M. Xiao<sup>2</sup>, L.K. Conlin<sup>1</sup>. 1) Division of Genomic Diagnostics, Children's Hospital of Philadelphia, Philadelphia PA; 2) Dept. of Biomedical and Health Informatics, Children's Hospital of Philadelphia, Philadelphia PA; 3) School of Biomedical Engineering, Science and Health Systems, Drexel University, Philadelphia PA; 4) Division of Gastroenterology, Hepatology and Nutrition, Children's Hospital of Philadelphia, Philadelphia PA.

Structural variations (SVs) are genomic aberrations greater than 1kb and include deletions, duplications, inversions, translocations and other complex rearrangements. While chromosomal microarray (CMA) is the gold standard diagnostic test for copy number variants (CNV), cytogenetics is still required to detect structural rearrangements. While whole-genome short-read sequencing (WGS) is poised to replace CMA as a standard diagnostic test, it suffers from short read lengths, mappability issues, and reference bias for accurately detecting complex rearrangements. Here, we set out to investigate the utility of third generation technologies such as optical genome mapping (>70x), 10X linked-read sequencing (30x) and mate-pair sequencing (30x) compared to the current standards such as WGS (30x), SNP array and karyotyping for two patients with constitutional chromothripsis-like events involving chromosomes 1 and 22. In order to understand the significance of the SVs in these individuals, both copy number and precise breakpoint determination are required for clinical interpretation. We identified hundreds of structural variations per sample from the WGS data using Delly (read-pair, split-read), Pindel (split-read) and CNVnator (read-depth). SVs identified from WGS were enriched for false-positive variants originating from the complex regions of the genome, and many breakpoints were not identified. For chr1q, we identified 23 novel adjacencies using mate-pairs (>3 fragments), 24 breakpoints using 10X linked-reads (>9 barcodes), 74 insertions, deletions and intra-chromosomal translocations using optical maps. Mate-pair sequencing resolved the most of the breakpoint regions associated with CNVs from SNP array and the optical mapping identified more novel insertions compared to the other methods. However the default pipeline for the optical maps do not provide the origins of the insertions. All three technologies identified mutually exclusive breakpoints and novel adjacencies unseen by the array. In contrast, all three technologies failed to resolve all the breakpoints on chr22. This may be due to the insertions in the acrocentric p-arm, or that this individual only had one large, derivative chr22. Our data suggest that the third-generation mapping and sequencing technologies show great promise for investigating complex SVs as compared to the short-read sequencing; however, no single technology could resolve the complete picture with existing analysis tools.

**Bohring-Optiz syndrome caused by an ASXL1 mutation inherited from a germline mosaic mother.** D. Copenheaver<sup>1</sup>, S. Bale<sup>1</sup>, M. Deardorff<sup>2</sup>, E. Bedoukian<sup>2</sup>. 1) GeneDx, Gaithersburg, MD; 2) Children's Hospital of Philadelphia, PA.

**Introduction:** Bohring-Optiz syndrome is a rare congenital disorder characterized by intrauterine growth retardation, poor feeding, mental retardation, trigonocephaly, prominent metopic suture, exophthalmos, nevus flammeus of the face, upslanting palpebral fissures, hirsutism, and flexion of the elbows and wrists. There have been approximately 60 reported cases of Bohring-Optiz syndrome and all have been reported to be due to de novo ASXL1 gene mutations (1). **Case Report:** We report a case of a 3 year old female who presented with intrauterine growth retardation, failure to thrive, microcephaly, seizures, choanal atresia, atrial septal defect, chronic respiratory failure, a facial hemangioma and facial dysmorphism. Previous testing included normal microarray and CDH7 sequencing. Both parents are cognitively normal without congenital malformations. The mother, 34 years old, has a history of Crohn's disease, immune thrombocytopenic purpura and degenerative disc disease. There are three normal siblings and no pregnancy losses. **Results:** Trio whole exome sequencing revealed a heterozygous pathogenic nonsense variant in ASXL1 (p.R965\*; c.2893C>T). The sequencing data demonstrated that the variant was inherited maternally but indicating that this maternal variant was underrepresented in comparison to the normal allele. These results suggested mosaicism for the variant in the mother. Additional testing on maternal buccal cell DNA was also consistent with mosaicism. **Conclusion:** This is the first report of Bohring-Optiz syndrome caused by a mutation inherited from an unaffected, somatic mosaic parent with presumed germline mosaicism. This phenomenon has been reported for other traditionally de novo dominant disorders like CHARGE syndrome and Cornelia de Lange syndrome (2)(3). This case demonstrates that haploinsufficiency of ASXL1 is not lethal in the germline, and emphasizes the need for accurate low but non-negative recurrence risk counseling for families with children with Bohring-Optiz syndrome. 1.Hoischen, A., et al. De novo nonsense mutations in ASXL1 cause Bohring-Optiz syndrome. *Nature Genet.* 43: 729-731, 2011. 2.Jongmans, M.C., et al. **Concurrent exome and copy number variation (CNV) analyses enable more precise diagnoses and shorten diagnostic testing time in patients with pediatric disorders.** A.V. Dharmadhikari<sup>1</sup>, A. Braxton<sup>1,2</sup>, S. Narayanan<sup>1,2</sup>, P. Ward<sup>1,2</sup>, J. Zhang<sup>2</sup>, W. He<sup>1</sup>, F. Vetrini<sup>1</sup>, J. Beuten<sup>1</sup>, X. Ge<sup>2</sup>, M. Tokita<sup>2</sup>, T. Santiago-Sim<sup>2</sup>, J. Smith<sup>1,2</sup>, P. Stankiewicz<sup>1,2</sup>, S.W. Cheung<sup>1,2</sup>, C. Bacino<sup>1,2</sup>, A. Patel<sup>3</sup>, A.M. Breman<sup>1,2</sup>, X. Wang<sup>1,2</sup>, M. Leduc<sup>1,2</sup>, P. Liu<sup>1,2</sup>, M. Walkiewicz<sup>1,2</sup>, R. Xiao<sup>1,2</sup>, F. Xia<sup>1,2</sup>, J.R. Lupski<sup>2</sup>, C. Eng<sup>1,2</sup>, Y. Yang<sup>1,2</sup>, W. Bi<sup>1,2</sup>. 1) Baylor Genetics, Houston, TX; 2) Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) Department of Pathology and Cell Biology, Columbia University Medical Center, New York, NY.

Exome sequencing detects single nucleotide variants (SNVs) and small indels in the coding region of the genome and has been increasingly applied in clinical genomics for molecular diagnosis. However, using exome data to detect CNVs is still in its early stage. Chromosomal microarray analysis (CMA) on the other hand has been an established method in the clinical lab to detect CNVs for various clinical indications including intellectual disability and multiple congenital anomalies. Here, we describe the findings from concurrent CMA and exome testing (WES/CMA) performed at Baylor Genetics in order to assess the diagnostic effectiveness of detecting SNVs and CNVs simultaneously. We analyzed 440 consecutive patients who underwent WES/CMA testing between September 2013 and March 2017. CMA testing was performed using custom designed Agilent microarrays with exonic coverage of >4,800 disease genes and 'backbone' genome-wide coverage of one interrogating oligonucleotide/30kb. Each sample was also concurrently analyzed by a HumanExome Beadchip SNP array for quality-control of exome data. A molecular diagnosis was established in 126/440 (29%) patients and consisted of pathogenic SNVs identified in 106/440 (24%) patients by exome and pathogenic CNVs identified in 24/440 (5%) patients by CMA. One patient had a homozygous deletion involving *TNNT1* and *TNNI3*, which was detected by CMA and also by NGS read depth. Examples of pathogenic CNVs include also a *de novo* ~2Mb 1p36 deletion associated with monosomy 1p36 syndrome, monosomy X in a patient with Turner syndrome, and a 7q11.23 deletion in the Williams-Beuren syndrome region. Notably, in 4/126 (3%) patients with a molecular diagnosis, both diagnostic SNVs and CNVs were detected. One patient with end-stage renal disease had a heterozygous pathogenic variant in the *WDR19* gene and an intragenic deletion of ~4 Kb including part of the *WDR19* gene on 4p14. The other three patients have a dual molecular diagnosis with pathogenic CNV and SNV mapping to different loci. Of the 24 patients with causative CNVs detected by CMA, the SNP array analyses performed for WES quality control detected 15/24 (62%) CNVs. The positives from the diagnostic CMA assay can also be used as controls to validate CNV deletions from exome sequencing data. In conclusion, the approach of concurrent detection of point changes, small indels and large CNVs provided more precise diagnoses, and shortened the diagnosis time by avoiding sequential studies.

**2529F**

**Diagnostic exome sequencing (DES) coupled with rules-based candidate gene analysis identifies a causative *RRAS* lesion in a patient with a novel RASopathy.** C.B. Mroske<sup>1</sup>, J.M. Hunter<sup>1</sup>, K.L. Helbig<sup>1</sup>, D.N. Shinde<sup>1</sup>, S.J. Hipp<sup>2</sup>, S.L. Whiteway<sup>2</sup>, J.M. Berg<sup>2</sup>. 1) Clinical Genomics, Ambry Genetics, Aliso Viejo, CA; 2) Pediatrics, Brooke Army Medical Center, San Antonio, TX.

Germline alterations in the RAS/ MAPK signaling network underlie a group of disorders collectively referred to as RASopathies. RASopathies, which include diseases like Noonan Syndrome, are characterized by a wide spectrum of variable symptoms such as cardiac and growth defects, facial dysmorphism, cognitive deficits, and predisposition to certain malignancies. Flex *et al.* recently reported two unrelated patients in whom germline alterations in the *RRAS* gene, which is a member of the RAS/ MAPK network hitherto unassociated with RASopathy, constituted the molecular etiology of symptoms that were nevertheless consistent with RASopathy. These patients, who were both female, harbored the respective germline *RRAS* alterations, p.G39DUP and p.V55M. Herein, we report a 7 year-old male who is unrelated to the patients reported by Flex *et al.* and who displays symptomatology consistent with RASopathy. By employing family-trio DES coupled with rules-based candidate gene analysis, we show that our proband's causative lesion is the previously reported *de novo*, germline *RRAS* alteration, p.G39DUP. Like the previous patient with this alteration, our proband displays motor delay and has a thick lower lip. Although our proband has not been diagnosed with a specific hematologic malignancy, he does exhibit splenomegaly and thrombocytopenia, both of which are associated with JMML. Notably, the aforementioned patient reported by Flex *et al.* developed AML, which was suspected to be secondary to JMML. Additional RASopathy features manifested by our proband that were not described in the previously reported *RRAS* patients include speech delay; VSD; scoliosis with pelvic tilt; craniosynostosis; joint hypermobility; hydrocele; and chronic fatigue. In summary, DES coupled with rules-based candidate gene analysis allowed us to efficiently determine the molecular lesion underlying our proband's symptoms. Not only do our data recapitulate the findings of Flex, 2014, they also expand the number and types of symptoms observed in patients with germline *RRAS* alterations. We propose that *RRAS* be added to the list of genes that are commonly sequenced in individuals suspected of having a RASopathy. We recommend that patients with *RRAS* alterations be monitored carefully for the emergence of hematological malignancy. The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of the Army, the Department of Defense, or the U.S. Government.

## 2530W

**Clinical evaluation with Holm's criteria for Prader-Willi syndrome in a cohort of 15 Mexican pediatric patients.** R. Lara-Enriquez<sup>1</sup>, C. García-Delgado<sup>1</sup>, A.B. Morales-Jiménez<sup>1</sup>, L.B. Muñoz-Martínez<sup>1</sup>, A. Cervantes<sup>2</sup>, V.F. Morán-Barroso<sup>1</sup>. 1) Genetics Department, Hospital Infantil de México, Federico Gómez, México City, México; 2) Genetics Service, Hospital General de México Dr. Eduardo Liceaga. Facultad de Medicina, Universidad Nacional Autónoma de México, México City, México.

**Introduction:** Prader-Willi Syndrome (PWS, MIM #176270) is an imprinting disorder caused by the absence of paternally expressed genes in 15q11.2-q13. PWS has a prevalence of 1 per 10,000 to 30,000 live births, and is characterized by neonatal hypotonia, hypogonadism, facial dysmorphic characteristics, psychomotor retardation, obesity, and intellectual disability. A paternal deletion is identified in 70% cases; 20 to 25% are due to maternal uniparental disomy, 5% are due to abnormalities in the imprinting control center, and a few cases are caused by chromosome rearrangements. **Objective:** To describe the type and frequency of clinical features in PWS Mexican patients with FISH analysis for del(15)(q11.2-q13). **Methodology:** From 2007 to 2016, 15 PWS were reviewed by direct clinical evaluation and/or medical chart review using Holm's criteria (HC). Cytogenetic GTG banding and FISH analyses using the *Prader Willi/Angelman Region Probe* – Tricolor Probe (Vysis®) were performed in peripheral blood. Three cases had other molecular studies. **Results:** The patients were 11 males (73%) and 4 females (27%) from 1 to 14 years old; 14 (93%) had a GTG karyotype analysis and only in one of them a del(15)(q11.2q13) was identified. All the patients had a FISH analysis (5 were performed in other Institution), in 10 (67%) patients a del(15)(q11.2q13) was identified. Patients were allocated in two different groups: Group I (GI) 10 FISH-positive patients with clinical diagnosis accordingly to HC; Group II (GII) 5 FISH-negative patients with clinical PWS diagnosis. Two patients of Group II had a methylation test. 30% of patients under 3 years old did not comply to HC, even though they had a PWS molecular diagnosis. Four patients of the GI were under 3 years old and only one of them had less than HC 6 points (pts). All patients over 3 years old had 8 pt except in one case that had 6.5 pts. Regarding GII, 2 patients had 8 pts for HC, and the rest were above 7 pts. **Discussion:** We confirm a higher association between specific symptoms such as feeding problems, characteristic facies, hypopigmentation, with paternal del(15)(q11.2q13). PWS was more frequently diagnosed in males, we consider that it may be associated to clinical manifestation of hypogonadism were more evident in them. This study suggests that the reported frequency of del(15)(q11.2q13) in PWS Mexican patients is similar to the reported frequency. HC were useful for the diagnosis of PWS in Mexican patients.

## 2531T

**Diversity of JAG1 mutations in Japanese patients with Alagille syndrome.** T. Togawa, K. Ohashi, T. Tokio, K. Ito, T. Endo, S. Saitoh. Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan.

Alagille syndrome (ALGS; OMIM 118450) is an autosomal-dominant multisystem disorder affecting the liver, heart, face, eyes, skeleton, and other organs. The prevalence is estimated to be 1 in 70,000 live birth. ALGS is caused by mutations in one of two genes in the Notch signaling pathway, *JAG1* or, rarely, *NOTCH2*. *JAG1* is located in 20p12 and consists of 26 exons. Mutations in *JAG1* can be identified in approximately 90% of clinically diagnosed patients with ALGS. To date, over 500 *JAG1* mutations have been reported from Western countries, while *JAG1* mutations of Japanese patients with ALGS have not been provided in large series. We aimed to elucidate the diversity of *JAG1* mutations in Japanese patients with ALGS. We carried out molecular genetic analyses with targeted next-generation sequencing (NGS) and/or multiplex ligation probe amplification (MLPA) covering the entire exons of *JAG1*. NGS analysis was performed with the Ion Torrent Personal Genome Machine system (Thermo Fisher Scientific) and MLPA was performed with the SALSA MLPA probemix P184-C2 *JAG1* (MRC-Holland). We detected 42 pathogenic variants in 42 unrelated patients who were diagnosed or highly suspected as ALGS. Thirty-five of 42 pathogenic variants were confirmed by the targeted NGS analysis and the other 7 were by MLPA. Regarding the mutation type, twenty-one single nucleotide variants (8 missense (19%), 10 nonsense (24%), 3 splice site (7%)), 9 small deletions (21%), 5 duplications (12%), 4 whole-exon deletions (10%), and 3 single exon deletions (7%) were detected. This prevalence of *JAG1* mutations by mutation type was similar to that reported in the previous report (Leonard LD, et al. Eur J Hum Genet, 2014). Twenty-eight (65%) of all the mutations were presented in 7 exons of *JAG1*; exon 2, 4, 6, 10, 17, 23, and 24. In contrast, there was no mutation in 13 exons; exon 1, 7, 8, 11, 14, 15, 16, 19, 20, 21, 22, 25, and 26. Distribution of mutations in *JAG1* was also similar to that of the previous study from Western country (Warthern DM, et al. Hum Mutat, 2006). By our 23 segregation analyses using parents' samples, we confirmed 17 (74%) as de novo, 6 (26%) as of maternal origin, and no paternal origin. These results could provide the characteristics of *JAG1* mutations in the patients with ALGS in Japan.

**2532F**

**Profile and characterization of genetic variants identified in 208 patients with Kabuki syndrome assists in pathogenicity determination.** C.F. Li<sup>1</sup>, E. Wei<sup>2</sup>, C. Baldwin<sup>2</sup>, J.M. Milunsky<sup>2</sup>. 1) Calgary Laboratory Services, Dept. of Pathology and Laboratory Medicine, University of Calgary, Calgary, AB, Canada; 2) Center for Human Genetics, Cambridge, MA, USA.

Kabuki syndrome is characterized by distinctive facial features, multiple congenital anomalies, and intellectual disability. It is caused by mutations in the lysine methyltransferase 2D (*KMT2D*) or lysine demethylase 6A (*KDM6A*) gene, which are involved in normal histone methylation. Patients with clinical features of Kabuki syndrome along with their parents if available were tested using Sanger sequencing and MLPA for both genes. Genetic variants found were classified into pathogenic, likely pathogenic, uncertain significance, likely benign and benign according to the American College of Medical Genetics (ACMG) standards and guidelines for interpretation of sequence variants. There were 179 genetic variants of *KMT2D* found in 203 patients and 8 healthy parents from 194 families, and 4 genetic variants of *KDM6A* found in 5 patients and 1 healthy parent from 4 families. The pathogenic and likely pathogenic variants are due to frameshift, nonsense mutation, splicing changes, and missense mutation that substitutes an amino acid with different properties. The variants of uncertain significance are due to missense mutation that substitutes an amino acid with different properties, missense mutation that substitutes an amino acid with same properties, variant in an intron or silent substitution not reported, in-frame deletion or duplication, variant in an intron or silent substitution near an acceptor splice site not affecting splicing, and variant in an intron that appears to reduce splicing. The likely benign and benign variants are due to missense variants that substitute an amino acid with the same properties, missense variants that substitute an amino acid with different properties found in an individual without phenotype or having a co-occurring pathogenic variant found at different site or a variant in an amino acid that is not conserved, in-frame deletion, duplication or insertion, variant in an intron or synonymous variant found in individual without phenotype. Hence, frameshift, nonsense mutation and a change in splicing were only found in pathogenic or likely pathogenic variants, while missense variants that substitute an amino acid with the same properties was only found in benign, likely benign, or variants of uncertain significance. In addition to the ACMG criteria for interpretation of genetic variants, analysis of the substituted amino acid properties may further assist in the classification of the missense variants found.

**2533W**

**Molecular diagnosis of tuberous sclerosis complex by next generation sequencing in pediatric patients from Mexico.** M.E. Reyna-Fabián<sup>1</sup>, N.L. Hernández-Martínez<sup>1</sup>, M.A. Alcántara-Ortigoza<sup>1</sup>, J.T. Ayala-Sumano<sup>2</sup>, A. Varela-Echavarría<sup>3</sup>, A.E. González del Ángel<sup>1</sup>. 1) Genetics, Instituto Nacional de Pediatría, Mexico City, Mexico; 2) Universidad Politécnica de Huatusco, Huatusco, Veracruz, Mexico; 3) Instituto de Neurobiología, Universidad Nacional Autónoma de México, Querétaro, México.

The tuberous sclerosis complex (TSC) is caused by mutations in the tumor suppressor genes *TSC1* and *TSC2*. To date, more than 1,500 disease-causing mutations have been described in these genes, where conventional molecular biology techniques as PCR and Sanger sequencing have helped in the identification of small mutations in ~80% of individuals who meet definitive diagnosis; however, the absence of an identification of the responsible genotype in the remaining cases difficult confirmatory diagnosis, genetic counseling and treatment. The Next Generation Sequencing (NGS) has emerged as an alternative approach to identify pathogenic variants in either coding and noncoding gene regions, besides variants in somatic mosaicism (~6% of the TSC cases) and small and large gene deletions/duplications (present in 17% of the TSC cases). In this study, we included five TSC pediatric patients that fulfill definitive diagnosis according to the most recent criteria and in which no mutation was previously been identified by Single Stranded Conformational Polymorphism and PCR-Sanger sequencing. The coding and noncoding regions from both *TSC1* and *TSC2* genes was subjected to NGS by an Illumina platform and analyzed for pathogenic variants using the Galaxy suite. The results lead us to identify disease-causing non-sense variants in three cases, two of those in *TSC1* (c.2102C>T, p.Gln701\*; c.2227C>T, p.Gln743\*) and one in *TSC2* (c.2448dup, p.Asp817\*). According to the search in ExAC, LOVD, dbSNP and HGMD databases, two out of those three variants have previously been reported in TSC cases, whereas the other one resulted in a novel variant (p.Asp817\*). The Sanger sequencing performed in probands and their parent's confirmed two cases as unique and one familial case that carries the p.Gln743\* pathogenic variant. The next step is to evaluate the presence of mosaicism in the other two patients in which no pathogenic variant was found. The results show that deep sequencing is an effective strategy for variant detection in those cases where conventional diagnostic methods were not effective. Identifying the disease causing genotype with new methodologies as NGS allows to extent the molecular diagnosis to other familial members in order to discard minimal expression of the disease and to suggest prenatal diagnosis.

**Application of next generation sequencing in NICU experiences from a 1239-patient pilot study.** *W. Zhou, L. Yang, H. Wang, B. Wu.* Division of Neonatology, Children's Hospital of Fudan University, Shanghai, China.

**OBJECTIVE:** To evaluate the clinical utility of using the focused medical exome as a first-tier screening /diagnostic tool for patients with suspected genetic diseases in NICU. **METHODS:** A total of 1239 patients enrolled into levels 3 and 4 NICU with suspected genetic conditions were offered for a ~2700-gene focused medical exome. The vast majority of patients were tested as singletons, no selections were made based on the type of genetic etiology, family history or prior testing. The study include 723 (58.4%) female and 516 (41.6%) male patients. **RESULTS:** Pathogenic or likely pathogenic variants in disease genes associated with patients' clinical phenotype were identified in 110/1239 (8.9%) patients. In addition, 133 (10.7%) patients were found to have variants of uncertain significance (VUS) in disease genes that were highly or partially associated with patients' clinical presentations. These include 19 patients with 1 pathogenic variant/1 VUS, 27 patients with 1VUS/1VUS in genes for autosomal recessive conditions and 87 patients with variants in genes for autosomal dominant or X-linked conditions. The primary abnormalities for these neonates include cardiovascular, neurological, metabolic, gastrointestinal, hematological, respiratory, allergy/immunologic/infectious disorders, dermatological, intrauterine growth retardation, urogenital and craniofacial malformations. Recurrent positive findings include ABCC8 gene for congenital hyperinsulinism, G6PD for Favism, BTK for Agammaglobulinemia, X-linked 1, KCNQ2 for neonatal seizures, COL7A1 for Epidermolysis bullosa dystrophica, MUT for Methylmalonic aciduria. For 35 patients who had pathogenic/likely pathogenic or even VUS findings in ABCC8, G6PD (G6PD deficiency), F7 (Factor 7 deficiency) and F8 (8 deficiency) genes, since the molecular findings were highly related to the patients' phenotype, immediate medical intervention was implemented right after the preliminary molecular findings were made. **CONCLUSION:** Our results successfully demonstrate the focused medical exome is a powerful tool for first tier screening /diagnosis in NICU. It complements the metabolic disease-focused newborn screening, detects broad spectrum of conditions and enables early intervention and decision making for a significant portion of NICU patients. The results of this pilot study enables us to promote the same strategy for future NICU care in China.

**2535F**

**Rapid Paediatric Sequencing (RaPS): Implementation of a framework for rapid genetic diagnosis in critically ill children using whole-genome sequencing.** *H. Williams<sup>1</sup>, L. Boukhibar<sup>2</sup>, E. Clement<sup>3</sup>, S. Drury<sup>4</sup>, W. Jones<sup>5</sup>, L. Ocaña<sup>6</sup>, A. Gagunashvili<sup>7</sup>, P. Le Quesne Stabej<sup>1</sup>, C. Bacchelli<sup>1</sup>, L. Jenkins<sup>2</sup>, M. Bitner-Glindzicz<sup>6</sup>, J. Hurst<sup>6</sup>, N. Lench<sup>2</sup>, M. Peters<sup>1</sup>, P. Beales<sup>1</sup>.* 1) GOSgene, Genetics and Genomic Medicine, UCL Great Ormond Street Institute of Child Health, London, United Kingdom; 2) Clinical Genetics and Genomic Medicine, Great Ormond Street Hospital for Children NHS Foundation Trust, London, United Kingdom; 3) Present address Congenica Ltd, Bioinnovation Data Centre, Wellcome Genome Campus, Cambridge, United Kingdom; 4) Experimental and Personalised Medicine, UCL Great Ormond Street Institute of Child Health, London, United Kingdom; 5) NE Thames Regional Genetics Laboratory, Great Ormond Street Hospital, London, United Kingdom; 6) Genetics and Genomic Medicine, UCL Great Ormond Street Institute of Child Health, London, United Kingdom; 7) UCL Great Ormond Street Institute of Child Health and Great Ormond Street NHS Foundation Trust, London, United Kingdom.

For children with undiagnosed genetic diseases on paediatric intensive care units (PICU) there is a pressing need to identify the molecular cause of illness rapidly. This may inform clinical management and sometimes permit therapeutic intervention to minimise disease related morbidity. The use of whole genome sequencing (WGS) alleviates many of the deficiencies associated with targeted sequencing approaches but in turn introduces novel challenges that need to be overcome before WGS is suitable for routine diagnostic testing. Our Rapid Paediatric Sequencing (RaPS) study involves a co-ordinated multidisciplinary team, comprising the academic research group GOSgene based at the UCL Great Ormond Street Institute of Child Health and consultant clinicians at Great Ormond Street Hospital (GOSH) departments; PICU and clinical genetics and genomic medicine. We used clear patient selection criteria to prioritise use in individuals where an urgent genetic result may significantly influence their current management. Turnaround time is drastically reduced through use of advanced bioinformatics and phased variant reporting to clarify the variant interpretation process for referring clinicians. To assess the clinical utility of RaPS we processed 20 patient/parent trios from GOSH PICU. We identified a pathogenic mutation in 35% (7/20) of families (*POLE1*, *GLDC*, *TBCE*, *COL3A1*, *CHD7*, *WT1* and *NSD1*), a further 4 families (20%) harboured Variants of Uncertain Significance (VUS) (*SLC30A6*, *PIGT*, *IL2RG* and *G6PD*) and 9 families (45%) had no candidate variants. We highlight in detail 4 cases where management was clearly changed by the genetic result, including a patient with an atypical *NSD1* phenotype in whom an early diagnosis obviated the need for further diagnostic testing and allowed targeted therapy. For VUS we propose a data sharing strategy to improve the identification of novel genes. We also show it is possible to complete this procedure in as little as 5 days in a diagnostic environment. The use of RaPS requires a considerable investment in time and resources, however, we demonstrate empirically for the first time in a UK NHS setting the potential of RaPS to influence point of care decisions and provide a robust framework that can be followed by other laboratories. Specifically, we detail our patient selection criteria checklist, bioinformatics data analysis pipeline and variant calling strategy that led to the reduced turnaround time and high diagnostic yield.

**2536W****Complete STK11 deletion and atypical symptoms in Peutz-Jeghers**

**Syndrome.** *Y.H. Hong.* Department of Pediatrics, Soonchunhyang University Bucheon Hospital, Bucheon, Gyeonggi, South Korea.

Peutz-Jeghers syndrome (PJS) is a rare autosomal dominant inherited disease characterized by gastrointestinal polyposis and mucocutaneous pigmentation. The gene involved in PJS is mapped to chromosome 19p13.3 and encodes a serine-threonine protein kinase (STK11) known as LKB1. Only a small number of large genomic deletions have been identified. We report a boy with PJS and multiple anomalies, neurologic manifestations. The boy was the second child of non-consanguineous and healthy parents. He was delivered at term, by vaginal delivery, after an uncomplicated pregnancy. The first child was an apparently normal boy. He had an atrial septal defect and underwent orchiopexy for cryptorchidism. He had global developmental delay and mental retardation. At about four years of age, black pigment spots appeared on his lips. He visited the emergency department complaining of acute hematochezia at 14 years old age. Colonoscopy showed a huge grape-shaped pedunculated polyp in the sigmoid colon. A few small sessile polyps were found in the terminal ileum, descending colon, and rectum. Polypectomy and multiple biopsies were obtained from the polyp. Histologically, the polyp fragments were hyperplastic. Initially, we performed PCR and direct sequencing using primers targeting the nine coding exons of the STK11 gene. No pathogenic or likely pathogenic variants were detected by this direct sequencing analysis. Next, gene dosage analyses were performed by using a multiplex ligation-dependent probe amplification (MLPA) kit (SALSA MLPA P101-A2 STK11 probemix; MRC-Holland, Amsterdam, Netherlands). Deletion of all 10 exons of STK11 gene was detected. Although large-scale deletions from STK11 have been reported in PJS, including deletion of the entire STK11 gene, these appear to be rare. Whole-gene and exonic deletions and duplications cannot be detected by using conventional screening tests for point mutations and small deletions/insertions. Hence, the prevalence of STK11 mutations in PJS may have been underestimated. This case emphasizes the importance of genetic testing to identify the genotype-phenotype relationship in PJS. The MLPA assay is a valuable method for detecting STK11 mutations in PJS. More studies would be needed to search for large deletions in patients who present with PJS clinically and have atypical clinical features of PJS.

**2537T****Whole ROR2 gene deletion uncovering a pathogenic mutation in a patient with autosomal recessive Robinow syndrome.**

*B.M. Ferreira<sup>1</sup>, A.R. Lima<sup>1</sup>, T.M. Canó<sup>2</sup>, M.A. Chiabai<sup>3</sup>, R. Pogue<sup>3</sup>, J.F. Mazzeu<sup>1,4</sup>.* 1) University of Brasília, Brasília, Distrito Federal, Brazil; 2) Secretary of State for Health of the Distrito Federal, Distrito Federal, Brazil; 3) Catholic University of Brasília, Distrito Federal, Brazil; 4) Robinow Syndrome Foundation, Anoka MN, USA.

**Statement of purpose:** Robinow Syndrome is a genetically heterogeneous disorder characterized by a triad of facial dysmorphism, including hypertelorism, short stature and genital hypoplasia with extreme clinical variability. More severe bone involvement and marked short stature are observed in the autosomal recessive form of the syndrome (RRS [MIM 602337]) caused by biallelic mutations in *ROR2* (receptor tyrosine kinase-like orphan receptor 2), whereas heterozygous mutations in *WNT5A* (DRS1 [MIM 180700]), *DVL1* (DRS2 [MIM 616331]) and *DVL3* (DRS3 [MIM 616894]) have been identified in a subset of patients with autosomal dominant Robinow syndrome. These genes encode for components of the Wnt signaling complex which play a key role in the regulation of cell differentiation and patterning. Here we report a patient with recessive Robinow syndrome caused by a whole *ROR2* deletion and a hemizygous mutation in the other allele. **Methods used:** Patient is a 3-month old boy born to non-consanguineous parents with typical recessive Robinow syndrome phenotype, referred to our genetic service for molecular confirmation of the diagnosis. Mutation screening was performed by using next generation sequencing (NGS) using ION PGM™ Inherited Disease Panel as described by the manufacturer. Investigation of deletions and duplications on *ROR2* was performed by MLPA using kit P179. Chromosome Microarray analysis was performed for delimitation of the deleted segment using the Affymetrix 750K platform. **Summary of results:** NGS revealed a single pathogenic mutation in *ROR2* (c.1970G>A, p.Arg657His), allegedly in homozygosity. Patient was homozygous for other polymorphic variants in *ROR2*. Considering that the parents were not consanguineous we performed MLPA that revealed a deletion of all probes for *ROR2*. Chromosome microarray analysis delimited the deletion to a 470 Kb on 9q22 (arr[hg19] 9q22.31(94,381,136-94,851,388) x1). The deletion includes *ROR2* and *SPTLC1* genes. **Conclusion:** The patient here described presents a chromosomal microdeletion including *ROR2* gene uncovering a pathogenic mutation on the other allele of *ROR2*. These findings corroborate the diagnostic of RRS and sheds light to the importance of a criterious evaluation of NGS data for differentiation of hemizygous and homozygous mutations.

**2538F**

**Expanding the spectrum of *TBL1XR* deletion: Report of a patient with brain and cardiac malformations.** S. Oliveira<sup>1</sup>, A. Vaqueiro<sup>2</sup>, C. Oliveira<sup>2</sup>, M. Cordoba<sup>3</sup>, B. Versiani<sup>3</sup>, C. Carvalho<sup>3</sup>, P. Rodrigues<sup>3</sup>, J. Mazzeu<sup>4</sup>, A. Pic-Taylor<sup>1</sup>. 1) Genética e Morfologia, Universidade de Brasília, Brasília, Brasília (Distrito Federal, Brazil); 2) Hospital de Apoio, Secretaria de Estado de Saúde do Distrito Federal, Brasília, Brazil; 3) Hospital Universitário, Universidade de Brasília, Brasília, Brazil; 4) Faculdade de Medicina, Universidade de Brasília, Brasília, Brazil.

The *TBL1XR1* gene (transducin beta-like 1 X-linked receptor 1-NM\_024665 – OMIM 608628), also known as *hTBL1XR1*, *hTBLR1* and *IRA1*, is located on 3q26.32 and belongs to the *TBL1XR1* family. This gene encodes a nuclear protein of 515 amino acids, which is a component of SMRT/N-CoR co-repressor complexes and participates in the molecular switch of specific gene transcription. Deletions of the this gene have been described as associated to intellectual disability and dysmorphism. Point mutations in this gene have been associated to autism and Pierpont syndrome. Here we describe a girl diagnosed with cardiac abnormalities - atrial and ventricular septum defects, a persistent truncus arteriosus and moderate mitral insufficiency - at three months of age. Language development was delayed and she displayed compulsive behaviour. Facial characteristics included a square face frontal bossing, sparse eyebrows, bilateral epicanthus, hooded eyes, midface hypoplasia, a bulbous nose, long philtrum, thin lips, crowded teeth, a narrow palate, and a large pointed chin. Hands were short with brachydactyly and bilateral clinodactyly of the fifth finger. Feet were small and padded, toes were small and splayed and she presented cutaneous syndactyly between the 2<sup>nd</sup> and 3<sup>rd</sup> toes. Her lower left limb was thicker than her right, with visibly protruding veins. Cranial tomography showed premature closing of the sagittal suture and antero-posterior growth of the cranium, although the scaphoid skull was not visible. In addition, we observed a Chiari I malformation, that has been asymptomatic to date. Chromosomal microarray analysis revealed a 1,3 Mb *de novo* microdeletion on chromosome 3q26.32: arr[hg19] 3q26.32(176,025,379-177,377,006) x1 encompassing one coding gene, *TBL1XR1*, and part of a long non-coding RNA *LINC00578*. Altogether, we can summarize the main clinical signs of the *TBL1XR1* gene deletion as: mild to moderate intellectual disability, delayed language development, a pointed chin, and, according to this study, cardiac and brain. The role of *TBL1XR1* on Wnt signalling and the consequences of this pathway on both brain and cardiac development is in accordance with the phenotype of the patient described herein and supports *TBL1XR1* as a strong candidate to explain ID and cardiopathy associations. Therefore, the data provided here contributes in defining the phenotype linked with haploinsufficiency of the *TBL1XR1* gene and affords a better understanding of its function.

**2539W**

**Study of genetic defects in patients with limb malformations.** A. Rai<sup>1</sup>, A. Moirangthem<sup>1</sup>, P. Srivastava<sup>1</sup>, N. Gupta<sup>2</sup>, RD. Puri<sup>3</sup>, S.J. Patil<sup>4</sup>, P. Ranganath<sup>5</sup>, K. Gowrishankar<sup>6</sup>, A. Dutta<sup>7</sup>, JP. Soni<sup>8</sup>, K. Mandal<sup>1</sup>, SR. Phadke<sup>1</sup>. 1) Medical Genetics, Sanjay Gandhi Post Graduate Institute of Medical Science, Lucknow, India; 2) Division of Genetics, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India; 3) Institute of Medical Genetics & Genomics, Sir Ganga Ram Hospital, New Delhi, India; 4) Department of Medical Genetics, Narayana Multispecialty Hospital, Bangalore, India; 5) Department of Medical Genetics, Nizam's Institute of Medical Genetics, Hyderabad, Telangana, India; 6) Kanchi Kamakoti CHILDS Trust Hospital, Chennai, India; 7) North Bengal Medical College & Hospital Sushrutnagar, Siliguri, India; 8) Dr. S.N. Medical College, Jodhpur, India.

Congenital limb malformations occur in approximately 1 in 500 human live births which makes them one of the most frequent birth defect and includes both gross reduction defects and more subtle alterations in the number, length and anatomy of the digits. Increasing numbers of genes are being identified for limb abnormalities and identification of causative gene mutations is important for genetic counselling and also provide insight into mechanisms those control limb development. We have studied 62 cases with limb malformations for genetic etiologies using Sanger sequencing, cytogenetic microarray and exome sequencing. For monogenic disorder where causative genes were known, Sanger sequencing has been done. Cases of unknown etiology were subjected to chromosomal microarray and exome sequencing. For genes of monogenic disorders having more than 10 exons exome sequencing has been done. Sanger sequencing identified causative variants in 11 cases (7 were known and 4 were novel) out of 25 monogenic limb malformation cases. These include *ECEL1*, *FGFR2*, *ROR2*, *PITX1*, *TP63* and *SOST1* genes. Chromosomal microarray identified copy number variations in two cases out of 10 cases; 7q21.2-q22.1 deletion (7 MB) in a patient with split hand-split foot malformation and sensorineural hearing loss and 13q31.1 deletion (1.4 MB) in a patient with short 5<sup>th</sup> metacarpal and ptosis, genu valgum. By homozygosity mapping, two candidate genes were identified in a patient with Arthrogryposis Renal Dysfunction and Cholestasis which was further subjected to exome sequencing due to its large genes. Samples for exome sequencing were outsourced which were sequenced using Nextera Rapid Capture Exome from Illumina and raw data were analysed for disease causing variations. Exome sequencing identified causative variants in 19 out of total 27 cases. So in this study the total diagnostic yield of single gene sequencing, chromosomal microarray and exome sequencing is 51% which is showing the efficacy of these three techniques in evaluating the genetic cause of limb malformation patients. The mutation data was used for providing genetic counseling to the families. Exome sequencing data of 8 cases in whom the causative variants were not identified is being analysed for variants in novel genes.

**AMELIE accelerates Mendelian patient diagnosis directly from the primary literature.** J. Birgmeier<sup>1</sup>, J.A. Bernstein<sup>2</sup>, G. Bejerano<sup>1,2,3</sup>. 1) Department of Computer Science, Stanford University, Stanford, California 94305, USA; 2) Department of Pediatrics, Stanford School of Medicine, Stanford, California 94305, USA; 3) Department of Developmental Biology, Stanford University, Stanford, California 94305, USA.

Rare diseases, in aggregate, affect up to 10% of the world's population. Patients with rare Mendelian diseases have 1-2 genetic mutations in a single gene primarily responsible for their phenotypes. The diagnosis of known Mendelian disorders requires matching a patient's phenotype and genetic variants against the published medical literature and can be highly labor intensive, with more than 40 hours of expert time needed for individual diagnoses. There are currently more than 5,000 diagnosable Mendelian diseases, caused by roughly 5,000 different genes, and manifesting in different subsets of over 10,000 documented phenotypes. Patients may present up to 300 candidate genes of 20,000 in our genome. To arrive at a differential diagnosis, the clinician must read about all of the patient's candidate genes to try and find one that may explain their patient. Our software system AMELIE (Automatic Mendelian Literature Evaluation) automates the process of literature curation for diagnosis of Mendelian diseases. AMELIE collects and parses hundreds of thousands of full-text articles from all of PubMed to find an underlying diagnosis that best explains the patient's phenotypes. Given a list of candidate genes and a patient's phenotypes, AMELIE uses its articles knowledgebase to rank the patient's genes by their likelihood of causing the patient's phenotypes, and offer the diagnostic paper(s) explaining its rationale. Diagnosis of singleton patients (where the patient, but not their relatives, is sequenced) is a common scenario that is both most challenging and most time-consuming. AMELIE's gene prioritization method was tested on 215 singleton patients with diagnosed Mendelian diseases. AMELIE ranked the causal gene in the top 2 in 63% of all cases and among the top 10 in 95% of all cases, out of a median of 124 candidate genes per patient. AMELIE significantly outperformed curation dependent methods. AMELIE's superior performance is explained by the fact that it holds over 3 times as many gene-phenotype relationships as are curated by HPO from OMIM and OrphaNet. We are launching a web portal where one can analyze patient cases based on the latest literature at AMELIE.stanford.edu. We will present on different patient cases from the Stanford Hospital whose diagnosis is greatly facilitated using AMELIE's automated literature-supported gene ranking.

**2541F**

**Two children with copy number variants in the critical regions of both Wolf-Hirschhorn and Cri du Chat syndrome.** L. Andoni<sup>1</sup>, L. Fuqua<sup>1</sup>, K. Ho<sup>1</sup>, J.C. Carey<sup>2</sup>, C. Bupp<sup>3</sup>. 1) Lineagen Inc, Salt Lake City, UT; 2) Department of Pediatrics, University of Utah, Salt Lake City, UT; 3) Spectrum Health Medical Group, Grand Rapids, MI.

When multiple pathogenic variants co-occur in a patient, clinical diagnosis can be greatly aided by genetic testing. Here we describe two infants with copy number variants (CNVs) involving the critical regions for both Wolf-Hirschhorn (WHS) and Cri du Chat (CdCS) syndromes. One infant has a deletion in both the WHS and CdCS regions, while the other has a duplication of the WHS critical region, also known as 4p16.3 microduplication syndrome, and a deletion of the CdCS region. In this report, we delineate how features of these two children correlate and contrast with known features of these conditions. Intellectual disability, developmental delay, and multiple congenital anomalies are common to all three conditions, while each also has unique characteristics, such as distinct craniofacial features for WHS and a cat-like cry for CdCS. Patient 1 was diagnosed by chromosome microarray testing (CMA) in the neonatal period with a pathogenic 8.86 megabase (Mb) terminal deletion of 4p16.3-p16.1, 1.18 Mb deletion of 4q11-q12 of uncertain clinical significance, and pathogenic 14.05 Mb terminal deletion of 5p15.33-p15.2, all of which were *de novo*. Born at 34 weeks, the patient had microcephaly, congenital heart and kidney malformations, dysmorphic features, and brain abnormalities. Interestingly, WHS and CdCS were not initially suspected, although with age the patient now demonstrates more of a WHS phenotype. Patient 2 was diagnosed by CMA at 10 months of age with a pathogenic 10.96 Mb terminal duplication of 4p16.3-p16.1 and a pathogenic 29.77 Mb terminal deletion of 5p15.33-p13.3. Parental karyotype has not yet been performed. Born at 36 weeks, the patient had microcephaly, TE fistula, esophageal atresia, and congenital cardiac defects. 22q11.2 deletion syndrome was high on the initial differential diagnosis, but FISH testing for 22q11.2 deletion syndrome was negative. With age, the patient demonstrates more of a CdCS phenotype, but is lacking the characteristic cry. While careful clinical assessment and phenotyping are keys to diagnoses, these two unique cases also underscore the importance of CMA. Having multiple CNVs can lead to unique phenotypes, as evidenced by these patients that are not completely clinically consistent with either WHS or CdCS. Including the family in the decision-making process when ordering genetic testing is crucial and the psychosocial aspects of these decisions are underscored.

**Recurrent unbalanced constitutional chromosomal translocation between chromosomes 8 and 12, der(8)t(8;12)(p23.1;p13.31), detected in three patients with similar phenotype.** D. Huang<sup>1</sup>, L. Matyakhina<sup>1</sup>, A. Wray<sup>1</sup>, V. Nelson<sup>1</sup>, R.L. Ladda<sup>2</sup>, S. Sell<sup>2</sup>, R. Davis<sup>2</sup>, J. Richards<sup>3</sup>, J. Condie<sup>4</sup>, J. Meck<sup>1</sup>. 1) Cytogenomics, GeneDx, Inc., Gaithersburg, MD; 2) Department of Pediatrics, Penn State Hershey Children's Hospital, Hershey, PA; 3) Pediatric Neurology P.A., 7485 Sandlake Commons Blvd, Orlando, FL; 4) St. Luke's Children's Neurology, 100E Idaho St., Boise, ID.

Recurrent constitutional reciprocal non-Robertsonian chromosome translocations are rare. To our knowledge, there are only three such translocations reported in the literature: the most common one is t(11;22)(q23;q11), while t(8;22)(q24.13;q11.21) and t(4;8)(p16;p23) are less frequently seen (PMID: 22260357 and 12058347). Recurrent unbalanced translocations, most notably der(4)t(4;11)(p16.2;p15.4), have been also reported (PMID: 21205869). Here we report an apparently recurrent unbalanced translocation between the short arms of chromosomes 8 and 12 found in 3 cases referred to our clinical diagnostic laboratory for chromosomal microarray. In all cases array detected a terminal 7 Mb deletion in 8p and a terminal 8.3 Mb duplication in 12p. Metaphase FISH using probes from within the deleted and duplicated regions performed on two probands showed that these aberrations were secondary to a derivative chromosome 8, der(8)t(8;12)(p23.1;p13.31). Parental metaphase FISH revealed normal results, consistent with a *de novo* occurrence of the unbalanced translocation. To date, three patients with apparently the same unbalanced translocation have been reported in the literature, one of which had clinical information (PMID: 21205869 and 22639464). Common clinical features include motor and language delay, hypotonia, childhood onset epilepsy, and autistic features. Additional features observed in more than one patient were facial dysmorphism, umbilical hernia, CNS abnormalities, and eye problems. The 8p23.1 and 12p13.31 chromosome regions are known to contain highly homologous LCR clusters: this genomic architecture likely underlies the recurrent occurrence of this translocation. In summary, the der(8)t(8;12) appears to be a recurrent *de novo* unbalanced translocation mediated by large LCRs and associated with the phenotype of developmental delay, hypotonia, childhood onset epilepsy, and autistic features.

**The first Japanese patient of Mandibular hypoplasia, deafness, progeroid features, and lipodystrophy syndrome (MDPL) diagnosed via *POLD1* mutation detection.** I. Imoto<sup>1</sup>, T. Kohmoto<sup>1</sup>, T. Naruto<sup>1</sup>, A. Goji<sup>2</sup>, A. Okada<sup>2</sup>, I. Yokota<sup>2,3</sup>, Y. Kotani<sup>2</sup>, A. Shimada<sup>4</sup>, Y. Miyamoto<sup>1</sup>, K. Masuda<sup>1</sup>, S. Kagami<sup>2</sup>.

1) Dept Human Genetics, Grad Sch Biomed Sci, Tokushima Univ, Tokushima, Tokushima, Japan; 2) Dept Paediatrics, Grad Sch Biomed Sci, Tokushima Univ, Tokushima, Tokushima, Japan; 3) Dept Pediatrics, Div Pediatric Endocrinol & Metabolism, Shikoku Medical Center for Children and Adults, Zentsuji, Kagawa, Japan; 4) Dept Otolaryngology, Grad Sch Biomed Sci, Tokushima Univ, Tokushima, Tokushima, Japan.

Mandibular hypoplasia, deafness, progeroid features, and lipodystrophy syndrome (MDPL, MIM#615381) is a rare autosomal dominant systemic disorder resulting from heterozygous mutations in the *POLD1* gene (MIM#174761). MDPL is clinically characterized by prominent loss of subcutaneous fat, a characteristic facial appearance, metabolic abnormalities including insulin resistance and diabetes mellitus, and sensorineural deafness occurring late in the first or second decades of life. Until now, 18 patients including 15 Caucasian, 2 Hispanic, and 1 Indian cases affected by this syndrome have been described. Among analysed 13 cases, only two causative *POLD1* mutations, an in-frame deletion (Ser605del, 11 cases) and a missense mutation (R507C, 2 cases), have been identified, and most of them have occurred *de novo*. Although these *POLD1* mutations in hot spots causing MDPL may occur regardless of race/ethnicity, no East Asian cases including Japanese cases have been reported. We herein report the first East Asian/Japanese case of MDPL with one of known heterozygous *POLD1* mutations. A clinically undiagnosed 11-year-old, Japanese boy, who noted joint contractures at age 7 years, was affected with various other symptoms, such as short stature, truncal obesity, mandibular underdevelopment, pinched nose, tight facial skin around the eyes, prominent upper teeth, healing loss, hypogonadism. Targeted-exome sequencing (TES) using a TruSight One Sequencing Panel (Illumina) performed as a genome-first approach detected an in-frame heterozygous deletion in exon 15 of *POLD1*, NM\_002691.3:c.1812\_1814del, affecting the polymerase-active site, NM\_002691.3:p.(Ser605del), which was confirmed by Sanger sequencing. This mutation has been shown to cause most cases of MDPL. Neither variations nor gross deletions in the coding regions of other progeroid-related genes were detected in TES. As a result of this molecular diagnosis and re-evaluation of the affected patient's clinical features, together with the clinical spectrum of patients harbouring *POLD1* mutations, the patient was diagnosed with the 19th MDPL and 14th *POLD1*-caused MDPL case reported worldwide caused by a known frame-shift deletion in *POLD1*. Notably, in addition, this patient is the first Japanese as well as East Asian case with MDPL, supporting the hypothesis that *POLD1* mutations causing MDPL, at least this in-frame deletion mutation, commonly occur at hot spot irrespective of race/ethnicity.

**Enhanced detection of uniparental disomy (UPD) and copy number variations (CNVs) with delineation of parental origin for clinical trio exome cases.** *H. Dai<sup>1</sup>, P. Liu<sup>1,2</sup>, W. Bi<sup>1,2</sup>, M. Walkiewicz<sup>1,2</sup>, M. Leduc<sup>1,2</sup>, T. Santiago-Sim<sup>1</sup>, I. Van den Veyver<sup>3</sup>, S. Stover<sup>4</sup>, J. George-Abraham<sup>5</sup>, C. Qu<sup>2</sup>, V. Pate<sup>2</sup>, X. Wang<sup>1,2</sup>, Y. Yang<sup>1,2</sup>.* 1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Baylor Genetics, Houston, TX; 3) Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX; 4) Genetics, Texas Children's Hospital, Houston, TX; 5) Dell Children's Medical Center, Austin, TX.

**Introduction:** Trio exome sequencing has been widely applied to provide molecular diagnoses for patients with a wide spectrum of genetic disorders. Yet the potential of trio exome data for identifying structural abnormalities and UPDs has not been fully utilized. **Objectives:** To develop a trio data analysis algorithm based on parental origins of alleles to identify UPDs and other structural abnormalities. **Methods:** SNP data from 1264 clinical trio exome cases were retrospectively analyzed using an algorithm based on the assignment of alleles by descendant. The patterns of uniparental disomy and other structural anomalies were flagged automatically based on the most likely parental origin of each allele or allele pair. For the confirmation of the results called by the computer program, the exome and/or cSNP array data were subsequently examined manually. **Results:** The findings include: 1) Seven (7/1264) UPD cases, including 5 for which UPD is the cause of the diseases in the patients. A heterodisomy UPD(14)mat, undetectable by microarray due to lack of absence of heterozygosity (AOH) on the chromosome, unveiled Temple syndrome presented in the first patient. An isodisomy UPD(15)mat was detected in the second patient confirming the clinical diagnosis of Prader-Willi syndrome. A complex UPD(16)mat with regions of isodisomy and heterodisomy was detected in the amniotic fluid sample of a fetus, indicating possible trisomy rescue during earlier fetus development. Two molecular diagnoses (Stargardt disease and Parkinson disease) were made in yet another patient with homozygous pathogenic variants in *ABCA4* and *PARK7* resulting from UPD(1)pat. Lastly, one case has mosaic UPD(1)mat exposing the pathogenic variant in *ZMPSTE24* associated with lethal restrictive dermopathy. 2) Nine cases with *de novo* del/dup events, of which the parental origins were also delineated, providing additional insights into disease etiology. Intriguingly a *de novo* loss on 6q27 and gain on 10q25.1q26.3 of paternal origin were detected in one patient diagnosed with 6p duplication by chromosome studies. Our results indicates that the cryptic 6q27 duplication based on karyotype actually resulted from translocation of the duplicated 10q25.1q26.3 bands. **Conclusion:** Expanding trio exome analysis to genome wide structural variations provides greater potentials to decipher the etiology of genetic diseases. This analysis has been incorporated into the routine trio exome analysis in our laboratory.

**A rapid and reliable chromosome analysis method for products of conception using interphase nuclei.** *R. Babu<sup>1</sup>, D. Van Dyke<sup>2</sup>, S. Bhattacharya<sup>3</sup>, V. Dev<sup>4</sup>, M. Liu<sup>4</sup>, M. Kwon<sup>4</sup>, G. Gu<sup>4</sup>, P. Koduru<sup>5</sup>, N. Rao<sup>6</sup>, C. Williamson<sup>2</sup>, E. Fuentes<sup>1</sup>, S. Fuentes<sup>1</sup>, S. Papa<sup>1</sup>, S. Kopuri<sup>1</sup>, V. Lal<sup>1</sup>.* 1) InteGen LLC, Orlando, FL; 2) Mayo Clinic, Rochester, MN; 3) Dr. Lal Path Labs, New Delhi, INDIA; 4) Genetics Associates Inc., Nashville, TN; 5) UT Southwestern Medical Center, Dallas TX; 6) David Geffen UCLA School of Medicine, Los Angeles, CA.

**Background:** Karyotype determination has a central role in the genetic workup of pregnancy loss, as aneuploidy and polyploidy are the main causes. Current methods of obtaining a karyotype using traditional cytogenetics, FISH with a limited number of probes, and CMA have limitations of culture failure, incomplete results, lower sensitivity, and longer turnaround time. **Methods:** A Standard Resolution Interphase Chromosome Profiling (ICP) probe set, a variation of a recently developed High Resolution probe set (Babu et al., in press), was developed that targets only the subtelomere and paracentromeric regions. Abnormalities commonly encountered in POC samples, such as trisomy and unbalanced translocations, can be easily detected with this design. To detect Robertsonian translocations, each acrocentric chromosome's paracentromeric area is targeted and a mixture of these five targets is used in a separate analysis. First, initial familiarization of signal patterns from the probe set was achieved, followed by validation of this method using 83 blind samples from miscarriages from three different laboratories. Finally, the clinical utility of the method was tested on 291 samples in two commercial reference laboratories on two different continents. A minimum of 20 interphase cells were analyzed for each chromosome to identify an abnormal clone. For detection of Robertsonian translocations, a normal cutoff was set at 20% for any two paracentromeric probes to co-localize by random chance or by satellite association. **Results:** All 374 samples had results by the ICP method and the average turnaround was less than 48 hours. This new molecular approach not only detected all the chromosomal changes observed by current methods, but significantly improved the abnormality detection by characterizing derivative chromosomes and finding subtle subtelomeric deletions (Xq and 17q) and A balanced translocation involving 2q and 10q. All Robertsonian translocations were also detected. Abnormalities detected only by ICP included trisomy 4, 7, 8, 14, 15, 16, 19, 20 and 22. The abnormality rate was 54% on clinical samples from commercial lab 1 and 63% from lab 2. **Conclusion(s):** The attributes of Interphase Chromosome Profiling (ICP), namely 1) near 100% results, 2) greater sensitivity than conventional methods, and 3) no need for cell culture or DNA isolation, make this novel method an ideal choice for first-line testing in the genetic workup of miscarriages.

**2546T**

**Clinical validation of whole-genome sequencing assay for constitutional disorders.** A. Abhyankar, W. Clarke, G. Narzisi, V. Felice, E. Dikoglu, L. Kozon, Y. Kasai, V. Jobanputra. New York Genome Center, New York, NY.

Next-generation sequencing technology has come a long way in making high-throughput genetic screens accurate, affordable and accessible. Though whole-exome sequencing (WES) assays are being used in clinical settings, whole-genome sequencing (WGS) assays have not yet been widely adopted for clinical use. There are many advantages of using WGS over WES assay. This approach can be used to identify SV, and CNV events more accurately as compared to WES. Additionally, this approach allows assessment of non-coding regions of the genome in the clinical context. We performed analytical validation of whole-genome sequencing assay for the purpose of clinical testing of constitutional disorders. WGS was performed on 88 samples that included singleton, trios and quads with undiagnosed disease and healthy individuals. We performed the validation on DNA derived from whole blood, archived dried blood spot and saliva specimens. We also sequenced NA12878 cell line obtained from NIST. The results were compared with Genome In a Bottle high-confidence call set for NA12878 to define the accuracy and analytical specificity of our assay. To estimate the degree to which repeated sequence analyses give the same result - repeatability (inter-assay precision) and reproducibility (intra-assay precision), we sequenced six samples in triplicate for inter-assay evaluation and five samples for intra-assay evaluation. All genomes were sequenced on Illumina HiSeqX system at mean genome coverage of 30x. The resulting raw reads in FASTQ format were processed through analysis pipeline designed to call SNVs, Indels, CNVs, and variants in the mitochondrial genome. Considering the circular nature of mitochondrial genome we developed a specialized workflow to identify homoplasmic and heteroplasmic variations as well as to estimate the relative mitochondrial DNA copy number. We also developed workflow to analyze parent-child trios and quads. Quality control metrics were assessed at various stages of the workflow and cutoffs were determined to ensure high quality of the resulting data. Clinically relevant variant prioritization and reporting strategy was developed to provide accurate variant discovery, evaluation and reporting in the context of provided clinical information.

**Analysis of 1374 comparative genomic hybridization (CGH) results: Indirect evaluation of carrier rate in a Colombian population.** M. Garcia-Acero, F. Suarez-Obando, A. Gomez. 1) Genetics, Pontificia Universidad Javeriana, Bogota, Colombia; 2) Instituto de Referencia Andino.

**Introduction:** Comparative Genomic Hybridization (CGH) is a high-resolution technique that allows the detection of microdeletions and microduplications unrevealed in the conventional microscopic karyotype. These chromosomal abnormalities are a common cause of developmental delay, non-syndromic cognitive disorders, autism spectrum disorders and multiple congenital anomalies. Although a considerable number of these patients are suspected of having cytogenetic imbalances, only a few are positive for copy number abnormalities that explain the phenotype. On the contrary, unexpected findings have been documented that modify family counseling and medical care. **Methodology:** Descriptive analysis of results of 1374 CGH performed in a Reference Laboratory in Colombia during the period 2009 - 2015. **Results:** 495 chromosomal alterations were found through CGH analysis, 302 (61%) of which were classified as pathogenic (4 of these not associated with the clinical phenotype), 92 (18.5%) as non-pathogenic, 65 (13.1%) were defined as variants of uncertain significance and 36 (7.27%) as variants that constitute alterations of a single allele in autosomal recessive inheritance pathologies, contributing as carrier variants in the population. **Conclusions:** The detection of genomic imbalances will increase knowledge of the human genome through phenotype-genotype correlations. Additional findings in the test not associated with the phenotype, could be useful for genetic counseling. The analysis of additional findings of a bigger sample should allow the description of carrier states in the evaluated population.

**10x Genomics® Chromium™ linked-read workflows fully optimized on PerkinElmer Sciclone® for high-throughput automation of exome and genome applications.** J. Garifallou<sup>1</sup>, F. Mafrà<sup>1</sup>, R. Pellegrino<sup>1</sup>, C. Siebert<sup>2</sup>, B. Gerwe<sup>1</sup>, M. Gonzalez<sup>1</sup>, M. Benway<sup>2</sup>, C. Kaminski<sup>1</sup>, C. Kao<sup>1</sup>, H. Hakonarson<sup>1</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) PerkinElmer, Inc.

Current massively parallel sequencing methods, while high-throughput and efficient in data generation, are limited due to the nature of the short read sequences that restrict certain applications such as the ability to phase/haplotype over long genomic distances, accurately map reads between highly homologous regions (e.g. genes vs. pseudogenes), and robustly detect particular types of structural variants. The Chromium instrument (10x Genomics) leverages advances in microfluidics technology and precision reagent delivery to generate a haplotype-level dilution of ~1 ng of high molecular weight DNA molecules in >1 million barcoded partitions, which creates a novel data type called 'Linked-Reads'. The in-partition biochemistry and subsequent processing generates Illumina®-compatible libraries in which all short reads that carry the same partition barcode are automatically associated with the same originating DNA molecule. Each short read retains up to hundreds of kilobases of positional context from that individual DNA molecule, thus enabling long-range dependent applications such as phasing, structural variant detection, and mapping reads of paralogous segments. Here we demonstrate how the PerkinElmer Sciclone® NGSx Workstation can successfully and fully automate the Chromium Genome workflow. We show the libraries have comparable quality to those of a manual preparation. Following Chromium partitioning, library generation, and pooling, samples were processed again on the Sciclone NGSx Workstation using an established automated workflow for exome/panel target capture using Agilent SureSelect™ baits. This end-to-end automated workflow was used to generate Linked-Read whole exome data on samples with unresolved structural rearrangements and difficult-to-map loci. Linked-Reads enable us to 1) fine-map structural rearrangements detected by karyotyping and 2) resolve variants in genes versus those in their homologous pseudogenes without invoking non-NGS methods such as MLPA or long-range PCR. The benefits of automation are critical to the scale-up of high-throughput projects in the clinical setting by removing manual variability and increasing efficiency/accuracy. Combining 10x Genomics technology with PerkinElmer automation yields a complete workflow solution for exome and panel-based Linked-Read sequencing, at scale, to expand the downstream application of regular short reads sequencing with minimal equipment and infrastructure changes.

**Human ring chromosome atlas: A web-based registry and a comprehensive review of ring chromosome cases in the Chinese population.** Q. Hu<sup>1,2</sup>, H. Chai<sup>1</sup>, P. Li<sup>1</sup>. 1) Genetics, Yale School of Medicine, New Haven, CT; 2) Cell Biology and Genetics, Guangxi Medical University, Nanning, Guangxi, China.

**Background:** Human constitutional ring chromosomes are a rare type of chromosomal structural abnormality. Ring chromosome syndrome featuring growth retardation and intellectual disability is likely attributed to the dynamic behavior of ring chromosome through cell cycles. Chromosomal specific phenotypes likely result from segmental losses and gains during the ring formation. Although recent applications of genomic analyses revealed various ring chromosome structures from an increasing number of case studies, there are no organized efforts for compilation and curation of ring chromosome findings.

**Human Ring Chromosome Registry and Tested Cases:** We developed a web-based 'Human Ring Chromosome Registry' using Microsoft Access relational database with online implementation by active server page and internet information services. To test and validate this ring chromosome registry, we collected and input ring chromosome cases reported in the Chinese population through a search of Chinese medical literature and PubMed publications from 1979 to 2017. **Ring Chromosomes in Chinese Population:** From a total of 95 cases, ring chromosomes were detected in all chromosomes except chromosomes 7, 16, 17 and 19. The most frequently seen by a decreasing order of relative frequencies were ring chromosomes 13 (14%), X (11%), 15 (9%), 22 (9%), 14 (8%), 18 (7%), 6 (5%), and 9 (5%). Distal deletions ranging from 60 Kb to 9 Mb were noted in thirteen cases analyzed by microarray analysis and in two cases by genome-wide sequencing. Four cases were diagnosed prenatally, 68 cases were noted in perinatal or pediatric clinic assessment, and six cases were noted in infertility clinics. Shared phenotypes of developmental delay, dysmorphic facial features, microcephaly, hypotonia, speech difficulty, low birth weight, growth retardation and intellectual disability were noted in most autosomal rings. Chromosomal or regional specific phenotypes included Wolf-Hirschhorn syndrome in a ring chromosome 4, cri-du chat in a ring chromosome 5, epilepsy in ring chromosome 14, Turner syndrome in ring chromosome X, and infertility in ring chromosomes 13, 21, 22 and Y. **Conclusions:** This newly-developed Human Ring Chromosome Registry summarized the relative frequencies, cytogenomic and clinical findings of reported constitutional ring chromosomes in the Chinese population. It represents an initial effort toward a systematic compilation of cytogenomic and phenotypic findings of ring chromosome cases.

**Uniparental isodisomy X: Evidence for monosomy rescue.** *K. Rudd<sup>1</sup>, J. Schleede<sup>1</sup>, S. Williams<sup>2</sup>, K. Lee<sup>3</sup>, J. Laffin<sup>2</sup>, R. Pasion<sup>1</sup>, J. Tepperberg<sup>1</sup>, P. Papenhausen<sup>1</sup>.* 1) Center for Molecular Biology and Pathology, Laboratory Corporation of America Holdings, Research Triangle Park, NC; 2) Savannah Perinatology Associates, Savannah, GA; 3) University of Wisconsin Madison, Wisconsin State Laboratory of Hygiene Clinical Genetics Laboratories, Madison, WI.

10-15% of girls with Turner syndrome have mosaicism for 45,X and 46,XX cell lines. Though X chromosome mosaicism has important implications for clinical presentation and fertility, the meiotic and/or mitotic mechanisms for monosomy X mosaicism are not well understood. Here we report four cases of 45,X/46,XX mosaicism with uniparental isodisomy (UPI) for the X chromosome. Subject 1 was first assessed prenatally due to IUGR and a positive non-invasive prenatal screen (NIPS) for monosomy X. Prenatal microarray analysis revealed normal copy number and homozygous SNPs across the entire X chromosome; microsatellite analysis confirmed paternal UPI X. Though FISH and chromosome analysis of amniocentesis and peripheral blood samples revealed two X chromosomes in all cells, FISH of the placenta showed a single X chromosome in 67% of nuclei, consistent with mosaic monosomy X that may be confined to the placenta (CPM). The other females were tested after birth and had monosomic and disomic X cells in peripheral blood. Subject 2 was a newborn with a 45,X[9]/46,XX[11] karyotype who was tested due to a family history of intellectual disability (ID). Subject 3 was tested at 14 years old due to short stature and had a 45,X[25]/46,XX[5] karyotype. Unlike the other subjects, Subject 4 had a structural X chromosome abnormality related to her ID. At 5 years old, chromosome analysis revealed three cell lines: 46,X,+mar[10]/45,X[2]/46,XX[8]. The small marker chromosome was visible via microarray analysis as a 5.86-Mb copy number gain that flanked the X centromere and did not include the *XIST* gene. SNP microarray analysis revealed homozygosity across the entire X chromosome for all three postnatal cases. These results support a model where the conceptuses arose as 45,X females, likely due to a nullisomic gamete or loss of an abnormal sex chromosome, and then doubled the remaining X chromosome during development to generate 45,X/46,XX mosaicism with UPI X. Rather than the more common trisomy rescue mechanism in autosomal UPD, we propose that UPI X arises via monosomy rescue. These findings have important implications for monosomy X detected during NIPS, since a monosomy X cell line that is rescued early in embryogenesis could be CPM with minimal effects on the fetus. This could explain at least some of the monosomy X false positives from NIPS. Furthermore, cryptic monosomy X rescue likely contributes to the survival of some Turner syndrome fetuses detected prenatally.

**2551W**

**Variant of Turner syndrome 45, X/46Xdel(X)(q21) mosaicism: A case report.** *G. Giraldo<sup>1</sup>, M. García-Acero<sup>1,2</sup>, O. Moreno<sup>1</sup>, F. Suarez-Obando<sup>1,2</sup>, C. Cespedes<sup>2</sup>, J. Perez<sup>2</sup>, J.C. Prieto<sup>1</sup>, N. Fernandez<sup>2</sup>, J. Auli<sup>2</sup>, A. Rojas<sup>1</sup>.* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogotá, Bogotá D.C., Colombia; 2) Hospital Universitario San Ignacio, Bogotá, Colombia.

**Introduction:** Turner syndrome (TS) is the most frequent alteration in the sex chromosomes. It results from the complete or partial absence of the X chromosome, associated with another cell line, which might be 46/XX, 46/XY or other rearrangement. The characteristics of the syndrome are short stature, gonadal dysgenesis, cardiac and renal defects, webbed neck, low-set ears and skeletal anomalies. Patients with Xp deletion have low stature and different birth malformations. Those with Xq deletion often have gonadal dysgenesis. It has been suggested that the phenotype is closely linked to the associated cell line in case of mosaicism. **Case presentation:** A 16-year-old female presented to genetic consultation because of primary amenorrhea. She is a product of normal spontaneous vaginal delivery and had normal development milestones. Physical examination revealed a young female with few secondary sexual characteristics, wide neck and short stature. G-band karyotype showed 45,X[29]/46,X,del(X)(q21).nuc ish(DXZ1x1,SRY-,DYZ1-) [59/100] / (DXZ1x2,SRY-,DYZ1-) [41/100]. The interpretation of this analysis revealed Turner syndrome in mosaicism form with two different cell lines; one with full monosomy X and a second with distal deletion of the long arm of the chromosome X. Other complementary lab tests showed hypogonadotropic hypogonadism. A pelvic ultrasound showed infantile uterus without evidence of ovaries. **Discussion:** The absence of the short arm of the X-chromosome is associated with the classic Turner syndrome, while deletions of the long arm are associated with gonadal dysgenesis. Proximal deletions of Xq are related to primary amenorrhea, lack of breast development and complete ovarian failure, in that Xq13 is the key region for ovary maintenance, unlike the compromise of Xq21, they may menstruate. About deletions, it is crucial to detect not only the presence of a structural alteration but also the chromosomal level where it occurred and to define the deleted area. This precision will make it possible to establish the diagnosis and the prognosis since there are some patients with structural alterations of chromosome X who only present menstrual irregularities or premature menopause, and given the reports of cases with familial inheritance, the genetic counseling becomes more meaningful.

**2552T**

**A unique case of male/female chimerism in buccal specimen due to a bone marrow transplant.** *H. Risheg<sup>1</sup>, R. Pasion<sup>2</sup>, K. Barnes<sup>3</sup>, M. Schwab<sup>3</sup>, S. Schwartz<sup>2</sup>.* 1) Laboratory Corporation of America® Holdings/Dynacare, Seattle, WA; 2) Laboratory Corporation of America® Holdings, Center for Molecular Biology and Pathology, Department of Cytogenetics, Research Triangle Park, NC; 3) Hackensack Meridian Health, Genetic Services, Hackensack, NJ.

Over the past decade microarray technology has allowed the detection of chromosomal aberrations not routine seen with standard analysis. However, it has also provided a better understanding of specimens from patients received in the laboratory. Here we describe a unique case of a 21 year old female with a clinical history of dysautonomia, cataracts, anxiety and short stature, and a history of acute lymphoblastic leukemia. Buccal swab was performed and sent in for SNP/CN microarray analysis which identified a sex chromosome mosaicism with 85% of cells with XX and 15% of cells with XY suggestive of chimerism. Based on the sex chromosome findings and the unusual pattern allele tracks and homozygosity seen, this was believed to be due to a bone marrow transplant from a male sibling, which was subsequently confirmed by the referring physician. Interestingly, the array also identified a mosaic 12 Mb interstitial deletion of 15q14-q21.1. However, this deletion was only present in 15% of the sample suggestive that the deletion is t in the male transplant donor rather than in the proband. By report this sibling has learning disabilities, which to date does not have an underlying etiology, but may be associated with the deletion. Overlapping deletions of this 15q deletion have been reported with clinical features that include craniosynostosis, congenital heart defects, limb abnormalities, urinary abnormalities and bone maturation. In this complicated array there were also multiple chromosomes identified with regions of allele homozygosity totaling 41.1 Mb, suggesting a distant parental relationship or common decent. This case highlights the clinical utility of the SNP microarray analysis in allowing the correct delineation of complex findings. In this patient it clearly indicated the true nature of the chimerism prior to clinical information being available and it was able to indicate that the deletion appears to be in the donor rather than proband.

**2553F**

**Landscape of disorders of sex development with mosaicism.** *A. Rojas<sup>1</sup>, O. Moreno<sup>1,2</sup>, M. García-Acero<sup>1</sup>, AS. Clavijo<sup>2</sup>, J. Perez<sup>2</sup>, N. Fernandez<sup>1</sup>, I. Zarante<sup>1</sup>.* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogota, 1, Colombia; 2) Hospital Universitario San Ignacio, Bogota, Colombia.

**Introduction:** Disorders of sex development (DSD) are congenital conditions in which the development of chromosomal, gonadal or anatomical sex is atypical. The chromosomal sex based on the result from karyotype is currently considered to be the main finding for classifying the DSD. 45,X/46,XY mosaicism and variants of it are considered to be a phenotypically very heterogeneous condition, the clinical phenotype may range from female external genitalia with mild clitoromegaly, through ambiguous genitalia, to isolated hypospadias or normal male external genitalia. **Cases series:** We report 3 patients with a DSD diagnosis in whom chromosomal mosaicism was found in a sample of peripheral blood or gonadal tissue. The chromosomal analysis included high-resolution G and FISH with a specific probe to evaluate the presence of the SRY gene in blood or gonadal tissue when it was possible. 2 patients were assigned male gender and 1 patient was assigned female gender. One of the boy clinically with hypospadias and bilateral cryptorchidism showed a karyotype 46,XX [100] with intraabdominal finding of Wolff duct derivatives in left side and Mullerian duct derivatives in right side with histology of fibrous bands of ovarian stroma. Gonadal karyotype showed RG 1: mos 92,XXXX[8]/46,XX[42] LG 2: mos 92,XXXX[12]/46,XX[38]. The other boy clinically with hypospadias and bilateral cryptorchidism showed a karyotype 45,X[4]/46,XY[96] with histological finding in gonadal biopsy of gonadoblastoma and gonadal karyotype showed mos 45,X[97]/46,XY[3]. The girl had hypertrophic clitoris, aorta coarctation and short stature in karyotype was evident mos 45,X[19]/46,XY[23]/47,XY[8]. ish Yp11.31(SRY-)/idic(Y)(p11.31)(SRY+ +)/idic(Y)(p11.31)(DYZ1-,SRY+ +)x2. **Discussion:** Mosaicism is defined as the presence of two or more chromosomal lineages in the same individual. The different distributions of the 45,X and 46,XY chromosomal cell lines among the tissues in individuals with this mosaicism presumably reflect the wide variety of phenotypes observed. In our study, the individuals with 45,X/46,XY mosaicism ranged from phenotypically men with hypospadias and to Turner syndrome phenotype. This explain one of the most important and difficult points in treating patients with 45,X/46,XY mosaicism, the decision about the sex of rearing.

**2554W****HLA-B\*1502 genotyping for the prevention of carbamazepine induced severe cutaneous adverse drug reactions (SCARs) in a children's hospital.**

*H. Law<sup>1</sup>, L. Ching<sup>1</sup>, W. Low<sup>1</sup>, Y. Tan<sup>1</sup>, A. Lai<sup>1</sup>, D. Chan<sup>2</sup>.* 1) Genetics Service, KK Women's & Children's Hospital, Singapore, Singapore; 2) Neurology Service, KK Women's & Children's Hospital, Singapore, Singapore.

Carbamazepine (CBZ) is a common medication prescribed to control recurrent seizures. Clinical studies have demonstrated a strong association between HLA-B\*1502 allele and risk of CBZ - induced Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) which are known to be associated with significant mortality and long term morbidity, with an odds ratio of 1357 for Han Chinese. Since 2013 genotyping for the HLA-B\*1502 allele has been made mandatory prior to the initiation of CBZ therapy in new patients of Asian ancestry. Our hospital started offering the test in 2014. Genotyping was carried out using the One Lambda-Micro SSP HLA Class I B Locus Specific Kit (SSP1B). Most of the results were returned within 24 hours. In 3 years (2014 to 2016), 309 patients aged 25 days to 20 year old (median age 7) were tested. HLA-B\*1502 was found to be positive in 34 (11.00%). Breaking down into 3 main ethnicities, the Chinese, Malay, and Indian, which make up 76.2%, 15.0% and 7.4% of the population respectively, the Malay was found to have the highest positive rate (9 out of 59, or 15.25%), followed by the Chinese (21 out of 195, or 10.77%). None of the 26 Indian patients tested carried the HLA-B\*1502 allele. However, a relatively high positive rate (4 out of 29, or 13.79%) were found in the "other" ethnic group. This "other" ethnic group, made up of migrants from Indonesia, northern Malayan peninsula and other mixed ethnicities, accounts for about 1.4% of the population. Since the implementation of HLA-B\*1502 genotyping there were no new cases of SJS and TEN. In contrast there were 5 cases of carbamazepine-associated SJS /TEN in this hospital in the 7 years prior to implementation of testing. HLA-B\*1502 testing has been effective in reducing morbidity due to administration of CBZ.

**2555T**

**Clinical whole genome sequencing in a pediatric hospital.** *C. Saunders<sup>1,2,4</sup>, E. Farrow<sup>1,3,4</sup>, N. Miller<sup>1</sup>, M. Gibson<sup>1</sup>, L. Zellmer<sup>1,2,4</sup>, D. Faller<sup>1,2</sup>, S. Soden<sup>1,3,4</sup>, I. Thiffault<sup>1,2,4</sup>.* 1) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO 64108; 2) Department of Pathology and Laboratory Medicine, Children's Mercy Hospital, Kansas City, MO 64108; 3) Department of Pediatrics, Children's Mercy Hospital, Kansas City, MO 64108; 4) University of Missouri-Kansas City School of Medicine, Kansas City, MO 64108.

Clinical exome sequencing is a widely used and powerful tool for the diagnosis of rare genetic diseases, affording coverage of the coding region at a fraction of the cost of running clinical whole genome sequencing (cWGS). However, there are pros and cons to both methods, with exomes offering higher sequencing depth, albeit more biased coverage. Paradoxically, the laboratory time to process a genome is shorter; but the costs of sequencing and storage are higher. Although WGS includes noncoding regions, they are largely unanalyzed in the clinical setting. For all these reasons, the use of WGS is generally limited to the research setting. Here we report for the first time, the use of cWGS in a pediatric setting, including our process, ordering metrics, diagnostic yield, and reimbursement. Parental samples are requested for concurrent WES, however only a single report, including inheritance, is issued for the proband. All consents are done by genetic counselors. Secondary findings of known and/or expected pathogenic variants, are reported for the recommended ACMG gene list, if requested. In an 18<sup>th</sup> month period, 74 cWGS were ordered with 73% performed with WES on both biological parents, ~5% on proband only. Insurance preauthorization was obtained for 73% patients and 26% were inpatient (no preauthorization required). Average insurance reimbursement was 28%, with yield for commercial payers significantly higher, at 66%. Moreover, 22% received definitive diagnoses, including 1 patient with 2 diagnoses. An additional 3 patients have likely positive results, pending functional studies. Of the 25% definitive or potential diagnoses, 47% were *de novo*. Incidental findings were reported in 4% of families who requested them; with 8% of families opting out. In two cases, cWGS revealed the breakpoints of large deletions and absence of heterozygosity in recessive genes harboring a missense variant on the other allele. Having this more complete information lead to a more direct and potentially faster diagnosis that may have been otherwise overlooked, however, in the majority of cases exome sequencing would have been comparable. Overall diagnostic yields for cWGS are similar to those reported for WES in this small but unbiased study, suggesting WES is currently more cost effective.

**2556F**

**Single exon resolution copy number analysis significantly increases clinical sensitivity of NGS.** *R.R. Kelly, N.A. Rouse, W.A. Langley, P.L. Nagy.* MNG Laboratories, 5424 Glenridge Drive NE, Atlanta, GA 30342.

The detection of copy number variants (CNVs) is essential to providing a comprehensive approach to reaching a differential diagnosis. Typically, a large-scale method such as array-based copy number analysis is used to detect larger variations across the genome. While these methods offer a more efficient approach to covering a wide genomic area, they often fail to identify smaller CNVs that may be causative of a patient's phenotype. In our custom next generation sequencing (NGS) panels, we seek to provide a more comprehensive diagnosis through the detection of CNVs down to a single exon resolution. Using a custom designed capture reagent and the EXCAVATOR copy number analysis software, we are able to detect CNVs of greater than ten exons across all genes included in our panels. Additionally, we are able to detect CNVs at single exon resolution through the use of supplementary intronic probes for all genes with known pathogenic CNVs of ten exons or fewer. Since the inclusion of copy number analysis with our custom NGS panels in September 2016, we have seen a 1.6% increase in the total number of positive reports issued. Here we present multiple case studies in which single exon resolution copy number analysis was crucial in reaching a diagnosis across a variety of phenotypes.

**2557W**

**A comparative study of the CYTAG® CGH and CYTAG® SuperCGH DNA labeling kits to detect CNVs with small amounts of DNA.** *A.L. Mosca-Boidron, N. Marle, M. Payet, C. Ragon, J. Szczepaniak, D. Callegarin, M. Poulleau, P. Callier.* Laboratoire de Génétique Chromosomique et Moléculaire, DIJON, France.

Array comparative genomic hybridization (aCGH) is a powerful clinical diagnostic tool that can be used to evaluate copy number variation (CNV) changes in the genome. The detection of CNVs (gains and deletions) depends on the quality and quantity of DNA, especially for prenatal or oncology samples. Until now, aCGH in diagnosis has been done using more than 1µg of DNA, as recommended by several manufacturers. The principle of aCGH is based on the quantitative comparison between a test DNA and a reference DNA, which depends on the labeling of DNA. Here, we present a new aCGH labeling kit called CYTAG® SuperCGH labeling kit that accurately detects CNVs with less than 100ng of DNA and compare this new kit with the one previously used in our laboratory, namely CYTAG® CGH Labeling kit. Validation of the labeling procedure with this new kit included a comparison between the two commercial kits on 100ng of seven different samples: three Glioma cases (96ng, 32ng and 8ng), one postnatal case with three DNA quantities (90ng, 50ng and 30 ng), and one prenatal case with 90ng. CNVs in tumor samples (Glioma), postnatal and prenatal samples were compared. QC metrics were compared for samples labeled separately using each kit. For Glioma, DLRS were 0.43 vs 0.34 and 0.26 vs 0.21 with the traditional and new labeling kit, respectively. The Glioma sample with only 8ng of DNA gave a DLRS of 0.19 with the new kit but no comparison was possible as there was not enough DNA for the other kit. For postnatal cases, the DLRS were 0.14 vs 0.12; 0.17 vs 0.13; 0.21 vs 0.14. Finally, DLRS were 0.21 vs 0.16 for the prenatal case. The two kits allowed the detection of CNVs with better DLRS spread values and higher signal-to-noise ratios with the new CYTAG® SuperCGH labeling kit. Requirements for validation were achieved successfully and the comparative study showed that the labeling efficiency of the CYTAG® SuperCGH kit was higher than that achieved with the CYTAG® CGH kit. This study showed that the CYTAG® SuperCGH labeling kit was especially useful for CGH experiments using prenatal, postnatal and tumor samples. Moreover, we showed that Glioma-CNV could be detected in as little as 8ng of DNA. This technology is particularly useful in diagnosis where small amounts of DNA are available, and offers new possibilities for aCGH analysis in prenatal, postnatal or oncology, where the samples are poor and precious.

**2558T**

**Gene-specific criteria for PTEN variant curation.** *J. Mester<sup>1</sup>, R. Ghosh<sup>2</sup>, T. Pesaran<sup>3</sup>, R. Karam<sup>3</sup>, R. Huether<sup>4</sup>, K. Hruska<sup>1</sup>, H. Costa<sup>5</sup>, K. Lachlan<sup>6</sup>, J. Ngeow<sup>7</sup>, J. Barnholtz-Sloan<sup>8</sup>, L. Zhang<sup>9</sup>, K. Sesock<sup>10</sup>, S. Plon<sup>2</sup>, M. Hegde<sup>11</sup>, C. Eng<sup>8,10</sup>.* 1) GeneDx, Gaithersburg, MD; 2) Baylor College of Medicine, Houston, TX; 3) Ambry Genetics, Aliso Viejo, CA; 4) Tempus, Chicago, IL; 5) Stanford University School of Medicine, Stanford, CA; 6) Princess Anne Hospital, Southampton, UK; 7) National Cancer Centre Singapore, Singapore; 8) Case Comprehensive Cancer Center, Cleveland, OH; 9) Memorial Sloan Kettering Cancer Center, New York, NY; 10) Cleveland Clinic Foundation, Cleveland, OH; 11) Emory University, Atlanta, GA.

*PTEN* was the first gene within the ClinGen Hereditary Cancer domain for which an expert variant curation group was assembled. The group was tasked with optimizing the ACMG/AMP Variant Interpretation Guidelines to specifically curate *PTEN* variants, with the hope of resolving variants with a ClinVar status of “conflicting interpretations of pathogenicity” or “uncertain significance”. We present our finalized benign and draft pathogenic *PTEN*-specific variant curation criteria. For benign criteria, modifications to current guidelines include setting allele frequency thresholds for stand-alone and strong criteria; creating criteria for homozygous observations, observations in trans with known pathogenic variants, and lack of segregation; and adding a supporting-level criterion for functional evidence. These criteria achieved a benign or likely benign classification for 13/15 (86.7%) consensus ClinVar benign/likely benign variants used as a test set. Optimizations to ACMG/AMP pathogenic criteria include setting boundaries for functional domains and use of very strong vs. moderate-level evidence for truncating variants; defining functional assays for strong or an added supporting-level evidence; defining phenotype required for supporting-level evidence; establishing numbers of meioses and families for segregation criteria; and allowing use of a strong criterion for more than one *de novo* occurrence without maternity/paternity confirmation. Given the paucity of known benign missense variants for validation of *in silico* predictors, the group did not adopt the existing pathogenic or benign supporting-level computational criteria for missense variants. The group also did not adopt the existing supporting-level evidence for a “reputable source” reporting a variant as pathogenic or benign given the requirement that classifications made by this group be highly evidence-based. Following testing of the pathogenic criteria on a set of 15 consensus ClinVar pathogenic/likely pathogenic variants, all criteria will be used to curate a final test set of ClinVar variants with conflicting interpretations or of uncertain significance. The final criteria will be incorporated along with the curation process into the expert panel application. These criteria will be compared with gene-specific optimizations developed by other ClinGen expert panels to identify common and unique modifications to the ACMG/AMP guidelines.

**Covering all the bases: Case vignettes and diagnostic pipelines at the Stanford Center for Undiagnosed Diseases.** *A.M. Dries<sup>1,2</sup>, J. Kohler<sup>1,2</sup>, D.B. Zastrow<sup>1,2</sup>, D. Bonner<sup>1,2</sup>, J. Davison<sup>1,2</sup>, L. Fernandez<sup>1,2</sup>, C. McCormack<sup>1,2</sup>, M. Majcherska<sup>1,2</sup>, S.B. Montgomery<sup>3,6</sup>, D. Waggot<sup>1,2</sup>, S. Marwaha<sup>1,2</sup>, C. Prybol<sup>1,2</sup>, N. Friedman<sup>1,2</sup>, U.D.N. Members<sup>9</sup>, J. Sampson<sup>1,8</sup>, J. Hom<sup>1,7</sup>, P. Fisher<sup>1,4,8</sup>, E.A. Ashley<sup>1,2,6</sup>, J. Bernstein<sup>1,4,5</sup>, M. Wheeler<sup>1,2</sup>.* 1) Stanford Center for Undiagnosed Diseases, Stanford University, Stanford, California 94305-5406; 2) Division of Cardiovascular Medicine, Stanford University, Stanford, California 94305; 3) Department of Pathology, Stanford School of Medicine, Stanford, California 94305-5324; 4) Department of Pediatrics, Stanford School of Medicine, Stanford, California 94305-5208; 5) Lucille Packard Children’s Hospital Stanford, Palo Alto, California 94304; 6) Department of Genetics, Stanford School of Medicine, Stanford, California 94305-5208; 7) Department of Medicine, Stanford School of Medicine, Stanford, California 94305; 8) Department of Neurology, Stanford School of Medicine, Stanford, California 94305; 9) NIH Undiagnosed Diseases Network, Common Fund, Office of the Director and the National Human Genome Research Institute, National Institutes of Health, Bethesda, Maryland 20892.

Since the launch of the Undiagnosed Diseases Network (UDN), the Stanford Center for Undiagnosed Diseases (CUD) has evaluated more than 60 cases of very rare or unique disease. Of those cases at the CUD with initial genetic and clinical evaluation completed, over 50% of these cases have either a clinical or genetic diagnosis while other cases remain unsolved. Initial evaluation at the Center includes: precise phenotyping, exome or genome sequencing, metabolomic studies, and network-wide clinical case matching. For the unsolved cases with completed initial evaluations, unique strategies are being employed to improve the diagnostic yield. The Stanford Center for Undiagnosed Diseases uses several multi-omics pipelines to investigate these initially unsolved cases. These clinical case driven pipelines include analyzing research genetic variants at the UDN Model Organism Screening Core, multi-tissue RNA-seq, immune profiling, microbiome analysis, long read genome sequencing, metabolomics, deep sequencing, and mosaicism analyses. With these additional tools, the Stanford Center for Undiagnosed Diseases can further evaluate these undiagnosed cases. Six unsolved cases are presented here and highlight these comprehensive diagnostic pipelines.

**VarSome, the Human Genomic Variant Search Engine.** A. Massouras. Saphetor, Lausanne, Vaud, Switzerland.

There is now a wealth of information available about human genomic variants. However, this is usually distributed across multiple, independent databases, which greatly complicates the collection of available information on a given variant. Here, we present VARSome, a novel knowledge base and aggregator for human genomic variants. It provides an intuitive web-based interface, offering access to the more than 30 billion items of variant and gene annotation we have accumulated in less than a second per query. Varsome provides functional annotation, calculated in real time using the RefSeq and Ensembl transcript databases; it correctly matches (and displays) equivalent indels to annotations; it displays disease and phenotype associations, drug interactions, relevant clinical trials, population frequencies, and prediction scores from a multitude of sources. The large number of external sources is regularly updated to the most recent release. Variants can be searched in VarSome in many different ways including dbSNP rsIDs, explicit descriptions using HGVS notation or genomic coordinates (e.g. BRAF:V600E, chr6-161127501-A-G) or even by pasting a line from a VCF file. Varsome is not limited to known variants: the user may obtain functional annotation for any variant. Users can mark favorite variants, post comments or link articles to specific variants which will be visible to anyone else who visits that variant. This provides an easy and centralized way of sharing information about known or novel variants. Varsome also provides stable, unique links to any variant, known or not, facilitating the sharing of variants between collaborators. VarSome is freely available to the community on [varsome.com](http://varsome.com).

**2561T**

**Going beyond the ACMG recommendations for reporting secondary findings: From decision-making to follow-up.** N.T. Strande<sup>1</sup>, J. Booker<sup>1</sup>, A.K. Foreman<sup>1</sup>, G.T. Haskell<sup>2</sup>, K. Lee<sup>1</sup>, J.M. O'Daniel<sup>1</sup>, B. Powell<sup>1</sup>, M. Roche<sup>1</sup>, B.A. Seifert<sup>1</sup>, J.P. Evans<sup>1</sup>, K.E. Weck<sup>1</sup>, J.S. Berg<sup>1</sup>. 1) UNC Hospitals, Chapel Hill, NC; 2) Duke University, Durham, NC.

As clinical laboratories implement genome-scale sequencing for diagnostic purposes, they must consider secondary findings (SF) and decide which to report. The American College of Medical Genetics and Genomics (ACMG) recommends reporting known or expected pathogenic variants in 59 genes deemed highly actionable, however only a small number of disease-associated genes were systematically reviewed for inclusion on the list. Furthermore, the full phenotypic spectrum and penetrance associated with suspected pathogenic variants in these genes has not been established. The North Carolina Clinical Genomic Evaluation by Next-generation Exome Sequencing (NCGENES) project analyzed participant exomes for pathogenic and likely pathogenic variants in a list of 165 medically actionable genes partially overlapping the ACMG recommended list and some additional conditions. The overall rate of SF was 2.99% (20/669) consistent with prior studies and did not vary by age, sex, or race. Variants reported as SF were found in 13 genes, including 4 on the ACMG list (*BRCA2*, *MSH6*, *KCNQ1*, and *SCN5A*) and 9 others (*BRIP1*, *PALB2*, *FH*, *BCHE*, *SERPIN1C*, *F8*, *HBB*, *PROC*, and *BTD*). Most SF were in *SCN5A* (3 cases) and *F8* (3 cases). Clinical follow-up (analyte testing and symptom review) to confirm a diagnosis consistent with the SF occurred in 12/20 cases: 6 negative, 3 positive, and 3 unclear. Negative follow-up evaluation could be due to variant over-interpretation (false positive) or an overdiagnosis (due to variable expressivity and/or incomplete penetrance). SF suggestive of long QT (LQT) syndrome comprised the majority of results with negative follow-up evaluation (4/6). The remaining 2 negative follow-up evaluations were in patients with *F8* SF and normal factor VIII levels. A third patient with a family history of hemophilia had a hypomorphic *F8* allele, but subclinical levels of factor VIII complicating clinical management. Although many of our SF were negative upon follow-up, it is unclear whether these patients will remain asymptomatic or if these results represent true false positives. Our results suggest a need to better define the spectrum of pathogenic variants found in medically actionable genes and their associated phenotypes, and highlight the need to better define the penetrance and expressivity of SF in asymptomatic populations. It will be critical to set thresholds for return of results that strike a balance between case finding versus false positive/overdiagnosis results.

**2562F**

**The discussion of whether in vitro fertilization (IVF) or preimplantation genetic diagnosis (PGD) in inv(9) carriers.** *H. Chen<sup>1</sup>, W.E.I. Wu<sup>1,2</sup>.* 1) Nanjing Medical University, Nanjing, China; 2) Jiangsu Province Hospital.

**Objective:** Research on whether and which type of INV(9); need PGD.  
**Design:** 453 Couples having INV(9); were analyzed in this retrospective case-control study, and some data come from periodical literature. Blastomeres or blastocysts from these couples were analyzed by next-generation sequencing technique. Data was tested by the chi-square test. **Results:** For various types of inv(9), 35.1% were inv(9)(p12;q21), 21.7% were inv(9)(p12;q13). The number of all fresh embryos and frozen embryo transplantation period is 723, the clinical pregnancy rate was 42.5%, biochemical pregnancy rate was 50.3%, the abortion rate was 5.4%. There were 63 couples not pregnant with two or more IVF, with the exception of the uncommon subtype (p11; q13) is the highest rate subtype with not pregnant, followed by (p12; q21). The age of Most of them are over 35 years old. The inverted segment located at the end of the chromosome such as p24, and q34 had a lower clinical pregnancy rate. In 41 couples with PGD, the number of transplantation period is 42, the clinical pregnancy rate was 66.7%, biochemical pregnancy rate was 71.4%, the abortion rate was 11.9%. The clinical pregnancy rate of PGD is higher than the rate of IVF, chi-square is equal to 9.45, the difference has statistical significance, and the miscarriage rate of PGD is higher than IVF abortion rate, chi-square is equal to 3.1, the difference do not has statistical significance. **Conclusions:** In this study, the distribution of the inv(9); subtype is in accordance with previous report that the common breaking point of INV(9); located in 9p12 or 9q13-21.1. Regular IVF can solve reproductive problems of most of the patients, but the pregnancy rate of only one transplanted is low. Compared IVF with PGD, PGD can increase the clinical pregnancy rate, but the impact on the abortion rate is not clear. In the case of recurrent miscarriage, advanced age, and the large inversion fragment were advanced to undergoing PGD. Besides on the basis of this study and the previously report that inv(9)(p24.3;q34.1) has had live births with adverse clinical phenotype, for segments of inversion is located at the end of chromosomes also recommend PGD. In addition depend on the report that the segment q21 - q22 may be pathogenic, the patients with q21-q22 inversion may be recommended to PGD to reducing the risk of neonatal have disease due to chromosomal problems.

**2563W**

**Improved molecular tracking of individual genomes for clinical whole-genome sequencing.** *S. Batalov, Y. Ding, S.A. Nahas, S. Chowdhury, J. Cakici, S. Caylor, S. Kingsmore, D.P. Dimmock, N. Veeraraghavan.* Rady Children's Institute for Genomic Medicine, San Diego CA.

The speed, accuracy and lowering costs of whole-genome sequencing (WGS) can change the acute care of infants in the intensive care units (ICU). In a clinical setting, it is imperative to establish a robust and scalable system for chain-of-custody of every patient's genome through all steps of the high volume rapid sequencing lab and *in silico* workflows. Beyond routine workflow solutions, such as barcoding of tubes and plates, most clinical laboratories employ some method of molecular fingerprinting of genomic samples. Many of these solutions are costly or not fast enough to be deployed in a clinical laboratory performing large numbers of rapid WGS tests. Short-tandem repeat (STR) variations have been useful in assigning identity in wide-ranging areas of human genetics. We present a scalable and cost-effective framework based on established STR markers, specifically tuned for ultra-rapid turn-around-time, and that is well suited to an Illumina-based clinical whole genome workflow. Upon parental consent, for each entering DNA sample, duplicate aliquots are stored – one for the Rapid WGS workflow, and the other for later confirmatory PCR-guided Sanger sequencing for the confirmation of pathogenic variants prior to the return of patient results, under IRB protocol 160468. PCR-guided Sanger sequencing and identity testing involves using a very small portion (0.5-1 ng) of extracted gDNA used in the conventional and inexpensive GlobalFiler STR allelotyping workflow using a standard ABI 3500 or 3100 sequencer. The identity match of the two aliquots is ensured by using short-read WGS sequencing data after Illumina 2500/4000 sequencing by *in silico* independent determination of the STR allelotyping using a modified lobSTR (Gymrek M. et al. (2012)) computational workflow. To reduce the computational time, the BAM file can be restricted to the vicinity of the 18 STR regions (as well as two non-STR X/Y-linked markers). Because all accurate genomic mapping are readily available after the computational workflow, the overhead for the STR allelotyping implementation is minimal (<5 CPU-minutes per sample; the reagent cost is ~\$25 / sample). The output alleles for all STR markers establish a unique fingerprint that ensures specificity of at least  $1/10^{15}$ . Recent improvements to the workflow (including additional non-STR marker (Y-indel) and a comprehensive cross-match testing in typical and in consanguineous families) will be presented.

**2564T**

**Workshop in genomic medicine for paediatric specialists.** *A.D. Gilbert<sup>1</sup>, E. Bedoukian<sup>7</sup>, L. Kyriakopoulou<sup>2</sup>, C.R. Marshall<sup>1,5,6</sup>, M.S. Meyn<sup>1,2,3,4</sup>, S.M. Jamal<sup>2,6</sup>, N. Monfared<sup>1</sup>, S. Bowdin<sup>1,2,3</sup>.* 1) Centre for Genetic Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Departments of Paediatrics, University of Toronto, Toronto, ON, Canada; 4) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 5) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Genome Diagnostics, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 7) Children's Hospital of Philadelphia - Roberts Individualized Medical Genetics Center, Philadelphia, PA, USA.

**Background:** The clinical application of exome and genome sequencing is revolutionizing the diagnosis of genetic disorders due to the high diagnostic yield of these genetic tests. Not only does this impact the services available to a family, it can provide an explanation, recurrence risk, anticipatory guidance and, in many cases, management improvement. Since there are not enough genetic health care professionals to facilitate the coordination and testing of all children suspected of a genetic disorder, more responsibility will rest with the paediatric specialist. The literature shows that the medical genetic knowledge base of the practicing non-genetics clinician is insufficient. Hence, our own ASHG: Genomic Medicine Education Consortium strives to improve access and quality of genomic educational resources for the practicing clinician. **Objective:** To establish the SickKids paediatric faculty's comfort level with counseling and offering genomic testing, a survey was electronically distributed. Based on the results of this e-survey, a half-day workshop was developed. **Method:** The Centre for Genetic Medicine hosted a 2.5-hour, small group, didactic workshop focusing on the key components of performing clinical genomic sequencing and returning results in the pediatric setting. The target audience was pediatric specialists at SickKids. **Results:** Twenty-five individuals registered for the workshop, and 14 attended. Data was obtained from question sets distributed at the beginning and end of the workshop, in addition to a feedback evaluation. **Conclusions:** Based on the feedback, this workshop was a needed addition to the genomic education of SickKids providers. 91% of the respondents said they would recommend the workshop, 67% thought the 2.5 hour time-frame was "just right" in length, the majority gave all the lecturers positive feedback, and 55% agreed strongly they were "more prepared to effectively integrate genome testing into my practice." Despite the apparent success from these parameters, the 44% no-show rate suggests another mode of information delivery should be considered. Thus, we will be offering 1-hour in-service educational sessions for paediatric specialists with delivery of a comprehensive slide deck designed so that any genetic provider can deliver with confidence.

**Developing frameworks to evaluate diagnostic genomic testing strategies for rare disease and cancer.** *R. Scott<sup>1</sup>, Z.C. Deans<sup>2</sup>, E.R.A Thomas<sup>1</sup>, A. Hamblin<sup>1,3</sup>, E.V. Davison<sup>2</sup>, E. Graham<sup>2</sup>, R. Snow-Miller<sup>2</sup>, S. Wordsworth<sup>4</sup>, C. Turnbull<sup>1</sup>, N. Murugesu<sup>1</sup>, S. Henderson<sup>1,2</sup>, T. Fowler<sup>1</sup>, M.J Caulfield<sup>1</sup>, S.L. Hill<sup>1</sup>.* 1) Genomics England, London, United Kingdom; 2) NHS England, London, United Kingdom; 3) Oxford University Hospitals NHS Foundation Trust, Oxford, United Kingdom; 4) University of Oxford, Oxford, United Kingdom.

Advances in genomic technologies, including the feasibility of whole genome sequencing (WGS) have been demonstrated by the UK 100,000 Genomes Project and other published studies, to present a significant opportunity to improve genomic testing in rare disease and cancer patients. In response the National Health Service (NHS) in England is planning a substantial reconfiguration of genomic testing covering the complete testing spectrum from single gene through to WGS. This approach will deliver mainstreaming of cutting edge genomic technologies into the NHS. To inform the testing strategy in this reconfigured service, a working group was formed consisting of experts in clinical and laboratory genetics, cancer specialists, health economists, healthcare policy and commissioning experts, and patient representatives. The group sought to develop objective tools to evaluate the optimal genetic testing strategy for each clinical indication, recognising the need to be flexible and responsive to the emerging evidence base. Separate approaches were developed in rare disease and cancer. The tools took into account technical considerations such as number of known genes, pace of new discoveries, variant types relevant to indication, and the suitability of different technologies to detect these. Health economic assessment determined the value of the genomic testing strategy, not only of variant detection but also the overall patient care pathway. The tools were optimised with disease area experts before being applied across the spectrum of rare inherited disease and cancer. In rare disease, the resulting recommendations for each clinical indication included guidance on optimal test technology, family structure (trio or proband-only sequencing), and technical requirements. In future, annual review of the recommendations will allow incorporation of new genetic knowledge, and adaptation as sequencing technology and costs evolve. In cancer the systematic evaluation of genomic tests for a range of targets, in different tumour types, with clinically relevant testing times, will enable access to genomic medicine for all patients using the most effective and efficient approach. These tools will be presented together with an overview of their outputs and implications for the architecture of a comprehensive genomic testing strategy for the NHS.

**Benchmarking the quality of diagnostic next generation sequencing.** S. Deans<sup>1</sup>, M.W. Gutowska-Ding<sup>2</sup>, F. Khawaja<sup>1</sup>, K. Brugger<sup>3</sup>, J. Wook Ahn<sup>4</sup>, S. Abbs<sup>5</sup>, J. Coxhead<sup>6</sup>, P. Westwood<sup>6</sup>, K. Thompson<sup>7</sup>, C. Boustred<sup>8</sup>, G. Taylor<sup>9</sup>, E. Souche<sup>9</sup>, S. Sander<sup>10</sup>, B. Ylstra<sup>11</sup>, S. Patton<sup>2</sup>. 1) UK NEQAS, Edinburgh, United Kingdom; 2) EMQN, Manchester, United Kingdom; 3) Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom; 4) Viapath Genetics Laboratories, London, United Kingdom; 5) Institute of Genetic Medicine, Newcastle University, Newcastle, United Kingdom; 6) NHS Greater Glasgow & Clyde, Glasgow, United Kingdom; 7) The Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom; 8) Genomics England, London, United Kingdom; 9) Center for Human Genetics, Leuven, Belgium; 10) MUMC Clinical Genetics, Maastricht, Netherlands; 11) VU University Medical Center, Amsterdam, Netherlands.

Next Generation Sequencing (NGS) is being introduced into clinical genetics laboratories worldwide. It is not possible for the large amount of data generated by NGS to be duplicated by alternative methods to enable internal validation of all results, therefore external assessment of data quality and consistency is required. The European Molecular Genetics Quality Network (EMQN) and the UK National External Quality Assessment Service (UK NEQAS) for Molecular Genetics have developed a joint External Quality Assessment (EQA) scheme for NGS, with the aims to assess and improve quality, enable laboratories to benchmark their NGS service against others, work towards consistency of reporting clinical results generated by NGS and contribute towards defining best practice. EMQN and UK NEQAS offer many disease-specific EQA schemes, and the objectives for developing an NGS EQA were to make it generic (independent of genes tested, diseases, and platforms used), applicable to as many users as possible and to provide them with a broad range of quality indicators on their NGS data. So far, four pilot schemes have been provided. Laboratories were sent a genomic DNA or FFPE sample for sequencing using their usual approach, submit technical details, and genotypes of reportable variants detected. The sequence of the DNA provided was validated in three clinical laboratories using different NGS platforms. The two latest EQA runs (2015, 2016) were divided into Germline and Somatic NGS, in order to address the different challenges of NGS in these settings. Participating laboratories has increased from 30 in 2013, to 303 in 2016. We have established a pipeline to produce a consensus genome based on the EQA detected variants, reducing the need to rely on time-consuming and expensive prior validation. This has required the development of sophisticated tools for the integration and benchmarking of NGS data. These NGS germline and somatic EQAs are technology and testing context independent and seamlessly fit with wet laboratory and bioinformatics processes. Disease-specific EQA has improved the quality of results and consistency in clinical reports. The NGS EQA results enable clinical diagnostic laboratories to address the quality of their NGS testing. These technical NGS EQAs will play an important role in enabling laboratories to benchmark this new technology, assess the accuracy of data and facilitate high quality reporting for patient benefit.

**Correctly building, evaluating and using clinical grade pathogenicity classifiers for variant of unknown significance.** G. Bejerano<sup>1,2,3</sup>, K.A. Jagadeesh<sup>2</sup>, J.M. Paggi<sup>2</sup>, J.S. Ye<sup>2</sup>, J.A. Bernstein<sup>3</sup>. 1) Developmental Biology, Stanford University, Stanford, CA; 2) Computer Science, Stanford University, Stanford, CA; 3) Pediatrics, Stanford University, Stanford, CA; 4) Biology, Stanford University, Stanford, CA.

The diagnosis of known monogenic Mendelian disorders can be highly labor intensive, with more than 40 hours of expert time needed for individual diagnoses, when each patient may present up to 300 candidate genes. One way to alleviate clinician load in patient data analysis (and reanalysis) is to predict the likelihood that any observed rare variant in the patient genome may be pathogenic. The goal, per patient, is to predict as many variants of unknown significance (VUS) as "likely benign" while never misclassifying the 1-2 actual pathogenic variants in the patient as such. Many current pathogenicity classifiers either do not focus on Mendelian diseases (e.g., in their choice of training data), or test their predictions on data other than actual patient data. We have recently published (1) a novel clinical-grade Mendelian disease non-synonymous VUS pathogenicity classifier named M-CAP (Mendelian Clinically Applicable Pathogenicity). M-CAP can be explored via a dedicated web portal (2) and has also been kindly integrated into Annovar and dbNSFP. In our paper we show that very popular variant pathogenicity classifiers misclassify up to 38% of known pathogenic Mendelian mutations. We show M-CAP to outperform these methods at all thresholds and correctly dismisses 60% of rare, missense VUS in a typical genome at 95% sensitivity. Here we will extend on our published work in two ways: First, we will discuss the recent flourish of pathogenicity prediction tools. We will discuss some inadvertent errors that are possible in building such tools, or in comparing these tools to each other. This includes conflating rare and common variants, inflating performance by testing on data that was used by some classifiers, or the features they use, for training, and poorly balancing positive and negative data points during training, testing or comparison. We will show how omitting any of these rules results in misleading conclusions. We will discuss ways of circumventing these pitfalls, improving any classifier performance, and performing a fair assessment of multiple classifiers performance. We will also discuss, and give examples of how to best use these classifiers in the clinic. Finally, we will present our most recent unpublished work to improve and extend VUS pathogenicity prediction from the coding into the non protein coding genome. (1) Jagadeesh et al, Nat Genet 2016 <https://doi.org/10.1038/ng.3703> (2) <http://bejerano.stanford.edu/mcap>.

**Paternal inheritance of X chromosome CNVs aid in the interpretation of pathogenicity.** *R. Burnside<sup>1</sup>, M.K. Rudd<sup>1</sup>, I. Gadi<sup>1</sup>, K. Phillips<sup>1</sup>, A. Penton<sup>1</sup>, V.R. Potluri<sup>2</sup>, H. Risheg<sup>2</sup>, J. Schleede<sup>1</sup>, S. Schwartz<sup>1</sup>, J.H. Tepperberg<sup>1</sup>, P. Papenhausen<sup>1</sup>.* 1) Cytogenetics, Laboratory Corporation of America Holdings, Research Triangle Park, NC; 2) Cytogenetics, LabCorp, Houston, TX; 3) Cytogenetics, LabCorp, Seattle, WA.

Clinical microarray analyses are performed for an ever-expanding number of indications including infertility, intellectual disability, congenital anomalies, and parental follow up studies. CNVs found on the X chromosome in female patients are particularly difficult to interpret due to protection offered from random X inactivation. Parental studies of X-linked CNVs are important since paternal inheritance from a clinically normal father supports a benign interpretation. We report on a large cohort of X chromosome CNVs identified in female probands by microarray analysis which were paternally inherited. From August 2008-November 2015, 1784 X chromosome CNVs were reported in males and females, including those resulting from unbalanced structural rearrangements of the X chromosome. Of these, 1073 (60%) were found in females and 428 (24% of total 1784) were followed up with at least one parent. Of the 428 cases with follow up, 217 were female patients and 63 CNVs were paternally inherited. Two fathers were followed up after abnormal microarray results for their daughters performed at outside labs, both of whom were found to be clinically normal carriers. Of the 63 total confirmed paternal CNVs, eleven were deletions and 52 were copy number gains. Four deletions occurred in the PAR1 region, and three deletions included the STS gene region. Two females had paternally inherited exonic DMD deletions, and two other females with exonic DMD deletions were shown not to be maternally inherited (no paternal studies were done). The CNVs ranged from 53 kb to 2.28 Mb. While clinical information on most fathers was lacking, three paternal carriers were reported to be similarly affected as their daughters, suggesting that the duplicated regions may be associated with X inactivation skewing or escape inactivation and affect both males and females. These data will aid in the interpretation of pathogenicity for paternally inherited X chromosome CNVs.

**2569W**

**Considering other mechanisms of gene regulation in disorders of sex development.** *M. Molina<sup>1</sup>, M. García-Acero<sup>1,2</sup>, O. Moreno<sup>1</sup>, F. Suarez<sup>1,2</sup>, C. Cespedes<sup>2</sup>, J. Perez<sup>2</sup>, N. Fernandez<sup>2</sup>, J. Prieto<sup>1</sup>, J. Auli<sup>2</sup>, A. Rojas<sup>1</sup>.* 1) Instituto de Genética Humana, Pontificia Universidad Javeriana, Bogota, 11, Colombia; 2) Hospital Universitario San Ignacio, Bogota, Colombia.

Introduction: Disorders of Sex Development (DSD) are a heterogeneous group of entities related to sex assignment. The DSD are classified according to the categories of the International Consensus of Chicago (2006) as 46, XX, 46, XY or variants of the sex chromosomes like 45,X or 47,XY among others. Sexual differentiation is a complex, dynamic and genetically controlled process that depends on a delicate balance between sexual and autosomes genes. These genes are responsible for the tissue differentiation and the correct production of steroidogenic enzymes. Nowadays with the use of available techniques of molecular diagnosis, only 30 to 40% of individuals with DSD achieve diagnostic etiology. Therefore, in search of further causes of DDS, epigenetic modifications, must be considered as a relevant component of gene expression regulation in sexual differentiation. Methodology: transdisciplinary group of DDS of the Hospital Universitario San Ignacio performed a clinical and genetic characterization of 24 patients. The chromosomal analysis included high-resolution G and R-banding and FISH with a specific probe to evaluate the presence of the SRY gene. For assessing alterations in the number of copies of the NR0B1, SOX9, SRY, WNT4 and NR5A1 genes MLPA (Multiplex Ligation-dependent Probe Amplification) analyzes were performed using the SALSA MLPA P185-C1 Intersex MRC-Holland kit. Results: Twenty-four patients with DSD were analyzed. The clinical characteristics of these patients included hypospadias (29%), genital ambiguity (37%), male infertility (4%), primary amenorrhea (21%) and gonadal tumor (8%). 14 patients (58%) were assigned male gender, and 10 patients (42%) were assigned female gender. 19 individuals (79%) were 46, XY, 3 individuals (12%) were 46, XX, two patients (8%) presented mosaicism. Analysis of SRY-FISH was positive in all individuals XY. MLPA analysis was performed in all patients. Discussion: Most of our patients had no cytogenetic correlation with the assigned phenotype, making it difficult to assign diagnostic but justifying further studies. However, these results highlight the importance of carrying out the karyotype as an approach to etiological diagnosis, although it has been a questioned technique since it does not solve the controversy among gender assignment. It is worthwhile considering the hypothesis that some other genes are involved in the gonadal development and are susceptible of expression regulation by epigenetic mechanisms.

**Identifying single fetal trophoblastic cells in the maternal circulation: A modified NGS genotyping method.** X. Zhuo, Q. Wang, L. Vossaert, A. Kim, S. Qdaisat, R. Salman, A. Breman, A. Beaudet. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

**Background:** One of the challenges for cell based non-invasive prenatal testing (CB-NIPT) is to distinguish individual presumptive fetal cells from maternal cells in female pregnancies. We have sought a rapid, robust, versatile and low cost method to facilitate this assessment. **Methods:** For samples from 12-16 weeks gestation pregnancies, fetal trophoblastic cells were picked from maternal blood using previously described methods (Breman et al. PMID:27616633). The isolated cells were processed using various types of whole genomic amplification (WGA) prior to genotyping. Multiple highly polymorphic genomic regions (including HLA-A and HLA-B) with 10-20 very informative SNPs around 200 bps interval were amplified with a modified method based on another published method (Debeljak et al. PMID:25132481). To enhance the power of identification, about 40 human identification (HID) amplicons were also utilized. Additional genotyping assays were established for common cystic fibrosis, Tay Sachs, and sickle cell mutations. For these disease mutations, testing was carried out using unfixed and fixed heterozygous single lymphoblasts and using normal fetal cells and results were compared for three different WGA protocols. NGS was performed on both Ion Torrent and Illumina platforms. **Results:** The genotyping method allowed reliable differentiation of fetal and maternal cells. Using multiple highly polymorphic amplicons each including >10 highly informative SNPs with >1000 reads for haplotyping, maternal and fetal cells could be distinguished in >70% of the samples. SNP typing of additional HID amplicons with >200 reads was used to resolve uninformative cases, so all together >90% cases were identified. A paternal DNA sample is not required for use of this method to distinguish maternal and fetal cells in informative cases. The assay also successfully detected mutations of interest in several spike-in diseases cells. **Conclusion:** We found this method to be superior to SNP arrays, multiplex genotyping methods, and STR analysis considering cost (<\$10 prep + sequencing), throughput (2-6 hrs prep for 1-96 cells), and reliable distinction of fetal from maternal cells. This method derives its power by combining a highly informative haplotyping within individual reads and SNP genotyping. Comparison of different WGA protocols suggested modest bias during amplification. This method will facilitate genotyping to confirm fetal cells within an overall platform for performing CB-NIPT.

**Comprehensive analysis of CYP2D6 variants and copy numbers using reverse-hybridization and real-time PCR based assays.** C. Oberkanins, A. Berndt, K. Gesson, H. Puehringer. ViennaLab Diagnostics, Vienna, Austria.

**Introduction:** The cytochrome P450 2D6 (CYP2D6) is an important liver enzyme involved in the metabolism of up to 25% of clinically used drugs. The CYP2D6 gene is highly polymorphic, with numerous (sub)variants described in the Human Cytochrome P450 Database ([www.cypalleles.ki.se](http://www.cypalleles.ki.se)). While the most frequent allelic variations are caused by single nucleotide polymorphisms and small insertions/deletions, highly homologous regions in the CYP2D6 gene locus facilitate unequal cross-over leading to large deletions, duplications and gene conversions. **Material and Methods:** We developed a reverse-hybridization assay (PGX-CYP2D6 XL StripAssay) for the simultaneous detection of 19 sequence variations in the CYP2D6 gene, which define the most prevalent alleles impacting enzyme activity in Caucasians. For the detection of copy number variations a real-time PCR based assay (CYP2D6 RealFast CNV Assay) was established. The StripAssay and real-time PCR assay were validated on 118 and 98 samples, respectively. **Results:** The PGX-CYP2D6 XL StripAssay correctly identifies allelic variants with normal (\*1, \*2, \*35, \*39), reduced (\*9, \*10, \*17, \*29, \*41) and no (\*3 to \*8, \*11, \*12, \*14, \*15, \*40, \*58) enzyme activity, and hence allows the classification of individuals into extensive (EM), intermediate (IM) and poor (PM) metabolizers. In addition, ultrarapid (UM) metabolizers and CYP2D6\*5 carriers can be identified by quantifying their abnormal copy number status using the CYP2D6 RealFast CNV Assay. Both assays demonstrate a test accuracy of >0.99. **Conclusions:** The metabolizer phenotype of patients treated with CYP2D6 substrates can be accurately determined by the combined use of both assays.

**A highly specific, cost-effective solution utilizing a unique 2-enzyme system for SNP genotyping in pharmacogenetic studies.** D. Tsang<sup>1</sup>, J. Graham<sup>2</sup>, K. Datta<sup>1</sup>, K. Beltz<sup>1</sup>, S. Rose<sup>1</sup>, Y. Wang<sup>1</sup>, M. Fiddler<sup>2</sup>, Y. Bao<sup>1</sup>. 1) Integrated DNA Technologies, Redwood City, CA; 2) Insight Medical Genetics, Chicago, IL.

**Introduction:** Drug-gene interactions have been widely studied to help predict the efficacy and potential toxicity of drug therapies. The cytochrome P450 enzyme family is primarily responsible for the metabolism of pharmaceutical drugs. In particular, CYP2D6 is important as it is responsible for a wide variety of phenotypic outcomes and has a highly homologous pseudogene that complicates genotype calling. IDT rhAmp™ SNP Genotyping Assays combine a unique 2-enzyme system with DNA-RNA hybrid primers to detect genetic variations, including single nucleotide polymorphisms (SNPs) and insertions/deletions (InDels). Allele-specific primers (ASPs) contain a 5' universal tail, a single RNA base targeting the SNP, and a 3' terminal blocking group. The thermostable RNase H2 only cleaves the primer at the RNA base, when the primer is hybridized to its perfectly matched target. Primer cleavage releases the 3' blocking group, which activates the primer for extension by a thermostable DNA polymerase engineered for enhanced specificity. **Methods:** rhAmp ADME assays, which target SNPs in genes known to be involved in drug absorption, distribution, metabolism, and excretion [ADME; published by the Clinical Pharmacogenetics Implementation Consortium (CPIC)], were generated using an optimized assay design algorithm that ensures high target specificity. The assays were tested with rhAmp Genotyping Master Mix using either gBlocks® Gene Fragments as artificial templates for positive controls or genomic DNA extracted from human whole blood, saliva, and buccal swab samples. rhAmp SNP reactions were run on a BioMark™ Real-Time PCR system (Fluidigm) utilizing the 96.96 Dynamic Array™ IFC for Genotyping (Fluidigm). **Result:** We successfully demonstrated >99% call rate for the SNP targets, and genotyping results were concordant with established orthogonal methods. CYP2D6 gene variants were accurately genotyped using genomic DNA without need for preamplification of the gene. **Conclusion:** rhAmp SNP Genotyping products provide a cost-effective and highly specific genotyping solution for pharmacogenetic studies. The assays are compatible with different sample types, and the results are concordant with those from an established technology.

**Long read capture sequencing for clinical applications.** K.C. Worley<sup>1,2</sup>, Y. Liu<sup>2</sup>, Q. Meng<sup>2</sup>, Y. Han<sup>2</sup>, G.M. Weissenberger<sup>2</sup>, J. Hu<sup>2</sup>, S. Richards<sup>1,2</sup>, D.M. Muzny<sup>2</sup>, R.A. Gibbs<sup>1,2</sup>. 1) Dept Molecular & Human Gen, Baylor College of Medicine, Houston, TX; 2) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

We use long read sequencing technologies including Pacific Biosciences RSII and Sequel and Oxford Nanopore for genomic applications such as *de novo* genome assembly and structural variant (SV) investigation. We report here the use of target enrichment capture with these long reads for assessment of repeats and phasing of heterozygous variants. Clinical exome sequencing with short read Illumina technology does not adequately address all known Mendelian diseases. Distinguishing between normal, pre-mutation, and full mutation triplet repeat expansion alleles is difficult or impossible with short reads. Phasing compound heterozygous mutations in a gene to determine if the mutations are in cis (on the same allele) or trans is also difficult or impossible with short reads. The goal of this project is to build a cost-effective sequencing platform for variant discovery in complex and difficult clinically important genomic regions. The initial capture design includes 94 genes with a total targeted capture size of 13.4 Mb. Nine of the genes are repeat expansion containing genes. The remaining genes were selected for their importance in clinical genetic diagnosis with both small genetic changes and SVs. Intact genomic DNA from 6 breast cancer patient samples was sheared to 2kb~6kb and amplified by ligation-mediated PCR. The pre-capture library was hybridized with NimbleGen SeqCap EZ platform probes and the capture products sequenced using RSII or Sequel platforms. In the preliminary analysis, filtered subreads were mapped using the long read aligner BLASR; the resulting BAM files were used to generate capture metrics and processed by PBHoney to generate SV calls. Robust capture efficiency was demonstrated with 94% of the targets covered at 20x with 1~2 cells. More than half of the repeat expansion disease genes were captured successfully. A HapMap DNA yielded contiguous coverage at 100x in high GC regions including the FMR1 5' UTR enabling determination of the copy number of this CGG repeat. We will report the initial results using long read sequencing technologies for targeted sequencing to assess genetic variation including SNPs, small indels and large SVs. We will also report laboratory experiments to refine and improve the regional capture and computational experiments to improve the sequence data assessment. Multiplex capability and customizable target selection provide a foundation for the clinical implementation of cost-effective long read sequencing.

**2574F****Clinical reassessment of post-laboratory variant call format (VCF) files.**

*L.F. Al Subaie<sup>1</sup>, S. Alturki<sup>2</sup>, A. Alothaim<sup>2</sup>, M. Alfadhel<sup>1</sup>, A. Alfares<sup>2</sup>.* 1) Division of Genetics, Department of Pediatrics, King Abdulaziz Medical City, Riyadh, Saudi Arabia; 2) Department of Pathology and Laboratory Medicine, King Abdulaziz Medical City, Riyadh, Saudi Arabia.

Next generation sequencing (NGS) has been leading the genetic study of human disease for the past ten years. And since then we have been dealing with a huge number of sequence variant data generated from both whole genome (WGS) and whole exome sequencing (WES) that is stored in Variant Call Format (VCF) files. To our knowledge there are few discussions about the utility of VCF files reanalysis. Here we retrospectively analyzed twenty samples. The samples were divided into WGS with 14 cases (70%) and WES with 6 cases (30%). All cases of WGS had a previous negative results from outside lab except one case of WGS had a previous result of variant of uncertain significance. and one WES case had a previous variant of uncertain significance. We reported seven cases (n=20) differently from the outside laboratory, this account for almost ~35% and mainly due to the ability to gather more information about the patient's phenotype. One WGS case changed to negative case despite the previous report of variant of uncertain significance. Also, we identified variants related to the patient's phenotype in six cases; Two of them were WGS with and four of them were WES with previous negative results. Comprehensive phenotyping of the individuals is crucial step in identifying candidate phenotype-related variants. We outline the benefit from access to the patient's medical records and communication with referring physicians. This study findings match up with previous researches that highlights particularly the importance of patient's clinical data for variant classification.

**2575W****A single assay system for CNV, AOH, and Seq Var genetic testing.**

*S. Shams<sup>1</sup>, A. Venier<sup>1</sup>, S. Verma<sup>1</sup>, A. O'Hara<sup>1</sup>, I. Simonic<sup>2</sup>.* 1) BioDiscovery, Inc., El Segundo, CA; 2) Addenbrooke's Hospital, Cambridge, UK.

Traditionally, large structural genomic aberrations, such as Copy Number Variations (CNV) and regions with Absence of Heterozygosity (AOH), have been the domain of Cytogenetics, using methods such as karyotyping, FISH, and Chromosomal MicroArrays (CMAs). Similarly, smaller structural aberrations, Sequence Variants (Seq Var), have been the domain of Molecular Genetics using tools such as PCR, Sanger sequencing, and more recently Next-Generation Sequencing (NGS). In this paper, we present an approach that utilizes NGS technology to simultaneously detect variants regardless of size and nature, e.g. CNV, AOH, and Seq Var. The benefits of integrated review include facilitating identification of heterozygous events, as well as providing rapid results when urgent diagnosis is required. The core component of the integrated system is a software platform that effectively extracts CNV and AOH data using read depth coverage, and using an integrated filtering and visualization framework, presents a single view to perform clinical case review in individual as well as trio samples. We will describe this system and workflow in detail and demonstrate the utility of the approach on a set of anonymized clinical samples referred for various constitutional conditions. These samples have been processed for molecular testing using the Illumina TrueSight One panel with targeted coverage across more than 4800 genes associated with disease. In the present study, we will evaluate the utility of obtaining CNV and AOH data from the same NGS data using the BAM MultiScale Reference algorithm and integrating this data along with Seq Var data into a single analysis pipeline. The results of this analysis will be presented.

Martin<sup>1</sup>.* 1) Autism & Developmental Medicine Institute, Geisinger Health System, Lewisburg, PA; 2) ARUP Laboratories, Salt Lake City, UT; 3) Department of Pathology, University of Utah, Salt Lake City, UT; 4) Invitae, San Francisco, CA; 5) GeneDx, Gaithersburg, MD; 6) New York Genome Center, New York, NY; 7) Columbia University Medical Center, New York, NY; 8) Quest Diagnostics Nichols Institute, San Juan Capistrano, CA; 9) Department of Genetics and Genomic Sciences, Icahn School of Medicine, Mount Sinai, New York, NY; 10) Department of Pathology and Laboratory Medicine, Mayo Clinic, Rochester, MN; 11) Courtagen Life Sciences, Inc., Woburn, MA; 12) Department of Pediatrics, Texas Children's Hospital, Baylor College of Medicine, Houston, TX; 13) Division of Genetics and Genomics, Boston Children's Hospital, Boston, MA; 14) Trillium Health Partners, Credit Valley Site, Mississauga, ON; 15) Department of Laboratory Medicine and Pathobiology, University of Toronto, ON.

Resolution of inter-laboratory conflicts in clinical variant interpretation is a critical step towards standardizing interpretations and improving patient care. Evaluating interpretation discrepancies in copy number variants (CNVs) is complicated by the fact that variants are often unique; with the exception of recurrent segmental duplication-mediated events, there is rarely another CNV with the same genomic coordinates available for comparison. As such, CNVs are typically evaluated by their overlapping genomic content, with a particular focus on genes in the region that may be subject to dosage sensitivity. The Clinical Genome Resource (ClinGen) is an NIH-funded effort dedicated to identifying clinically relevant genes and variants. As part of ongoing curation efforts, ClinGen evaluates genes and genomic regions for evidence of dosage sensitivity; to date, over 1000 genes/regions have been evaluated, 318 of which meet criteria to be considered known haploinsufficient (HI) or triplosensitive (TS) genes/regions. In general, we recommend that deletions containing known HI genes and duplications containing known TS genes be interpreted as "likely pathogenic" (LP) or "pathogenic" (P), and that CNVs involving the same known dosage sensitive genes receive the same clinical interpretation regardless of other factors, such as size. Currently, ClinVar contains 19,000 CNVs; of these, there are approximately 3594 discrepancies (19%) amongst CNVs of the same copy number with at least 50% overlap. It is possible that some of these conflicts, particularly older ones, could be resolved by comparing against the current ClinGen dosage map; evidence for dosage sensitivity may have emerged since the CNVs were last evaluated. Within the ClinVar CNV dataset, we identified 896 deletions overlapping known HI genes and 37 duplications overlapping known TS genes with interpretations other than LP or P. ClinGen will work with the original submitters of these data to determine whether changing these classifications is appropriate within the context of the particular clinical case(s). Updating these calls to reflect the current understanding of dosage sensitivity for these genes/regions could result in the resolution of up to 25% of existing conflicts in ClinVar CNV data. Efforts such as this one to address "easily resolvable" discrepancies will put more consistent interpretation data into the public domain and allow laboratories to focus attention on more complex discrepancies.

**2577F**

**Defining quality standards for clinical whole exome sequencing: A national collaborative study of the Dutch Society for Clinical Genetic Laboratory Diagnostics (VKGL).** *M.G. Elferink<sup>1</sup>, I.J. Nijman<sup>1</sup>, M.A. Haagemans<sup>2</sup>, A.H.B. Bollen<sup>3</sup>, R.W.W. Brouwer<sup>4</sup>, B. de Koning<sup>5</sup>, L.F. Johansson<sup>6</sup>, D. van Beek<sup>7</sup>, O.R. Mook<sup>8</sup>, M. van Slegtenhorst<sup>6</sup>, S. Stegmann<sup>9</sup>, B. Sikkesma-Raddatz<sup>6</sup>, M. Nelen<sup>9</sup>, Q. Waisfisz<sup>7</sup>, M. Weiss<sup>7</sup>, J.D.H. Jongbloed<sup>6</sup>, N. van der Stoep<sup>3</sup>, K.L.I. van Gassen<sup>1</sup>.* 1) Department of Genetics, University Medical Center Utrecht, Utrecht, the Netherlands; 2) Department of Clinical Genetics, Academic Medical Center, Amsterdam, the Netherlands; 3) Department of Clinical Genetics, Leiden University Medical Center, Leiden, the Netherlands; 4) Center for Biomics, Erasmus Medical Center, Rotterdam, the Netherlands; 5) Department of Clinical Genetics, University Medical Center Maastricht, Maastricht, the Netherlands; 6) Department of Genetics, University Medical Center Groningen, Groningen, the Netherlands; 7) Department of Clinical Genetics, VU University Medical Center, Amsterdam, the Netherlands; 8) Department of Clinical Genetics, Erasmus Medical Center, Rotterdam, the Netherlands; 9) Department of Human Genetics, Radboud University Medical Center, Nijmegen, the Netherlands.

Clinical whole exome sequencing (WES) has proven to be very effective for diagnosing heterogeneous genetic diseases, and has therefore been adopted in standard Dutch genetic diagnostic services. Quality standards have been described for gene panel based next generation sequencing, but for clinical WES these have not been determined yet. In this study, we present a nationwide quality assessment scheme within all eight university medical centers in the Netherlands in order to improve and harmonize quality and to formulate a quality standard for clinical WES. The exome of Genome-in-a-Bottle (GIAB) sample NA12878 was sequenced and processed by the Dutch genetic diagnostic centers according to their own standard diagnostic protocols. Anonymized VCF and BAM files were collected and used for comparisons. VCF files were used to calculate variant detection sensitivity and precision using the GIAB high confidence call set (v2.19). BAM files were used to calculate informative exome coverage statistics based upon a standardized target defined by all coding exons of UCSC and Ensembl  $\pm 20$ bp intron flanks. Results showed that single nucleotide variant (SNV) detection sensitivity varied between 96.3% and 99.1% (average 98.1%) and that INDEL detection sensitivity varied between 86.1% and 96.1% (average 90.4%). Precision of SNV detection was between 98.0% and 99.8% (average 98.9%), and precision for INDEL detection was between 74.8% and 97.0% (average 91.0%). The mean coverage of the exome varied between 55X and 152X. Completeness of the exome (defined as the percentage of bases with  $\geq 15$ x informative coverage) varied between 90.0% and 96.4% (average 93.5%). Downsampling analysis indicated that completeness is a good predictor for quality and can be used to determine the required sequencing output for a desired quality threshold. The nationwide quality assessment scheme shows an acceptable concordance between the Dutch genetic diagnostic centers, although harmonisation of lab protocols and bioinformatics may lead to improved concordance and quality. We propose the following quality standards for a clinical WES based upon the GIAB high confidence call set (v2.19): a minimum sensitivity of 97% for SNVs and 85% for INDELS, and a minimum precision of 98% for SNVs and 85% for INDELS. These quality assurance standards will be deposited as field standards at the Dutch accreditation council for use in ISO15189 laboratory accreditation.

**2578W**

**Characterization of incidental findings identified by targeted testing for gene deletions and duplications.** A.M. Janze, T. Brandt, A. Ondov, L. Butler, G. Richard, K. Hruska, J. Meck. GeneDx, Gaithersburg, MD.

A clinical diagnostic laboratory sometimes encounters an unexpected test result that is unrelated to the indication for testing. These events are considered incidental findings (IFs). While clinicians are familiar with unexpected results in the context of whole genome array or whole exome sequencing, IFs may also be detected on targeted multi-gene panels that have array CGH testing as a component of the test or as a method of confirmation. Microarray designs have probe placement in targeted genes of interest and, in addition, in surrounding genes and in intergenic stretches of DNA to create a backbone for the array. While bioinformatic techniques are used to mask areas outside of targeted regions, viewing the whole of the data is a commonly employed quality control measure that may incidentally reveal constitutional or acquired large copy number variants (CNVs) involving genes not included on the testing panel. Our laboratory has developed strategies for evaluating and reporting unexpected CNV findings. Incidental findings are deemed reportable if they contain a targeted gene, or if they lack a targeted gene but are pathogenic, are medically actionable, and are not already known. In this retrospective study we reviewed reported incidental findings from exon array cases that were unrelated to the indication for testing. Of the most recent 22,489 cases, there were only 26 (0.1%) with unrelated reportable IFs. Of these, 16 (62%) contained a targeted gene and 10 (38%) did not. Five (19%) of the patients had an acquired abnormality likely related to a hematologic malignancy, 21 (81%) had a constitutional aneuploidy, and 1 had a large genomic duplication. The patients with an identified acquired abnormality were either being tested for a cancer-related indication (and may have been undergoing chemotherapy) or were elderly. Of the reported constitutional aneuploidies, 18 (90%) were sex chromosome aneuploidies and 2 (10%) were trisomy 21. Additionally, the referring providers were previously aware of at least 3 (14%) of the observed constitutional aberrations. These data show that detection of IFs by exon array testing at our laboratory is rare and typically involves either a relatively benign sex chromosome aneuploidy or a finding already known to the provider. We propose a standard and consistent policy for reporting incidental findings to be considered by all genetic testing laboratories.

**2579T**

**Diagnostic digital PCR copy number assay for NKX2-1 related disorders.** K.M. Robbins<sup>1</sup>, K.M.B. Vinette<sup>1</sup>, S.M. Kirwin<sup>1</sup>, K.W. Gripp<sup>1,2</sup>, V.L. Funanage<sup>1</sup>. 1) Molecular Diagnostics Laboratory, Nemours/A. I. duPont Hospital for Children, Wilmington, DE; 2) Division of Medical Genetics, Nemours/A. I. duPont Hospital for Children, Wilmington, DE.

The *NKX2-1* gene encodes a transcription factor that is critical for embryonic development of the brain, thyroid, and lung. Haploinsufficiency of *NKX2-1* is responsible for NKX2-1 related disorders including benign hereditary chorea (BHC; OMIM #118700) and choreoathetosis, congenital hypothyroidism, with or without pulmonary dysfunction (CAHTP; OMIM 610978). These rare autosomal dominant disorders occur due to either mutations or copy number variations in *NKX2-1*. *NKX2-1* related symptoms typically appear before age five years and characteristics may include early onset chorea, delayed motor development, and dysarthria; however, the disease is not associated with cognitive deterioration. This disorder typically improves or does not progress after the second decade of life. Choreoathetosis, congenital hypothyroidism, with or without pulmonary dysfunction, also known as brain- thyroid- lung-syndrome, has a more severe phenotype. The characteristics of this disorder include neonatal respiratory distress, involuntary movements, congenital hypothyroidism with elevated levels of thyroid stimulating hormone, developmental delays, hypotonia, and ataxia. Our molecular diagnostic laboratory previously developed a multiplex PCR with fluorescently labeled primers to detect copy number/gene dosage to determine if one or more exons of *NKX2-1* are deleted. The goal of this work was to determine if a copy number/dosage assay utilizing droplet digital PCR was comparable to the current assay. Digital polymerase chain reaction (dPCR) enables determination of absolute copy number analysis without using known reference controls and positive controls. Additionally, this assay will improve our turnaround. We used the QuantStudio 3D digital PCR system to develop a Taqman copy number assay for each of the three exons of *NKX2-1*. Optimization of the *NKX2-1* copy number assays was necessary throughout assay development. Through troubleshooting of these assays, we determined that predigestion of the genomic DNA was required in order to improve signal separation and amplification. After optimization, each *NKX2-1* dPCR assay was validated with several calibrator controls and deletion positive controls. We will use the dPCR *NKX2-1* copy number/dosage assay as proof of principle; in the future, we plan to develop additional dPCR copy number/dosage assays for diagnostic testing of other rare pediatric disorders.

**2580F****An open-source quality control monitoring system for clinical NGS.**

*N.R. Tawari, J.J.W. Seow, S. Ang, P. Dharuman, P. Ng.* Computational and Systems Biology, Genome Institute of Singapore (GIS), Singapore, Singapore, Singapore.

In the clinic, regular quality control (QC) meetings are conducted where laboratory tests' performances are reviewed and compared with historical data. We present an open-source, interactive, record-keeping QC system for clinical implementation of NGS. ChronQC tracks and displays NGS QC data such as total reads, depth of coverage, % duplicates, and Ti/Tv ratio. ChronQC captures QC data from raw NGS files (e.g. bam and VCF files) and stores the metrics in a database. ChronQC then automatically generates interactive time-series plots for various metrics, allowing comparison of the current run to historical runs. In QC meetings, users can record their notes and corrective actions directly onto the graphs for long-term record-keeping. Outliers are flagged based on 1) hospital-defined thresholds derived from clinical validation experiments and 2) Westgard rules (e.g.  $\pm 2$  standard deviations). ChronQC can identify bias, excessive scatter, shift, or trends in the clinical results, so that corrective and preventive actions can be taken to ensure patient test results remain clinically valid. The source code is available at <https://github.com/nilesh-tawari/ChronQC>.

**2581W****Application of comprehensive actionable medical panel and whole exome sequencing in critical care of pediatric patients.**

*H. Wang<sup>1</sup>, B. Wu<sup>1,2</sup>, Y. Lu<sup>1</sup>, H. Sun<sup>3</sup>, P. Fang<sup>3</sup>, X. Fan<sup>4</sup>, W. Zhou<sup>1,2</sup>.* 1) Molecular Diagnosis Laboratory of Children's Hospital of Fudan University, Shanghai Key Laboratory of Birth Defects, The Translational Medicine Center of Children Development and Disease of Fudan University, Shanghai 201102, China; 2) Division of Neonatology, Children's Hospital of Fudan University, Key Laboratory of Neonatal Diseases, Ministry of Health, Shanghai 201102, China; 3) Wuxi NEXTCODE, 288 Fute Zhong Road, Waigaoqiao Free Trade Zone Shanghai 200131, China; 4) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston TX, USA.

**Background** Comprehensive evaluation of critically ill patients to identify or rule out genetic causes is a key in precision medicine. NGS technology based whole exome sequencing (WES) is desirable in this aspect, which cost is considerably high for low-income families. We developed a sequencing test as the comprehensive actionable medical panel (CAMP), including ~3,000 genes thoroughly evaluated by medical expertise. CAMP is aim for low-cost and rapid turnaround time (TAT). **Methods** We continuously evaluated about 4,800 pediatric patients referred to the Molecular Diagnosis Laboratory of Children's Hospital of Fudan University. Both CAMP and WES options are offered to the families. 2/3 of them have chosen CAMP test. Data analysis and clinical genetic reports were performed in the Molecular Diagnosis Laboratory. For WES, average target sequencing depth of 100X is required; and mean depth of 200X is achieved for CAMP samples. The TATs are 3-4 weeks and 6-12 weeks for CAMP and WES, respectively. **Results** There are 586 of WES cases and 635 of CAMP cases received diagnosis. In WES, the largest component of patients is of neonate in NICU and neuromuscular disorders. There are 47.68% patients are neonate. In the diagnosed patients, 51.30% (298/586) of them are neonate onset patients. Copy number variations analyzed using deep sequencing is also accounted. 79 patients are diagnosed as chromosome deletion/duplication. In the 233 autosomal dominant gene mutations, 89 (38.20%) of them are confirmed as de novo. For CAMP cases, 50.87% (323/635) of the diagnosed patients are neonate onset. There are 220 autosomal dominant gene mutations, 215 autosomal recessive, and 121 are diagnosed as CNV. For cases received positive findings, the parents did further consultation of the possible treatment improvement, the future of the patients, or consulted family planning on prenatal and preimplantation options. For negative results, families are offered research opportunities including enrollment in Undiagnosed Disease Program center (UDP) of our Hospital. **Conclusion** This is the largest cohort utility of genetic diagnosis in Chinese pediatric clinics. We present an all-in-one pipeline from clinic patient samples to laboratory genetic data analysis and molecular diagnosis in a pediatric specialize hospital. The precise genetic diagnosis can change clinical treatment, change the life quality of patients. Family planning can greatly benefit from genetic diagnosis results.

**2582T**

**Structural variant detection with optical mapping and microfluidic partitioning: A t(9;13) case report.** D. Baldrige<sup>1</sup>, D. Wegner<sup>1</sup>, J. Wambach<sup>1</sup>, T. Graves-Lindsay<sup>2</sup>, K. Meltz Steinberg<sup>2</sup>, R. Fulton<sup>2</sup>, F.S. Cole<sup>1</sup>. 1) Department of Pediatrics, Washington University in St. Louis, St. Louis, MO; 2) The McDonnell Genome Institute, Washington University in St. Louis, St. Louis, MO.

Detection and characterization of structural variants (SVs) including copy number variants, translocations, inversions, and complex re-arrangements are important for increasing diagnostic yield, for understanding genotype-phenotype correlation, and for complementing whole exome and whole genome sequencing. As a proof-of-principle approach to evaluate recently developed technologies in a single sample with a known, complex chromosomal translocation (46,XX,der(9)t(9;13)(p23;q13)), we performed 1) next-generation optical mapping in collaboration with Bionano Genomics, and 2) microfluidic-based partitioning in collaboration with 10X Genomics. The subject's phenotypic features include global developmental delay, hearing loss, autism spectrum disorder, dysmorphic facial features, polydactyly, vertebral anomalies, scoliosis, coarctation of the aorta, bicuspid aortic valve, and superior mesenteric artery syndrome. The SV detection methods that we used successfully identified the deletion and translocation previously identified by karyotype. Characterization of specific genomic locations of the chromosome 9 breakpoint and the translocated portion of chromosome 13 by optical mapping or microfluidic-based partitioning are reported, with resolution capability of 2-3kb and single base pair, respectively. This single case suggests that detection and characterization of SVs will benefit from new sequencing and mapping technologies.

**2583F**

**Confirmation of copy number variations from massively parallel sequencing using a chromosomal microarray with single exon level detection.** J.M. Devaney, B.W. Meltzer, M. Tun, S.L. Everhart, M.B. Seprish, K.P. Cusmano-Ozog. Laboratory Medicine, Children's National Health System, Washington, DC.

Statement of Purpose: The adoption of copy number variation (CNV) analysis in the clinical diagnostic laboratory will have an effect on the rate of positive analysis for the discovery of pathogenic variants. This will have a major consequence on the field of medical genetics. It will help refine genotype-phenotype relationships in known disorders and will lead to the discovery of new syndromes. We present a process for CNV analysis with MPS as a discovery method coupled with the confirmatory use of a microarray with capabilities to discover single exon deletion/duplication events. Methods: We examined 42 samples with MPS and a microarray capable of analyzing single exon CNV events. This group included 14 Coriell Institute for Medical Research cell lines with described CNVs and 32 samples with CNVs discovered using MPS. For the MPS, genomic DNA was prepared for targeted sequencing using the TruSight One panel. The samples were analyzed on an Illumina NextSeq 500. We performed alignment to the hg19 genome with BWA (v 0.7.7) and GATK (v1.6) to generate BAM files. The BAM files were analyzed with the NextGENe software (v2.4.0.1; SoftGenetics) for exon level CNV detection. For the exon level array, we used a whole genome microarray (Applied Biosystems, Thermo Fisher) with probes targeting single nucleotide variants and CNVs for single exon resolution focusing data analysis in 5,376 genes. Results: Thirty-nine samples were evaluated with 50 CNVs and three negative samples without deletions/duplications. In this sample set, there were 29 deletions from single exons to 25.9 MB and duplications from two exons to entire chromosome duplications. In addition, there were three samples with negative deletion/duplication results for single genes. A partial deletion spanning two exons in the *PLP1* gene was not seen on MPS but was present on array CNV analysis. The sensitivity, positive predictive value, and the negative predictive value were all 100%. Conclusions: Massively parallel sequencing is a powerful analysis tool for detecting small genomic losses and gains that are relevant to human genetic disease. The MPS technique for CNV discovery can be fraught with false positives and the use of second method for confirmation of those results will add to its clinical viability. The combination of MPS and arrays will add to the detection of CNVs in clinical samples and present a reliable method allowing for reporting of these results with confidence.

**New systematic rubric for clinical interpretation of copy number variants (CNVs) improves interpretation consistency across laboratories.** D. *Pineda Alvarez*<sup>1</sup>, E. *Riggs*<sup>2</sup>, E. *Andersen*<sup>3</sup>, A. *Cherry*<sup>4</sup>, S. *Kantarci*<sup>5</sup>, H. *Kearney*<sup>6</sup>, A. *Patel*<sup>7</sup>, G. *Raca*<sup>8</sup>, D. *Ritter*<sup>9</sup>, S. *South*<sup>10</sup>, E. *Thorland*<sup>11</sup>, S. *Aradhya*<sup>12</sup>, C. *Martin*<sup>13</sup> *On behalf of the ACMG/ClinGen Copy Number Variant Interpretation Guidelines Working Group.* 1) Courtagen Life Sciences, Woburn, MA; 2) Geisinger Health System, Lewisburg, PA; 3) ARUP Laboratories, Salt Lake City, UT; 4) Stanford University, Palo Alto, CA; 5) Mayo Clinic, Rochester, MN; 6) Columbia University Medical Center, New York, NY; 7) Baylor College of Medicine, Houston, TX; 8) Children's Hospital of Los Angeles, Los Angeles, CA; 9) Ancestry.com, San Francisco, CA; 10) Invitae, San Francisco, CA; 11) Quest Diagnostics, San Juan Capistrano, CA.

Analysis of CNVs by chromosomal microarray analysis (CMA) is the first-tier genetic test in patients with neurodevelopmental disorders and/or multiple congenital anomalies. In addition, due to advancements in microarray and sequencing technologies, CNVs are now being analyzed at higher resolutions extending down to single-exon CNVs. Despite the existence of CNV interpretation standards from ACMG and mounting experience from laboratories analyzing CNVs, inconsistencies in clinical interpretation persist, a large portion of which can be attributed to differences selecting and weighing evidence used to classify the variants. The current ACMG CNV interpretation guidelines provide a high-level review of evidence that may be considered to determine pathogenicity of CNVs in a diagnostic setting. However, to improve consistency of CNV interpretation across laboratories, the ACMG and the Clinical Genome Resource (ClinGen) have established a collaboration to update these guidelines with a more standardized clinical classification framework. We have developed a framework to interpret deletions, duplications, CNVs involving non-coding regulatory loci and intragenic CNVs, which uses a point-based, hierarchical scoring system to determine the pathogenicity of CNVs by assigning and weighing evidence from several categories. These categories include overlap with CNVs reported in affected or unaffected individuals, presence of dosage-sensitive genes, case-control studies, segregation data, and number of protein coding genes. The metric was initially tested using a set of 33 deletions with defined clinical significance from previous clinical laboratory testing. Each deletion was evaluated independently by two geneticists using the new schematic, and 14 of these were also analyzed using the existing guidelines. Concordance between evaluators and both rubrics were compared. The new rubric determined the correct interpretation in more than 80% of the CNVs, and improved the concordance of clinical interpretation between evaluators from 40% to 80%. A similar analysis is now in progress for duplications. The framework will be further tested by a broader group of clinical laboratory geneticists to identify nuances and refine its guidance. Given that the updated guidelines are being developed to be applied to any method capable of defining discrete CNV events, this rubric is expected to have broad impact by providing a robust system to support the consistent interpretation of CNVs.

**No consistent phenotype in patients with copy number variants of the SHOX downstream regulatory domain.** A. *Wray*, J. *Meck*, L. *Matyakhina*. GeneDx, Gaithersburg, MD.

Copy number variants (CNVs) within the SHOX downstream regulator domain (DRD) have been reported in cohorts of individuals with Leri-Weill dyschondrosteosis (LWD), a skeletal dysplasia characterized by short stature and/or Madelung deformity, and isolated idiopathic short stature (ISS). Concern for ascertainment bias in studies performed on individuals with a clinical diagnosis of LWD or ISS led us to retrospectively review from our diagnostic laboratory 18,646 postnatal chromosomal microarray (CMA) cases for deletions (dels) or duplications (dups) involving the SHOX DRD. In total, 107 patients had CNVs within the SHOX DRD (0.57%): 85 with a recurrent 47.5 kb del [no other deletions within this region were detected] (22 F, 63 M) and 22 had duplications (11 F, 11 M). Nineteen patients (17 with del, 2 with dup) were excluded from analysis either due to presence of a known pathogenic CNV fully explaining their phenotype (n=14) or lack of clinical information (n=5). Twelve of the remaining 88 cases (9%) had an additional CNV of uncertain significance (6 dels, 2 dups, 1 female patient had LWD) or large regions of homozygosity (3 dels, 1 dup). There was no consistent phenotype in individuals with CNVs in the SHOX DRD. Reported test indications primarily included the standard neurodevelopmental phenotypes which generally trigger CMA testing: autism, learning disability/intellectual disability/developmental delay, dysmorphic features, congenital heart defect, and seizures. A minority of cases (n=8; 9%) reportedly had a spectrum of phenotypic features including short stature (n=6, 3 F and 3 M) or possible LWD (n=2, both female), but not ISS. For 20/88 probands parental testing was performed, and showed that all CNVs involving SHOX DRD were inherited. Two mothers (10%) had a phenotype suggestive of LWD: 1 with short stature and bowing of the legs, 1 with possible abnormality of the elbow without reduced movement. Our findings suggest that CNVs within the SHOX DRD are relatively common, are typically inherited, may be seen in association with other CNVs, and either are not associated with a consistent phenotype or show greatly reduced penetrance. Further large cohort studies would be necessary to determine if CNVs in SHOX DRD might act as a modifying factor for developing LWD or ISS.

**Clinical variant reclassification and scaling support for the return of updated genetic results.** *H.L. Rehm<sup>1,2,3</sup>, S. Harrison<sup>1</sup>, S. Baxter<sup>1,3,4</sup>, M. Oates<sup>1,5</sup>, L. Babb<sup>1,4</sup>, M. Varughese<sup>4</sup>, E. Clark<sup>4</sup>, S.J. Aronson<sup>1,5</sup>, M. Lebo<sup>1,2</sup>.* 1) Laboratory for Molecular Medicine, Partners Healthcare Personalized Medicine, Cambridge, MA; 2) Department of Pathology, Brigham & Women's Hospital and Harvard Medical School, Boston, MA; 3) The Broad Institute of MIT and Harvard, Cambridge, MA; 4) GeneInsight, Sunquest Information Systems, Boston, MA; 5) Research Information Sciences and Computing, Partners HealthCare, Cambridge, MA.

Variant interpretations are constantly changing as 1) new evidence is identified, 2) variants are reassessed with new guidelines, 3) labs resolve interlaboratory differences in interpretation enabled by data sharing and 4) variants are interpreted by experts. This creates challenges for labs, physicians and patients to manage updates and adjust care accordingly. Given that irreversible decisions can be initiated in symptomatic patients and at risk individuals, it is critical that knowledge updates be communicated as rapidly as possible. Yet patients change health care providers frequently and laboratories lack reimbursement to support report updates, both contributing to challenges in supporting this critical aspect of genomic medicine. We analyzed our data from the Partners Laboratory for Molecular Medicine over twelve years to understand variant reclassification rates. In that time period, 2,519 variant reclassifications occurred across 2,192 variants out of 18,766 total variants (12%). Of these reclassifications, 1,390 (55%) were changes in confidence (e.g. Likely Pathogenic (LP) vs Pathogenic (P) or Likely Benign (LB) vs Benign (B)) unlikely to impact clinical care; however, 1,129 (45%) were more substantive changes, more likely have impact. Interestingly, while 83% of variants moved to a category of more certainty (VUS to LP, LP to P, VUS to LB, LB to B), 17% moved to a less certain (16%) or opposing (between P/LP and B/LB; 1%) category. These later changes are the most critical for communication as they are unanticipated, and physicians and patients are less likely to check in with the lab for an update on non-VUS variants. This creates enormous challenges for labs wishing to provide updates, yet have difficulties re-contacting the original ordering provider and lack the resources required for amendments in the absence of reimbursement. To address the challenge of variant reclassification, we support three main mechanisms to deliver updates back to patients: 1) amended reports (upon request or for the most impactful and unanticipated changes), 2) automated updates delivered through a web-based portal (GeneInsight) with electronic health record integration where available, and 3) publically sharing current variant interpretations through ClinVar. This talk will present the details and the benefits and drawbacks of each approach, our experience supporting each method and considerations of legal liabilities and professional best practices.

**Linked-read sequencing for molecular cytogenetics.** *S. Garcia, S. Williams, J. Herschleb, P. Marks, A.W. Xu, M. Schnall-Levin, D. Stafford, D.M. Church.* 10x Genomics, Pleasanton, CA., USA.

Structural variants (SVs), including deletions, duplications, insertions, inversions, and translocations, are important contributors to disease. However, they remain one of the most difficult types of variation to accurately ascertain, in part because they tend to cluster in duplicated and repetitive regions. Clinically, aCGH and karyotype remain the most commonly used assays for genome-wide SV detection, though there is clear potential benefit to an NGS-based assay that accurately detects both SVs and SNVs. Recently, laboratories have demonstrated that low coverage long-insert WGS (liWGS) can identify both CNVs and balanced rearrangements at a cost and speed similar to aCGH/ karyotype. This introduces the possibility of a hybrid NGS assay (liWGS+genome/exome) but liWGS protocols are difficult and time-consuming to establish. Linked-Read sequencing is a relatively simple, fast, and cost-effective alternative that is applicable to both genome and targeted assays. Linked-Reads are generated by performing haplotype-level dilution of long input DNA molecules into >1 million barcoded partitions, generating barcoded short reads within those partitions, and then performing short read sequencing in bulk. We performed 30x Linked-Read genome sequencing on 24 GetRm CNVPanel samples with known balanced or unbalanced SVs. Downsampling was performed on a subset to determine the lowest sequencing depth required to detect variation. 22/24 variants were identified, and another known event was called as a candidate. The remaining sample had a balanced structural variant involving 16q11.2, a region known to be difficult to assess due to gaps in the reference assembly. With current algorithms, CNVs can be called with as little as 1-2x sequencing depth (5-10Gb) while balanced events require on the order of 10x coverage. We demonstrate that there is specific signal in the data for balanced events down to ~2x coverage. Similar to recent observations, we find complexity at breakpoints not previously detected by conventional technologies.

**2588T****High throughput linked-read sequencing for improved variant detection.**

A. Fehr, S. Garcia, M. Prout, C. O'Keeffe, A. Price, A.W. Xu, S. Williams, C. Catalanotti, P. Marks, D.M. Church. 10x Genomics, Pleasanton, CA., USA.

Causal single nucleotide variants (SNVs) and small indels tend to impact genes across the genome, including in regions with known paralogs that are difficult to assess with short read (SR) next generation sequencing (NGS) techniques. To address variant detection shortcomings, we developed a technology that retains long-range information while maintaining the power, accuracy, and scalability of short read sequencing. The 10x Genomics Chromium™ Genome solution utilizes haplotype-level dilution of high molecular weight DNA molecules into >1 million barcoded partitions to create a novel data type referred to as 'Linked-Reads'. These Linked-Reads (LR) enable high-resolution genome analysis with minimal DNA input (~1 ng). Here, we describe a high throughput workflow that interfaces an Agilent Bravo Liquid Handling platform with the Chromium system to automate the LR library preparation solution. Using this reliable and reproducible workflow, we generated both genome-level Linked-Read NGS data in addition to using Agilent SureSelect Human V6 exome baits to capture a subset enriched for exonic targets, on multiple reference samples including NA12878. Of particular interest are the exome data wherein for ~60x median coverage on NA12878 samples, LR sequencing yielded 73.4% of bases with >10x coverage at mapq>30 compared to 71.4% for SR. For clinically-relevant genes in loci with known paralogs, this metric ranged between 73.1 and 84.4% for LR but only 53.6-75.4% for SR. The fraction of exons with at least 99% of bases with >10x coverage at mapq>30 in difficult loci ranged from 71.3-77.6% for LR and 48.6-64.8% for SR. With this additional coverage, LR detected 1,597 novel SNPs in degenerate regions with 78.6% in the coding sequence of 414 total genes, versus only 527 SNPs for SR. Improvements were also seen for whole genome LR data including 74,667 novel SNPs in degenerate regions versus only 32,295 for SR. Single exon deletions and duplications are not routinely assessed in exome sequencing because coverage is highly variable but haplotype reconstruction in LR data improves the signal:noise ratio for duplications and reveals deletions as a complete loss of coverage on one haplotype. For NA12878 50 exon-level deletions are called with LR with a heterozygous sensitivity of 72.7% (PPV= 72%) and a homozygous sensitivity of 83.3% (PPV= 100%). Duplications are robustly detected when phasing is present over the affected region.

**2589F****A clinical molecular genetics laboratory experience with whole exome sequencing.** J. Machado, D. Allingham-Hawkins, B. Dorshorst, G. Londre, E. McPherson, R. Steiner, G. Sun, J. Weber. PreventionGenetics, Marshfield, WI.

Whole exome sequencing (WES) is a test that is intended for health care providers to look for a genetic diagnosis when the clinical phenotype is unclear and/or previous test results have been uninformative. We performed WES on patients and family members' (where available) DNA in a clinical diagnostic laboratory utilizing Agilent Clinical Research Exome v1 hybridization probes on Illumina's NextSeq 500 using 150 by 100 bp paired end reads. Quality metrics included >97% of target bases at >20x, and mean coverage of target bases at >120x. Sequencing data was analyzed using our internal Titanium-Exome software, where output data was converted to FASTQ using Illumina Bcl2Fastq 1.8.4, and mapped by BWA. Variant calls were made by the GATK Haplotype caller and annotated using in-house software and SnpEff. Variants were filtered and annotated using VarSeq ([www.goldenhelix.com](http://www.goldenhelix.com)). Variant interpretations and reports were made by PreventionGenetics' PhD molecular geneticists. The top clinical indications for whole exome sequencing included 45% for neurological disorders, 31% for multiple congenital abnormalities, and 14% for neuromuscular diseases. We observed positive molecular diagnoses in 32% of cases, 52% of cases were indeterminate, and 16% of cases were negative. We observed a similar positive rate for singleton and trio (i.e. proband and parents) exomes of 35% vs. 31%, respectively. About 50% of positive cases were due to an autosomal dominant disorder, and from these 56% of variants were classified as likely pathogenic due to *de novo* variant status, emphasizing the importance of trio testing. In fifty-nine genes recommended by the American College of Medical Genetics and Genomics (ACMG) that have potential medical value that are separate from the primary clinical indication (e.g. secondary findings), we found approximately 1.7% of exome cases had a pathogenic/likely pathogenic variant in one of these genes. We also gave the option of selecting additional Mendelian disorders genes, which may result in disease, and found that 35% of individuals were positive for a potentially pathogenic disease. We also recently gave the option of obtaining carrier status for pathogenic/likely pathogenic variants for recessive diseases. Nearly all individuals (94%) carried at least one positive finding. In conclusion, whole exome sequencing is a powerful tool for determining a genetic diagnosis in a clinical laboratory setting.

**2590W**

**Diagnostic exome sequencing identifies a homozygous whole-gene deletion of *DPY19L2* that was not detected by a high-density single nucleotide polymorphism (SNP) array.** S. Sajan<sup>1</sup>, S. Saliganan<sup>1</sup>, K.L. Helbig<sup>1</sup>, B. Barrows<sup>2</sup>, R. Martinez<sup>2</sup>, Z. Powis<sup>1</sup>, R. Burns<sup>3</sup>, L. Rohena<sup>3</sup>, J.A. Massie<sup>4</sup>, E. Spiteri<sup>1</sup>, W.A. Alcaraz<sup>1</sup>. 1) Department of Clinical Genomics, Ambry Genetics, Aliso Viejo, CA; 2) Clinical Laboratory Department, Ambry Genetics, Aliso Viejo, CA; 3) Departments of Pediatrics and Obstetrics and Gynecology, San Antonio Military Medical Center, San Antonio, TX; 4) Department of Obstetrics and Gynecology, Madigan Army Medical Center, Tacoma, WA.

While both exome sequencing and high-density single nucleotide polymorphism (SNP) arrays are capable of detecting copy number variants (CNVs), neither methodology is comprehensive and each can miss certain regions of the genome. In a clinical setting, SNP array testing usually precedes exome sequencing primarily due to its lower cost and ability to reliably detect large CNVs that are at least 100 kilobases (kb) in length. It is therefore important for SNP arrays to be able to detect, at the very least, known clinically relevant CNVs that meet the length cutoff so as to minimize additional unnecessary investigations towards a genetic diagnosis. We present a case example of an adult male with globozoospermia, a spermatogenic defect that can cause male infertility, who pursued diagnostic exome sequencing at our clinical genetic testing laboratory after having a negative CytoscanHD Array (Affymetrix) result. His exome data showed complete or almost-complete absence of coverage in all coding exons of *DPY19L2*, a gene known to cause globozoospermia when homozygously deleted. Homozygous deletions of this gene, which are approximately 200kb, are a common cause of this condition due to nearly-identical low copy repeats on either side of this gene that facilitate non-allelic homologous recombination. We confirmed the deletion in the patient by polymerase chain reaction-based amplification of three of the 22 coding exons (3, 11, and 22) of this gene, which showed no amplification. In contrast, two of six coding exons of the nearest gene *TMEM5* located 111kb away amplified successfully. Due to the presence of four pseudogenes in the genome, probe coverage of *DPY19L2* on the CytoscanHD array is poor, with only three intragenic SNPs in the entire 110kb length of the gene. However, homozygous deletions of *DPY19L2* have previously been detected by array comparative genomic hybridization (aCGH). This case illustrates the utility of exome sequence data in revealing CNVs previously missed by a high-density SNP array and suggests that a clinical high-density aCGH may be a favorable alternative for cases where discovering pathogenic CNVs is the primary intent before pursuing other genetic diagnostic tests.

**2591T**

**Towards automated variant pathogenicity assessment: A Bayesian classification framework.** L.G. Biesecker<sup>1</sup>, M.S. Greenblatt<sup>2</sup>, S.M. Harrison<sup>3</sup>, R.L. Nussbaum<sup>4</sup>, S. Prabhu<sup>5</sup>, K.M. Boucher<sup>6</sup>, S.V. Tavtigian<sup>7</sup>, ClinGen Sequence Variant Interpretation Working Group. 1) NHGRI/NIH, Bethesda, MD; 2) University of Vermont, Burlington, VT; 3) Partners Healthcare Laboratory, Boston, MA; 4) Invitae Corp, San Francisco, CA; 5) Dept of Genetics, Stanford University, Palo Alto, CA; 6) Dept of Medicine, Univ Utah, Salt Lake City; 7) Dept of Oncologic Sciences, Huntsman Cancer Inst, Salt Lake City, UT.

In 2015, the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP) published recommendations for interpretation of Mendelian disease gene variants (PMID: 25741868). The committee recognized the guideline as a starting framework that would evolve. One goal of the Clinical Genomics Resource (ClinGen) Sequence Variant Interpretation (SVI) Group is to refine and evolve those guidelines. We have initiated this by asking whether the criteria could be reframed as a Bayesian heuristic using conditional probabilities scaled to the categorical descriptors. The recommendations were evaluated to determine whether the rules are internally consistent and whether the qualitative, categorical "rules for combining criteria" to evaluate variants were quantitatively consistent. To do this, the criteria for and against pathogenicity were translated into a naïve Bayesian classifier, assuming four levels of evidence and exponentially scaled odds of pathogenicity. Results of this analysis show that the ACMG/AMP were in general valid and compatible with a quantitative framework and that 16 of 18 of ACMG/AMP pathogenicity combining criteria were internally consistent. However, two out of the 18 combining criteria were inconsistent (Likely Pathogenic combination i and Pathogenic combination ii). We will recommend changes for these two combining rules. The Bayesian classifier was extended to model additional combinations that currently lead to a VUS pathogenicity level (by including evidence for and against pathogenicity), for which we show that certain combinations can lead to posterior probabilities in the range of likely pathogenic or even pathogenic, and can be readily calculated. Finally, this formal Bayesian framework will facilitate the transition from categorical evidence (e.g., allele frequency above or below a set threshold) to continuous variable evidence types, which extract maximal information from quantitative datasets (e.g., ExAC or functional data). By transforming the ACMG/AMP recommendations into a quantitative, Bayesian framework, we provide a mathematical foundation to what was a qualitative, categorical heuristic and validates the fundamental approach adopted by the ACMG/AMP. More importantly, it advances the science of variant interpretation by providing a mathematical foundation to further refine evidence and combining rules, and supports efforts to automate components of variant pathogenicity assessments.

**2592F**

**Protocols to keep NGS gene panels and annotation content current.** *N.A. Rouse, M.J. Snyder, T.J. McMahan, W.A. Langely, P.L. Nagy.* MNG Laboratories, 5424 Glenridge Drive NE, Atlanta, GA 30342 USA.

With decreasing sequencing costs and growing numbers of out of the box bioinformatics solutions, the landscape of clinically relevant genes and variants is changing at an unprecedented rate. Staying at the forefront of clinical relevancy requires frequently scheduled curation and updating of both gene lists and annotation databases. A two-fold approach is taken to keep data interpretation up to date. Gene list classifications are updated quarterly and annotation databases are updated monthly, coinciding with ClinVar's monthly release. Gene classification is determined by the combined use of OMIM and ClinVar and review of the scientific literature. Newly pathogenic or reclassified genes are individually examined to confirm correct placement for each panel based on multiple lines of independent scientific evidence. This gene curation results in a quarterly custom capture redesign and NGS panel updates. To ensure that annotations are precisely defined and up to date, our bioinformatics solution processes variant and gene annotation from external databases monthly through a normalization pipeline. Frequently updating custom capture reagent in conjunction with updating annotation content on a monthly basis increases diagnostic sensitivity in NGS panels.

**2593W**

**Elective whole genome testing in clinical practice.** *D. Bick<sup>1,2</sup>, K. East<sup>1,2</sup>, W. Kelley<sup>1,2</sup>, C. Aiken<sup>2</sup>, A. Crouse<sup>1</sup>, H. Jacob<sup>1</sup>, A. Hott<sup>1</sup>, N. Lamb<sup>1</sup>, M. Schroeder<sup>1</sup>, C. Birch<sup>1</sup>, D. Brown<sup>1</sup>, L. Handley<sup>1</sup>, S. Newberry<sup>1</sup>, E. Worthey<sup>1</sup>, M. Cochran<sup>1,2</sup>.* 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) Smith Family Clinic for Genomic Medicine, Huntsville, AL.

Genomic testing (whole genome and whole exome sequencing) has entered routine clinical practice worldwide for the diagnosis of genetic disorders. Recently, individuals who do not have a standard indication for sequencing have begun to request genomic testing. These tests are referred to as elective genomic tests. As the availability of testing has spread and the cost has diminished, more individuals are choosing to have elective testing. Elective genomic testing generally includes one or more of following categories of results for adults interested in their personal or family risk: (1) Variants that are associated with diseases already present in the individual. (2) Secondary or incidental variants that result in a Mendelian disorder where the individual has not manifested the disorder. (3) Carrier status for recessive disorders. (4) Pharmacogenomic variants. (5) Multi-SNP genetic risk profiles for actionable common adult-onset diseases. In July 2016, we initiated Insight Genome, an elective whole genome sequencing and pharmacogenetic test for adults. Insight Genome patients provide medical history, medical records through their physician, have a physical examination, pre-test genetic counseling and post-test results discussion. Clinical whole genome sequencing and pharmacogenetic results are returned to the patient and referring provider. To date 30 individuals have participated in the program. Among the first 24 to complete testing and reporting, 7 (29%) were found to have a variant associated with their phenotype (a primary finding). One was found to have a variant not associated with their phenotype (secondary finding). 17 (71%) were found to be carriers for 1 to 5 autosomal recessive disorders. 12 (50%) were found to have variant(s) where guidelines recommend selection of an alternative drug affecting 3 or more medications. Patients received findings that may explain part of their medical history. Few of these individuals had a standard indication for diagnostic testing. Many patients were carriers for disorders not covered by available pan-ethnic carrier screening and were found to harbor important pharmacogenomics variants. Both patients and their providers have been enthusiastic about and receptive to the results and have indicated that they plan to use this information for future care. Elective genomic testing provides important medical information that individual and their physicians can use today.

**2594T**

**Clinically significant small indels detected by whole genome sequencing: A proof of concept case series.** C.M. Brown<sup>1</sup>, A. Gross<sup>1</sup>, K. Bluske<sup>1</sup>, N.J. Burns<sup>1</sup>, A. Chawla<sup>1</sup>, A.J. Coffey<sup>1</sup>, R.T. Hagelstrom<sup>1</sup>, M.C. Jones<sup>2</sup>, A. Malhotra<sup>1</sup>, D. Masser-Frye<sup>2</sup>, D.L. Perry<sup>1</sup>, A. Scocchia<sup>1</sup>, E. Thorpe<sup>1</sup>, J.L. Williams<sup>3</sup>, M.S. Williams<sup>3</sup>, R.J. Taft<sup>1</sup>. 1) Illumina Inc., 5200 Illumina Way, San Diego, CA 92122; 2) Rady's Children's Hospital San Diego, Division of Dysmorphology/Genetics, 7920 Frost Street, Suite 200, San Diego, CA, 92123; 3) Geisinger Health System, Genomic Medicine Institute, Weis Center for Research, 100 North Academy Ave., Danville PA 17822.

Insertions and deletions (indels) between ~10 bp and 10 kb represent a diagnostic challenge and often are not captured by current genetic testing platforms including chromosomal microarray (CMA), whole exome sequencing (WES) and many next generation sequencing panels. Small indels can be detected by targeted techniques including multiplex ligation probe amplification or custom CMA, but these methods require prior identification of candidate genes or loci. Consequently, routine clinical testing for small indels is restricted to single gene or panel analyses. Although the prevalence of disorders caused by small indels is unknown, it is likely that individuals with genetic disorders caused by these variants go undiagnosed, particularly when non-specific features or atypical presentations make the differential diagnosis challenging. Whole genome sequencing (WGS) is a diagnostic platform which has the capability of simultaneously detecting small nucleotide variants, like WES, and indels greater than 10 kb, like CMA, across the genome. There is also emerging evidence that WGS has the capability to detect small indels on a genome-wide scale. Three cases with clinically significant indels less than 10 kb detected by WGS (TruGenome Undiagnosed Disease Test, Illumina Inc.) are presented; a heterozygous 8.4 kb loss at Xq13 (NM\_018486.2:c.1112-7725\_\*615del) causing a partial deletion of *HDAC8* in a child with X-linked Cornelia de Lange syndrome, a 1.7 kb deletion in *CHRNA1* (NM\_000747.2:c.821-990\_1045-311del) in trans with a missense variant, p.Pro271Leu (NM\_000747.2:c.812C>T), in a child with congenital myasthenic syndrome and a 46 bp deletion in *ECEL1* (NM\_004826.2:c.110\_155del) in trans with a nonsense variant, p.Gln265Ter (NM\_004826.2:c.793C>T) in a child with distal arthrogryposis type 5D. Orthogonal testing performed to validate these findings is also presented. This case series illustrates that in addition to capturing variant types typically detected by WES and CMA, WGS has the potential to detect indels less than 10 kb, addressing a known diagnostic gap in clinical genomics.

**2595F**

**Safely washing and reusing pipette tips for Next Generation Sequencing (NGS) qPCR.** A. Graham. Grenova, LLC, 483 Southlake Blvd., Richmond VA 23236.

**Statement of Purpose:** Disposable pipette tips provide an easy and carryover free process for liquid transfers. Once discarded, these polypropylene plastics enter the waste stream and are either incinerated as biohazard waste or moved to a landfill. Because of potential carryover, washing pipette tips for reuse is not generally accepted as safe for many scientific assays. Using recently introduced technology, Grenova tip washer devices demonstrate that pipette tips can be safely and effectively washed for NGS qPCR reuse.

**Methods:** Validation test methods were performed with 384 Hamilton CO-RE nested tip racks. Carryover studies were performed by soaking control and experimental wash pipette tip racks in a DNA solution. Control group pipette tips were subsequently used in qPCR preparation. Experimental pipette tips were washed then used in qPCR preparation. **Results:** Amplification resulted in a five orders of magnitude difference between control and washed pipette tips. Control tips qPCR resulted in expected Ct values indicating normal amplification. Washed pipette tips qPCR amplification resulted no amplification or Ct values between 25.4 – 30. **Conclusion:** This study indicates that pipette tips washed and dried in a Grenova tip washer performed as expected. Washing and reusing over 15,000 pipette tips daily rather than discarding, resulted in over \$500,000 cost savings in addition to waste reduction for the NGS labs.

Petrikin<sup>2,3,4</sup>. 1) Rady Children's Institute for Genomic Medicine, San Diego, CA; 2) Center for Pediatric Genomic Medicine, Children's Mercy - Kansas City, Kansas City, MO; 3) Department of Pediatrics, Children's Mercy - Kansas City, Kansas City, MO; 4) School of Medicine, University of Missouri-Kansas City, Kansas City, MO; 5) Department of Pathology, Children's Mercy - Kansas City, Kansas City, MO; 6) Department of Pediatrics, University of California – San Diego, Rady Children's Hospital, University of California – San Diego, CA.

There is increasing evidence that genome sequencing has diagnostic utility in the acute care of infants with genetic diseases in neonatal and pediatric intensive care units (NICU, PICU). Since genetic diseases are a leading cause of mortality in infants and disease progression can be very rapid, genetic diagnoses must be made quickly to permit consideration of precision medicine interventions in time to decrease morbidity and mortality. Though there is evidence that standard whole genome and whole exome sequencing (WGS, WES) have higher diagnostic rates than other genetic tests in children with likely genetic diseases, diagnoses generally occur too late to guide NICU and PICU management. In a retrospective study, 57% of infants received genetic diagnoses by rapid whole genome sequencing (rWGS) in a median of 23 days (day of life [DOL] 49). We report results from the first randomized controlled trial comparing trio rWGS plus standard tests (cases) with standard tests alone (controls) in a regional NICU and PICU from 2014 - 2016. The primary end-point was rate of genetic diagnosis within 28 days of enrollment. 65 families with infants <4 months old and suspected of a genetic disease completed the study. The study was terminated early due to loss of equipoise: 63% (21) of 33 controls received standard WGS, WES, or next-generation sequencing panels. Nevertheless, an intention-to-treat analysis showed the rate of confirmed genetic diagnosis within 28 days of enrollment to be higher in cases (31%, 10 of 32) than controls (3%, 1 of 33;  $p=0.003$ ). Among infants enrolled in the first 25 days of life, the rate of diagnosis by DOL 28 was higher in cases (32%, 7 of 22) than controls (0%, 0 of 23;  $p=0.004$ ). Overall time to diagnosis and age at diagnosis also differed significantly between cases and controls after accounting for non-proportional rates of diagnosis ( $p=0.040$  and  $p=0.043$ , respectively). We suggest that rWGS should be considered as a first-tier genetic test in NICU and PICU infants with likely genetic diseases. Since genetic diseases are among the leading cause of death in infants, these results may have broad implications for pediatric precision medicine.

**Challenges and solutions for FFPE DNA quantitation.** K. Plasman, T. Boonefaes, T. Martens, T. Duthoit, T. Montoye. Trinean, Gentbrugge, Belgium.

As large collections of FFPE samples have been gathered over many years, FFPE tissue derived DNA or RNA are popular subjects in genetic studies and cancer research. The success of downstream tests with DNA isolated from FFPE tissue blocks however cannot be guaranteed as samples can be fragmented, chemically altered and/or heavily contaminated with carry-over molecules from the source material and extraction buffer constituents. Proper quantification and purity analysis after isolation are therefore desirable. In this poster we present experimental data to demonstrate the advantages and shortcomings of the most used FFPE DNA quantification technologies, being A260 absorbance, Qubit fluorescence and DropSense/cDrop. Finally, we propose ways to standardize FFPE DNA QC in order to achieve higher success-rates of downstream assays.

**CLIP-Cap: Combined Long-Insert Paired-End and Capture sequencing, a novel method for the analysis of complex genomic aberrations.** C. Purmann<sup>1</sup>, X. Zhu<sup>1</sup>, D. Palejev<sup>2</sup>, J. Bernstein<sup>1</sup>, J.F. Hallmayer<sup>1</sup>, A.E. Urban<sup>1</sup>. 1) Stanford University, Palo Alto, CA, United States; 2) Bulgarian Academy of Sciences, Sofia, Bulgaria.

CLIP-Cap is a method that allows to completely resolve complex chromosome rearrangements in the human genome using standard laboratory equipment and an efficient and multiplexable workflow. CLIP-Cap is a combination of long-insert paired-end and capture sequencing. It is based on creating a paired-end sequencing library where the inserts of genomic DNA are of variable length in the kilobase-range (i.e. 2-8 kbp as opposed to 400-800 bp in standard paired-end sequencing), also known as mate-pair or jumping library. From this paired-end library a semi-targeted capture is carried out using capture oligomers representing one of the chromosomes involved in the structural genome aberration at hand. This is then followed by limited (i.e. benchtop or multiplexed) 'next-generation' DNA sequencing and data analysis with standard software tools (for mate pair mapping, split-read analysis and read-depth analysis, respectively). We resolved the three main Philadelphia Chromosome aberrations, in three different cancer cell lines (Kasumi-4, which contains a three-way translocation, SUP-B15 and K562). Furthermore, we resolved the complex rearrangements in four cases with developmental disorders that all involved chromosome 22, but also other chromosomes (9, 10 or 11) or multiple different aberrations (e.g. deletions and dicentric inversions) present in a mosaic manner. Currently there is no single approach to resolve typical complex chromosomal rearrangements that are a common hallmark of cancer and also of developmental disorders. We have tested CLIP-Cap on seven different cases of genomic rearrangements to demonstrate that it is sufficient to resolve a wide range of scenarios, the only requirement at the outset being knowledge of one of the chromosomes involved in the aberration. .

**Frequencies of *BCHE* variants in a large cohort of US individuals.** G. Zhu, H. Fang, F.G. Espin, E.S. Dawson, T.A. Moreno, A.L. Del Tredici. Millennium Health, LLC, San Diego, CA.

The *BCHE* gene encodes butyrylcholinesterase (also known as plasma cholinesterase or pseudocholinesterase), an enzyme responsible for the hydrolysis and deactivation of the neuromuscular blocking agent succinylcholine. BChE deficiency increases the risk of prolonged neuromuscular blockade and respiratory depression in response to succinylcholine. The common *BCHE* variants atypical (A, rs1799807) and Kalow (K, rs1803274), and rarer variants fluoride-1 (flu-1, rs28933389), fluoride-2 (flu-2, rs28933390) and silent-1 (sil-1, rs398124632) are associated with various degrees of reduction in the activity of the BChE enzyme. A real-time PCR-based method was developed to test for these variants in a large (n > 13,000), multi-ethnic cohort in the United States. Test subjects received pharmacogenetic testing and were not selected based on planned surgeries or history of any perioperative complication. The allele frequencies of A, K, flu-1, flu-2 and sil-1 were 0.016, 0.199, 0.0008, 0.0047, and 0.0004, respectively, in this cohort. Approximately 0.06% of individuals were predicted to have severe BChE deficiency because they were homozygotes or compound heterozygotes of A, flu-1 and/or flu-2. Approximately 8% of individuals were predicted to have moderate BChE deficiency because they had two copies of K or one copy of A, flu-1, flu-2 or sil-1. Compared to other ethnic groups, Caucasians were predicted to have the highest frequencies of both severe and moderate BChE deficiencies. This is the first screening of *BCHE* genetic variants in a large cohort and, especially, this is the first time frequencies of *BCHE* genetic variants are estimated in African-American, Asian and Hispanic ethnic groups in the US.

**2600T****WGS is an imperfect but valuable tool for predicting the risk of genetic disease in children.**

To pilot paediatric genomic medicine we developed the SickKids Genome Clinic, a research project centered on diagnostic whole genome sequencing (WGS) of children undergoing genetic evaluation. With parents' consent, we also search for predictive secondary variants (PSVs) associated with occult or future disease. For our first 100 patients, analysis of WGS data for candidate PSVs revealed 4 variants associated with the ACMG list of reportable disorders. Expanding the search to 3000+ ClinGen genes identified returnable PSVs in more than 25% of children. Four children had 2 PSVs and one child had 3. The majority were rare variants in genes that cause dominant Mendelian disorders. The rest included variants linked to attenuated Mendelian phenotypes, common disease risk variants, an X-linked variant and a protective variant. To date, reverse phenotyping of the proband and 1<sup>st</sup> degree relatives found evidence of the phenotype predicted by the PSV in 44% of cases. On multiple occasions, evidence for the predicted phenotype was hidden "in plain sight," as the patient's medical record contained clinical or laboratory findings consistent with the predicted phenotype that had not been acted upon (e.g., long QT syndrome). As all predictive secondary variants in our dataset were inherited, we compared the predictive performance of WGS to a) routine family histories obtained by the referring clinical geneticists/genetic counselors, b) comprehensive family histories obtained by the research team *prior* to disclosure of PSVs, and c) family histories obtained by the research team *after* disclosure of PSVs. Importantly, family histories obtained prior to disclosure of PSVs by either the referring clinician or the research team did not predict the phenotypes associated with the PSVs. However, in almost 50% of cases in which the PSV was found to be penetrant, parents revised their family histories in response to being informed of the phenotypes predicted by the PSV and reported previously undisclosed PSV-associated phenotypes in the proband and/or family members. Our results suggest that, routine family histories substantially underestimate genetic risk, as many parents edit family history and clinicians frequently target their family history inquiries. Predictive analysis of WGS data currently outperforms family history in identifying the risk of occult or future genetic disease in children, but this greater sensitivity is accompanied by a significant false positive rate.

The gnomAD browser brings together genome and exome sequence data of 138,632 unrelated individuals from diverse populations, providing an unprecedented reference resource, particularly for variant analyses that leverage allele frequency information. By contrast, current repositories of genetic variation for Mendelian diseases do not record allele frequency in cases, critically limiting the application of contemporary quantitative approaches in clinical variant interpretation. We present an aggregated case series comprising genetic data from more than 10,000 cardiomyopathy patients, together with a web-browser interface (VariantFX) that allows for seamless integrative analysis with the gnomAD resource. This is the largest genetically characterized cardiomyopathy series to date, stratified by cardiomyopathy subtype and ethnicity, and includes representation of ethnic groups in whom the architecture of cardiomyopathy has been previously uncharacterized. We leverage this data to derive quantitative parameters for the interpretation of individual variants observed in cardiomyopathy, including estimates of the probability that a variant is causal in the disease, and variant penetrance. Integrative analysis of regional clustering of rare variation in cases with regional constraint in gnomAD yields insights into the molecular mechanisms of pathogenicity for missense variants in cardiomyopathy genes, and allows for extrapolation of quantitative measures for interpretation of novel and very low frequency variants. Population analyses identify distinct disease architectures in different ethnic groups. In addition to the new dataset and resulting biological insights, we have developed a data integration and visualization platform explicitly designed to be readily expanded to additional cardiovascular diseases and genes, and for modular redeployment in other disease areas. A containerized architecture allows for distributed VariantFX instances hosting new disease-specific case series, with native integration of the gnomAD resource implemented via API. Our resource is available via [cardiac.variantfx.org](https://cardiac.variantfx.org), and the variantfx framework is available open source at <https://github.com/ImperialCardioGenetics/variantfx>.

**Analysis of 181 selected genes associated with dilated cardiomyopathy by next-generation sequencing.** *K. Al Harbi<sup>1</sup>, Z. A. Bhuiyan<sup>2</sup>, AM. Abdallah<sup>3</sup>, S. Justin Carlus<sup>1,4</sup>.* 1) Pediatrics Department, College of Medicine, Taibah University, Al-Madinah, Saudi Arabia; 2) Molecular Genetics Laboratory, Lausanne, Switzerland; 3) West Midlands Regional Genetics Laboratory, Birmingham Women's NHS Foundation Trust, Birmingham, UK; 4) Global Gene Corp Pvt. Ltd, India.

Inherited cardiomyopathy is the major cause of sudden cardiac death (SCD) and heart failure (HF). Genetic defects could be elucidated in 50-70% of patients with cardiomyopathy. Mutations have been described in about 70 genes; this number is on the rise. Currently, there is no information available on genetic pathology of various cardiomyopathies in Saudi Arabia. We undertook the pilot initiative for the first time to systematically screen the sporadic Dilated cardiomyopathy (DCM) patients in Saudi Arabia, to understand the prevalence of this disease entity, prominent genes involved into the pathology of cardiomyopathies and to identify several founder mutations in our Kingdom.

**Methods:** A cohort of 45 samples - 15 sporadic DCM samples and 30 unaffected parents' samples as controls were collected. Their parents displayed no phenotypic evidence of DCM on screening by echocardiography. Initially next generation sequencing was performed using NimbleGen custom design Cardiomyopathy Enrichment Panel (181 genes) in conjunction with Illumina HiSeq 2500@ instrument. Our sequencing panel covered coding exons, exon-intron boundaries and known variants in intronic regions of target genes. **Results:** NGS identified 12 putative pathogenic variants in various cardiac expressed genes (LAMA4, MYH7, ACADVL, SCN5A, RBM20, TCAP, DPP6, PKP2) in 7 patients (46.6%). No genetic variants were identified in 8 cases (53.3%).

**Conclusion:** Our data support the potential role of the detected variants in pathogenesis of DCM. Mutations in LAMA4, MYH7, SCN5A, RBM20, ACADVL and TCAP have been reported to be associated with DCM and HCM. Variants in PKP2 gene was associated with Arrhythmogenic right ventricular dysplasia 9. This initial analysis suggests that these mutations are very likely pathogenic and confirmed by the Sanger sequencing. .

**Loss of ADAMTS3 activity causes Hennekam lymphangiectasia-lymphedema syndrome 3.** P. Brouillard<sup>1</sup>, L. Dupont<sup>2</sup>, R. Helaers<sup>1</sup>, R. Coullie<sup>1</sup>, G. Tiller<sup>3</sup>, J. Peeden<sup>4</sup>, A. Colige<sup>2</sup>, M. Vikkula<sup>1</sup>. 1) de Duve Institute, Human Molecular Genetics, Universite catholique de Louvain, Brussels, Belgium; 2) Université de Liege, Laboratory of Connective Tissues Biology, Liege, Belgium; 3) Vanderbilt University, Medical Center, Nashville, TN, USA; 4) University of Tennessee Medical Center, East Tennessee Children's Hospital, Knoxville, TN, USA.

Primary lymphedema is due to developmental and/or functional defects in the lymphatic system. It may affect any part of the body, with predominance for the lower extremities. Twenty-seven genes have already been linked to primary lymphedema, either isolated, or as part of a syndrome. The proteins that they encode are involved in VEGFR3 receptor signaling. They account for about one third of all primary lymphedema cases, underscoring the existence of additional genetic factors. We used whole-exome sequencing to investigate the underlying cause in a non-consanguineous family with two children affected by lymphedema, lymphangiectasia and distinct facial features. We discovered bi-allelic missense mutations in *ADAMTS3*. Both were predicted to be highly damaging. These amino acid substitutions affect well-conserved residues in the prodomain and in the peptidase domain of *ADAMTS3*. *In vitro*, the mutant proteins were abnormally processed and sequestered within cells, which abolished proteolytic activation of pro-VEGFC. VEGFC processing is also affected by *CCBE1* mutations that cause the Hennekam lymphangiectasia-lymphedema syndrome type 1. Our data identifies *ADAMTS3* as a novel gene that can be mutated in individuals affected by the Hennekam syndrome. These patients have distinctive facial features similar to those with mutations in *CCBE1*. Our results corroborate the recent *in vitro* and murine data that suggest a close functional interaction between *ADAMTS3* and *CCBE1* in triggering VEGFR3 signaling, a cornerstone for the differentiation and function of lymphatic endothelial cells.

**Titin rare genetic variants in arrhythmogenic cardiomyopathy.** R. Celegghin, E. Lazzarini, I. Rigato, K. Ludwig, M. Cason, G. Thiene, C. Basso, B. Baucé, K. Pillichou. Department of Cardiac, Thoracic and Vascular Sciences, University of Padua, Padua, Italy.

**Introduction.** Arrhythmogenic cardiomyopathy (AC) is a heart muscle disease characterized by life-threatening ventricular arrhythmias and progressive dystrophy of the ventricular myocardium with fibro-fatty replacement. Due to an estimated prevalence of 1:2000-1:5000, AC is defined as a rare disease with autosomal-dominant transmission and incomplete penetrance. It is considered a disease of intercalated discs, however about 1% of AC patients harbor a mutation in non-junctional proteins such as RYR2, TTN, LMNA, DES, PLN. Non-junctional proteins mutation frequency in AC patients is probably underestimated due to gene size-related sequencing and interpretation difficulties. In fact 60,000 *TTN* missense variants have been identified with the advent of massive parallel sequencing. The purpose of this study was to assess the frequency of *TTN* variants in AC patients. **Methods.** Eighty-nine consecutive AC index cases, fulfilling 2010 Task Force Criteria, underwent DNA sequencing on the MiSeq platform (Illumina) using the Trusight Cardio panel (174 genes). Variant selection was based on current ASHG guidelines and a threshold <0.0002 minor allele frequency in the general population. Cascade genetic screening in probands' families was performed to study the segregation of variants and their impact on the clinical phenotype. **Results.** Variant filtering for amino acid conservation and pathogenicity based on at least two *in silico* prediction algorithms (i.e. Polyphen-2, SIFT, Mutation Taster) reduced the number of initially detected rare *TTN* variants from 49 (in 41 AC patients) to 29 (in 23 AC patients 26%). Only three out of the 23 AC index cases carried an additional putative pathogenic variant in AC related genes (*DSP*, *DSC2*, *PKP2*). **Conclusions.** Preliminary data demonstrates a high frequency of rare *TTN* variants in AC patients. Additional clinical studies as to the possible phenotypical differences between *TTN*-only carriers and those carrying additional variants in other AC-related genes will help to clarify the causative or modulatory role of *TTN* in the etiopathogenesis of AC.

**2606T**

**Novel heterozygous mutations of *KCNQ1* gene in a Jervell and Lange-Nielsen syndrome patient with gastric neuroendocrine tumor.** *K. Choi, J. Kim, Y. Jee.* Department of Laboratory Medicine, Dankook University Hospital, Cheonan-si, Chungnam, South Korea.

The Jervell and Lange-Nielsen syndrome (JLNS) is a rare autosomal recessive syndrome characterized by congenital hearing loss, prolongation of the QT interval, ventricular arrhythmias, and high risk of sudden death. JLNS has been primarily caused by homozygous variants in *KCNQ1* or *KCNE1* gene. There have been very few clinical case reports on JLNS in Korea. Recently, we identified novel heterozygous variant of *KCNQ1* gene using massively parallel sequencing method in a Jervell and Lange-Nielsen syndrome patient, who underwent surgery due to gastric neuroendocrine tumor. She complained epigastric pain for 6 months and her laboratory results showed iron deficiency anemia. Her electrocardiogram revealed a markedly prolonged QT interval. Targeted next generation sequencing analysis were performed and it revealed the presence of novel heterozygous variant (c.826T>C, p.Ser276Pro). The same variant was found in the parents, a sister, and two children, and all of them appeared to have prolonged QT interval. This is the first report of gastric neuroendocrine tumor in a Jervell and Lange-Nielsen syndrome patient although iron-deficiency anemia and gastric hyperplasia have been reported previously.

**2607F**

**MCTP2 gene change detected by whole exome sequencing in an infant with endocardial fibroelastosis syndrome who underwent heart transplantation.** *D. Ercelen<sup>1</sup>, B. Monteleone<sup>2</sup>, G. Wallis<sup>3</sup>.* 1) Carolinas Health System, Charlotte, NC; 2) Carolinas Health System, Charlotte, NC; 3) Carolinas Health System, Charlotte, NC.

This is the first report of a patient with Endocardial Fibroelastosis (EF) Syndrome. Whole exome analysis demonstrated a variant of unknown change in MCTP2 gene: c.2156A>G (p.Y719C) that was inherited from the father. This variant was not detected in the NHLBI Exome Sequencing Project, indicating it is not a common benign variant. In silico analysis predicts this variant is probably damaging to protein structure and function. 5 days old girl was born at 39 weeks with a large left ventricle cardiac mass detected by ECHO. Birth weight: 3.74 kg, length: 49.5 cm, head circumference: 35.5 cm. Physical exam was normal. MRI of the brain and kidneys were normal. Her clinical findings were not sufficient for a diagnosis of Tuberous sclerosis with normal TSC1 and TSC2 genetic. Patient did not respond to several courses of sirolimus. Cardiac MRI showed several masses in the left ventricle, causing severe obstruction and diastolic dysfunction. She subsequently developed signs of atrial hypertension with concomitant pulmonary hypertension. and received heart transplant at 9 months of age. Endocardial fibroelastosis (EF) syndrome is a pronounced, diffuse thickening of the ventricular endocardium that presents as an unexplained heart failure in infants and children. The disease can be primary or secondary to various congenital heart diseases. Primary EF is not associated with any significant cardiac structural abnormalities, and one of the causes of unexplained heart failure. 25% of children who were transplanted for dilated cardiomyopathy demonstrated significant endocardial fibroelastosis on histopathology of the explanted hearts. MCTP2 gene are calcium-binding domains works in proteins involved in signal transduction or membrane trafficking. In animal models, MCTP2 gene has been shown to be associated with cardiogenesis. More, disruption of MCTP2 has been reported to contribute to congenital left heart obstructive cardiac defects in humans. Previously, 2 patients with 15q26.2 deletion involving MCTP2 gene was reported with EF syndrome caused by pre and postnatal left ventricular outflow tract (LVOT) obstruction. Their mother had similar heterozygous deletion with normal ECHO. The penetrance for the cardiac phenotype is not complete with Mctp2 knock-down. In summary, we have preliminary evidence that variants in MCTP2 gene are associated with primary and secondary EF syndrome. More patients are warranted to investigate these associations further.

**Use of the ClinGen clinical validity framework to evaluate the strength of evidence for genes implicated in hypertrophic cardiomyopathy.** J. Goldstein<sup>1</sup>, J. Ingles<sup>2</sup>, C. Caleshu<sup>3</sup>, E. Corty<sup>4</sup>, S. Crowley<sup>5</sup>, K. Dougherty<sup>6</sup>, J. McGlaughon<sup>7</sup>, L. Milko<sup>8</sup>, A. Morales<sup>9</sup>, B. Seifert<sup>10</sup>, C. Semsarian<sup>2</sup>, N. Strande<sup>1</sup>, C. Thaxton<sup>1</sup>, K. Thomson<sup>6</sup>, P. van Tintelen<sup>7</sup>, K. Wallace<sup>1</sup>, R. Walsh<sup>8</sup>, J. Ware<sup>6</sup>, Q. Wells<sup>1</sup>, N. Whiffin<sup>8</sup>, L. Wikowski<sup>10</sup>, R. Hershberger<sup>6</sup>, B. Funke<sup>10</sup>, *ClinGen Cardiovascular Clinical Domain Working Group*. 1) UNC-Chapel Hill, Chapel Hill, NC; 2) Sydney Medical School, University of Sydney, Australia; 3) Stanford University, CA, USA; 4) Eastern Virginia Medical School, VA, USA; 5) Ohio State University, OH, USA; 6) Oxford Medical Genetics Laboratory, Oxford, UK; 7) Academic Medical Center, Amsterdam, Netherlands; 8) Imperial College London, London, UK; 9) Vanderbilt University Medical Center, TN, USA; 10) Harvard Medical School/MGH, MA, USA.

Hypertrophic cardiomyopathy (HCM) is defined as unexplained left ventricular hypertrophy (LVH) in the absence of other causes. The clinical presentation ranges from asymptomatic LVH to progressive heart failure, arrhythmia, and sudden cardiac death. In the majority of cases, HCM is caused by a pathogenic variant in one of 8 genes encoding components of the cardiac muscle sarcomere. Z-disc and calcium-handling genes have also been implicated. Commercial laboratory gene testing panels can include 50 or more genes with variable levels of evidence to support their association with HCM. Using the Clinical Genome Resource (ClinGen) gene-disease clinical validity framework, we curated publically available data to classify the clinical validity for 55 genes and HCM. The gene list was based on (1) Presence on >30% of HCM gene panels in the NCBI Genetic Testing Registry, (2) Inclusion in the TruSight HCM gene panel (Pua et al, 2016, PMID: 26888179), and (3) Expert opinion. Curations were performed by biocurators, overseen by a cardiac expert, and discussed on regular conference calls to reach a final gene-disease validity classification. Initially, we targeted genes that appeared to be associated with isolated HCM. Of 37 genes curated to date, 8 had a definitive association, 2 strong, 4 moderate, 16 limited, and 7 had no reported evidence. As we began to curate genes associated with HCM as part of a wider syndrome (e.g. GLA, FHL1) we recognized the need to fully evaluate the range of disorders caused by all of the genes on our list, and whether it was appropriate to "split" the curation to include only individuals with isolated HCM or "lump" cases into a wider syndrome. Following the recommendations of the newly-formed ClinGen Lumping and Splitting working group, we binned all 55 genes on our list into one of three groups: genes causing isolated HCM, genes associated with multiple cardiac phenotypes, and syndromic genes that include HCM as part of the phenotypic spectrum. We will present the rationale for the binning process and our curation results to date. We conclude that the ClinGen clinical validity classifications will be beneficial to the development and interpretation of genetic testing in patients with HCM.

## 2609T

**Cardiologic findings in 101 patients with Williams Syndrome.** R.S. Honjo<sup>1</sup>, J.R.M. Ceroni<sup>1</sup>, P.H.S. Castro<sup>1</sup>, J.G. Salomão<sup>1</sup>, S.P.O. Saldaña<sup>1</sup>, D.C.S. Bermeo<sup>1</sup>, E.A. Furusawa<sup>2</sup>, G.N. Lea<sup>3</sup>, J. Wagenführ<sup>4</sup>, E.A. Zanardo<sup>5</sup>, L.D. Kulikowski<sup>5</sup>, D.R. Bertola<sup>1</sup>, C.A. Kim<sup>1</sup>. 1) Genetics Unit, Instituto da Criança, São Paulo, São Paulo, Brazil; 2) Nephrology Unit, Instituto da Criança - HC-FMUSP, São Paulo - SP, Brazil; 3) Echocardiography Service, Instituto da Criança - HC-FMUSP, São Paulo - SP, Brazil; 4) Pediatric Cardiology Unit, Instituto da Criança - HC-FMUSP, São Paulo - SP, Brazil; 5) Medical Investigation Laboratory (LIM 03) - FMUSP, São Paulo - SP, Brazil.

**Objective:** To identify and describe the cardiologic findings of 101 patients with Williams Syndrome (WS) confirmed by molecular studies. **Methods:** Retrospective and observational study of the cardiologic findings in 101 patients with molecularly confirmed WS, evaluated from 2008 through 2016. **Results:** The total cohort consisted of 101 patients, 62.4% males and 37.6% females. A total of 77 (76.2%) WS children had a congenital structural heart defect. Overall 44/77 (57.1%) patients with heart anomalies had a single defect, while the remaining 33/77 (42.9%) had combined heart defects. The most common abnormality was supravalvular aortic stenosis (48%), found in 37 patients, of whom 15 (40.5%) had another heart defect. Other defects included: Aortic stenosis (7.8%), pulmonary stenosis (26%), stenosis of the branch pulmonary arteries (14.3%), mitral valve prolapse (19.5%), mitral insufficiency (11.7%), aortic coarctation (7.8%), aortic insufficiency (3.9%), ventricular septal defect (3.9%), atrial septal defect (3.9%), bicuspid aortic valve (2.6%). Dilated aortic root, tricuspid insufficiency and hypertrophic cardiomyopathy were all found each in one patient (1.3%). A total of 28/80 (35%) had normal ECG, while left ventricle overload, the most common ECG abnormality, was found in 5 patients (6.3%). Other findings: abnormal ventricular depolarization (2.5%), right atrial overload (1.2%), conduction delay (1.25%), and ectopic atrial rhythm (1.2%). High blood pressure was diagnosed in 42 of 101 (41.6%) patients. Heart transplantation was carried out in a 19-year-old female patient who presented supravalvular aortic stenosis and refractory congestive heart failure. This patient had been previously submitted to aortic stenosis correction twice. Unfortunately, the patient died due to CMV infection on the 47th day after transplant. **Conclusions:** A high incidence of potentially hazardous congenital heart diseases has been reported in patients with WS. There are few descriptions of heart transplantation procedures in patients with genetic syndromes and, up to date, only one in a WS patient. Cardiovascular diseases are responsible for the greatest morbidity and mortality in WS, but are preventable and treatable with the appropriate care. It is recommended that all patients have periodic cardiology and nephrology follow-up, in order to prevent, manage, and treat possible complications and improve both quality of life and survival rates. (Support: CNPQ / FAPESP).

**2610F****Toward genetics-driven early intervention in dilated cardiomyopathy:****The DCM Precision Medicine Study.** *D.D. Kinnamon<sup>1</sup>, A. Morales<sup>1</sup>, D.J.*

*Bowen<sup>2</sup>, W. Burke<sup>2</sup>, R.E. Hershberger<sup>1</sup> on behalf of the DCM Consortium.* 1) Division of Human Genetics, Department of Internal Medicine, The Ohio State University Wexner Medical Center, Columbus, OH; 2) Department of Bioethics and Humanities, University of Washington, Seattle, WA.

The etiology of idiopathic dilated cardiomyopathy (DCM) is unknown by definition, but its familial subtype is considered to have a genetic component. We hypothesize that most idiopathic DCM, whether familial or non-familial, has a genetic basis, in which case a genetics-driven approach to identifying at-risk family members for clinical screening and early intervention could reduce morbidity and mortality. Based on this hypothesis, we have launched the NHLBI- and NHGRI-funded DCM Precision Medicine Study, which aims to enroll 1,300 individuals (600 non-Hispanic African ancestry, 600 non-Hispanic European ancestry, and 100 Hispanic) who meet rigorous clinical criteria for idiopathic DCM along with 2,600 of their relatives. Enrolled relatives undergo clinical cardiovascular screening to identify asymptomatic disease, and all individuals with idiopathic DCM undergo exome sequencing to identify relevant variants in genes previously implicated in DCM. Genetic test results are returned by genetic counselors 12-14 months after enrollment. The data obtained will be used to describe the prevalence of familial DCM among idiopathic DCM cases and the genetic architecture of idiopathic DCM in multiple ethnicity-ancestry groups. We are also conducting a randomized controlled trial (NCT #: NCT03037632, <https://www.clinicaltrials.gov>) to test the effectiveness of *Family Heart Talk*, an intervention to aid family communication, for improving uptake of preventive screening and surveillance in at-risk first-degree relatives. In this presentation, we describe the design and analysis plan for the DCM Precision Medicine Study while summarizing current progress and lessons learned since accrual began in June 2016. At its conclusion, we anticipate that the study will demonstrate that idiopathic DCM has a genetic basis and guide best practices for a genetics-driven approach to early intervention in at-risk relatives.

**2611W**

**Familial TAPVR with 15q11.2 (BP1-BP2) microdeletion.** *Y. Kuroda<sup>1,3</sup>, I. Ohashi<sup>1</sup>, T. Naruto<sup>1</sup>, K. Ida<sup>1</sup>, Y. Enomoto<sup>1</sup>, T. Saito<sup>2</sup>, J. Nagai<sup>2</sup>, K. Kurosawa<sup>1</sup>.* 1) Division of Medical Genetics, Kanagawa Children's Medical Center, Yokohama, Japan; 2) Department of Clinical Laboratory, Kanagawa Children's Medical Center, Yokohama, Japan; 3) Department of Pediatrics, University of Tokyo, Tokyo, Japan.

Congenital heart diseases (CHDs) were found in 20-30 % of the 15q11.2 (BP1-BP2) deletion patients. We reported familial TAPVR patients with microdeletion of 15q11.2. Patient 1 was the first child of nonconsanguineous and healthy parents. He was delivered at a gestational age of 37 weeks and 3 days after an uneventful pregnancy. His birth weight was 2486 g. Echocardiography showed total anomalous pulmonary venous return (TAPVR) type 1a and surgical repair was performed at the next day after birthday. He started controlling head at 4 months, rolling over at 5 months, sitting at 7 months, and walking at 17 months. He spoke the first word at 1 year, and two-word sentences at 3 years of the age. He had learning disability and attended a special class. Patient 2 was the second child of parents of Patient 1. She was delivered at a gestational age of 38 weeks. Her birth weight was 3066 g. At a gestational age of 34 weeks, the diagnosis of TAPVR type 3 was confirmed by fetal echocardiography. After birth, surgical repair was performed. She died of renal failure due to chylothorax at 8 months-old of the age. Patient 3 was the fourth child and younger sister of dizygotic twins. She was delivered at a gestational age of 36 weeks and 3 days by emergency caesarean section because of threatened premature delivery. Her birth weight was 2823g. At a gestational age of 31 weeks, the diagnosis of TAPVR was confirmed and surgical repair was performed at the birthday. At the age of 4 years and 6 months, she had speech delay. In Patient 1, karyotyping revealed normal karyotype. No deleterious mutation was identified by exome sequencing. Array CGH revealed an approximately 222 kb deletion at 15q11.2, spanning from position 22,860,857 to 23,082,821 bp (GRCh37/hg19). FISH analysis confirmed the deletion in Patient 1, 3 and their father. Healthy sibling (the third child) and their mother did not have the deletion. More than 27 patients of CHD have been reported associated with the 15q11.2 deletion, and no familial case has been reported. The penetrance of CNV was estimated as 10.4%. In this family, higher penetrance was observed, since TAPVR were shown in all three siblings harboring the CNV.

**Genetic testing in arrhythmogenic cardiomyopathy: New insights into the disease determinants and new doubts.** E. Lazzarini, R. Celegghin, K. Ludwig, M. Cason, I. Rigato, D. Corrado, C. Basso, G. Thiene, B. Baucé, K. Pillichou. Dept of Cardiac, Thoracic and Vascular Sciences, University of Padua, Padua, Italy.

**Background:** Arrhythmogenic Cardiomyopathy (AC) is an inherited cardiac disease (MIM#107970) characterized by fibro-fatty replacement of myocardium and increased risk of sudden cardiac death. AC is mainly linked to variants in desmosomal genes, detected in about 50% of cases. **Purpose:** AC familial cascade screening can be life-saving, thus the aim of the study is to define the genetic spectrum of AC in a large patient cohort. **Methods:** 189 consecutive AC index cases (73F, 116M, mean age 35±12y) fulfilling revised 2010 Task Force diagnostic criteria, were enrolled at the Referral Clinical-Genetic Centre of Padua University during years 2013-2017. Molecular genetic testing was performed on a Miseq platform using a cardiovascular gene panel of 174 (TruSightCardio, Illumina). Alignment and variant calling were realized by Miseq Reporter and VariantStudio softwares (Illumina). Variants filtering and prioritization were carried out considering a population frequency <0.02%, protein conservation (10 species), clinical data, literature and co-segregation analyses. Potentially pathogenic variants and regions with insufficient coverage were Sanger sequenced. **Results:** Almost 50% (94/189) of AC index cases carried a rare nucleotide variant in AC-related genes, of whom 44.5% (84/189) were desmosomal variant carriers and 5.3% (10/189) displayed rare variants in non-desmosomal AC-related genes (*CTNNA3*, *DES*, *SCN5A*, *FLNC*, *TMEM43*). Specifically, 15 were single-variant *DSP* carriers, 7 *DSG2*, 29 *PKP2*, 7 *DSC2*, 2 *JUP*, and 24 patients were compound or digenic heterozygous carriers in desmosomal genes and 2 *CTNNA3*, 3 *DES*, 2 *SCN5A*, 1 *FLNC*, and 2 *TMEM43*. Moreover, all 94 index cases carried additional rare variants (according to the minor allele frequency ≤ 0.5%, ASHG guidelines) in AC-unrelated genes, mostly encoding for sarcomeric proteins (*OBSCN*, *MYH7*, *MYBPC3*) or ion channels subunits (*CACNA1B*, *CACNA1C*, *SCN10A*, *KCNQ1*); the significance of these additional variants remains to be elucidated. **Conclusions:** Analysis of a large AC cohort broadens our knowledge regarding the genetic complexity of the disease. AC patients carried a combination of pathogenic variants and/or multiple rare variants in AC-unrelated genes. Our data highlights the importance of AC family cascade genetic screening in order to determine the clinical significance of rare genetic variants.

**2613F**

**A report of a patient with hypertrophic cardiomyopathy without myopathy associated with FLNC heterozygous pathogenic variant and review of literature.** B. Monteleone<sup>1</sup>, C. Strachan<sup>2</sup>. 1) Carolinas Health System, UNC Charlotte, Charlotte, NC; 2) UNC Charlotte.

This is a 7-month-old male diagnosed with cardiomyopathy status post heart transplant. Dilated and hypertrophic cardiomyopathy panel to Gene Dx were all normal. Chromosome microarray showed normal male, 46, XY. Urine Hex4 and GAA enzyme levels were normal. Metabolic screening was normal. His physical exam was otherwise normal. Whole exome analysis identified a heterozygous likely pathogenic variant in *FLNC* gene: IVS21-1G>C (c.3791-1G>C) that was inherited from his father. His family history is significant for father's sudden cardiac death, and resuscitated and ICD was placed. *FLNC* gene is essential for sarcomere attachment to the plasmatic membrane. Patient and his father have no sign of myopathy or any other neurological issues. It is known to be associated with myofibrillar myopathy 5 as well as cardiomyopathy, familial restrictive 5 (RCM5), and Cardiomyopathy, familial hypertrophic 26 (CMH26) that leads to cardiomyopathy, arrhythmias as well as sudden death. Patients with myopathy has been reported to have risk to develop cardiomyopathy as well. However, there is little evidence that patients with cardiomyopathy and harbor *FLNC* mutations do not develop myopathy. More studies are needed to understand patients with *FLNC* gene mutations who present with cardiomyopathy initially and their risk to develop subsequent myopathy.

**2614W**

**Comparison of genetic architecture of isolated left ventricular non-compaction cardiomyopathy and familial dilated cardiomyopathy as assessed by whole exome sequencing.** L. Piherová<sup>1</sup>, H. Hartmannová<sup>1</sup>, V. Stranecky<sup>1</sup>, A. Pristoupilová<sup>1</sup>, K. Hodanova<sup>1</sup>, V. Baresova<sup>1</sup>, M. Kubanek<sup>2</sup>, A. Krebsova<sup>2</sup>, R. Kockova<sup>2</sup>, T. Palecek<sup>3</sup>, F. Malek<sup>4</sup>, V. Melenovsky<sup>2</sup>, S. Krmoch<sup>1</sup>. 1) Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University, Prague, Czech Republic; 2) Department of Cardiology, Institute of Clinical and Experimental Medicine Prague, Czech Republic; 3) Second Internal Clinic, First Faculty of Medicine, Charles University, Prague, Czech Republic; 4) Department of Cardiology, Na Homolce Hospital, Prague, Czech Republic.

Isolated left ventricular noncompaction cardiomyopathy (LVNC) is an unclassified cardiomyopathy which may overlap with genetic forms of dilated cardiomyopathy. We aimed to compare genetic architecture of LVNC and familial DCM (DCM) to elucidate whether LVNC represents a distinct disease entity. A representative cohort of 42 patients with LVNC and 245 probands with familial DCM from three major Czech hospitals was assessed by whole exome sequencing (WES; SeqCap EZ MedExome, Roche, USA; Illumina, USA). Detected variants were confirmed by Sanger sequencing and their segregation was assessed in available families. Diagnosis of LVNC was made by two specialists based on echocardiographic criteria and/or cardiac magnetic resonance imaging. Three probands with LVNC had familial disease with either LVNC (2 cases) or hypertrophic cardiomyopathy (1 case) in a first degree relative. In LVNC patients, WES revealed one pathogenic mutation in 55% of cases, ≥2 pathogenic mutations in 20% and an inconclusive result in 25% cases. In two cases we have found large deletion of 2 sarcomeric genes. The corresponding results of WES in familial DCM were as follows: one pathogenic mutation in 30%, ≥2 pathogenic mutations in 43% and an inconclusive result in 27% cases. Our data indicate that LVNC is predominantly caused by mutations affecting sarcomeric genes. On the other hand, truncating mutations of *TTN* were the most common etiology of familial DCM followed by mutations of sarcomeric and desmosomal genes.

**2615T**

**High incidence of *SCN5A* c.5350 G>A (p.Glu1784Lys) heterozygotes and prolonged QT intervals in a large biobank cohort.** M.L.B. Schwartz<sup>1</sup>, J.Z. Luo<sup>1</sup>, A.C. Sturm<sup>1</sup>, M.F. Murray<sup>1</sup>, R. Pulk<sup>1</sup>, M.S. Williams<sup>1</sup>, D. Hartzel<sup>1</sup>, F.E. Dewey<sup>2</sup>, U.L. Mirshahi<sup>1</sup>, K. Manickam<sup>1</sup>, T. Mirshahi<sup>1</sup>. 1) Genomic Medicine Institute, Geisinger Health System, Danville, PA; 2) Regeneron Genomics Center, Tarrytown, NY.

**Background** The MyCode Community Health Initiative at Geisinger Health System has over 140,000 participants who have agreed to sample collection, genomic sequencing, use of their Electronic Health Record (EHR) data and the return of actionable genomic results. One variant of clinical interest is *SCN5A* c.5350 G>A (p.Glu1784Lys), a well-described cause of both Long QT syndrome type 3 (LQT3) and Brugada syndrome. **Methods** A bioinformatics analysis found *SCN5A* variants, including the c.5350 G>A (p.Glu1784Lys) variant, among the first 60,873 participants sequenced. Personal and family histories of cardiac phenotypes in variant carriers were ascertained by an EHR data pull and chart review. A relatedness analysis was conducted using the Pedigree Reconstruction and Identification of a Maximum Unrelated Set (PRIMUS) package. Comparison of QTc intervals was done using a one-way ANOVA with Tukey's post-hoc test. **Results** Eighteen people had the *SCN5A* c.5350 G>A (p.Glu1784Lys) variant. Fifteen (86.7% female, mean age 55.7y) had ≥1 EKG available for review. The mean QTc interval in carriers was 557.3 ms in males and 483 ms in females, which was significantly different from the Geisinger EHR average (male 429.8 ms, p<0.0001 female 437.6 ms, p<0.0001). Chart review was allowed for 14 patients and revealed that 6 (42.9%) had an EKG flagging a prolonged QT interval; however, only 1 had prolonged QT on the EHR problem list. One 84-year-old male with multiple cardiac comorbidities had a history of sudden cardiac arrest and an ICD and a 27-year-old female had a history of unexplained syncope. All 14 patients had a family history of a "heart disorder" including 8 with a first-degree relative (FDR) with a "heart attack" (7/8 male), including 2 male FDRs with an event in their 20s. Only two variant carriers were FDRs. No patient had a clinical diagnosis of LQT3, Brugada syndrome or genetic testing independent of the study. **Conclusions** While 18 carriers of the previously reported *SCN5A* c.5350 G>A (p.Glu1784Lys) variant were found in this cohort, the variant is absent in other large genomic databases such as ExAC and gnomAD. It is unclear if a regional founder effect influenced variant frequency in this cohort. Some variant carriers had prolonged QT intervals but were not recognized to have LQT3 by their clinical teams. One hypothesis for the sex ratio skew in variant carriers is higher disease-related mortality among male carriers.

**2616F**

**Germline loss-of-function mutations in *EPHB4* cause a second form of capillary malformation–arteriovenous malformation (CM-AVM2) deregulating RAS-MAPK signaling.** M. Vikkula<sup>1</sup>, M. Amyere<sup>1</sup>, N. Revencu<sup>2</sup>, R. Helaers<sup>1</sup>, E. Pairet<sup>2</sup>, J.B. Mulliken<sup>3</sup>, L.M. Boon<sup>1,4</sup>. 1) de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) Center for Human Genetics, Cliniques universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium; 3) Vascular Anomalies Center, Boston Children's Hospital, Harvard Medical School, Boston, MA, USA; 4) Center for Vascular Anomalies, Division of Plastic Surgery, Cliniques universitaires Saint-Luc, Université catholique de Louvain, Brussels, Belgium.

**BACKGROUND** Most AVMs are localized and occur sporadically; however they also can be multifocal in autosomal dominant disorders, such as Hereditary Hemorrhagic Telangiectasia (HHT) and Capillary Malformation–Arteriovenous Malformation (CM-AVM). Previously, we identified *RASA1* mutations in 50% of patients with CM-AVM. Herein we studied non-*RASA1* patients to further elucidate the pathogenicity of CMs and AVMs. **METHODS** We conducted a genome-wide linkage study on a CM-AVM family. Whole exome sequencing was also performed on 9 unrelated CM-AVM families. We identified a candidate-gene and screened it in a large series of patients. The influence of several missense variants on protein function was also studied in vitro. **RESULTS** We found evidence for linkage in two loci. Whole-exome sequencing data unraveled four distinct damaging variants in *EPHB4* in five families that co-segregated with CM-AVM. Overall, screening of *EPHB4* detected 47 distinct mutations in 54 index patients: 27 lead to a premature stop codon or splice-site alteration, suggesting loss of function. The other 20 are non-synonymous variants that result in amino-acid substitutions. In vitro expression of several mutations confirmed loss of function of *EPHB4*. The clinical features included multifocal CMs, telangiectasias, and AVMs. **CONCLUSIONS** We found *EPHB4* mutations in patients with multifocal CMs associated with AVMs. The phenotype, CM-AVM2, mimics *RASA1*-related CM-AVM1 and also HHT. *RASA1* encoded p120RASGAP is a direct effector of *EPHB4*. Our data highlights the pathogenetic importance of this interaction and indicates *EPHB4*-RAS-ERK signaling pathway as a major cause for arterio-venous malformations.

**Predisposition genetic screening for actionable cardiovascular conditions in patients undergoing heritable cancer syndrome testing: Prevalence of pathogenic variants in 10,812 individuals.** S. Yang<sup>1</sup>, E. Esplin<sup>1</sup>, E. Haverfield<sup>1</sup>, S. Aradhya<sup>1</sup>, R. Nussbaum<sup>1,2</sup>. 1) Invitae, San Francisco, CA; 2) UCSF, San Francisco, CA.

**Background** The ACMG published recommendations for reporting medically actionable pathogenic variants in a set of 59 curated genes as secondary findings in patients undergoing whole exome or genome sequencing. We report an initial estimate of the prevalence of secondary findings in genes implicated in dominant cardiovascular disorders in 10,812 individuals with personal or family history of cancer, and stratify the prevalence by ethnicity. **Methods** Per an IRB approved protocol, we analyzed data from 10,812 de-identified patients, originally referred for cancer genetic testing, for 68 genes associated with Mendelian cardiovascular conditions considered medically actionable by in-house experts; which encompass all the 30 cardiovascular disease genes recommended by ACMG for secondary findings. We identified known pathogenic (P) or likely pathogenic (LP) variants and predicted LOF variants and stratified the patients according to reported ethnicity. **Results** In 10,812 de-identified individuals, we found 250 patients (2.31%) with P/LP variants in 68 cardiovascular disorder-related genes. The prevalence is lower if only consider the ACMG 30 is considered. We also observed that in this cohort, 37 patients (0.34%) have positive findings in both cancer and cardiovascular genes. **Conclusions** Overall, 2.31% of unaffected individuals have positive findings in 68 genes associated with Mendelian cardiovascular disorders; the prevalence is lower (1.64%) for 30 cardiovascular ACMG genes. People with Caucasian, black and Ashkenazi Jewish ethnicity have a higher prevalence than Hispanic individuals while people of Asian descent have the lowest rate. We also observed 0.34% of patients referred for heritable cancer syndrome testing carried P/LP variants in both cancer and cardiovascular genes. This information could be potentially important for guiding the choice of chemotherapy with cardiotoxic effects. The overall prevalence estimate is likely underestimated. Nonetheless, the findings observed in this study contribute to our knowledge concerning genetic screening for heritable cardiovascular disorders in individuals with a personal or family history of cancer.

	All (n=10812)	Caucasian (n=7320)	Hispanic (n=706)	Black (n=667)	Ashkenazi Jewish (n=497)	Asian (n=241)
Positive findings in-house panel	250 (2.31%)	172 (2.35%)	11 (1.56%)	15 (2.25%)	13 (2.26%)	2 (0.83%)
Positive findings in ACMG panel	120 (1.64%)	120 (1.64%)	10 (1.42%)	12 (1.80%)	8 (1.61%)	2 (0.83%)

**Novel CACNA1C variant associated with Long QT syndrome in a multi-generational family.** V. Novelli<sup>1,4</sup>, F.D Tiziano<sup>2</sup>, G. Pelargonio<sup>1</sup>, G. LaRosa<sup>2</sup>, P. Zeppilli<sup>3,4</sup>, F. Crea<sup>2</sup>, M. Genuardi<sup>1</sup>. 1) Institute for Genomic Medicine, Fondazione Policlinico Gemelli, Catholic University of the Sacred Heart, Rome, Italy; 2) Department of Cardiovascular Sciences, Catholic University of the Sacred Heart, Fondazione Policlinico Gemelli, Rome, Italy; 3) Sports Medicine Unit, Catholic University of Sacred Heart, Rome, Italy; 4) Center, Benito Stirpe, for the prevention of the Sudden Cardiac Death in the young athletes. Fondazione Policlinico Gemelli, Roma Italy.

**Background** Long QT syndrome (LQTS) is a potentially lethal cardiac disease characterized by a prolongation of the QT interval and by a propensity for life-threatening arrhythmias. Genetic alterations in the *KCNQ1*, *KCNH2* and *SCN5A* genes, encoding for ion cardiac channels, account for the 75-80% of the genotype-positive patients. Additional minor genes have been involved in this conditions. Recently, genetic variants in the *CACNA1C* gene, encoding for the  $\alpha$ -subunit of the cardiac L-type calcium channel (LTCC), have been identified in 2 families: one with LQTS and one with a complex phenotype of LQTS, hypertrophic cardiomyopathy, sudden death and congenital heart defects. Here we show the results from a LQTS multigenerational pedigree with negative screening in the main LQT genes. **Methods** A 43 years old woman was referred to our center for evaluation of long QT (QTc>490 ms) and aspecific T-wave abnormalities on ECG. Two of her three sons (age 8y and 14y) also had a diagnosis of LQTS (QTc=510ms and 500ms) with a syncope episode reported in the younger brother. To identify a causative genetic variant associated with the phenotype in this family, we performed genetic testing, using a custom targeted panel, containing 12 genes, associated with the disease. **Results and Conclusions** A novel variant in *CACNA1C*, c.4879 T>C, p.(Tyr1627His) was identified in the proband and in her two affected sons. Cascade screening in the family members confirmed the presence of the variant also in the mother and in the brother of the proband, who both had borderline QT interval (QTc>460ms). The variant was not presented in her sister and in the third son who had a normal QT interval. The variant is not reported in GnomAD (gnomad.broadinstitute.org) and in literature. **Conclusion** Co-segregation of this novel *CACNA1C* variant with the clinical phenotype of LQTS in multiple family members supports the hypothesis that *CACNA1C* is a novel player in the spectrum of LQTS. This work demonstrates the importance of using targeted sequencing panels in LQTS, updated with the new disease-associated genes, in order to identify causative variants.

**Mutation spectrum of Long QT Syndrome in Singapore.** R.Y.Y. Yong<sup>1</sup>, B.Y. Tan<sup>2</sup>, L.S.H. Gan<sup>1</sup>, P.S. Wasan<sup>1</sup>, M.A.L. Teo<sup>1</sup>, C.K. Ching<sup>2</sup>, D.TT. Chong<sup>2</sup>, K.L. Ho<sup>3</sup>, L. Wang<sup>4</sup>, W. Chow<sup>4</sup>, J.TL. Choo<sup>5</sup>, S. Moochhala<sup>1</sup>, E.PH. Yap<sup>6</sup>, M. Uttamchandani<sup>1</sup>, S.C. Seow<sup>2</sup>, W.S. Teo<sup>2</sup>. 1) Defence Med & Environmental, DSO National Labs, Singapore, Singapore; 2) National Heart Centre, Singapore General Hospital, Singapore; 3) Cardiac Department, National University Hospital, Singapore; 4) Headquarters Medical Corps, Singapore Armed Forces, Singapore; 5) KK Women's and Children's Hospital, Singapore; 6) Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore.

Long QT syndrome (LQTS) is an inherited arrhythmia syndrome with an increased risk of sudden death. It is characterized by a prolonged QT interval on 12-lead ECG that can progress to a polymorphic ventricular tachycardia known as torsades de points in the absence of structural abnormal heart. Clinically, torsades de points can produce syncope, ventricular fibrillation and even sudden cardiac death. The prevalence of LQTS is reported to be 1 in 2000 in Caucasians. LQTS is known to be genetically heterogeneous with at least 16 genes been implicated. However, mutations in 3 genes (*KCNQ1*, *KCNH2*, *SCN5A*) can account for 70% to 75% of diagnosed patients in Caucasians. Genetic testing plays an important role in the diagnosis of LQTS according to expert consensus statement. This study investigated the mutation spectrum of the 3 genes (*KCNQ1*, *KCNH2*, *SCN5A*) in 26 unrelated LQTS patients in Singapore. LQTS cases are diagnosed with a Schwartz score >3 in the absence of a secondary cause for QT prolongation. Bi-directional Sanger sequencing was carried out on all the exons cum flanking sequence of the 3 genes, including 5' and 3' UTRs. The minor allele frequency of all potential mutations in normal controls was determined by genotyping 105 healthy Singapore Chinese controls, and with reference to ExAC and 1K Genome databases. Putative mutations were identified in 13 probands (Combined diagnostic yield 50%), with one proband harbouring 3 mutations in *SCN5A*. A total of 15 mutations were identified, including 4 for *KCNQ1*, 5 for *KCNH2*, and 6 for *SCN5A*. These comprised of 12 missenses, 1 nonsense and 2 indel/frame-shift. Many of these mutations have been reported in recent literature, except for 2 novels for *KCNH2*. Among this patient cohort, family samples were available for 7 probands. Five families have mutation identified demonstrating Mendelian segregation. The study is on-going. To our knowledge, this is the largest study of LQTS mutation spectrum in Singapore to date.

**2620W****Clinical evolution and recommendations for management of the smooth muscle dysfunction syndrome due to mutations of the ACTA2 arginine 179.**

Smooth muscle dysfunction syndrome (SMDS) due to heterozygous ACTA2 arginine 179 mutations is characterized by complex congenital heart defects, pulmonary arterial hypertension, cerebrovascular disease, thoracic aortic aneurysms and dissections, arterial aneurysms, and chronic conditions affecting organs dependent on smooth muscle actin. We examined the clinical history and outcomes of 33 SMDS cases identified worldwide and developed recommendations for evaluation, surveillance, and management of this condition. All 33 cases had congenital mydriasis and presented with a patent ductus arteriosus or aorto-pulmonary window and required surgical repair during infancy (median age at repair at 61 days). Cerebrovascular disease characterized by Moyamoya-like distal internal carotid artery stenosis was present in 53% of cases and small vessel disease as evidenced by T2 weighted- hyperintense periventricular white matter lesions on magnetic resonance imaging in 95% of cases. Overt ischemic strokes occurred in 9 cases (27%), with 7 of the cases presenting before the age of 10 years, and seizures occurred in 6 cases (19%) between the ages of 1 and 19 years. Thoracic aortic disease requiring ascending aortic aneurysm repair or presenting as dissections was fully penetrant by the age of 25 years. Severe cerebrovascular disease delayed aortic aneurysm repair in 3 cases, leading to deaths due to aortic rupture. Three cases had subclavian artery aneurysms resulting in thromboembolic episodes and multiple surgical operations to repair the aneurysms. Pulmonary complications, including pulmonary arterial hypertension or chronic bronchopulmonary disease, were prevalent in 73% of cases and across all age groups. Gastrointestinal complications including intestinal malrotation, immotility or gall bladder sludge or stone were observed in 58% of cases. Hypotonic bladder and urinary tract complications were noted in 64% of cases. Cryptorchidism was present in 40% of males. Premature deaths occurred in 8 cases between the ages of 0.5 and 32 years due to pulmonary disease, aortic dissection or rupture, or stroke. These data demonstrate the clinical evolution of SMDS and emphasize the importance of early detection, multi-disciplinary and coordinated care, and timely management of the SMDS. These findings define the SMDS complications so that therapies can be initiated and tested to reduce the high mortality and morbidity in this patient population.

**2621T****HIVEP2 as a cause hypoplastic left heart syndrome: A report of a rare condition in an 18 month old boy.** *H. Holway<sup>1</sup>, B. Monteleone<sup>2</sup>.* 1) UNC Chapel Hill, Chapel Hill, NC; 2) Carolinas Health System, UNC Charlotte.

Human immunodeficiency virus type 1 enhancer binding protein (HIVEP2) is part of a family of zinc-finger-containing transcriptional proteins that known to be involved in brain growth and development as well as cellular immunity, bone remodeling, and adipogenesis. HIVEP2 gene defects have been previously associated with intellectual disability, developmental delay, behavioral problems, and dysmorphic feature. This is the 10th case of pathogenic HIVEP2 mutation reported in the literature to our knowledge. Previously described changes in patients include nonsense, missense, and frameshift mutations. Here we describe an 18 month old patient with hypoplastic left heart syndrome (HLHS), hydrocephalus, and global developmental delays. He is the second child born to a G3P1012 mother at 39 weeks and 2 days of gestation. He was born via unremarkable vaginal delivery. Apgars were 8 and 9 at 1 and 5 minutes. Birthweight was 4.43 kg (98 %) with length 49 cm (28%) and head circumference 34 cm (32%). He later developed hydrocephalus requiring shunt placement and feeding issues requiring G-tube placement; he also has a tracheostomy. Other medical comorbidities include t-cell lymphopenia, hypogammaglobulinemia, hyperopia, and astigmatism. On physical exam, he has distinctive features including broad, depressed nasal bridge, upturned nasal tip, wide set eyes, full cheeks, high forehead, and macrocephaly. He is social and interactive. This patient was initially evaluated by genetics at 2 days of life for HLHS. A routine chromosome analysis and microarray showed normal, 46, XY. At seven months of age, the Invitae Isolated and Syndromic Congenital Heart Defect was drawn and also returned negative. Ultimately, whole exome analysis (WES) was performed, showing likely pathogenic change to HIVEP2 (MRD 43; OMIM #616977). The change to HIVEP2: c.1799C>A (p.Ser600\*) is anticipated to cause premature protein termination. This patient had no other pathogenic changes on WES, indicating that mutations in HIVEP2 most likely contributed to his significant cardiac anomalies. Further research is necessary to understand the role of HIVEP2 as a potential cause of HLHS.

**2622F*****EIF2AK4* mutations are not likely a common genetic modifier of disease in *BMPR2* mutation positive pulmonary arterial hypertension patients.**

K. Sumner<sup>1</sup>, Y. Ha<sup>1</sup>, J. Sanders<sup>1</sup>, A. Morris<sup>2</sup>, E. Paul<sup>3</sup>, D.H. Best<sup>1,3,4</sup>. 1) R&D Molecular Genetics, ARUP Laboratories, Salt Lake City, UT; 2) Genomics, ARUP Laboratories, Salt Lake City, UT; 3) Dept. of Pathology, University of Utah School of Medicine, Salt Lake City, UT; 4) Dept. of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

**Background:** Pulmonary arterial hypertension (PAH) is a rare, but lethal disorder most commonly caused by autosomal dominant (with reduced penetrance) mutations in the *BMPR2* gene. PAH can also result from mutations in the *ACVRL1*, *ENG*, *CAV1*, *KCNK3*, and *EIF2AK4* genes. A second-hit model has been theorized to account for the reduced penetrance seen with *BMPR2* mutation positive patients. A recent study by Eichstaedt, et al. reported a mutation in *BMPR2* that showed reduced penetrance in a family of ten. Interestingly, a second mutation in the *EIF2AK4* gene was also identified and was found to segregate with disease. The authors of this study suggested that *EIF2AK4* mutations were likely to be a genetic modifier in *BMPR2* mutation positive patients. Based on this study we decided to sequence the *EIF2AK4* gene in a cohort of *BMPR2* mutation positive patients. **Method:** PAH patients with a known *BMPR2* mutation (n=14) were evaluated by Sanger sequencing for mutations in the coding regions and intron/exon boundaries of the *EIF2AK4* gene. **Results:** None of the 14 PAH patients with known *BMPR2* mutations were found to have mutations in the *EIF2AK4* gene. **Conclusion:** The results of our study suggest that *EIF2AK4* mutations are not likely to be a common genetic modifier in patients with *BMPR2*-related PAH.

**2623W****Loss-of-function variant in *FNDC3B* is associated with dominant pulmonary arterial hypertension in a pedigree.**

M. Cousin<sup>1</sup>, N. Boczek<sup>2</sup>, P. Byers<sup>3</sup>, D. Riegert-Johnson<sup>4</sup>, E. Klee<sup>1,2,5</sup>. 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN 55905, USA; Center for Individualized Medicine, Mayo Clinic, Rochester, MN 55905, USA; 2) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN 55905, USA; 3) Department of Pathology, Collagen Diagnostic Laboratory, University of Washington, Seattle, WA 98195-7655, USA; Department of Medicine (Medical Genetics), University of Washington, Seattle, WA 98195, USA; 4) The Department of Clinical Genomics, Mayo Clinic, Jacksonville, FL 32224, USA; Center for Individualized Medicine, Mayo Clinic, Jacksonville, FL 32224, USA; 5) Department of Clinic Genomics, Mayo Clinic, Rochester, MN 55905, USA.

A 47-year-old woman presented with pulmonary arterial hypertension (PAH), dyspnea, lower extremity edema, arthralgia with gait disturbance, severe osteoarthritic changes in the spine and severe scoliosis, Raynaud's phenomenon, joint laxity, and periodontal disease requiring removal of all but two teeth by age 28. She has a strong family history of PAH, scoliosis, periodontal disease, and joint laxity. *C1S* and *C1R* alterations were ruled out by gene sequencing. Clinical WES on the proband and her daughter, sister, and maternal aunt revealed a heterozygous loss-of-function (LOF) variant in *FNDC3B* (c.1154delC, p.P385Lfs\*11) in all four affected individuals. The daughter had not manifested PAH and retained teeth at 26 years old. *FNDC3B*, the Fibronectin Type III Domain Containing 3B gene, also known as factor for adipocyte differentiation 104 (FAD104), encodes a protein with a single transmembrane domain and nine fibronectin type-III domains. It has been seen deleted in two children with mild facial dysmorphisms and one of the two reported children had respiratory distress syndrome. *FNDC3B* has also been associated with central corneal thickness and intraocular pressure phenotypes in GWAS of glaucoma, but has not yet been associated with a single gene disorder. *FNDC3B* is expressed broadly, but highest in adipose, arterial, and lung tissues and is intolerant to LOF variation (pLI = 1.00). *FNDC3B* has reported roles regulating adipogenesis, osteogenesis, and lung development with *fdnc3b*<sup>-/-</sup> mice unviable after birth due to cyanosis-associated lung dysplasia with absent gas exchange. Surfactant-releasing cells in the lungs of these mice were immature with decreased surfactant-associated protein expression. *FNDC3B* has been shown to bind to and down regulate SMAD1/5/8 phosphorylation and is a negative regulator of BMP/SMAD signaling in a study of calvarial bone formation and osteoblast differentiation. Pathogenic alterations in *BMPR2*, which signals through SMAD1/5/8, are a known cause of FPAH. Consistently, *FNDC3B* has been shown to activate the TGF- $\beta$  pathway in cancer studies. Thus, the LOF *FNDC3B* variant segregating with disease in this family lies in a gene shown to be critical for normal lung development and implicated in pathways associated with PAH and connective tissue dysfunction. *FNDC3B* is a strong candidate gene that may explain the dominant PAH in this family.

**Mutation spectrum of the *KCNQ1*, *KCNH2*, and *SCN5A* genes for the long QT syndrome in Korea.** *M. Kim<sup>1</sup>, S. Kim<sup>2</sup>, E. Bae<sup>3</sup>, J. Noh<sup>3</sup>, S. Cho<sup>1</sup>, M. Seong<sup>1</sup>, S. Park<sup>1</sup>.* 1) Department of Laboratory Medicine, Seoul National University Hospital, Seoul, Korea; 2) Department of Laboratory Medicine, National Medical Center, Seoul, Korea; 3) Department of Pediatrics, Seoul National University Hospital, Seoul, Korea.

Long QT syndrome (LQTS) is an inherited cardiac disease with multiple causative genes and characterized by QT interval prolongation, arrhythmia, and sudden cardiac death. Among Koreans, both the prevalence of symptomatic patients and apparently healthy but with abnormal electrocardiogram subjects are at least as high as in other ethnicities; however, their genetic mutation spectrum has not yet been elucidated comprehensively. We aimed to characterize the mutation spectrum and characteristics in Korean LQTS patients through analyzing three causative ion-channel-encoding genes. For 57 unrelated LQTS probands and their 67 family members, mutations in the genes *KCNQ1*, *KCNH2*, and *SCN5A* were identified by Sanger sequencing and gene dosage analyses using multiplex ligation-dependent probe amplification. This study revealed that 45.6% of probands (26 patients) harbored causative mutations in one of the LQTS genes: *KCNQ1* (53.8%, 14 probands), *KCNH2* (23.1%, 6 probands), *SCN5A* (23.1%, 6 probands). The *KCNQ1* exon deletions were frequent (28.6% of *KCNQ1* mutations, 4 probands). The *KCNH2* mutations were clustered in exon 7 (66.7%). The *SCN5A* mutations were much frequent than in previous reports. De novo mutation rate was 11.5%. This study indicated that the *KCNQ1* is the most important causative gene among Koreans, and mutations were heterogeneous in three genes. Mutation was not identified in approximately half of the probands, therefore other multi-gene panel tests may be helpful.

**2625F**

**Whole-exome sequencing identified a *de novo* *PDE3A* mutation causing autosomal dominant hypertension with brachydactyly.** *D. Wang<sup>1,2</sup>, Z. Li<sup>3,4</sup>, C. Li<sup>3,4</sup>, J. Liu<sup>1,2</sup>, D-W. Wang<sup>3,4</sup>.* 1) The Center for Clinical Reproductive Medicine, Jiangsu Province Hospital, Nanjing, Jiangsu, China; 2) State Key Laboratory of Reproductive Medicine, Jiangsu Province Hospital, Nanjing, Jiangsu, China; 3) Division of Cardiology, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China; 4) Genetic Diagnosis Center, Tongji Hospital, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China.

**Purpose:** Autosomal dominant hypertension with brachydactyly type-E syndrome caused by mutations in *PDE3A* gene was firstly reported in 2015. To date, there are only two reports of this kind of hypertension. Other patients are still lack of genetic diagnosis. **Methods:** Whole-exome sequencing was performed in an 18-year-old female with clinical diagnosis of Hypertension with brachydactyly syndrome (HTNB). After bioinformatics analysis and healthy control database filtering, potential disease-causing variants in genes associated with HTNB were validated using Sanger sequencing in the proband and her healthy parents. To make sure the mutation is not a rare single nucleotide polymorphism, we also re-sequenced it in 800 ethnically and geographically matched healthy controls by Sanger sequencing. **Results:** We identified a novel *de novo* heterozygous missense mutation c.1346G>A in exon 4 of the *PDE3A* gene. This mutation was carried by the patient and was absent in her healthy parents. The mutation, resulting in p.Gly449Asp, was located in a highly conserved cluster region of reported *PDE3A* mutations. Importantly, this mutation was predicted to affect the protein function by both SIFT (score=0) and Polyphen-2 (score=1). **Conclusion:** Our study presents a third report linking a novel *de novo* *PDE3A* mutation to autosomal dominant hypertension with brachydactyly type-E syndrome.

**A novel workflow for analysis of whole genome sequencing in cardiac disease using tissue-specific biological datasets.** *S.M. Hosseini<sup>1</sup>, R. Manshaei<sup>1,2</sup>, E. Liston<sup>1,2</sup>, R.R. Chaturvedi<sup>3,4</sup>, R.H. Kim<sup>1,5,6</sup>, S. Bowdin<sup>1,2,4</sup>.* 1) Ted Rogers Cardiac Genome Clinic, The Hospital for Sick Children, Toronto, ON, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Canada; 3) Division of Cardiology, The Hospital for Sick Children, Toronto, Canada; 4) Department of Paediatrics, University of Toronto, Toronto, Canada; 5) Fred A Litwin Family Centre in Genetic Medicine, University Health Network, Toronto, Canada; 6) Department of Medicine, University of Toronto, Toronto, Canada.

Next-generation sequencing (NGS) technology has greatly enhanced our ability to investigate the genetic basis of mono- and oligo-genic diseases. Yet, interpreting a multitude of variants is a major challenge. Available guidelines rely heavily on variant level evidence to screen variants and using gene level biological data to boost diagnostic yield has not been fully examined. We developed a computational framework, based on the MUGQIC (McGill University and Génome Québec Innovation Centre) NGS analysis pipeline, by integrating cardiac specific annotations. This set of annotations takes advantage of functional, cross-species and tissue evidence to prioritize genes before genome interpretation. We also used Gpsy, a cross-species gene prioritization bioinformatics tool (<http://gpsy.genouest.org/>). Ten datasets encompassing molecular interaction, animal model, expression, proteome and disease-specific data were selected for annotation through extensive literature review. These annotations fall into five different categories: functional, cross-species, tissue, disease expression signatures and predictive. For each gene, gaining support from two evidence categories was considered a positive prediction. To investigate the performance of our strategy, we compared 26 established genes for hypertrophic and dilated cardiomyopathy (positive set) against 34 retinitis pigmentosa genes (negative set). Our strategy correctly predicted 22 cardiomyopathy genes and ruled out 29 of the negative set (sensitivity = 0.85,  $p=5.3E-4$ ; specificity = 0.85,  $p=3.9E-5$ ) showing significant advantage over an organ blind framework (diagnostic OR = 31.9). Functional and tissue datasets were the categories with highest information content (TPR 0.65 & 0.77 vs. FPR 0.12 & 0.09 respectively) with the least contribution from disease expression signatures (TPR 0.077 vs FPR 0.029). Gpsy had a mediocre performance when using the top 100 ranking genes for heart development (TPR 0.35 vs FPR 0). These values remained robust to other negative gene sets. Our approach for prioritizing variants leverages the wealth of biological data to facilitate downstream genome interpretation. Efforts are underway to further quantify our framework and to apply our strategy to other diseases predominantly affecting a specific organ system.

**2627T**

**Novel PIEZO1 mutations in patients with autosomal recessive hereditary lymphedema.** *L. Lai<sup>1,2</sup>, M.H. Witte<sup>3</sup>, M. Bernas<sup>3</sup>, M.F. Hammer<sup>4</sup>, R.P. Erickson<sup>5</sup>.* 1) Laboratory Medicine, UCSF, San Francisco, CA; 2) Chemistry and Biochemistry, U of Arizona, Tucson, AZ; 3) Surgery, U of Arizona, Tucson, AZ; 4) Neuroscience and Anthropology, U of Arizona, Tucson, AZ; 5) Pediatrics, U of Arizona, Tucson, AZ.

Mutations in PIEZO1, a mechanically activated ion channel, cause an autosomal dominant dehydrated hereditary stomatocytosis and autosomal recessive hereditary lymphedema. We report the finding of novel PIEZO1 mutations in a multi-generation consanguineous family with many affected subjects in each generation. Peripheral blood DNA samples from male subject A and two of his affected first cousins (B, C) were subjected to whole exome sequencing using the Agilent SureSelect Exon V6 target enrichment kit followed by paired-end sequencing on Illumina HiSeq 2500. Only variants shared by all three cousins were further investigated. We identified compound heterozygous variants, a missense variant c.7316G>A;p.Gly2439Asp and a nonsense variant c.3373C>T, in PIEZO1 gene in subjects A and B, and homozygous variant c.7316G>A in subject C. Neither variants have been listed in the publicly available human genomics databases 1000 Genomes, Exome Sequencing Project or the Exome Aggregation Consortium. Family segregation analyses using Sanger sequencing confirmed that subject A inherited variant c.7316G>A from his affected mother and variant c.3373C>T from unaffected father, and that neither of the identified variants were present in his unaffected sister. Furthermore, the computational programs SIFT, PolyPhen2, MutationTaster, MutationAssessor, and FATHMM MKL Coding, all predict variant 7316G>A to be pathogenic. Further study of the variant c.7316G>A found that it is the last nucleotide of the exon 50 (total 51 exons), and predicted to cause loss of the canonical splice donor site and creation of alternative splice sites, resulting in loss of function, either from gain of stop codon or frame shift. RNA sequencing to verify the result of this putative alternation in splice sites is ongoing. Additionally, subject A, but not B or C, also carries a missense variant c.1331A>G;p.Gln444Arg in FOXC2, previously reported in a child with lymphedema, varicose veins, and aortic valve stenosis. This variant was found in subject A's affected mother, but not in unaffected father, brother, sister, or affected brother. Whether the mother's lymphedema is associated with this FOXC2 variant requires further investigation. In summary, the identification of two novel pathogenic variants in PIEZO1 responsible for autosomal recessive hereditary lymphedema further confirms the role of channelopathy in the pathogenesis of lymphedema.

**2628F**

**Exome sequencing in children with pulmonary arterial hypertension demonstrates a different genetic architecture of disease compared to adults.** C.L. Welch<sup>1</sup>, N. Zhu<sup>1,5</sup>, C. Gonzaga-Jauregui<sup>2</sup>, L. Ma<sup>1</sup>, H. Qi<sup>1,5</sup>, A.K. King<sup>2</sup>, U. Kishnan<sup>1</sup>, E.B. Rosenzweig<sup>1,6</sup>, D. Ivy<sup>3</sup>, E.D. Austin<sup>3</sup>, W.C. Chung<sup>1,3,7</sup>. 1) Department of Pediatrics, Columbia University, New York, NY, USA; 2) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, New York, USA; 3) Herbert Irving Comprehensive Cancer Center, Columbia University Medical Center, New York, New York, USA; 4) Department of Applied Physics and Applied Mathematics, Columbia University, New York, New York, USA; 5) Departments of Systems Biology, Columbia University, New York, New York, USA; 6) Departments of Biomedical Informatics, Columbia University, New York, New York, USA; 7) Department of Medicine, Columbia University Medical Center New York, New York, USA; 8) Children's Hospital Colorado, Department of Pediatric Cardiology, Denver, Colorado, USA; 9) Division of Allergy, Immunology and Pulmonary Medicine Department of Pediatrics, Vanderbilt University School of Medicine, Nashville, Tennessee, USA; 10) Division of Human Genetics, Cincinnati Children's Hospital Medical Center and the Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH, USA.

Pulmonary arterial hypertension (PAH) is a rare disease characterized by distinctive changes in pulmonary arterioles that lead to progressive elevation of pulmonary arterial pressure, right-sided heart failure, and a high mortality rate. To study the genetics of PAH and compare the differences between children and adults, we selected 134 pediatric-onset and 289 adult-onset PAH patients. Among pediatric-onset patients, 28 had familial PAH (FPAH) and 106 had sporadic, idiopathic PAH (IPAH). Among adult-onset patients, 85 had FPAH and 204 had IPAH. FPAH cases were initially evaluated by Sanger sequencing of *BMPR2* and *ACVRL1*, and *BMPR2/ACVRL1* mutation-negative FPAH cases and all IPAH cases were evaluated by exome sequencing. We found a similar frequency of *BMPR2* mutations in pediatric and adult PAH patients: 50% in FPAH and 8-11% in IPAH patients. However, pediatric-onset patients were significantly more likely to carry mutations in *TBX4* than adult-onset IPAH patients (11/106, 10% versus 2/204, 1%; odds ratio=11.6; p-value=0.0002). About 5-14% of pediatric and 2-12% of adult PAH patients had mutations in other known risk genes (*ACVRL1*, *BMPR1A*, *BMPR1B*, *CAV1*, *EIF2AK4*, *ENG*, *KCNK3*, *SMAD4* and *SMAD9*). In 34 pediatric IPAH patients without mutations in known risk genes, we observed a marginally significant enrichment of *de novo* likely gene damaging (LGD) and deleterious missense (predicted by MetaSVM) variants in genes that are highly expressed in the developing lung and heart (enrichment=4.2x, p-value=1.6E-03; based on background mutation rate). In summary, mutations in all known PAH genes accounted for 64-70% of FPAH (both pediatric-onset and adult-onset), 26% of pediatric-onset IPAH, and 11% of adult-onset IPAH. Notably, in pediatric patients without mutations in known risk genes, there was evidence for the existence of novel IPAH genes due to *de novo* LGD variants, suggesting the need for additional studies with expanded pediatric IPAH cohorts to enable identification of novel genetic causes and to provide insights into the pathophysiology and potential new targets for treatment for PAH.

**CRISPR-Cas9 mediated knockout of SEL1L and proteasomal inhibition reveal divergent degradation pathways for corresponding LDLR and VLDLR disease-causing mutants.** B.R. Ali, P. Kizhakkedath, A. John, L. Al-Gazali. College of Medicine and Health Sciences, United Arab Emirates University, Al-Ain, Al-Ain, United Arab Emirates.

Terminally misfolded proteins in the early secretory pathway are mainly degraded by the ubiquitin-proteasome systems known as ER associated degradation (ERAD) which has been implicated in the pathogenesis of numerous congenital disorders. Therefore, ERAD has been a promising target for therapy of such diseases. In this study we compare and contrast the degradation behavior of equivalent disease-causing mutations in LDLR and VLDLR, two LDLR family receptors. HRD1-SEL1L knockout (KO) HEK293 cell lines have been generated using CRISPR/Cas9. The missense mutants were generated by QuikChange site-directed mutagenesis. The expressed proteins in HeLa and HEK293 cells were analyzed biochemically and by microscopy. We found that the disequilibrium syndrome-causing VLDLR missense mutants (p.D487Y, p.D521H and p.C706F) are retained in the ER whereas only p.D482H and p.C667F of the LDLR corresponding mutants are retained. Two of the ER-retained VLDLR mutants were found to be aggregation-prone leading to ER stress as measured by spliced-XBP mRNA levels. However, there was no differences between LDLR wild type and mutants with regard to their aggregation status or ER stress. Treatment with inhibitors of autophagy seemed to stabilize the degradation of wild type receptors. In addition, p.C706F VLDLR mutant stabilized during early phase of both proteasomal and autophagy inhibition. Cycloheximide chase analysis in SEL1L-KO cells revealed that the HRD1-SEL1L complex could be involved in the clearance of ER-retained VLDLR mutants. The downstream degradation and ER stress induction behavior of ER-retained corresponding LDLR and VLDLR mutants are divergent suggesting different clearance mechanisms despite their structural similarities.

**2630T**

**Thoracic aortic disease outcomes in 987 cases with pathogenic variants in *ACTA2*, *PRKG1*, *TGFBR1*, *TGFBR2* and *SMAD3* ascertained by the Montalcino Aortic Consortium.** D. Milewicz<sup>1</sup>, J. De Backer<sup>2</sup>, C. Boileau<sup>3,10,11</sup>, S. LeMaire<sup>4</sup>, R. Jeremy<sup>5</sup>, R. Pyeritz<sup>6</sup>, S. Morris<sup>7</sup>, A. Braverman<sup>8</sup>, A. Evangelista<sup>9</sup>, G. Jondeau<sup>3,10</sup>, E. Regalado<sup>1</sup>, Montalcino Aortic Consortium. 1) University of Texas Health Science Center at Houston, Houston, TX, USA; 2) University Hospital Ghent, Ghent, Belgium; 3) LVTS, INSERM U1148, Université Paris Diderot, Hôpital Bichat, Paris, France; 4) Baylor College of Medicine, Houston, TX, USA; 5) Royal Prince Alfred Hospital, New South Wales, Australia; 6) Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, USA; 7) Baylor College of Medicine, Texas Children's Hospital, Houston, TX, USA; 8) Washington University School of Medicine, St. Louis, MO, USA; 9) Hospital Universitari Vall d'Hebron, Barcelona, Spain; 10) Centre de Référence Maladies Rares Syndrome de Marfan et pathologies apparentées, Service de Cardiologie, Assistance Publique-Hôpitaux de Paris, Hôpital Bichat, Paris, France; 11) Département de Génétique, Assistance Publique-Hôpitaux de Paris, Hôpital Bichat, Paris, France.

The Montalcino Aortic Consortium was established to characterize the phenotype associated with novel heritable thoracic aortic disease (HTAD) genes. Thoracic aortic disease presentations and outcomes in the initial 987 cases from North America, Europe, Asia, and Australia with pathogenic variants in *ACTA2* (n=319), *TGFBR2* (n=265), *SMAD3* (n=190), *TGFBR1* (n=176) and *PRKG1* (n=37) were analyzed. Average age at first aortic event, defined as aortic aneurysm repair or aortic dissection, was significantly older among *SMAD3* mutation carriers (mean 46 years, standard deviation (SD) 11.5) when compared to *ACTA2* (mean 34, SD 13.9; p<0.0001), *PRKG1* (mean 34, SD 12.4; p<0.0001), *TGFBR2* (mean 32, SD 14.3; p<0.0001), and *TGFBR1* (mean 30, SD 16.9; p<0.0001) mutation carriers. For *TGFBR1* and *TGFBR2* mutation carriers, these aortic events were more frequently elective repair of aortic aneurysms, whereas for *SMAD3*, *ACTA2* and *PRKG1*, the vast majority of presenting aortic events were aortic dissections. Overall cumulative risk of an aortic event was lowest among *SMAD3* mutation carriers compared to *ACTA2* (p=0.003), *PRKG1* (p<0.0001), *TGFBR1* (p=0.0007), and *TGFBR2* (p<0.0001). Cases with the only variant in *PRKG1* that causes aortic disease (p.R177Q) have the highest cumulative risk of aortic events, but childhood onset of aortic events (<13 years) only occurred in cases with *TGFBR2* (n=18), *TGFBR1* (n=5) and *ACTA2* (n=6) mutations, including recurrent mutations disrupting the *ACTA2* arginine 179, *TGFBR2* aspartic acid 446 and arginine 528 residues. Gender influenced the risk of aortic event only among cases with *TGFBR1* (p<0.0001) and *ACTA2* (p=0.02) mutations with higher risk of aortic event in men than women. Additionally, risk of aortic events was found to be higher among cases recruited in North America compared to cases recruited in Europe (p=0.002). These findings indicate thoracic aortic disease phenotype varies with the underlying HTAD gene and often the specific mutation in the gene, gender and site of recruitment. Thus, these data support gene- and mutation-specific management of thoracic aortic disease of HTAD cases and argue against grouping these patients together under one diagnosis, as well as provide baseline data to determine if the proposed management of these patients improves outcomes.

**Exome sequencing of 103 Williams syndrome cases rules out variation in the remaining elastin allele as a major contributor to variance in blood pressure and arterial stenosis.** P.C.R. Parrish<sup>1</sup>, M. Lugo<sup>1</sup>, K. Shields<sup>2</sup>, Y.P. Fu<sup>1</sup>, R.H. Knutsen<sup>1</sup>, B.A. Kozel<sup>1</sup>. 1) National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD; 2) Department of Pediatrics, Washington University School of Medicine, St. Louis, MO.

Elastin (*ELN*) is an extracellular matrix protein that allows tissues to stretch and recoil. Diseases of elastin insufficiency include supravalvular aortic stenosis (SVAS), which is caused by mutations in the *ELN* gene, and Williams syndrome (WS), which is caused by the deletion of 26-28 genes including *ELN* at the 7q11.23 locus. Patients with these conditions have stiff and narrow arteries, in addition to focal stenosis and hypertension. As in many diseases of haploinsufficiency, phenotype severity varies widely among affected individuals. A possible source of this variation is changes in the remaining *ELN* allele which impact the residual quantity and quality of elastin deposited. To assess the effect of quantitative differences in elastin on vascular phenotype, 80 C57Bl/6 *Elm*<sup>-/-</sup> × DBA/2 WT F2 intercross mice underwent vascular phenotyping. Aortic desmosine, an elastin-specific crosslink, was then measured and correlated with blood pressure, aortic diameter and ascending aortic length. For human genetic studies, vascular phenotypes were obtained from a review of medical records from 103 WS subjects. Whole-exome sequencing was performed and common and rare *ELN* variants were evaluated for association with SVAS and hypertension. Within *Elm* genotypes, no correlation was identified between desmosine concentration and mouse aortic diameter, aortic length and systolic blood pressure (all R<sup>2</sup> ≤0.06). Similarly, in human studies, Fisher's exact tests revealed no association between *ELN* variants and SVAS or hypertension. Burden testing on rare exonic variants (n=11 for MAF <10%, n=5 for MAF <5%) revealed no correlation with SVAS (MAF <10%, p=0.5 and MAF <5%, p=0.4) or hypertension (MAF <10%, p=0.5 and MAF <5%, p=0.6). Common *ELN* variants (MAF ≥10%) were analyzed by single-variant testing for all intronic (n=7) and exonic (n=1) variants. Neither type of variation was significantly associated with SVAS (intronic alleles, p>0.1 for all and exonic, p=0.3) or hypertension (intronic, p>0.7 and exonic, p=0.4). With more than 100 rare disease patients studied, this is the largest WS modifier study to date. The results show that genetic variation in the remaining elastin allele is unlikely to play a large role in modifying vascular disease severity, although more modest effects may be detected by increasing sample size. Future modifier work will focus genes and pathways outside the WS locus.

**Treatment of RIT1-associated cardiomyopathy with trametinib: Initial results in two patients.** G. Andelfinger<sup>1</sup>, C. Marquis<sup>2</sup>, M.J. Raboisson<sup>2</sup>, A. Karalis<sup>3</sup>, S. Waldmüller<sup>4</sup>, G. Wiegand<sup>5</sup>, B.D. Gelb<sup>6</sup>, M. Zenker<sup>7</sup>, M. Hofbeck<sup>6</sup>, M.A. Delrue<sup>3</sup>. 1) Cardiovascular Genetics, CHU Sainte Justine, Department of Pediatrics, Université de Montréal, Montréal, QC, Canada; 2) Service of Cardiology, CHU Sainte Justine, Department of Pediatrics, Université de Montréal, Montréal, QC, Canada; 3) Service of Genetics, CHU Sainte Justine, Department of Pediatrics, Université de Montréal, Montréal, QC, Canada; 4) Institute of Medical Genetics, University Hospital of Tübingen, Germany; 5) Department of Pediatric Cardiology, Pulmonology and Paediatric Intensive Care Medicine, University Children's Hospital Tübingen, Germany; 6) Mindich Child Health and Development Institute and Departments of Pediatrics and Genetics and Genomics Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 7) Institute of Human Genetics, University Hospital Magdeburg, Germany.

RASopathies are associated with substantial cardiovascular morbidity, mainly due to the occurrence of hypertrophic cardiomyopathy (CMP). CMP with biventricular obstruction carries a particularly severe prognosis, and therapeutic options are limited. In animal models, MEK/ERK inhibition alleviates RASopathy-associated phenotypes. Here, we report the treatment of two infants with severe obstructive CMP caused by *RIT1* mutations with trametinib. The first patient (P1), diagnosed prenatally with semilunar valve thickening, developed rapidly progressive CMP after birth despite high-dose propranolol treatment (8 mg/kg/d). The second patient (P2) was diagnosed in the neonatal period with pulmonary stenosis and hypertrophic CMP. Distinct *de novo* RIT1 mutations were identified in each patient: S35T and F82L, respectively. CMP progressed rapidly, resulting in severe bilateral outflow obstruction with consecutive pulmonary edema despite propranolol treatment (9 mg/kg/d). P2 was resuscitated and required mechanical ventilation at the age of 12 weeks. Having exhausted conventional treatment for both patients, we used pharmacological MEK inhibition as last resort after approval of local ethics boards for off-label use and obtaining informed consent. We started trametinib at 14 and 13 weeks of age respectively, at a dose of 0.025 mg/kg/d, and monitored side effects. After three months of treatment, we observed dramatic improvement of cardiac status. In P1, outflow tract obstruction decreased (RVOT, peak 70 mmHg to 42 mmHg; LVOT, peak/mean 71/23 to 37/15 mmHg), and progression of hypertrophy ceased. In P2, hypertrophy and pulmonary edema regressed, allowing extubation at 18 weeks of age. Side effects were limited to accentuation of physiological alopecia in P1 and a persistent acneiform eruption in P2, which was treated topically. In summary, trametinib proved to be an effective, well-tolerated treatment for *RIT1*-associated progressive CMP in two selected patients over a short time period. This preliminary experience raises important questions for the treatment of similar cases, in particular with respect to long-term effects, long-term side effects and dosing regimens. MEK inhibition may prove most effective during a fixed time window before the onset of irreversible cardiac remodeling in RASopathies, including those caused by genes other than *RIT1*. In addition, future studies will also need to address the effect of MEK inhibition on other organ systems.

## 2633T

**Genetic architecture of pulmonary arterial hypertension with congenital heart disease.** N. Zhu<sup>1,4</sup>, C. Gonzaga-Jauregui<sup>2</sup>, C. Welch<sup>1</sup>, L. Ma<sup>1</sup>, E.B. Rosenzweig<sup>1,5</sup>, U. Kishnan<sup>1</sup>, A.K. King<sup>2</sup>, J.G. Reid<sup>2</sup>, J.D. Overton<sup>2</sup>, A.R. Shuldiner<sup>2</sup>, A.B. Baras<sup>2</sup>, F.D. Dewey<sup>2</sup>, Y. Shen<sup>3,4,5</sup>, W.K. Chung<sup>1,3,6</sup>. 1) Department of Pediatrics, Columbia University, New York, NY; 2) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, NY; 3) Herbert Irving Comprehensive Cancer Center, Columbia University Medical Center, New York, NY; 4) Departments of Systems Biology, Columbia University, New York, NY; 5) Departments of Biomedical Informatics, Columbia University, New York, NY; 6) Department of Medicine, Columbia University Medical Center, New York, NY.

Among group I pulmonary arterial hypertension (PAH), approximately 40% of children and 10% of adults have congenital heart disease (CHD). Left-to-right (systemic-to-pulmonary) shunts increase pulmonary blood flow and the risk of PAH, but not all PAH-CHD is associated with prolonged increased pulmonary blood flow, and the PAH may be due to another cause. Missense variants in *BMPR2*, a major gene contributing to familial and idiopathic PAH, have been identified in 5-7% of PAH-CHD patients, suggesting that the majority of cases are not due to *BMPR2* mutations. To identify novel genetic causes of PAH-CHD, we performed reflexive *BMPR2* sequencing and MLPA, followed by exome sequencing in a total of 270 PAH-CHD patients, including both parents in 52 patients without mutations in established PAH genes. Twenty-eight patients (10.3%) carried likely pathogenic variants in established PAH-risk genes, including *TBX4* (11) and *BMPR2* (11). We estimated the contribution of *de novo* variants in novel candidate genes. Based upon the background mutation rate, we identified a significant enrichment of missense *de novo* variants in PAH-CHD cases in genes highly expressed in the developing lung (p-value=0.02, enrichment=1.71), explaining ~14% of cases. Additionally, we assessed the extremeness of deleteriousness of rare variants in each patient using population sampling probability (PSAP). Using the PSAP-score based association test, we identified a new candidate risk gene *SOX17*, a transcription regulator involved in Wnt signaling and required for normal looping of the embryonic heart tube. *SOX17* is intolerant of deleterious mutations (ExAC pLI = 0.87, misZ = 3.25). Eight PAH-CHD patients (p-value<1e-6) with either a patent ductus arteriosus or secundum atrial septal defect carry 5 predicted loss of function (LoF) and 3 novel missense that are predicted to be more deleterious than the most deleterious variants in the gene in 99.9% population. Interestingly, 3 patients carried 2 novel missense and 1 LoF variants in a separated cohort of 426 PAH patients without CHD, supporting *SOX17*'s role in PAH. In summary, we characterized the genetic architecture of PAH-CHD and found there is a lower contribution from known PAH risk genes than in patients without CHD, with 5% associated with *TBX4* mutations and a potentially substantial contribution from *de novo* missense variants. Finally, we identified a novel candidate PAH-CHD risk gene *SOX17* harboring rare, predicted deleterious variants.

**2634F**

**Probing for modifiers of X-inactivation in a cohort of Amish families with hemophilia B.** A. Ozel<sup>1</sup>, K. Desch<sup>2</sup>, D. Siemeniak<sup>3</sup>, M. Heiman<sup>4</sup>, A. Shapiro<sup>4</sup>, D. Ginsburg<sup>1,3</sup>, J. Li<sup>1</sup>. 1) Dept. of Human Genetics, University of Michigan-Ann Arbor, Ann Arbor, MI; 2) Dept. of Pediatrics, University of Michigan-Ann Arbor, Ann Arbor, MI; 3) HHMI, University of Michigan - Ann Arbor, Ann Arbor, MI; 4) Indiana Hemophilia and Thrombosis Center, Inc., Indianapolis, IN.

To balance gene dosage in mammals between males and females, one of the X chromosomes is randomly inactivated early in female embryonic development in all cells except oocytes, with gene expression primarily restricted to genes on the active X. On average, each X-chromosome will be inactivated in ~1/2 of somatic cells in a given female. The presence of preferential or non-random inactivation of the X chromosome, a.k.a. X-inactivation skewing, in a female carrier for an X-linked recessive disease, can lead to deviation from the 50/50 distribution of cells expressing the normal and mutant chromosomes. This skewing could be by chance or directed by genetic factors. Coagulation Factor IX (Xq27.1-q27.2) is produced by liver hepatocytes. Therefore, plasma Factor IX levels should be an excellent proxy for skewing of X-inactivation in carriers of severe hemophilia B, an X-linked recessive disorder. We measured plasma Factor IX activity levels in 166 female carriers from three large Amish pedigrees with severe Hemophilia B. Factor IX activity in carriers ranged from 14-142%. We used deviation from 50% Factor IX activity levels as a quantitative trait in linkage and association testing. Genotyping was done using the Human Omni Express-24 BeadChip and Factor IX activity were measured using a chromogenic assay. Heritability ( $h^2$ ) of the deviation in activity levels from 50% was estimated as 6.6% (using *SOLAR*), similar to the results from *Merlin-Regress* (14.6%). Genome-wide association analysis didn't identify a major locus for X-inactivation skewing, though a suggestive signal was detected at the *DBC1* locus on Chromosome 9 (rs1013282(G), MAF=0.42,  $p=4.3E-7$ ). This top SNP didn't exhibit a significant cis-eQTL in any of the tissues in the *GTeX* database, but was found to alter 7 regulatory motifs as reported by *HaploReg*. The lowest p-value observed on Chromosome X was at the *FGF13* locus (rs7052771(A), MAF=0.081,  $p=1.6E-6$ ) with no significant cis-eQTLs in any of the tissues in the *GTeX* database and evidence for alteration of 2 regulatory motifs by *HaploReg*. Linkage analysis on the female carriers in these 3 pedigrees using *Merlin-Regress* and *SOLAR* also failed to detect any significant linkage or association with skewed X inactivation suggesting the absence of a single, specific X-inactivation modifier in these families. These data are consistent with the relatively low heritability estimates and suggest that the majority of skewed X-inactivation is due to non-genetic factors.

**Novel genetic associations for blood pressure identified via gene-alcohol consumption interaction in about 570K individuals.** M.F. Feitosa<sup>1</sup>, A.T. Kraja<sup>1</sup>, M.A. Province<sup>1</sup>, D. Levy<sup>2</sup>. 1) Division of Statistical Genomics, Department of Genetics, Washington University School of Medicine, Saint Louis, MO; 2) Framingham Heart Study, Framingham, MA and the Population Sciences Branch, National Heart, Lung, and Blood Institute, Bethesda, MD; on behalf of the Gene-Lifestyle Interactions Working Group.

Blood pressure (BP) levels are influenced by alcohol consumption even after adjusting for environmental confounders. Genome-wide association (GWA) of gene-by-alcohol consumption status for BP may identify additional loci and contribute to the understanding of alcohol-BP metabolism. We conducted GWA analyses with joint (2df) test of main genetic (G), alcohol exposure (E) and their interaction (G×E) effects, using 1000G imputed markers on systolic BP, diastolic BP, mean arterial pressure, and pulse pressure. In Stage-1, meta-analyses with double genomic corrections were applied in up to 130,828 individuals, and in each ancestry: African (AA: N=21,417), European (EA: N=91,102), Asian (ASA: N=9,838), Hispanic (HA: N=4,056) and Brazilian (N=4,415). 3,713 SNVs representing 126 loci (+/-500kb SNV-distance) that reached suggestive associations ( $P \leq 1E-06$ ) were analyzed in Stage-2 (Replication). Stage-2 included 440,824 individuals from AA (N=5,041), ASA (N=141,026), EA (N=281,380), and HA (N=13,377). We identified 5 novel loci (in EA and in multi-ancestry) and 44 BP-known loci (in multi-ancestry and 37 in EA). Further, we meta-analyzed Stage-1 and Stage-2 combined using 3,713 SNVs (126 loci) and found 21 potential novel loci ( $p < 5E-08$ ), where 18 of them are in AA, 2 in EA, and 1 in multi-ancestry. In addition, Stages 1 and 2 yielded 20 BP-known loci (18 in EA, 12 in ASA and 4 in AA). Many of our genes belonging to the above loci (e.g., *PINX1*, *GATA4*, *FTO*, *BLK*, *GABBR2*, *CHAT*, and *BAG3*) have been linked to alcohol dependence. Some genes belonging to these loci (*KCNMB2*, *BAG3*, *SGK1*, and *CDH17*) have also been reported as suggestive in associations with BP traits in humans or animal models. Our novel variants interacting with alcohol consumption for all four BP traits on 8p23.1 region (e.g., *PINX1*, *BLK* and *MIR4286*) show evidence of cis- and trans- regulatory functions. Our study extends evidence from previously reported BP-findings in European ancestry cohorts to other ancestries (e.g., *LSP1-TNNT3* in Asians). Our novel and known BP loci are enriched for several biological terms and pathways that capture important information for BP and cardiovascular disease risk factors, alcohol dependence, personality, neurodegenerative and neuropsychiatric disorders. These findings may provide insights into mechanisms by which alcohol consumption impacts BP and hypertension risk. *This work was supported in part by the NHLBI grant HL118305.*

**2636T**

**Genome-wide association study of cardiotoxicity and cardiac gene expression in NCCTG N9831 (Alliance) Adjuvant Trastuzumab Trial.** *D.J. Serie<sup>1</sup>, J.E. Crook<sup>1</sup>, B.M. Necela<sup>2</sup>, T.J. Dockter<sup>3</sup>, G. Colon-Otero<sup>4</sup>, E.A. Perez<sup>2</sup>, E.A. Thompson<sup>2</sup>, N. Norton<sup>2</sup>.* 1) Health Sciences Research, Mayo Clinic, Jacksonville, FL; 2) Department of Cancer Biology, Mayo Clinic, Jacksonville, FL; 3) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Department of Hematology/Oncology, Mayo Clinic, Jacksonville, FL.

The major clinical side-effect of the *ERBB2* targeted breast cancer therapy, trastuzumab, is decline in left ventricular ejection fraction (LVEF). Improved methods are required to better identify patients susceptible to cardiotoxicity. NCCTG N9831 trial compared adjuvant doxorubicin and cyclophosphamide followed by either weekly paclitaxel (Arm A); paclitaxel then trastuzumab (Arm B); or concurrent paclitaxel and trastuzumab (Arm C) in patients with HER2-positive breast cancer. GWAS was performed across 618,863 SNPs and 1,191 patients. We used linear regression to identify SNPs associated with decline in LVEF, adjusting for age, baseline LVEF, and anti-hypertensive medications. We used Predixcan to perform association testing of decline in LVEF with the estimated heritable gene expression levels in left ventricular tissue of patients in N9831, using genotype and expression data from 159 individuals in the GTEx database as a training set. SNPs at six loci were associated with decline in LVEF, ( $p=7.73 \times 10^{-6}$  to  $8.93 \times 10^{-6}$ ): *LDB2*, *BRINP1*, chr6 intergenic, *RAB22A*, *TRPC6* and *LINC01060*, in patients who received combination chemotherapy and trastuzumab (Arms BC, N=800). We replicated association,  $p < 0.05$ , with SNPs previously associated with anthracycline cardiotoxicity at *CBR3* and *ABCB1*. Predixcan estimated heritable levels of cardiac gene expression at 4,853 genes, of which, 228 were associated with decline in LVEF,  $p < 0.05$ . Estimated *TRPC6* and *CBR3* expression levels were associated with decline in LVEF,  $p=0.005$  and  $0.08$  respectively. Our study identified six putative novel cardiotoxicity loci in patients treated with combination chemotherapy and trastuzumab and replicated known associations of anthracycline induced cardiotoxicity. In the case of *TRPC6* and *CBR3*, cardiotoxicity may be related to genetic variants that alter cardiomyocyte gene expression.

**2637F**

**The association of TMPO and RYR1 genes with cardiovascular diseases in a Turkish Cypriot Family.** *M.C. Ergoren<sup>1</sup>, R. Kalkan<sup>2</sup>, B. Turkgenç<sup>3</sup>, S.G. Temel<sup>4</sup>.* 1) Medical Biology, School of Medicine, Near East University, Nicosia, Cyprus; 2) Faculty of Medicine, Department of Medical Genetics, University of Near East, Nicosia, Cyprus; 3) Genetic Diagnostic Center, University of Acibadem, Istanbul, Turkey; 4) Faculty of Medicine, Department of Histology and Embryology, University of Uludag, Bursa, Turkey.

The protein encoded by Thymopoietin (TMPO) gene may play a role in the assembly of the nuclear lamina, and thus help maintain the structural organisation of the nuclear envelope. Furthermore, Ryanodine receptor is encoded by Ryanodine Receptor 1 (RYR1) gene and functions as a calcium release channel in the sarcoplasmic reticulum but also serves to connect the sarcoplasmic reticulum and transverse tubule. Mutations in TMPO and RYR1 genes are associated with dilated cardiomyopathy and mini core myopathy with external ophthalmoplegia, respectively. The 50 years old male propositus was referred to our clinic after having artery blockage of 90% and 99% that was fixed by stent operation. This was followed by by-pass cardiac surgery. He is the middle son of his parents and the family history was significant for sudden death of his father (<40 yrs), and his mother and his younger brother has similar phenotype with him and had by-pass heart surgery in their early ages. TMPO and RYR1 exon sequencing of the probing revealed c.289A>C (p.Lys97Gln) heterozygote missense variation (rs778356103) in exon 2 of TMPO gene and c.1354G>A (p.Glu452Lys) heterozygote missense variation within exon 13, c.6310C>T (p.Arg2104Cys) (rs541757529) heterozygote missense variation in exon 30 and a heterozygote c.9743G>A (p.Arg3248Gln) (rs553187437) missense variation within exon 66 of RYR1 gene. Heterozygote missense variation c.1354G>A (p.Glu452Lys) in RYR1 gene is not identified before, so it is de novo. None of these variants have been reported before in the mutational databases and additionally, no phenotype has been reported with these variants. Moreover, population studies showed that minor allele frequencies of those variants are much more less than 1% and they are located within conserved region between species. To conclude, we found a direct association with three variants that in exon regions of both TMPO and RYR1 genes with cardiovascular diseases in a Turkish Cypriot family.

## 2638W

**Association of a polymorphism in *ITGB3* with resistance to clopidogrel in early acute coronary syndrome in an admixed population from Colombia.** A.V. Valencia-Duarte<sup>1</sup>, N. Gallego<sup>1</sup>, L. Franco<sup>1,2</sup>, C.A. Velarde<sup>1</sup>, D.M. Valencia<sup>1</sup>, K.J. Betancur<sup>3</sup>, I.C. Ortiz<sup>1</sup>, H. Cuervo<sup>1,3</sup>, N. González<sup>3</sup>, C. Rúa<sup>4</sup>, C. Saldarriaga<sup>1,3</sup>, C.A. Martínez<sup>1,3</sup>, N. López<sup>3</sup>, L.M. Parra<sup>1</sup>, P. Parra<sup>1</sup>, E.A. Jiménez<sup>1</sup>, S. Carvalho<sup>1</sup>, C.I. Vergara<sup>5</sup>, J. García<sup>6</sup>, G. Bedoya<sup>7</sup>. 1) Faculty of Medicine, Universidad Pontificia Bolivariana, Medellín, Antioquia, Colombia; 2) National Faculty of Public Health, University of Antioquia, Medellín, Antioquia, Colombia; 3) CardioVID Clinic, Medellín, Antioquia, Colombia; 4) Hematology Department, Hospital San Vicente Fundación, Medellín, Antioquia, Colombia; 5) School of Medicine, Johns Hopkins University, Baltimore, MD.,USA; 6) Faculty of Medicine, University of Antioquia, Medellín, Antioquia, Colombia; 7) Institute of Biology, University of Antioquia, Medellín, Antioquia, Colombia.

Dual antiplatelet therapy with clopidogrel and aspirin is the standard treatment to prevent ischemic events in patients undergoing percutaneous coronary intervention (PCI), which reduces the rate of recurrent infarctions and thrombotic events. However, the antiaggregant response of clopidogrel varies individually and at population levels due to different factors including genetics. We aimed to evaluate the association between genetic variants in genes related to absorption, metabolic activation and biologic activity of clopidogrel with the response to clopidogrel and recurrent coronary events in an admixed population from Colombia. The study included 212 patients with diagnosis of early acute coronary syndrome, undergoing PCI and with stenosis  $\geq 50\%$ . Platelet aggregation was measured using light transmittance aggregometry with adenosine diphosphate as agonist. Outcome variables were clopidogrel resistance, defined as platelet aggregation  $\geq 70\%$  after 600 mg loading dose of clopidogrel (38 resistance/153 non resistance) and risk of major adverse cardiac events (MACE), such as infarction, stent thrombosis or death during 1 year of follow-up (9 events/203 no events). Polymorphisms in the genes *ABCB1* (rs1045642), *CYP2C19* (rs4244285), *CYP3A5* (rs776746), *CYP1A1* (rs1048943) *ITGB3* (rs5918) and *P2RY12* (rs6785930 and rs6809699) were genotyped using RT-PCR. Association analyses were performed using logistic regression, including age, sex, socioeconomic status, cholesterol levels and treatment as covariates in the model. rs5918 SNP in *ITGB3* was associated with clopidogrel resistance (CC/CT adjusted OR: 0.261; 0.071 - 0.961, P-value: 0.043) suggesting that patients carrying the one or two copies of the C allele in rs5918 have lower risk to present clopidogrel resistance. Genetic variants located in *P2RY12* were associated with clopidogrel resistance in the bivariate analysis (AA/AC OR: 2.418; 1.058 - 5.524, P-value: 0.033) but the results were not significant after adjusting by covariates. There was no association between any analyzed polymorphism and MACE. In summary, clopidogrel resistance has a high frequency among the evaluated population and it might be explained by a genetic variant in the *ITGB3* gene. Further analysis are needed to understand the biological mechanisms underlying the observed association.

## 2639T

**Identifying and characterizing causal genes in GWAS-identified loci for heart rate variability using high-throughput, image-based screens in zebrafish larvae.** B. von der Heyde<sup>1</sup>, A. Emmanouilidou<sup>1</sup>, T. Klingström<sup>1</sup>, S. Vicenzi<sup>1</sup>, H. Brooke<sup>2</sup>, A. Allalou<sup>3</sup>, M. den Hoed<sup>1</sup>. 1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Institute of Environmental Medicine, Karolinska Universitet, Stockholm, Sweden; 3) Department of Information Technology, Uppsala Universitet, Uppsala, Sweden.

**Introduction:** Heart rate variability (HRV) is associated with an increased risk for cardiovascular disease (CVD), the major cause of death worldwide. A recent meta-analysis of genome-wide association studies (GWAS) in data from 53,172 individuals has identified variants in eight loci that show robust associations with HRV. The causal genes and mechanisms through which these loci influence heart rate variability are still unknown. We aimed to characterize positional candidate genes for HRV using a zebrafish model system. **Methods:** We prioritized 18 candidate genes for functional follow-up based on results from five bioinformatic tools. Twelve of these genes had a total of 16 orthologous genes in zebrafish. We targeted these 16 orthologues in three pools of up to eight targeted genes using a multiplex CRISPR-Cas9 approach in fertilized eggs from fish that transgenically express green fluorescent protein on smooth muscle cells, which enables visualization of the beating heart. After three months, founder mutants were crossed, and heart rate and rhythm were visualized and quantified *in vivo* in the offspring by recording 30 sec videos of the atrium at 2 and 5 days post-fertilisation (dpf, repeated measures). Heart rate and two different measures for HRV were quantified in batch mode using a custom-written MatLab script. CRISPR-Cas9 induced mutations were quantified using next-generation sequencing and data were analyzed using mutually adjusted multiple linear/logistic regression models (additive model). **Results:** We have so far characterized one of three multiplex mutant lines and show that: 1) each additional disrupted allele in *rgs6* increases the odds of cardiac arrests at 2dpf by 2.52 (95% CI 1.13-5.61, n=372); 2) each additional disrupted allele in *gngt1* is associated with a 0.21 $\pm$ 0.09 higher RMSSD (n=303), a 3.49 higher odds of a reduced contractility (95% CI 1.29-9.43, n=326) and an 8.88 higher odds of an abnormal morphology of the heart (95% CI 2.16-36.48, n=297) at 5dpf; and 3) each additional affected allele in *kiaa1755* results in a 0.14 $\pm$ 0.06 (SD) higher heart rate (n=289). **Conclusion:** Zebrafish larvae facilitate large-scale, objective, image-based genetic screens of heart rate and rhythm, and allowed us to identify previously unanticipated genes that influence heart rate variability and early cardiac development (*gngt1*); the risk of cardiac arrests (*rgs6*); and heart rate (*kiaa1755*).

Abdominal aortic aneurysm (AAA) is a common disorder with a strong hereditary component and rare fully penetrant, dominant inheritance. However, no gene of Mendelian AAA was identified to date. The power of recently developed strategies comes from combining exome or genome sequencing with new genetic association analysis tools, allowing for the identification of rare variants with stronger effects. We used this strategy and first performed exome sequencing in a large 3-generations pedigree showing dominant inheritance. Five affected cases had exome analysis, completed by segregation analysis in 5 affected and unaffected relatives. Using classical filtering tools and segregation, we identified only one candidate variant, R377W, in *APOL3*, a gene of unknown function. A Z-score of 4.14 ( $p=2.10^{-5}$ ) at *APOL3* locus confirmed linkage with the condition. Gene-centered association analysis was performed, focused on *APOL3* rare and very rare variants. A large cohort of 2500 sporadic and 500 familial AAA cases was compared to 3000 age and sex-matched controls by sequencing and genotyping. 12 rare variants (MAF<1%) and 7 very rare variants (MAF<1‰) were identified. A significant excess of very rare variants was found in the AAA cases compared to controls (Burden test;  $p=0.03$ ). Western-blot and immunohistochemistry demonstrated the expression of *APOL3* protein in the smooth muscle cells and endothelium of one affected case, and in control samples. Inflammatory and viral stimuli like TNF $\alpha$  and TLR3 strongly induce *APOL3* expression in endothelial cells and trigger cell death. *APOL3* function is still unknown, but it belongs to a family of 6 proteins regulating apoptosis. We show that *APOL3* regulates the cell cytoskeleton in various cell types. The mutant *APOL3* R377W is suggested to induce a dominant-negative effect rather than a loss of function, as a heterozygous nonsense variant is present at very high frequency in the African-American population (EXAC database, rs11089781: MAF=0.22). Preliminary observations after transfection of smooth muscle cells by the R377W *APOL3* mutant shows alteration of the cellular phenotype in terms of survival, shape, and cytoskeleton dynamics. Identification of an *APOL3* mutation indicates that AAA can result from underlying genetic variants that significantly alter the phenotype of vascular smooth muscle cells, through a mechanism distinct from atherosclerosis.

**2641W****Is HDL-C causally associated with risk of cardiovascular diseases in Han Chinese? A Mendelian randomization study with 10,000 subjects.**

*M.I. Biradar*<sup>1</sup>, *K.M. Chiang*<sup>2</sup>, *H.C. Yang*<sup>3</sup>, *W.H. Pan*<sup>1,2</sup>. 1) Taiwan International Graduate Program in Molecular Medicine, National Yang-Ming University and Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Science, Academia Sinica, Taipei, Taiwan; 3) Institute of Statistical Science, Academia Sinica, Taipei, Taiwan.

Plasma high density lipoprotein-cholesterol (HDL-C) level is known as a risk factor for cardiovascular disease and is influenced by various genetic & environmental factors. Plasma HDL-C level has been consistently associated with reduced risk of cardiovascular diseases, but whether this association is causal has not been carefully examined in Han Chinese. Considering the fact that genotypes are randomly distributed during meiosis, independent of non-genetic confoundings, and not modified by the disease process; Mendelian randomization can be applied to test whether the HDL-C is causally associated with CVD. Recent GWAS studies have identified several loci associated with HDL levels, but these loci have been primarily reported in European and Caucasian populations. In order to identify the loci associated with HDL levels in the Chinese population, we have conducted a two-stage GWAS study using 5000 Han Chinese data from Taiwan Biobank. Replication was performed in another 5,000 subjects of Han Chinese ethnicity. Further, we performed Mendelian randomization analysis using weighted genetic risk score (wGRS) as the instrumental variable. A total of 77 SNPs was significantly associated with HDL-C levels. These SNPs are located in *APOA5*, *BUD13*, *CETP*, *DOCK6*, *APOA5-BUD13* cluster, *LIPC*, *LIPG*, and *LPL & ZPR1*. Due to high linkage disequilibrium among the SNPs in each region, only one most significant SNP was chosen for each gene to compute the wGRS. Analyzing data from 10,000 Han Chinese, we found that although HDL-C level was significantly associated with the status of CVD; HDL-C wGRS, an instrumental variable representing the lifelong genetic exposure dosage, was not with the development of CVD event with Cox Proportional Hazard Model. In conclusion, we have identified and confirmed the 10 SNPs associated with the HDL-C level, but Mendelian randomization study does not support its causal relationship with CVD risk in Taiwan Han Chinese.

**Genome-wide association study of congenital heart disease in the UK Biobank.** A. Córdova-Palomera<sup>1</sup>, S. Gustafsson<sup>2</sup>, E. Ingelsson<sup>3</sup>, J.R. Priest<sup>1,4</sup>. 1) Department of Pediatrics, Stanford University, Stanford, CA; 2) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 4) Cardiovascular Institute, Stanford University School of Medicine, Stanford, CA.

Affecting nearly 1 per 100 live births, congenital heart disease (CHD) is the most common congenital anomaly in newborns. While previous findings indicate an important etiological role for inherited factors such as structural variation, additional genetic variants influencing disease risk remain to be discovered. Using publicly available resources from the first release of data from the UK Biobank, a genome-wide association study of 1,387 CHD cases and 114,509 controls was performed with PLINK; putative associations of rare genetic variants were validated with Firth's penalized regression. Additionally, genetic correlation analysis of the most frequent CHD subtypes (aortic valve stenosis, atrial septal defect, left ventricular outflow tract obstruction, mitral valve abnormalities and other septal defects) was implemented using LD score regression (LDSC). Markers at twenty-six loci displayed statistically significant associations with CHD, including rare coding variants in *DSG2* (rs536617217, Firth's penalized regression OR: 8.02,  $p = 1.8e-9$ ) and *ITGB2*, loci previously associated with CHD-related phenotypes. In addition, genetic correlations were detected between the main diagnostic subtypes. The results suggest novel candidate loci as determinants of genetic risk for CHD in the general population, and indicate a shared genetic architecture between different types of CHD. Follow-up analyses in additional datasets (Pediatric Cardiac Genomics Consortium and second UK Biobank data release) will be performed to confirm the findings. Though use of adult populations to study childhood disease is prone to selection and survivorship biases, large-scale public datasets offer an unprecedented opportunity to study the genetic architecture of childhood diseases, such as CHD.

**Genetic correlation of human lipidomic endophenotypes and cardiometabolic phenotypes in the Busselton Family Heart Study.** G. Cadby<sup>1</sup>, P.E. Melton<sup>1</sup>, J. Hung<sup>2</sup>, J. Beilby<sup>3,4</sup>, M.P. Dubé<sup>5</sup>, F. van Bockxmeer<sup>6</sup>, G.F. Watts<sup>2,7</sup>, J. Blangero<sup>8</sup>, P.J. Meikle<sup>9</sup>, E.K. Moses<sup>1</sup>. 1) Centre for Genetic Origins of Health and Disease, The University of Western Australia and Curtin University, Western Australia; 2) School of Medicine, The University of Western Australia, Western Australia; 3) Busselton Population Medical Research Institute Inc., Western Australia; 4) PathWest Laboratory Medicine WA, Western Australia; 5) Université de Montréal Beaulieu-Saucier Pharmacogenomics Centre, Montreal Heart Institute, Quebec; 6) School of Surgery, The University of Western Australia, Western Australia; 7) Lipid Disorders Clinic, Department of Cardiology, Royal Perth Hospital, Western Australia; 8) South Texas Diabetes and Obesity Institute, The University of Texas Rio Grande Valley School of Medicine, Texas; 9) Metabolomics Laboratory, Baker Heart and Diabetes Institute, Victoria.

Cardiometabolic disease (CMD) is the leading cause of death globally. Genetic investigations into the human lipidome (>1000 lipid species) may provide insight into CMD risk. Due to the biologically simpler nature of lipid species, their determinants are likely to be closer to the causal action of genes than more complex integrated lipid measures. The aim of this study was to estimate the heritability of lipidomic endophenotypes and their genetic correlation with CMD. Targeted lipidomic profiling was performed on 4671 individuals from the Busselton Health Study (BHS) using electrospray ionization-tandem mass spectrometry to quantify >300 lipid species from >20 lipid classes. The BHS is a community-based study that included both related and unrelated individuals. To exploit both known and unknown relatedness, we estimated empirical kinship probabilities using LDAC. The general linear mixed model incorporated in SOLAR was used to estimate narrow-sense heritabilities of lipid species and classes, and genetic correlations between lipid classes and CMD traits: HDL-C, LDL-C, triglycerides (TG), systolic blood pressure (SBP), diastolic blood pressure (DBP) and HOMA-IR. Analyses were adjusted by age, sex and use of lipid-lowering and antihypertensive medications. Over 98% of the lipid species were significantly heritable ( $h^2$ : 0.11-0.52) and all lipid classes were significantly heritable ( $h^2$ : 0.15-0.50). The most heritable lipid classes were total monohexosylceramide (MHC) and total acylcarnitine (both  $h^2=0.50$ ,  $P<1\times 10^{-40}$ ). Total MHC was genetically correlated with TG ( $r_g=-0.26$ ,  $P=6\times 10^{-5}$ ) and LDL-C ( $r_g=0.25$ ,  $P=1\times 10^{-5}$ ). LDL-C was genetically correlated with 22 of the 24 lipid classes ( $h^2$ : 0.25-0.78). The largest genetic correlations were between TG and total diacylglycerol ( $r_g=-0.88$ ,  $P=1\times 10^{-24}$ ) and total triacylglycerol ( $r_g=0.81$ ,  $P=3\times 10^{-23}$ ). DBP was not genetically correlated with any lipid class and SBP was only correlated with lysophosphatidylcholine ( $r_g=0.38$ ,  $P=1\times 10^{-4}$ ). HOMA-IR was only genetically correlated with total sulfatide ( $r_g=-0.32$ ,  $P=1\times 10^{-4}$ ); HDL-C showed the strongest genetic correlation with total sulfatide ( $r_g=0.47$ ,  $P=5\times 10^{-14}$ ). We have demonstrated, using empirically-derived kinship estimates, that lipidomic endophenotypes are heritable and genetically correlated with CMD. Future work includes identifying lipid species that represent the best potential CMD-related endophenotypes, and whole genome sequencing to identify causal genetic variants.

**Genome-wide association analysis identifies multiple loci associated with coronary artery calcification in Koreans.** S. Choi<sup>1,2</sup>, H. Lee<sup>1,2</sup>, H. Park<sup>1,2</sup>, S. Choi<sup>1,2</sup>, E. Choe<sup>1,3</sup>, S. Oh<sup>1,4</sup>, C. Lee<sup>1,2</sup>, E. Shin<sup>5</sup>. 1) Internal medicine, Healthcare System Gangnam Center, Seoul National University Hospital, Seoul, South Korea; 2) Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Korea; 3) Department of General Surgery, Seoul National University College of Medicine, Seoul, Korea; 4) Department of Family Medicine, Seoul National University College of Medicine, Seoul, Korea; 5) DNA Link, Inc., Seoul, Korea.

**Background/Aims:** Coronary artery calcium score (CACs) represents a measure of overall coronary atheromatous plaque burden and is a strong predictor of coronary heart disease. The development of coronary atherosclerosis is associated with multiple genetic and environmental factors, and life style. We report an analysis of genome-wide association studies (GWAS) for coronary artery calcification in Koreans. **Methods:** We performed a GWAS to identify genetic factors related to coronary artery calcification in large Korean population based samples of 1,729 subjects using the Affymetrix Axiom® Korean Biobank Array 1.0, customized biobank genotyping arrays. We replicated the data in another sample of 460 subjects. Quantitative CACS were calculated according to the Agatston method. We investigated SNPs that are associated with severe coronary calcification, defined as above 90th percentile of CACS by each 5-year age group and gender category in the Korea Initiatives on Coronary Artery calcification (KOICA) registry (85,945 asymptomatic Koreans, 69.3% in male). The genetic analysis was used with additive model by SAS version 9.1 (SAS Institute Inc., Cary, NC, USA.) and PLINK version 1.9 (<https://www.cog-genomics.org/plink2>). **Results:** Rs2227593 located in the SERPINC1 gene in chromosome 1 was significant associated with severe coronary artery calcification;  $p = 3.5 \times 10^{-4}$ , OR 0.65 (95% CI 0.51-0.82) in the discovery set and  $p = 4.6 \times 10^{-2}$ , OR 0.65 (95% CI 0.42-0.99) in replication set. Rs16981779 and rs76229963 located in the ANKRD60, C20orf85, PPP4R1L gene in chromosome 20 were significant associated with severe coronary artery calcification;  $p = 6.0 \times 10^{-4}$ , OR 2.2 (95% CI 1.4-3.3) in the discovery set and  $p = 2.2 \times 10^{-2}$ , OR 2.6 (95% CI 1.3-5.3) in replication set and  $p = 5.0 \times 10^{-4}$ , OR 2.3 (95% CI 1.5-3.5) in the discovery set and  $p = 1.6 \times 10^{-2}$ , OR 2.7 (95% CI 1.3-5.5) in replication set, respectively. Rs16981779 and rs76229963 were in strong linkage disequilibrium (R-square = 0.78 and D' = 0.95). **Conclusions:** We identified associations among these loci with coronary artery calcification. These findings provide new insights into the genetic susceptibility to coronary atherosclerosis in Koreans.

## 2645T

**The search for coronary heart disease biomarkers: A large scale reanalysis of gene expression data.** B. Cunha, F. Vargas, L. Cordeiro. UNIRIO, Rio de Janeiro, Brazil.

Cardiovascular disease remains the leading global cause of death and, more specifically, coronary heart disease (CHD) still represents a serious public health problem throughout developed countries. In the United States approximately 16 million individuals over 20 years of age have CHD and its prevalence is projected to increase by more than 18% in 2030. Direct and indirect costs of heart disease are expected to be over \$200 billion in 2017 and it is estimated that in every 40 seconds one North American will die of cardiovascular disease and another will suffer a myocardial infarction (MI). In spite of its clinical relevance, precise risk stratification of CHD patients is still lacking, posing one of the biggest challenges in modern cardiology. The objective of this study is to identify specific gene expression signatures associated with different stages of CHD. We undertook a reanalysis of public gene expression data related to CHD and constructed a unique dataset of over 440 microarray samples collected from peripheral blood mononuclear cells of healthy patients and patients with angina and myocardial infarction (MI). We identified different gene expression patterns between healthy controls and the MI group – 192 differentially expressed genes (DEGs) – as well as between the angina and MI groups – 134 DEGs. Interestingly, there was no DEGs between the angina group and healthy controls. Top DEGs between healthy controls and MI patients are: *CXCL2*, *IL1B*, *IL1R2*, *NR4A2*, *CCL20*, *LILRB2*, *CSTA*, *RPS4Y1*, *TREM1*, *NFIL3*, *MGAM*, *C5AR1*, *IRAK3*, *MGP*, and *PTX3*. The top most DEGs between the MI group and the angina group are: *S100A12*, *AQP9*, *TREM1*, *NR4A2*, *SERPINA1*, *CHI3L1*, *IER3*, *MGP* and *PLBD1*. All DEGs are upregulated in both comparisons, *i.e.*, there was not a single downregulated gene in the MI group relative to both the angina group and healthy controls. Pathway analysis shows that several signaling pathways are deregulated in the MI group: cell cycle regulation, cell differentiation, TNF signaling, TLR signaling, NF- $\kappa$ B signaling and hematopoietic stem cell activation; all previously associated with CHD. We also found that the IL-17 signaling pathway is suppressed in the MI group, lending support to the hypothesis of its protective role. Moreover, the rheumatoid arthritis signaling pathway is activated in the MI group as well. Taken together, these results corroborate the significant role of inflammatory signaling pathways in the etiopathogenesis of coronary heart disease.

**2646F****Identification of rare variation influencing CVD risk in Mexican Americans.** J.E. Curran<sup>1</sup>, N.B. Blackburn<sup>1</sup>, J.M. Peralta<sup>1,2</sup>, M.A. Almeida<sup>1</sup>, H.H. Goring<sup>1</sup>, L. Almasy<sup>3,4</sup>, M.C. Mahaney<sup>1</sup>, D.C. Glahn<sup>5,6</sup>, R. Duggirala<sup>1</sup>, J. 1) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX, USA; 2) Menzies Institute for Medical Research, University of Tasmania, Hobart, TAS, AUS; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 4) Department of Biomedical and Health Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 5) Department of Psychiatry, Yale University School of Medicine, New Haven, CT, USA; 6) Olin Neuropsychiatry Research Center, Institute of Living, Hartford Hospital, Hartford, CT, USA.

Cardiovascular disease (CVD) is the leading cause of mortality worldwide and encompasses conditions of the heart and vasculature. CVD risk is attributable to several factors including blood pressure, smoking, increasing age, sex, and genetics. Although CVD risk is heritable and there have been a number of successes localizing QTLs that influence disease risk, the genetic basis is still relatively unknown and likely differs substantially between families. Here we show the utility of whole genome sequencing (WGS) for the discovery of rare CVD risk variants. We have prospectively followed 1,222 Mexican American individuals from large pedigrees in the San Antonio Family Heart Study and have their histories of heart attack, heart surgery for arterial blockages, and incidences of cardiac-related death. The large extended pedigrees provide opportunity to potentially capture sufficient numbers of very rare functional variants to permit variant-specific association testing. The age-standardized prevalence of CVD in this cohort is 16% and we have calculated the heritability of CVD using the normal threshold model to be 25.9% ( $P=0.01$ ). Using WGS, we searched for rare ( $MAF \leq 0.01$ ), non-synonymous, highly deleterious ( $CADD \geq 15$ ) variants influencing the risk of CVD. We identified multiple rare variants significantly (after taking into account the multiple testing scheme) associated with CVD in our large pedigrees including an apparently Hispanic-specific *ALKBH3* variant (*G95R*) and an *ATG4C* variant (*K326Q*) that show a greater than 6-fold increase in risk overall and are suggestive of early onset CVD. Other interesting variants include a pair of variants in compete linkage disequilibrium on chromosome 1 in the *P1GC* and *RABGAP1L* genes whose heterozygotes exhibit more than 2 times the risk for disease as their common homozygotes. Our results suggest that extended pedigrees are useful for the capture of rare functional variants of relevance to CVD risk. Given the rarity of such variants, it is unlikely that traditional statistical replication will be possible and we are actively pursuing biological experimental validation. Given the large effect sizes of these variants, our results suggest the likelihood of widely varying genetic causes of individual risk and family specificity of predominant causal factors in CVD.

**2647W****Pharmacogenetic study on clopidogrel response among Filipinos.** E.C. Cutiongco de la Paz<sup>1,2</sup>, R.G. Sy<sup>1,2,3</sup>, R.P. Tiongco II<sup>3</sup>, J.B. Nevado, Jr<sup>1,2</sup>, E.B. Llanes<sup>3</sup>, J.A. Magno<sup>3</sup>, D.D. Ona<sup>3</sup>, F.R. Punzalan<sup>3</sup>, P.M. Reganit<sup>3</sup>, L.G. Santos<sup>3</sup>, R.L. Santos-Cortes<sup>4</sup>, J.A. Aherrera<sup>3</sup>, L.L. Abrahan IV<sup>1,3</sup>. 1) Institute of Human Genetics, National Institutes of Health, University of the Philippines Manila, Manila, Philippines; 2) Philippine Genome Center, University of the Philippines; 3) Section of Adult Cardiology, Department of Medicine, Philippine General Hospital, University of the Philippines Manila, Philippines; 4) Department of Otolaryngology, School of Medicine, University of Colorado, USA.

Dual antiplatelet therapy with clopidogrel and aspirin is the standard of care for patients with acute coronary syndromes, and is often recommended to prevent acute thrombotic events. Clopidogrel selectively and irreversibly inhibits the P2Y<sub>12</sub> ADP receptor, which is responsible for platelet activation and aggregation. However, response to this antiplatelet has been significantly variable, and nonresponse may lead to fatal outcomes. The use of genetic markers may provide guided therapy to prevent such outcomes. An observational study involving Filipino participants (80 non-responders and 165 responders; 150 males and 95 females) taking clopidogrel was conducted. DNA from blood samples were extracted and were genotyped using customized Illumina Goldengate microarray chips for 384 gene variants. From these variants, two were found to be of statistical significance after adjusting for multiple testing. These are the SNPs affecting apolipoprotein A-V (*APOA5*) and matrix metalloproteinase 3 (*MMP3*), which are associated in regulating plasma triglyceride levels and progression of atherosclerosis, respectively. Both variants were observed to be more frequent among non-responders: *APOA5* (allelic trend, OR 2.77,  $p$ -value 0.0000049) and *MMP3* (allelic trend, OR 4.50,  $p$ -value 0.0000016), and both are not previously associated with clopidogrel nonresponse. Further validation studies may need to be done before concluding a definite association between these markers and clopidogrel response.

**Arrhythmia and night vision blindness: Chicken and egg? Or could be chicken or egg?** A. Faucon, X. Zhang, P. Evans, A. Konkashbaev, P. Straub, N. Cox. Human Genetics, Vanderbilt University, Nashville, TN.

PrediXVU, the gene by medical phenome catalog created by applying PrediXcan to BioVU, the biobank at Vanderbilt University, currently serves results on about 10,000 European descent subjects. The top gene associated with atrial fibrillation is *LRIT3*, Leucine-rich repeat, immunoglobulin-like and transmembrane domain 3, which is a Mendelian gene in which recessive mutations cause night vision blindness. This is an intriguing pattern because drugs used to treat arrhythmias can have as a side effect night vision blindness. *LRIT3* is thought to direct the localization of *TRPM1* to dendritic tips of ON-bipolar cells in the eye, as well as altering cone synapse formation. We identified an additional 22 genes with associations to both cardiac arrhythmia phenotypes and visual disturbances including night vision blindness: *BBOX1*, *BCAN*, *BPIFC*, *C20orf197*, *CLCNKB*, *ELP2*, *F2R*, *FAM115C*, *GALNT14*, *GOLT1B*, *HGS*, *IL36RN*, *MAF1*, *NR2F6*, *PIK3C2G*, *PPIP5K2*, *PTGFRN*, *RAD9A*, *RCBTB1*, *SCOC*, *SLC25A4*, and *STRADA*. A number of these are channel genes, while others have been previously reported to be involved in drug response phenotypes.

**2649F**

**Associations of circulating protein levels with lipid fractions in the general population.** S.M. Figarska<sup>1</sup>, S. Gustafsson<sup>2</sup>, J. Sundström<sup>3,4</sup>, J. Ärnlöv<sup>5,6</sup>, L. Lind<sup>3</sup>, E. Ingelsson<sup>1,2</sup>. 1) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA, USA; 2) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Medical Sciences, Cardiovascular Epidemiology, Uppsala University, Uppsala, Sweden; 4) Uppsala Clinical Research Center; 5) Division of Family Medicine and Primary Care, Department of Neurobiology, Care Sciences and Society, Karolinska Institutet, Huddinge, Sweden; 6) School of Health and Social Sciences, Dalarna University, Falun, Sweden.

**Background and aims:** Revealing patterns of associations between circulating protein and lipid levels could improve biological understanding of cardiovascular disease, the main cause of death worldwide. The aim of this study was to investigate associations between protein biomarkers shown to be related to cardiovascular disease, and triglyceride (TG), total cholesterol (TC), LDL and HDL cholesterol (LDL-C and HDL-C) levels in three population-based cohorts. **Methods:** We measured lipid fractions and plasma protein levels using the Olink ProSeek CVD I or II+III arrays in fasting individuals without lipid-lowering treatment from the EpiHealth (n=2086, 52% women, median age 61 years), PIVUS (n=833, 51% women, all aged 70 years) and ULSAM (n=598, all men aged 77 years) studies. We included 57 proteins that overlapped between the different arrays and that passed QC in all three cohorts. A discovery analysis was performed in EpiHealth in a regression framework, and associations with FDR<0.05 were further tested in a meta-analysis of PIVUS and ULSAM, where p-value of 0.05 was considered a successful replication (validation FDR of 0.1%). All analyses were adjusted for sex, age, BMI, smoking, glucose levels, systolic blood pressure, blood pressure medication, diabetes medication and CVD history. **Results:** Out of 57 tested proteins, 42 demonstrated a replicated association with at least one lipid fraction; 35 were associated with TG, 15 with TC, 9 with LDL-C, and 24 with HDL-C. Among these associations, we found kidney injury molecule (KIM1), tumor necrosis factor receptor 1 and 2 (TNF-R1 and TNF-R2) to be associated with all four lipid fractions. Further, 17 proteins were related to both TG and HDL in a consistent and biologically expected manner, i.e. higher TG and lower HDL or *vice versa*. For instance, higher stem cell factor (SCF) and growth hormone (GH) were associated with lower TG and higher HDL; thus, a pattern generally associated with lower insulin resistance and CVD risk. Another common pattern of associations was concomitantly higher TG, TC and LDL, which often is associated with higher CVD risk. This was observed for example for higher C-X-C motif chemokine 16 (CXCL16), Gal3 (Galectin-3) and monocyte chemoattractant protein 1 (MCP-1). **Conclusions:** Our comprehensive analysis of plasma proteins and lipid fractions of >3,500 individuals from the general population provide new information about lipid biology and inform about potential links to cardiovascular disease.

**2650W**

**Association of common variants in arrhythmogenic cardiomyopathy desmosomal genes with ECG traits in the general population.** L. Foco<sup>1</sup>, C. Fuchsberger<sup>1</sup>, M. Gögele<sup>1</sup>, F. Murgia<sup>1</sup>, G. Schmidt<sup>2</sup>, A. Rossini<sup>2</sup>, P.P. Pramstaller<sup>1,3</sup>, C. Pattaro<sup>1</sup>. 1) Institute for Biomedicine, Eurac research, Bolzano, Bolzano, Italy; 2) Medizinische Klinik und Poliklinik, Klinikum rechts der Isar, Technische Universität München, Munich, Germany; 3) Department of Neurology, General Central Hospital, Bolzano, Italy.

**Purpose** Arrhythmogenic cardiomyopathy (AC) is a rare condition, with familial inheritance, featuring life-threatening arrhythmias and cardiomyocyte replacement with fibro-fatty cells. Such alterations are reflected in both depolarization and repolarization abnormalities at the electrocardiogram (ECG) level. Mutations in genes encoding cardiac desmosomal proteins are an established cause of AC. Given that common genetic architecture is often observed between Mendelian diseases and related complex traits, we hypothesised that common variants in desmosomal genes, involved in the electrical coupling between cardiomyocytes, could influence the cardiac conduction traits in the general population. **Methods** Through linkage-disequilibrium analysis of SNPs from the HumanOmniExpressExome Bead Chip imputed using 1000 Genome panel Phase 3, we selected 2429 SNPs in the desmosomal genes Desmoplakin (*DSP*), Plakophilin 2 (*PKP2*), Desmoglein 2 (*DGS2*), Desmocollin 2 (*DSC2*), and Junction Plakoglobin (*JUP*). SNPs were tested for association with P wave, PR, QRS, and QT intervals, derived from 10 sec ECGs, in 4979 participants to the Cooperative Health Research in South Tyrol (CHRIS) study. We fitted age- and sex- adjusted linear mixed models accounting for population relatedness and assuming additive genetic effects. Multiple testing corrected significance was set at  $1.9 \times 10^{-4}$  based on the percentage of genome covered by the tested regions. **Results** Two independent SNPs, rs115171396 (MAF=0.02) and rs72835665 (MAF=0.49) in *JUP*, were associated with P wave length, with effects of 4.87 (SE=1.08, P-value= $6.6 \times 10^{-6}$ ) and -1.10 (SE=0.27, P-value= $4.5 \times 10^{-6}$ ) milliseconds (ms) per copy of the minor allele, respectively. Variant rs2744389 in *DSP* was associated with QRS duration: effect= -1.10 ms (SE=0.24, P-value= $3.5 \times 10^{-6}$ ). We did not find evidence of association with PR interval and QT duration. **Conclusions** While awaiting independent replication, the results suggest that variants in desmosomal genes could impact the cardiac electric function in the general population. Ongoing whole exome sequencing analyses will allow finer mapping of the investigated genes.

**2651T**

**Genome wide association study identifies nine novel loci for subclinical atherosclerosis traits and highlights genetic correlation with clinical cardiovascular disease.** N. Franceschini<sup>1</sup>, C. Giambartolomei<sup>2</sup>, J. Liang<sup>3</sup>, J.P. Casas<sup>4</sup>, C.J. O'Donnell<sup>5</sup>. 1) Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Human Genetics, University of California Los Angeles, Los Angeles, California, USA; 3) Department of Epidemiology & Biostatistics, School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 4) Farr Institute of Health Informatics Research, UCL Institute of Health Informatics, University College London, London, UK; 5) Cardiology Section and Center for Population Genomics, Boston Veteran's Administration (VA) Healthcare, Boston, MA, USA.

Carotid intimal medial thickness (cIMT) and carotid plaque are measures of subclinical atherosclerosis associated with clinical cardiovascular disease events - myocardial infarction, stroke and death. Genetic studies may help to identify biologic pathways contributing to subclinical and clinical manifestations of atherosclerosis. To search for genetic loci for subclinical atherosclerosis, we conducted meta-analyses of genome-wide association study (GWAS) in up to 71,129 participants for cIMT and up to 41,145 participants for carotid plaque. cIMT and plaque measures were evaluated using high-resolution B-mode ultrasonography. Each study imputed up to the Phase 1 integrated reference panel from the 1000 Genomes Project data and followed standardized protocols for quality control and association analyses. Fixed effect meta-analyses identified nine novel loci for cIMT (*1q32.2*, *ARP6AP11L*, *AIG1*, *PIK3CG*, *MCPH1*, *VTI1A*, *SGK223*, *CBFA2T3*) or plaque (*TRIM44*) at  $P$  value  $< 5.0 \times 10^{-8}$ , and replicated five previously described loci for cIMT (*ZHX2*, *PINX1*, *APOE*) and plaque (*EDNRA*, *PIK3CG*). To better understand the shared genetic influences between subclinical atherosclerosis and atherosclerotic clinical disease, we tested the genetic correlation between cIMT or carotid plaque with coronary heart disease or stroke using genome-wide summary statistics from our meta-analyses and the CARDIoGRAMPlusC4D and the METASTROKE consortia using the LD score regression approach. Both cIMT and carotid plaque showed significant genetic correlations with coronary heart disease and ischemic stroke (all  $P < 0.05$ ), though the magnitude of correlation was almost twice stronger for carotid plaque and coronary heart disease (0.54) or ischemic stroke (0.60) compared to cIMT (0.20 and 0.30 for coronary heart disease and ischemic stroke, respectively). When looking at stroke sub-types (cardio-embolic, large vascular disease strokes) against cIMT and carotid plaque, the magnitude of the correlation was similar though with larger uncertainty (all  $P > 0.05$ ). In conclusion, we provide here the largest genomic study of cIMT and carotid plaque using high-density imputed genotypes. Our meta-analyses of cIMT and carotid plaque identified nine novel loci. The correlations with coronary heart disease and stroke highlight novel biological pathways for further evaluation.

Blood pressure (BP) is a heritable trait and high BP is associated with significant global morbidity and mortality. We conducted a genome-wide association study (GWAS) of systolic (SBP) and diastolic blood pressure (DBP) using electronic health record (EHR) data from the Million Veteran Program (MVP) cohort ( $n > 301,000$ ) and the UK Biobank (UKB;  $n \sim 145,000$ ). DBP and SBP were regressed onto additively encoded genotypes imputed to the 1000 Genomes reference panel, adjusting for age, age-squared, sex, body mass index, and top 10 principal components. Primary analyses were conducted by self-reported race/ethnicity status for MVP (White non-Hispanic, Black non-Hispanic and Hispanic) and UKB separately, followed by inverse-variance weighted fixed-effects meta-analysis across strata using METAL. Meta-analyses identified 233 associated loci with  $p$ -value  $< 5 \times 10^{-8}$ ; 4,982 SNPs at 111 loci were associated with DBP explaining 1.1% of the phenotypic variance, and 7,873 SNPs at 145 loci were associated with SBP explaining 1.6% of the variance. Among these, we detected 66 novel signals, 12 of which were significant in both SBP and DBP, with 33 and 21 unique previously unreported signals for SBP and DBP, respectively. Novel signals explained 0.4% and 0.3% of the variance in SBP and DBP respectively, increasing the total variance explained by 25% for each trait. Furthermore, we provide confirmatory evidence for 167 previously identified BP loci at genome-wide significance. The strongest evidence for association with SBP was rs12705390 near *CCDC71L* – *PIK3CG* ( $p$ -value =  $1.44 \times 10^{-43}$ ), while the top association with DBP was rs12509595 near *PRMD8* – *FGF5* ( $p$ -value =  $6.14 \times 10^{-35}$ ). The most significant novel locus was near *RXFP2* at rs1869800 ( $p$ -value =  $4.27 \times 10^{-26}$ ) for SBP and rs7983337 ( $p$ -value =  $1.78 \times 10^{-13}$ ) for DBP ( $r^2=0.99$ ). In DBP alone, the most significant novel signal was near *TRIM39* – *RPP21* (rs3094704;  $p$ -value =  $6.13 \times 10^{-11}$ ), while rs10265221 ( $p$ -value =  $5.82 \times 10^{-14}$ ) in *PRKAG2* was the strongest novel signal with SBP. Trans-ethnic fine-mapping analyses, which leverage the differences in linkage disequilibrium patterns between populations, are likely to refine associated loci into credible sets of potentially causal SNPs. These results represent the largest reported discovery-stage GWAS of BP traits to date and can offer new insights into vascular biology.

**Prevalence of variants of *FVL*, *PTH*, *PAI-1*, *MTHFR* and *EPCR* among Cardiovascular patients.** M. Hosseini moghadam, N. Mahdiah. Cardiogenetic Research Laboratory, Rajaie Cardiovascular Medical and Research Center, Tehran, Tehran, Iran.

**Introduction** Venous thromboembolism (VTE) is a multifactorial condition with genetic and acquired risk factors. Thrombosis could be associated with cardiovascular disorders. Here, we study five common variants G1691A (Factor V Leiden, *FVL*), G20210A (Prothrombin, *PTH*, *FII*), 4G/5G (Plasminogen activator inhibitor-1, *PAI-1*), A4600G (Endothelial protein C receptor, *EPCR*) and C677T (Methylene-tetrahydrofolate reductase, *MTHFR*) referring Rajai Center. **Material and Method** We studied a case series of 50 CVD patients (24 women and 26 men) with VTE condition that referred to our center. After, DNA extraction, PCR-RFLP was applied to determine the variants. **Results** The allele frequencies of *FVL* (G1691A), *PTH* (G20210A), Plasminogen activator inhibitor-1, *PAI-1* (4G/5G), Endothelial protein C receptor, *EPCR* (A4600G) and Methylene-tetrahydrofolate reductase, *MTHFR* (C677T) were 0.02, 0.03, 0.67, 0.11 and 0.3 respectively. **Conclusion** *PAI-1* (4G/5G) and *MTHFR* (C677T) are the common variants among VTE patients in our population. In addition, *FVL* (G1691A) and *PTH* (G20210A) variants are not common in our population. **Keywords:** Thrombophilia; venous thromboembolism (VTE); cardiovascular disease (CVD).

**Elucidating the molecular causes of severe hypercholesterolemia in Finland.** *N. Junna, P. Ripatti, I. Surakka, S. Ripatti, E. Widén.* Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland.

Severe hypercholesterolemia is a major risk factor for coronary artery disease (CAD). Patients suffering from its familial inherited forms have more than 10-fold increased risk for CAD. Although CAD may be prevented by lowering cholesterol levels, less than 20% of hypercholesterolemia patients are identified or treated in Finland and only half of the patients carry hypercholesterolemia-associated mutations. Our study aims at unraveling the genetic architecture underlying severe hypercholesterolemia in Finland by studying individuals with high LDL cholesterol ( $\geq 5$  mmol/l), who are identified in our ongoing population study GeneRISK, encompassing 10,000 subjects aged 45-64 in Southern Finland ([www.generisk.fi](http://www.generisk.fi)). Hitherto 6,817 study participants have been recruited. 4% of them had severe hypercholesterolemia, of which only 5% received lipid-lowering therapy. 200 hypercholesterolemia cases have been screened for the 7 most common known familial hypercholesterolemia-associated *LDLR*-mutations enriched in Finland. Surprisingly, all subjects were mutation negative. Whole exome sequencing of 141 subjects has not revealed other previously known hypercholesterolemia-causing mutations in the *LDLR*, *APOB* or *PCSK9* genes either. Nonetheless, 4 subjects carried rare or novel variants in *APOB* with probably damaging *in silico* predictions (P877L, R1689H, I2305V and N3257S). Polygenic modeling (genomic risk score (GRS) encompassing 142 SNPs explaining 17% of the LDL cholesterol variation in the population) suggested slight clustering of polygenic risk in 34 (24%) of the exome sequenced patients (GRS within the top 10% of population distribution). Lifestyle factors, such as consumption of saturated fats, did not correlate with LDL cholesterol levels. In conclusion, treatment of hypercholesterolemia appears gravely suboptimal and the contribution of known hypercholesterolemia-associated mutations may be smaller than previously anticipated in Southern Finland. At present, the exome sequencing analyses of up to 200 hypercholesterolemia cases are still ongoing. Our intention is to evaluate identified putative novel pathogenic variants by seeking replication in a larger Finnish population cohort, and to assess function both by *in silico* and *in vitro* methods.

**Gender specific modification of heart failure with preserved ejection fraction risk by mitochondrial haplogroups.** *R.T. Levinson<sup>1</sup>, E. Farber-Eger<sup>1</sup>, J.D. Mosley<sup>1</sup>, D.C. Samuels<sup>2</sup>, Q.S. Wells<sup>1</sup>.* 1) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Molecular Physiology and Biophysics, Vanderbilt University School of Medicine, Nashville, TN.

Heart failure (HF) is a complex syndrome characterized by dyspnea, fatigue, reduced exercise tolerance, and fluid retention, that may result from a variety of structural or functional cardiac impairments. HF is frequently partitioned into subgroups using cutoffs of left ventricular ejection fraction (EF), with patients having an EF  $\leq 40\%$  termed HF with reduced EF (HFrEF) and those with EF  $\geq 50\%$  having HF with preserved EF (HFpEF). HFpEF disproportionately affects women, and no current therapies exist. A consistent feature of HF is altered mitochondrial (mt) function and cardiac bioenergetics, including oxygen availability and mt ATP production. However, the role of mt genetic variation in HF and its subtypes is incompletely understood. We proposed to evaluate the role of mt genetics in HF and its subtypes, including the gender specific influence of mt genetics. We curated electronic health records (EHRs) from BioVU, the Vanderbilt DNA biobank, and assigned HF status in 6,512 individuals (55% male, median age 66) of European ancestry with genotyping available on the MEGA chip. EFs extracted from echocardiography data were used to assign HF subtype (HFpEF or HFrEF) when possible. Our analysis dataset consisted of 3,259 HF cases and 3,253 controls. In total, 2,170 (67%) of HF cases were assigned to a subtype (HFpEF=964 and HFrEF=1,206). We extracted 894 mtSNPs and group assignment was done with Haplogrep. MT haplogroups (HG) were tested for association with HF, HFpEF, and HFrEF. We also conducted gender stratified analyses and analyses accounting for the interaction between gender and HG. Analyses were adjusted for age, BMI, myocardial infarction, hypertension, diabetes, and estimated glomerular filtration rate (eGFR). HG Uk was significantly associated with risk of HFpEF in males (OR[95%CI]= 1.46 [1.11, 1.92],  $p=0.006$ ) but not in females. HG T was protective for HFpEF in males (OR[95%CI]= 0.61[0.41, 0.92],  $p=0.02$ ), but had a risk effect in females (OR[95%CI]= 1.54 [1.08, 2.19],  $p=0.01$ ). Terms for the interaction of male gender with both Uk ( $p=0.03$ ) and T ( $p=0.001$ ) were significant when added to their respective models. No mt HGs were significantly associated with HF status or HFrEF in any analysis. These results establish a possible role for mt genetics in risk of HFpEF, and the gender specific effects of mt variation.

**Family study of noncompaction cardiomyopathy shows variability of cardiac phenotype within and between families.** *D. Majoor-Krakauer<sup>1</sup>, J.I. van Waning<sup>2</sup>, M. Michels<sup>2</sup>, R.M.W. Hofstra<sup>1</sup>, K. Caliskan<sup>2</sup>, M.A. van Slegtenhorst<sup>1</sup>.* 1) Clinical Genetics, Erasmus Medical Center, Rotterdam, Netherlands; 2) Cardiology, Erasmus Medical Center, Rotterdam, Netherlands.

The objective of this study was to explore which cardiomyopathies occur in families of NCCM patients. In total 152 families of NCCM patients were screened for familial cardiomyopathy at the Erasmus Medical Center. The families had genetic counseling and DNA testing and were enrolled retrospectively from 2005 till 2017. In 61 (41%) of the 152 families 108 relatives were diagnosed with a cardiomyopathy. The diagnoses of the affected relatives were: 78 NCCM, 13 HCM and 17 DCM. In 37 (24%) families all affected relatives had NCCM; 24 / 37 of the families had a (L)PV (likely) pathogenic variant in one of the 52 tested cardiomyopathy genes. Sixteen (of 24 (likely) pathogenic variants involved the *MYH7* gene. The (L)PV in these 16 families all occurred in the head region of this gene. In contrast *MYH7* (L)PV associated with DCM or with familial NCCM and DCM were located in other parts of the *MYH7* gene. In 16 (13 with a (L)PV) families the combination of NCCM and DCM was observed in the family. In these NCCM/DCM families *MYH7* (5, 31%) and *TTN* (4, 25%) was involved. In seven (5 with (L)PV) families HCM was diagnosed in relatives. These were mostly families of patients with complex *MYBPC3* genotypes, in which relatives with HCM had a single *MYBPC3* (L)PV. In conclusion, familial NCCM is likely to be caused by defects in the head of the *MYH7* gene. DCM and HCM may occur in familial NCCM. The cause of the phenotypic variability in families remains to be elucidated.

**2657T**

**Novel compound homozygous mutations in genes involved in mitochondrial function associated with sudden death with cardiac fibrosis in infancy.** *K. Mittal<sup>1</sup>, T.T. Koopmann<sup>1</sup>, D. Chatterjee<sup>1</sup>, J. Cameron<sup>2</sup>, T. Paton<sup>3</sup>, A. Rafiq<sup>1</sup>, S. Aafaqui<sup>1</sup>, D. Chiasson<sup>2</sup>, C. Ackerley<sup>2</sup>, M. Fatah<sup>1</sup>, C. Marshall<sup>1</sup>, R.H. Hamilton<sup>1</sup>.* 1) Translational Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Pediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Genetics and Genome biology, The Hospital for Sick Children, Toronto, Ontario, Canada.

Sudden death is a rare event between age 1 and 2 years, with most sudden infant death syndrome (SIDS) victim usually being healthy infants less than one year of age. Although the causes of SIDS remain largely unknown, several recent reports have suggested the involvement of inherited cardiac diseases as a causal factor underlying SIDS. The genetic analysis of the SIDS cases has revealed genes encoding cardiac ion channels and in cardiomyopathy-associated genes. A role for abnormal/ defective energy production in SIDS infants is warranted because infants with SIDS tend to be sleepier, less active, and have lower activity scores. In the present study, we identified a consanguineous family originally from Pakistan who had lost three of five children to sudden death between the ages of 8 and 18 months. We performed homozygosity mapping and whole exome sequencing (WES) followed by segregation analysis and phenotype genotype correlation to identify the genetic mechanism responsible for the sudden deaths in this family. High-density homozygosity mapping revealed a contiguous block of homozygous SNVs at the loci on chromosomes 4, 8 and 15, shared between the two affected individuals, but not the parents. WES analysis revealed the presence of two homozygous pathogenic mutations. One variant was found in the gene encoding for Isocitrate Dehydrogenase 3A (IDH3A), a human mitochondrial NAD<sup>+</sup>-specific isocitrate dehydrogenase alpha subunit that is part of the citric acid cycle, and the second was found in mitochondrial inorganic pyrophosphatase (PPA2). We have identified a case of compound homozygous mutations in association with a consanguineous family with sudden infant death syndrome. The functional assays showing no enzyme activity in either of the genes, in the patient, combined with the bioinformatics support a causal link. Together, this data support a deficient energy production process related to perturbations in the IDH3A and PPA2 functions. Our findings highlight the importance of genes involved in mitochondrial function in SIDS and warrant further replication studies. Further work is required to more precisely delineate the pathogenic mechanisms underlying mutations in mitochondrial proteins involvement in SIDS.

**2658F****Identifying new therapeutical targets for congestive heart failure. A.**

*Moreira, F. Vargas, L. Cordeiro.* UNIRIO, Rio de Janeiro, Brazil.

Though gene expression analysis has allowed greater understanding of the pathophysiological development of congestive heart failure (CHF), clinical and tissue heterogeneity in microarray samples, in addition to the small number of cases in any individual study, makes it difficult to correctly interpret the results of such studies. Through reanalysis of public microarray gene expression data we were able to construct a dataset of about 200 left ventricular samples. Classifying patients in three groups: healthy, non-ischemic CHF, and ischemic CHF, we found 100 differentially expressed genes (DEGs) between healthy subjects and non-ischemic HF patients, and 96 DEGs between controls and ischemic HF samples. Analysing DEGs with the greater expression log fold changes allowed us to pinpoint a few therapeutic targets. It is worth mentioning the genes *FOS*, *SERCA3* and *OGN*, which are already subject of clinical investigation. Pathway analysis uncovered several altered biomolecular pathways, specially the ones directly involved with the reorganization of the extracellular matrix and cell adhesion, specially the BMP signalling, integrin and heparin binding, all of them presenting clear therapeutic opportunities. Other pathways related to inflammatory response, cellular proliferation, proteolysis, blood pressure regulation and oxidative stress may also be potential objects of future clinical research in CHF.

Hyperlipidemia, particularly increased LDL cholesterol (LDL-C) and triglycerides (TG), are established and treatable risk factors for coronary artery disease (CAD). In addition to well-known familial hypercholesterolemia (FH) mutations, hyperlipidemias have also been shown to be caused by polygenic burden. Whereas monogenic FH increases CAD risk considerably likely due to high lifelong exposure to LDL-C, it is unclear whether high polygenic load of LDL-C or TG increasing variants causes similarly increased CAD risk in a population or familial setting. We constructed clinical CAD endpoints from the FINRISK population cohort ( $n = 20\,499$ ) and a collection of 86 Finnish dyslipidemia families ( $n = 1316$ ) with high total cholesterol (TC) and TG traits (identified from probands with premature CAD) linked with hospital discharge, causes-of-death and prescription drug registries. We tested if high polygenic scores for LDL-C or TG ( $> 90^{\text{th}}$  percentile) were associated with increased CAD risk in hypercholesterolemic/-triglyceridemic (LDL-C or TG  $> 90^{\text{th}}$  percentile) population samples ( $n = 2249$  and  $1709$ , respectively) or family members ( $n = 230$  and  $166$ , respectively). High polygenic score for LDL-C was associated with a  $0.8$  ( $0.7$ - $0.8$ ) mmol/l increase in LDL-C values and a  $21\%$  increase in CAD risk in all population samples (HR  $1.21$  [ $0.99$ - $1.48$ ]). In hypercholesterolemic population samples, the polygenic LDL-C increase was  $0.2$  ( $0.1$ - $0.3$ ) mmol/l and did not confer additionally increased CAD risk (HR  $1.06$  [ $0.75$ - $1.52$ ]). High polygenic score for TG was associated with a  $0.6$  ( $0.5$ - $0.7$ ) mmol/l increase in TG values and a  $26\%$  increase in CAD risk in all population samples (HR  $1.26$  [ $1.04$ - $1.54$ ]). Further, in hypertriglyceridemic population samples, high polygenic score for TG increased TG values by  $0.5$  ( $0.3$ - $0.8$ ) mmol/l and CAD risk by  $63\%$  (HR  $1.63$  [ $1.07$ - $2.48$ ]). Only  $4.6\%$  of the hypertriglyceridemic individuals were treated with fibrates during follow-up. In family-based samples, similar effects on lipid values were observed. High TG due to polygenic burden increases CAD risk more than high TG due to other causes. Measuring polygenic scores for TG may refine risk estimation for CAD in young and/or hypertriglyceridemic individuals.

**Evaluating the role of genetic variants on blood cell count variability in the Jackson Heart Study.** *J.R. Shaw<sup>1</sup>, R.W. Corty<sup>2</sup>, L.M. Raffield<sup>2</sup>, A.P. Reiner<sup>2</sup>, J.G. Wilson<sup>3</sup>, L.A. Lange<sup>1</sup>, W. Valdar<sup>2</sup>, E.M. Lange<sup>1</sup>.* 1) University of Colorado Anschutz Medical Campus, Aurora, CO; 2) University of North Carolina, Chapel Hill, NC; 3) University of Washington, Seattle, WA; 4) University of Mississippi, Jackson, MS.

The realization of precision medicine will require understanding how genetic variation can impact both the mean and variability of patient characteristics. While genome-wide association studies (GWAS) have identified thousands of genetic variants associated with differences in mean values of human quantitative traits, variants associated with trait variability around the mean (vQTL) remain relatively uninvestigated in human populations. Variants associated with trait variability may represent direct genetic influence on phenotypic variability, or indirect influence due to genetic interaction or imperfect linkage disequilibrium with a causal variant. Identifying vQTLs can therefore improve power to detect genetic interactions and aid in finemapping quantitative trait loci. Building on the R package DGLM, we used the double generalized linear model to perform a genome scan on 2257 unrelated African American participants from the Jackson Heart Study (JHS), simultaneously modeling the effects of each variant on the mean and variance of cardiovascular disease-related blood cell count measures including platelet and red and white (WBCC) blood cell counts. Covariates included age, sex, and ten principal components for ancestry. Our models showed good control of type I error for all traits. Our top finding for a vQTL was at chromosome 7 variant rs12535735 ( $p=1.7 \times 10^{-7}$ ) for WBCC, an intronic variant in DPP6 that with no evidence of a mean effect ( $p=0.79$ ). The top mean effect, also for WBCC, was observed at chromosome 1 variant rs2518564 ( $p=1.3 \times 10^{-7}$ ) in the previously established DARC region. Interestingly, this variant also showed nominal evidence for a variance effect ( $p=7.3 \times 10^{-3}$ ), suggesting either a genetic interaction (epistasis or environmental) or moderate linkage disequilibrium with the causal variant (likely rs2814778, a previously reported null variant in DARC that is monomorphic in non-African descent populations). Our future plans include using JHS whole genome sequence data and targeted genetic interaction tests to further interrogate this region. Finally, we will increase our analysis sample size using additional cohorts and expand the phenotypes tested to both identify variants that directly influence the variance of cardiovascular disease-related quantitative traits, and to identify subsets of mean-effect variants for follow-up of possible interaction or haplotypic effects.

**Elevated genetic risk for coronary artery disease increases hospitalization burden and mortality.** *M. Sjögren, P. Almgren, O. Melander.* Clinical Sciences, Malmö, Lund University, Malmö, Sweden.

**Background:** Coronary artery disease (CAD) is one of the leading causes of mortality and a heavy burden on health care worldwide. Several genome wide association studies (GWAS) have identified common variants associated with CAD. Combining these SNPs into a genetic risk score (GRS) can estimate an individual's genetic burden and individuals in the highest quintile of GRS have nearly doubled risk of CAD. **Aim:** The aim of our study was to investigate whether GRS for CAD could predict future hospitalization and mortality in individuals from Malmö Diet and Cancer study (MDC). **Materials & Methods:** MDC is a population based prospective study from the city of Malmö in southern Sweden. 23 594 individuals without CAD at baseline and with complete data for all covariates were investigated. The weighted GRS was constructed from 50 SNPs previously associated with CAD at GWAS significant level. The GRS was divided into quintiles and three groups were compared; low genetic risk (quintile 1, reference group), intermediate genetic risk (quintiles 2-4) and high genetic risk (quintile 5). Negative binomial regression was used to investigate hospitalizations and Cox proportional Hazards model was used for mortality analysis, all analyses were adjusted for age, sex, follow-up time, hypertension, diabetes, smoking, ApoA1 and ApoB. Data on hospitalizations and mortality were retrieved from Swedish National Inpatient registry and Swedish National Cause of Death Registry. **Results:** Individuals with higher genetic risk of CAD were hospitalized more often compared to individuals with low genetic risk (Intermediate genetic risk (IGR): IRR 1.07 [95% CI 1.02-1.12],  $p=0.005$ ; High genetic risk (HGR): 1.10 [1.04-1.16],  $p=0.001$ ) and this was mainly due to cardiovascular causes (IGR: 1.17 [1.09-1.26],  $p=0.00003$ ; HGR: 1.31 [1.20-1.43],  $p=5.17 \times 10^{-10}$ ). No association was found to hospitalization due to non CVD causes. Individuals with high and intermediate genetic risk were approximately 16% and 9% more likely to die of any cause during the follow-up as compared to individuals with low genetic risk. These individuals had highly increased risk of CVD mortality (IGR: HR 1.23 [1.08-1.39],  $p=0.001$ ; HGR: 1.44 [1.25-1.66],  $p=6.56 \times 10^{-7}$ ) but not the risk of mortality due to other causes. **Conclusion:** Our results suggest that genetic predisposition for CAD can predict hospitalization burden and premature death, especially due to cardiovascular causes, independently of traditional risk factors.

**2662W****Uncovering the genetic determinants of variation in arterial stiffness through joint location and scale association testing.**

*D. Soave, H.A. Edgington, P. Awadalla.* Informatics and Bio-computing, Ontario Institute for Cancer Research, Toronto, Ontario, Canada.

Arterial stiffness (AS) plays a major role in hypertension in aging adults and is associated with cardiovascular events such as stroke and heart attack. As individuals age, the structure and function of the arterial wall changes leading to increased stiffening. An improved understanding of the molecular mechanisms underlying AS will help to identify high-risk individuals and better inform therapeutic targets, however, our current knowledge of the genetic architecture underlying AS is limited. GWAS results from the Framingham Heart Study discovered several SNPs significantly associated with AS; however, regulatory variation associated with AS has not been investigated. With the goal of gaining better insight into the genetic determinants of AS we conducted a study integrating genomic and transcriptomic data with measures of the central augmentation index (cAI), a proxy for AS, in a sample of 700 individuals from Quebec. Specifically, we first modeled transcript expression levels as a function of cAI, controlling for age at measurement. We also conducted genome-wide expression quantitative traits loci (eQTL) mapping using main effects and interactions between genetic variant and cAI. Throughout our study, we incorporated joint location and scale testing to increase the power to identify genetic factors involved in complex genetic architecture, such as gene-gene interaction, not being directly modeled. Our findings show that gene-transcript relationships depend on AS variation. Additionally, we uncovered gene-transcript signatures associated with AS using our joint modeling approach that would otherwise be left undetected through traditional location-only testing.

**2663T****Genetics and outcome of noncompaction cardiomyopathy: A Dutch multicenter study.**

*J. van Waning<sup>1</sup>, Y.M. Hoedemaekers<sup>2</sup>, K. Caliskan<sup>5</sup>, M.A. van Slegtenhorst<sup>1</sup>, J.D.H. Jongbloed<sup>2</sup>, K.Y. van Spaendonck<sup>4</sup>, A.F. Baas<sup>3</sup>, R.H. Lekanne Dit Deprez<sup>4</sup>, D. Dooijes<sup>3</sup>, R.M.W. Hofstra<sup>1</sup>, A. Ijzma<sup>1</sup>, D. Majoor-Krakauer<sup>1</sup>, Dutch NCCM consortium.* 1) Clinical Genetics, Erasmus Medical Center, Rotterdam, the Netherlands; 2) Clinical Genetics, University Medical Center Groningen, the Netherlands; 3) Clinical Genetics, University Medical Center Utrecht, The Netherlands; 4) Clinical Genetics, Amsterdam Medical Center Department, Amsterdam, the Netherlands; 5) Cardiology, Erasmus Medical Center, Rotterdam, the Netherlands.

This is a large multicenter cohort study with 327 (52 children and 275 adult) Noncompaction cardiomyopathy (NCCM) patients from four major cardiogenetic centers in the Netherlands. This study outlined the differences and similarities in genetic causes between children and adults patients. According to the results of DNA testing of cardiomyopathy gene panels and family histories the 327 NCCM index patients were classified into three groups; 1) genetic; with a mutation, ie (likely) pathogenic variant, 2) probably genetic; familial cardiomyopathy without a (likely) pathogenic variant, or 3) sporadic; no family history, no (likely) pathogenic variant. In this way we presented novel insight in long-time follow up separately for children and adults from these different groups of patients. Genetic NCCM occurred in 32% (81 adults; 23 children), probably genetic in 16% (45 adults; 8 children) and 52% of the patients were sporadic (149 adults; 21 children). *MYH7*, *MYBPC3* and *TTN* explained 71% of genetic NCCM. Older NCCM patients were more likely sporadic (OR 0.987 per year; CI 95% 0.975-0.99; p=0.029). Genetic NCCM, with multiple mutations was more frequent in children (p=0.04). Left ventricular (LV) dysfunction was more pronounced in genetic patients (p=0.02), in particular with *TTN* or multiple mutations (p=0.02). Risk for major adverse cardiac events (MACE) was related to LV dysfunction (HR 2; p=0.01), age at diagnose before one year (HR 3; p=0.05), and multiple mutation in *MYBPC3* (HR 5; p=0.01). *MYH7* related NCCM had low risk of MACE. In conclusion, almost half the patients had (probably) genetic NCCM. The most important causes for genetic NCCM were mutations in *MYH7*, *MYBPC3* and *TTN* gene. Young children were more likely to have severe disease caused by complex genotypes. In the large proportion of cases that we classified as sporadic, we observed a better prognosis. Major cardiac events in the sporadic patients were less related to NCCM than in the patients with a mutation. This suggests a clinically distinct form of NCCM in sporadic, mostly adult cases, and has implications for revising the management of these cases and their families. From a clinical perspective age and genetics are important predictors of outcome of NCCM, highlighting the role of genetics testing and a detailed family history in management of and clinical surveillance of NCCM.

**2664F**

**Evaluating the burden of pathogenic variants for the inherited arrhythmia syndromes.** Y.P. Fu<sup>1</sup>, J. Kaltman<sup>2</sup>. 1) Office of Biostatistics Research, Division of Cardiovascular Sciences, NHLBI, NIH, Bethesda, MD; 2) Heart Development and Structural Diseases Branch, Division of Cardiovascular Sciences, NHLBI, NIH, Bethesda, MD.

**Background:** Inherited arrhythmia syndromes (IAS), including long QT syndrome (LQTS), Brugada syndrome (BrS), catecholaminergic polymorphic ventricular tachycardia (CPVT), short QT syndrome (SQTS), idiopathic ventricular fibrillation (IVF), and progressive cardiac conduction system disease (PCCD), are important causes of sudden cardiac death. Family-based genetic studies have identified many pathogenic variants underlying these diseases but the burden of these variants in the general population was rarely investigated.

**Objective:** To evaluate the distribution of pathogenic variants associated with IAS among the 8 populations in the Genome Aggregation Database (gnomAD), and examine the functional impact of variants in different protein domains in the 3 most commonly mutated genes, *KCNQ1*, *KCNH2*, and *SCN5A*.

**Methods:** We extracted disease-causing (DM) and likely disease-causing (DM?) variants associated with IAS from the Human Gene Mutation Database (HGMD) and merged them with the gnomAD dataset (n=123,136) to assess the overall and population-specific allele frequencies (AF). The function of individual variants was predicted by MetaSVM. We also evaluated the intolerance of genetic sub-regions using the Residual Variation Intolerance Score (subRVIS) in *KCNQ1*, *KCNH2*, and *SCN5A*. **Results:** A total of 2129 IAS variants were identified across 58 genes from the HGMD, where 583 (27.4%) variants were also presented in the gnomAD. Among these 583 disease-causing variants, 135 (23.2%) had an AF  $\geq 0.01\%$  and 27 (4.6%) had an AF  $\geq 0.1\%$  in the overall gnomAD subjects. The AF distribution across the 8 sub-populations in gnomAD was significantly different ( $p < 0.0001$ ), where the proportion of AF  $\geq 0.01\%$  ranged from 7.5% in the Finns population to 25.6% in those without assigned ethnicity. The prediction algorithm MetaSVM estimated that 50.8% of the gnomAD variants with AF  $\geq 0.01\%$  were functionally tolerated, compared to 22.6% of gnomAD variants with AF  $< 0.01\%$  ( $p < 0.0001$ ). In *KCNQ1*, *KCNH2* and *SCN5A*, the variant distribution was significantly different by functional domains: most pathogenic variants located in the ion channel domains were not observed in the gnomAD, and many gnomAD variants located in regions without specific function (all  $p < 0.0001$ ). **Conclusion:** A significant number of disease-causing IAS variants in HGMD have a relatively common allele frequency and insufficient evidence for pathogenicity. The AF distribution also varies across different populations.

**2665W**

**The importance of epistatic interactions and fitness costs in congenital heart disease.** E.O. Akhrome<sup>1</sup>, S.D. Regmi<sup>1</sup>, R. Magnan<sup>1</sup>, Y. Qin<sup>1</sup>, J.M. Chilverud<sup>2</sup>, P.Y. Jay<sup>1</sup>. 1) Pediatrics & Genetics, Washington University School of Medicine, St. Louis, MO; 2) Biology, Loyola University Chicago, Chicago, IL.

Although congenital heart disease (CHD) is the most common type of birth defect, its genetic basis is still poorly understood. Efforts to identify a causal mutation fail in  $\sim 70\%$  of cases. Even when one is found, the same mutation can cause different heart defects or sometimes none. This complexity suggests that CHD risk depends on epistasis – interactions between multiple genetic elements. Here, we demonstrate the importance of epistasis in the pathogenesis of CHD. As in humans, *Nkx2-5* haploinsufficiency elicits a range of incompletely penetrant heart defects in our mouse model. We identified genetic loci that epistatically interact with *Nkx2-5*<sup>-/-</sup> ( $G \times G_{Nkx}$ ) and each other ( $G \times G \times G_{Nkx}$ ) to modify risk for distinct heart defects. We found a positive correlation between a defect's fitness cost and the magnitude of its associated epistatic effects, meaning that epistasis influences the risk for severe defects more than mild defects. For instance, one  $G \times G \times G_{Nkx}$  interaction explained 50% of individuals with severe atrioventricular septal defects. Remarkably,  $G \times G \times G_{Nkx}$  effects were 3 times more likely to suppress heart defect risk when the alleles at both modifier loci were inherited from the same inbred strain rather than different strains. Our findings unveil the oft-overlooked contributions of epistasis to the genetic architecture of CHD and other complex traits. Moreover, these results underscore the importance of epistasis for phenotype prediction in personalized medicine.

Edwards<sup>1</sup>, the COGENT BP Consortium; on behalf of the VA Million Veteran Program. 1) Division of Epidemiology, Department of Medicine, Institute for Medicine and Public Health, Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Tennessee Valley Healthcare System (626)/Vanderbilt University, Nashville, TN; 2) Department of Population Quantitative Health Science, School of Medicine, Case Western Reserve University, Cleveland, OH; 3) VA TVHS Nashville, Division of Nephrology & Hypertension, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Epidemiology, Emory University Rollins School of Public Health; Department of Biomedical Informatics, Emory University School of Medicine, Atlanta, GA; 5) Atlanta VAMC and Emory Clinical Cardiovascular Research Institute, Atlanta, GA; 6) VA Palo Alto Health Care System; Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, CA; 7) Nephrology Section, Memphis VA Medical Center, Memphis, TN; 8) Division of Nephrology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 9) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 10) Vanderbilt Genetics Institute, Vanderbilt Epidemiology Center, Department of Obstetrics and Gynecology, Vanderbilt University Medical Center; Tennessee Valley Health Systems VA, Nashville, TN; 11) VA Boston Healthcare, Section of Cardiology and Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

African Americans (AA) experience a high burden of hypertension and related complications, but have been underrepresented in genetic studies of blood pressure traits. To identify novel loci for blood pressure (BP) and hypertension in AAs, we performed a genome-wide association study (GWAS) of systolic (SBP) and diastolic blood pressure (DBP) in the largest group of AAs to date in a single cohort (N ~ 59,900) from the Million Veteran Program (MVP). We evaluated BP and GWAS data imputed to the 1000 Genomes reference panel in common variants (frequency > 1%) with additive genetic models adjusted for age, age-squared, sex, body mass index, and the top ten principal components. We then performed *in silico* replication and meta-analysis with previously calculated summary statistics from the COGENT BP Consortium study of AA BP genetics (N ~ 31,000). GWAS in MVP detected 99 SNPs representing 10 loci associated with SBP and 155 SNPs from 10 loci associated with DBP at p-value  $\leq 5 \times 10^{-8}$ . Seven loci for SBP and four for DBP were previously identified. Summary statistics from 396 lead SNPs (p-value <  $1 \times 10^{-5}$ ) were obtained from COGENT and after meta-analysis all loci identified in MVP were more significant. The most significant SNP for DBP after meta-analysis was at *CACNA1D* (p-value =  $1.26 \times 10^{-12}$ ), while the most significant SNP for SBP had p-value =  $7.02 \times 10^{-13}$  ( $r^2 = 0.27$ ). The top novel results that have not been previously reported in studies of BP in African, Asian, or European populations were at *KCNN3* (rs1984285; p-value =  $1.10 \times 10^{-9}$ ) for SBP and *HTR4* (rs4554204; p-value =  $3.84 \times 10^{-11}$ ) for DBP. Additional novel loci include *LRRC38* and *RXFP2* for SBP and *OXSR1*, *CCR8*, *EIF1B*, *CCDC12*, and *RBMS2* for DBP. We further evaluated the relationship between genetically predicted gene expression and BP traits in 44 tissues based on the genotype-tissue expression (GTEx) project data using summary statistics from the MVP GWAS with the MetaXcan method. Increased predicted expression of *CCDC71* in pancreas was associated with DBP (p-value =  $1.97 \times 10^{-9}$ ), while predicted reduced expression of *TMEM110* (near the *CACNA1D* GWAS signal) in the nucleus accumbens-basal ganglia of the brain was associated with SBP (p-value =  $1.12 \times 10^{-9}$ ), suggesting that *TMEM110* may be the relevant gene in that region. Further studies are underway with additional independent AA samples and meta-analysis of all available variants from COGENT and MVP.

## 2667F

**Exome sequencing identifies multiple variants associated with glyca, a novel biomarker of cardiovascular events.** L.C. Kwee<sup>1</sup>, S. Giamberardino<sup>1</sup>, J. Overton<sup>2</sup>, J. Reid<sup>2</sup>, S.G. Gregory<sup>3</sup>, R. McGarrath<sup>1</sup>, A. Baras<sup>2</sup>, C.B. Newgard<sup>1,3</sup>, W.E. Kraus<sup>1</sup>, S.H. Shah<sup>1</sup>. 1) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC; 2) Regeneron Pharmaceuticals, Inc., Tarrytown, NY; 3) Sarah W. Stedman Nutrition and Metabolism Center, Duke University, Durham, NC.

Glyca is a novel NMR-based inflammatory biomarker associated with incident cardiovascular (CV) events and all-cause mortality. The glyca signal reports on N-acetyl methyl groups of several glycoproteins in the acute-phase response, and exhibits less intra-individual variability than other available inflammatory biomarkers. We hypothesized that genetic variation may explain some inter-individual variability in glyca levels, and that associated variants may help clarify the biological underpinnings of the relationship between glyca and poor CV outcomes. We conducted an association study using whole-exome sequencing and glyca levels from subjects in the CATHGEN biorepository of cardiac catheterization patients. After QC, data were available from 5882 subjects of European ancestry (EUR) and 1671 subjects of African ancestry (AFR). Using ancestry-stratified linear models, we tested 328,608 variants (MAF > 1%) for association with glyca levels under an additive genetic model. Our initial model adjusted for sex, age, batch, and three ancestry-based principal components. Variants associated with glyca (p <  $5 \times 10^{-6}$ ) were then tested in a clinical model including diabetes, hypertension, hyperlipidemia, smoking, BMI, coronary artery disease, and ejection fraction. In the initial model, nine variants were associated with glyca levels in AFR individuals and 19 were associated in EUR individuals. All of the AFR variants and 14 of the EUR variants lie in a 200kb region on chr16 spanning several genes (*PKD1L3*, *HP*, *HPR*, *DHODH*, *TXNL4B*, *PMFBP1*), including the top two overall hits: rs5471 (p =  $2 \times 10^{-21}$ , AFR) and rs11648353 (p =  $8 \times 10^{-13}$ , EUR). Three of the chr16 variants show opposite directions of effect in the two subgroups. The remaining EUR variants are in *PMS1* (min. p =  $6 \times 10^{-9}$ ) and *TNC* (min. p =  $2 \times 10^{-9}$ ). Variants remained associated with glyca levels after adjustment for clinical covariates. Conditional analyses suggest five independent chr16 loci associated with glyca in EUR samples and two in AFR samples. Using exome sequencing in a large CV cohort, we have identified genetic loci associated with inter-individual variation in glyca, a novel inflammatory biomarker. These loci highlight potential genetic markers of high CV risk individuals and may help elucidate the genetic architecture of glyca. The lack of overlap with genetic loci for other inflammatory biomarkers (e.g. CRP) suggests that glyca potentially mediates CV risk through different inflammatory pathways.

**2668W**

**Genetic determinants in the *LILR* gene family predicting statin intolerance.** M.K. Siddiqui<sup>1</sup>, D. Carr<sup>2</sup>, M. Pirmohamed<sup>2</sup>, P. Ridker<sup>3</sup>, D. Chasman<sup>3</sup>, C.N.A. Palmer<sup>1</sup>. 1) Clinical and Molecular Medicine, University of Dundee, Dundee, United Kingdom; 2) University of Liverpool, United Kingdom; 3) Brigham and Women's Hospital, Harvard Medical School, USA.

The *LILR* are a gene family located in the leukocyte receptor complex on chromosome 19; encoding inhibitory and stimulatory receptors. There is increasing interest in their role in immune system function, as certain regions are known to interact with the HLA class I molecules, and might have immunomodulatory functions. In the sub-family *LILRB5* (Asp247Gly), is associated with muscle breakdown enzymes: serum creatine kinase (CK) and lactate dehydrogenase levels. Evidence suggests the variant is also associated with statin intolerance and myalgia. Due to their potentially interconnected nature, we decided to further explore the gene family and their role in statin intolerance. An association study of this region with statin intolerance was performed in the GoDARTS population (University of Dundee) and the results were meta-analyzed with cases of statin-induced myopathy from the CPRD-STAGE cohort (University of Liverpool). The meta-analysis showed a strong signal from SNPs in *LILRA3* and *LILRB2*. The strongest candidate SNP in *LILRB2*, (His20Arg) was selected, OR 1.48 (95% CI: 1.19, 1.85), *P-value*= $4 \times 10^{-4}$ . This variant was in strong linkage disequilibrium (LD) with neighbouring SNPs showing congruent effects. His20Arg was not in LD with the previously characterized myalgia variant- *LILRB5* Asp247Gly ( $r^2 = 0.04$ ,  $D' = 0.54$ ). Conditional analyses in GoDARTS showed carriers of both the *LILRB2* Arg37 and *LILRB5* Asp247 variants had higher odds of developing statin intolerance OR 1.44 (95% CI: 1.002, 2.06), *P-value*=0.04. The joint effect of these variants was replicated in the JUPITER trial, when examining the changes in CK levels between the start and end of the trial, as well as for the development of myalgia. We present a novel region of interest in the *LILR* family for statin intolerance and myalgia. The findings show the independent roles that individual *LILR* genes might play in statin intolerance and predisposition to statin-independent myalgia. These findings lend more evidence to the hypothesis of the immune system's involvement in statin intolerance, muscle repair and maintenance. The findings warrant further investigation into the immune-physiology of statin-induced muscle damage.

**2669T**

**Mendelian randomization to identify causal risk factors for atrial fibrillation.** L. Weng<sup>1,2</sup>, S.A. Lubitz<sup>1,2,3</sup>, AFGen Consortium. 1) Cardiovascular Research Center, Mass General Hospital, Boston, MA; 2) Program in Medical and Population Genetics, The Broad Institute of Harvard and MIT, Cambridge, MA; 3) Cardiac Arrhythmia Service, Massachusetts General Hospital, Boston, MA.

**Background:** Atrial fibrillation (AF) affects nearly 34 million individuals worldwide and is associated with substantial risks for stroke, dementia, heart failure, and death. Multiple clinical risk factors for AF have been identified. Understanding which risk factors are causally related to AF may help direct efforts focused on AF prevention. **Methods:** We tested whether a comprehensive set of established clinical AF risk factors are causally associated with AF using a two-sample Mendelian randomization approach. From published genome-wide association studies of each risk factor, we identified genetic variants associated with the risk factors (systolic blood pressure, body mass index, estimated glomerular filtration rate, smoking, type 2 diabetes, and coronary artery disease). Variants with *p*-values exceeding study-specific significance thresholds were included in our analyses. Variant effect sizes for AF were obtained from a prior genome-wide association study of AF. We used Wald-type estimation to calculate associations between risk factors and AF for each variant. We then summarized the effects across variants to evaluate the unconfounded estimates for each risk factor using both fixed and random-effects meta-analyses. Additionally, we evaluated associations after excluding potentially pleiotropic SNPs to minimize bias. **Results:** Genetically driven blood pressure and body mass index were both positively associated with AF risk. Each 10 mm Hg higher systolic blood pressure was associated with a 1.21-fold increased odds for AF (95%CI 1.05-1.39; *n*=25 variants). Each one kg/m<sup>2</sup> higher body mass index was associated with a 1.08-fold increased odds for AF (95% CI 1.04-1.13; *n*=32 variants). The results were similar after removing potentially pleiotropic variants. We did not observe significant associations between AF and genetically-determined estimated glomerular filtration rate, smoking, type 2 diabetes, or coronary artery disease. **Conclusions:** We found that increased blood pressure and body mass index are likely causally related to AF. Public health efforts focused on improving blood pressure and reducing body mass index may lower the incidence of AF and morbidity attributable to the arrhythmia.

**2670F**

**Localization and dissection of a major quantitative trait locus influencing vascular endothelial growth factor plasma levels.** *M. Almeida<sup>1</sup>, M.P. Johnson<sup>1</sup>, J.M. Peralta<sup>1</sup>, J.E. Curran<sup>1</sup>, E.K. Moses<sup>2</sup>, J. Blangero<sup>1</sup>.* 1) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley. One West University Blvd. STDOI Modular Building #100 Brownsville, TX 78520; 2) Centre for Genetic Origins of Health and Disease (GOHaD) The University of Western Australia (M409) 35 Stirling Highway CRAWLEY WA 6009 Australia.

The use of large human pedigrees to investigate the association between genetic variants and phenotypes of interest has gained a new impulse by the development of cost-effective sequencing platforms. They are able to detect millions of rare genetic variants exclusive to a single family or to a population under study. The San Antonio Family Heart Study (SAFHS) is a long running (~26 years) genomics project with considerable contributions for the identification of genetic *loci* associated with human complex diseases. The SAFHS now has approximately 1,600 complete genomes from 50 large extended families of Mexican American individuals living in the South Texas. We identified over 29 million SNVs (Single Nucleotide Variants) and among them 18.2 million were rare variants (MAF < 0.01). Rare genetic variants are generally missed in conventional genome wide association studies or are captured in too few numbers to permit variant-specific analysis in sequencing studies of unrelated individuals. Vascular endothelial growth factor (VEGF) plays a central role in angiogenesis and SNVs within the gene have been associated with arteriosclerosis, diabetes, preeclampsia and cancer. We isolated plasma derived VEGF and quantified total protein levels in a set of 1,210 SAFHS participants. VEGF concentrations were highly heritable ( $h^2=0.7$ ) in our sample. We searched for QTLs influencing VEGF levels using empirical IBD matrices in SOLAR and localized a major QTL (LOD = 10.84) on chromosome 6 near the *VEGFA* structural locus. We tested SNVs in this QTL region for association with VEGF concentration using a linear mixed model and significant genetic association were detected. The leading association was the common SNV rs6921438 ( $p$ -value= $2.07 \times 10^{-7}$ ) located in a highly conserved sequence region 200 kb downstream of the gene *VEGFA*. Conditional multi-variant analysis in the gene region revealed 5 independent putative functional variants accounting for 23.4% of the total phenotypic variation including a rare variant, rs73736911, with a very strong biological effect (+0.7 SD). These SNVs completely accounted for the original linkage signal (residual LOD = 0.07). These potential functional variants will require additional independent biological validation. Our results highlight the unique power of whole genome sequencing for QTL dissection when applied to quantitative risk factors in large human pedigrees.

**2671W**

**A genome-wide gene by cigarette smoking interaction study on elevated blood pressure.** *M. Kang, J. Sung.* Department of Epidemiology, Graduate School of Public Health, Seoul National University, Seoul, South Korea.

**Introduction:** Epidemiologic studies showed hypertension and cigarette smoking might result in a synergistic effect on the atherosclerotic cardiovascular disease risk, but the susceptible genes for this interaction are not well investigated. Although dozens of genetic markers were associated with hypertension, fewer studies were performed about genes that interact with smoking behavior to increase blood pressure. A gene-environment wide interaction study (GEWIS) is an effective approach particularly designed to identify these interactive genes. **Methods:** 18,025 individuals from two Korean cohorts, the subcohorts of the Korean Genome and Epidemiology Study (KoGES), were involved. Systolic and diastolic blood pressure were measured following the American Heart Association (AHA) guideline, and smoking status (current and ever smoking) were assessed using valid questionnaires. We conducted an exhaustive GEWIS on elevated blood pressure (EBP) for 4.1 million SNPs imputed using the 1000 genomes GRCh37 reference panel: the risk of EBP was adjusted for age, age<sup>2</sup>, sex, and BMI in each logistic regression model. We applied various exhaustive scans (case-control, case-only, and empirical Bayesian approaches) and two-step methods (Hybrid, Cocktail, and EDGxE) in parallel. For exhaustive scans, the genome-wide significance level of  $p < 5 \times 10^{-8}$  was applied to screen GxE interactive genes; step-wise penalties according to the marginal  $p$ -value were applied for two-step methods. **Results:** We identified five loci which modified the risk of EBP by current smoking: three loci near known hypertensive genes (*ABCG8*, *ATP2B1*), and two loci near *CWC27*, *PRSS45*. About 4.1% of Korean population had risk alleles of the locus near *ABCG8* which synergistically increase the risk of EBP with current smoking. The heritability of EBP explained by *ABCG8* was 0.9% by a conventional genome-wide association study (GWAS), but was increased to 5.7% when smoking habits were considered in a GEWIS. All of the identified GxE interactive SNPs from a discovery set were replicated with the other study population:  $p < 0.01$  was applied for the replication  $p$ -value. **Conclusion:** The identified SNPs in this GEWIS might be used as genetic markers to give a personalized guideline for those who are particularly susceptible to smoking consequences. Considering substantial differences between the conventional marginal GWAS and GEWIS, some amount of missing heritability should be explained by discovering more GxE interactive loci.

**Large-scale validation of zebrafish larvae as a model system for genetic screens in dyslipidaemia, atherosclerosis and coronary artery disease.**

M. Bandaru<sup>1,2</sup>, A. Emmanouilidou<sup>1,2</sup>, P. Ranefall<sup>1,3</sup>, B. von der Heyde<sup>1,2</sup>, T. Klingström<sup>1,2,4</sup>, J. Ledin<sup>2,4</sup>, A. Larsson<sup>5</sup>, C. Wählby<sup>2,3</sup>, E. Ingelsson<sup>6</sup>, M. den Hoed<sup>1,2</sup>.

1) Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden; 2) Science for Life Laboratory, Uppsala University, Uppsala, Sweden; 3) Department of Information Technology, Uppsala University, Uppsala, Sweden; 4) Department of Organismal Biology, Uppsala University, Uppsala, Sweden; 5) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 6) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford.

**Background:** Genome-wide association studies have identified 77 loci that are robustly associated with coronary artery disease (CAD). In all but a few of these loci the causal genes and mechanisms remain unknown. Results from small-scale studies suggest that zebrafish larvae represent a promising model system for genetic screens in dyslipidemia, early-stage atherosclerosis and CAD. We aim to confirm or refute these results in a large-scale study, expand the phenotypic pipeline, and increase the throughput. **Methods:** At the core of our setup is an automated positioning and imaging system that allows visualization and quantification of atherogenic traits in ~100 zebrafish larvae per day at 10 days post-fertilization, by making use of fluorescent transgenes and dyes. We used a three-tiered approach to validate the zebrafish model system: 1) a dietary intervention to examine the effect of overfeeding and cholesterol supplementation (N=2193); 2) a treatment regime with atorvastatin and ezetimibe (N=956); and 3) a genetic screen for zebrafish orthologues of *LDLR*, *PCSK9*, *APOB* and *APOE* using a multiplex CRISPR-Cas9 approach (N=2x384). After imaging, whole-body lipid and glucose levels were assessed using enzymatic assays, and CRISPR-Cas9 target sites were sequenced on a MiSeq. **Results:** Overfeeding and cholesterol supplementation have independent pro-atherogenic effects, including elevated total cholesterol and triglyceride levels, more vascular deposition of lipids and oxidized LDLc, and more co-localization of lipids with macrophages and neutrophils. Treatment with atorvastatin and ezetimibe results in lower whole-body total cholesterol, LDLc and triglyceride levels, as well as in less vascular lipid deposition and less co-localization of lipids and macrophages. Finally, mutations in *APOE* orthologues result in higher whole-body LDLc levels and more co-localization of lipids with macrophages or neutrophils compared with wildtypes. Mutations in *APOB* orthologues tend to result in higher LDLc levels, more vascular lipid deposition, and more co-localizing lipids and neutrophils. Treatment with lipid lowering drugs and mutations in *pcsk9* both result in higher whole-body glucose levels. Data from all larvae combined show that atherosclerosis in 10-day-old zebrafish larvae is mainly driven by higher triglyceride but not LDLc levels. **Conclusion:** Zebrafish larvae can be used to systematically identify and characterize causal genes for CAD.

## 2673F

**Sequence data processing and analysis of 70,000 human genomes in the NHLBI TOPMed sequencing program.** T. Blackwell<sup>1</sup>, G. Abecasis<sup>1</sup>, W. Gan<sup>2</sup>, S. Gogarten<sup>3</sup>, C. Jaquish<sup>2</sup>, H.M. Kang<sup>1</sup>, C.C. Laurie<sup>3</sup>, G. Papanicolaou<sup>2</sup>, J.G. Wilson<sup>4</sup>, Q. Wong<sup>3</sup>, Study Investigators of the NHLBI TOPMed Sequencing Program. 1) TOPMed Informatics Research Center, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI; 2) National Heart, Lung and Blood Institute, NIH, Bethesda Md; 3) TOPMed Data Coordinating Center, Department of Biostatistics, University of Washington, Seattle, Wa; 4) VA Medical Center and the University of Mississippi Medical Center, Jackson Mississippi.

The National Heart Lung and Blood Institute's Trans-Omics for Precision Medicine (TOPMed) initiative aims to stimulate discovery of fundamental mechanisms that underlie heart, lung, blood and sleep disorders by adding whole genome sequence data to existing high quality phenotypes and clinical diagnoses. The first two years of the project have generated deep whole genome sequence data for > 70,000 diverse samples, of which 46% have non-European ancestry. These populations are traditionally under-represented in genomic research. This project represents a collaboration between diverse groups of scientists, 7 genome sequencing centers, a project data coordinating center, an informatics research center and staff at the National Institutes of Health and the National Center for Biotechnology Information. Here, we describe the process of integrating sequence data across participating studies and sequencing centers being carried out at the project's Informatics Research Center (IRC). Currently, > 70,000 samples from 31 studies have been sequenced to an average sequencing depth of 38.3x (after duplicate removal), resulting in 98.9% of the genome covered to depth 10 or greater. The current data freeze with 18,526 sequenced individuals yields 199.5 million SNPs and 9.9 million short indels, of which 43.8% and 44.9% are singletons, respectively. Each individual carries a non-reference allele at between 3.5 and 4.5 million sites, depending on ancestry. As of abstract submission, variant filtering is ongoing for a new data set which will cover 64,960 individuals. Deep sequencing, PCR-free sample preparation protocols and harmonized data processing allow us to achieve < 5x10<sup>-6</sup> genotype discordance when duplicate samples are sequenced at different sites. A primary goal of the project is to allow investigators employing many different study designs and phenotypes to benefit from access to high-quality sequence data and analysis. There are also many opportunities for combined analysis of project data, including a diverse catalog of genetic variation, a potential resource of deeply sequenced controls for genetic association studies, and an imputation reference panel. We discuss some of these opportunities and associated logistical and technical challenges, as well as opportunities for any scientist to access project results.

**2674W****Genome-wide association study using whole-genome sequencing recapitulates both rare and common risk alleles for Brugada syndrome.**

The Brugada syndrome (BrS) is an inherited cardiac disorder associated with ST-segment elevation in the right precordial leads and a high risk for sudden cardiac death. Although rare variants in *SCN5A* (encoding the major cardiac Na-channel isoform) are found in ~20% of cases, the genetic basis of the disorder remains largely unresolved. In a previous genome-wide association study on 312 patients with BrS, we had identified 3 common haplotypes predisposing to the disorder, including two at the *SCN5A-SCN10A* locus. Additionally, by testing the burden of rare coding variation in 45 known or suspected arrhythmia-susceptibility genes among 167 patients with BrS, we have recently reported a significant enrichment in rare coding variation (with a minor allele frequency below 0.1%) only for *SCN5A*. Here we aimed to assess whether association testing based on whole genome sequencing would allow for simultaneous detection of both rare and common alleles associated to BrS. After sequencing the whole genomes of 328 French index cases with BrS and 404 ancestry-matched reference individuals to depth greater than 30X on Illumina HiSeq X station, we applied classical association scanning and gene burden testing on genotypes produced by multi-sample calling in line with the Broad/GATK best practices. By this strategy, we could reproduce both the previously reported association signals at the *SCN5A-SCN10A* locus and the significant enrichment in rare coding variation in the *SCN5A* gene. These results demonstrate the relevance of whole-genome sequencing to interrogate the full spectrum of genetic variation, from rare variants to common haplotypes, associated with susceptibility to complex disorders. We are currently investigating whether our whole-genome sequencing approach enables identifying additional low-frequency as well as structural variants conferring higher susceptibility to BrS, which could hardly be detected using former strategies.

**2675T****Genome-wide association study of susceptibility to rheumatic heart disease in South Asians: Preliminary results.**

K. Auckland<sup>1</sup>, A. Mentzer<sup>1</sup>, S. Kumar<sup>2</sup>, M. Bhatt<sup>3</sup>, N. Garg<sup>3</sup>, J. Kado<sup>4</sup>, M.L. Perman<sup>4</sup>, A. Steer<sup>5</sup>, A. Hill<sup>1</sup>, B. Mittal<sup>1</sup>, T. Parks<sup>1</sup>. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, Oxfordshire, United Kingdom; 2) Babasaheb Bhimrao Ambedkar University, Lucknow, Uttar Pradesh, India; 3) Sanjay Gandhi Postgraduate Institute of Medical Sciences, Lucknow, Uttar Pradesh, India; 4) Fiji National University, Suva, Fiji; 5) Murdoch Children's Research Institute, Melbourne, Victoria, Australia.

**Background:** Rheumatic heart disease (RHD), a chronic consequence of an abnormal immune response to *Streptococcus pyogenes*, affects 16 million individuals worldwide, causing an estimated 300,000 premature deaths each year. Previously a major public health concern in Europe and the United States, the disease remains a leading cause of morbidity and premature mortality in developing countries. Recently, large-scale genetic studies have begun to provide much needed insight into the underlying pathogenesis. We therefore sought to identify common genetic variants affecting susceptibility to RHD in South Asians. **Methods:** We undertook a genome-wide association study of RHD susceptibility in 1163 individuals of Indian ancestry recruited in Fiji (n=309) and Northern India (n=854). Patients with incident or prevalent RHD were recruited as cases, while members of the general population were recruited as controls. We genotyped all individuals at ~250,000 variants using the Illumina HumanCore platform before estimating the genotypes of an additional ~5,000,000 variants by imputation. We used linear mixed models to analyse genotyped and imputed variants before combining association statistics from the two datasets using fixed-effects meta-analysis. **Results:** We observed a single signal at genome-wide significance, located in the human leukocyte antigen (HLA) class III region (OR=1.91,  $P=6.8 \times 10^{-9}$ ). Using conditional analyses, we demonstrated this was comprised of two independent signals, the first spanning HLA class I (HLA-B) and the second HLA class II (HLA-DQA1/B1). While the *IGHV4-61* signal was apparent, as previously reported in the Fijian Indian data ( $P=0.006$ ), the signal was absent in the Northern Indian data ( $P=0.25$ ), leaving only a negligible signal in the pooled analysis (OR=1.21,  $P=0.084$ ). **Discussion:** By combining new data from India with previously reported data from Fiji, we provide the first insight into the genetic architecture of RHD susceptibility in South Asians with a promising finding in the HLA locus. To our knowledge, South-East Asian populations are poorly represented in existing HLA imputation reference panels and as such, the imputation of HLA classical alleles is likely to be inaccurate in these populations. To address these problems, we are building and validating a custom imputation panel optimised for South Asian populations and will provide an update on these efforts and its application to our GWAS at the meeting.

**2676F****Updated genome-wide association study and functional annotation**

**reveals new risk loci for mitral valve prolapse.** *N. Bouatia-Naji<sup>1</sup>, M. Yu<sup>1</sup>, Z. Alsaman<sup>1</sup>, J.J. Schott<sup>2</sup>, T. Le Tourneau<sup>2</sup>, P. Galan<sup>3</sup>, A. Hagege<sup>1</sup>, X. Jeunemaitre<sup>1</sup>, C. Dina<sup>2</sup>.* 1) Paris Cardiovascular Research Center U970 HEGP Research Center, INSERM, Paris, France; 2) INSERM UMR 1087, CNRS UMR 6291, Institut du Thorax, Centre Hospitalier Universitaire (CHU), Nantes University, Nantes, France; 3) Nutritional Epidemiology Research Group, Sorbonne-Paris-Cité, UMR University of Paris 13/Inserm U-557/INRA U-1125/CNAM, Bobigny, France F-93017, Bobigny, FRANCE.

Mitral valve prolapse (MVP) is common degenerative valve disease, a risk factor for arrhythmia, atrial fibrillation and sudden death and the leading indication for surgical repair of mitral regurgitation. We have previously reported 6 risk loci for MVP and aimed to use high-resolution imputation to improve our genetic map density and increase chances to find additional risk loci. To achieve these goals, we used genotypes from two European case control cohorts to generate ~40 million genotypes. We used SHAPE-IT for phasing and Minimac 3 for imputation through the online Michigan Imputation Server. We applied MAF specific imputation quality cut-offs as  $R^2 > 0.80$  if  $MAF > 0.05$ , or  $R^2 > 0.95$  if  $0.01 < MAF \leq 0.05$ . We performed the association analysis of ~5.2 million genotyped or imputed SNPs using SNPTEST in two case control sets and performed a GWAS meta-analysis using METAL that included 1,590 MVP cases and 2,548 controls. We identified 22 GWASig SNPs ( $P < 5 \times 10^{-8}$ ). Compared to our previous GWAS based on 1000G imputations, we replicated the association signal located on Chr2 near TNS1 (rs6708579,  $P = 1.2 \times 10^{-8}$ ) and Chr22 near MN1/PITPNB (rs11703195,  $P = 2.1 \times 10^{-9}$ ) providing further support with additional SNPs to these risk loci. Most interestingly, we identified two new loci on Chr1 (MAF=0.19, OR=1.70,  $P = 4.3 \times 10^{-10}$ ) intronic to *SPAG17* encoding a central pair protein part of cilia structure that we have recently demonstrated to be important to valvular development; and on Chr19 (MAF=0.39, OR=1.37,  $P = 6.6 \times 10^{-10}$ ) near *UQCRC1* encoding a ubiquinol cytochrome c reductase, highly expressed in heart and involved in cardiac muscle contraction. ENCODE annotation of 156 SNPs with  $P < 10^{-5}$  showed that 43 locate in DNase hypersensitive sites and 28 are transcription factors binding sites variants. In summary, our updated GWAS provided improved genetic information on known loci prior to functional exploration and identified new loci with potential candidate genes to be confirmed through replication in additional MVP cohorts.

**Circulating cholesteryl ester transfer protein (CETP) concentration: A genome-wide association study followed by Mendelian randomization on coronary artery disease.** *D. Mook-Kanamori<sup>1,2</sup>, L.L. Blauw<sup>1,3</sup>, R. Li-Gao<sup>1</sup>, R. Noordam<sup>4</sup>, R. de Mutser<sup>4</sup>, S. Trompet<sup>4,5</sup>, J.F.P. Berbee<sup>3,6</sup>, Y. Wang<sup>3,6</sup>, T. Christen<sup>1</sup>, D. van Heemst<sup>4</sup>, F.R. Rosendaal<sup>1</sup>, J.W. Jukema<sup>5</sup>, P.C.N. Rensen<sup>3,6</sup>, K. Willems van Dijk<sup>6,7</sup>.* 1) Clinical Epidemiology, Leiden University Medical Center, Leiden, Netherlands; 2) Public Health and Primary Care, Leiden University Medical Center, Leiden, Netherlands; 3) Internal Medicine, Div. Endocrinology, Leiden University Medical Center, Leiden, Netherlands; 4) Internal Medicine, Div. Gerontology and Geriatrics, Leiden University Medical Center, Leiden, Netherlands; 5) Cardiology, Leiden University Medical Center, Leiden, Netherlands; 6) Einthoven Laboratory for Experimental Vascular Medicine, Leiden University Medical Center, Leiden, Netherlands; 7) Human Genetics, Leiden University Medical Center, Leiden, Netherlands.

**Background/aims:** Cholesteryl ester transfer protein (CETP) facilitates the net flux of cholesteryl esters from high-density lipoproteins (HDL) towards (very-) low-density lipoproteins ((V)LDL), coupled to a net flux of triglycerides from (V)LDL to HDL. Therefore, inhibition of CETP has been regarded a promising therapeutic strategy to attenuate dyslipidaemia and ultimately prevent the development of cardiovascular disease (CVD). The genetic basis of CETP concentration is largely unknown and therefore we performed a genome-wide association study on circulating CETP. Subsequently, causal effects of variation in CETP concentration on circulating lipids and cardiovascular disease risk were assessed using Mendelian Randomization. **Methods:** A genome-wide association discovery and replication study on serum CETP concentration were embedded in the Netherlands Epidemiology of Obesity (NEO) study. Based on identified variants, Mendelian randomization was conducted on serum lipids (NEO study) and coronary artery disease (CAD) (CARDIoGRAM-plusC4D consortium). **Results:** In the discovery analysis ( $N = 4,248$ ), we identified three independent variants ( $P < 5 \times 10^{-8}$ ; rs247616, rs12720922 and rs1968905) all mapped to *CETP*, that were replicated in a separate subpopulation ( $N = 1,458$ ). Per-allele increase (SE) in serum CETP was 0.32 (0.015)  $\mu\text{g/mL}$  for rs247616-C, 0.35 (0.019)  $\mu\text{g/mL}$  for rs12720922-A, and 0.12 (0.02)  $\mu\text{g/mL}$  for rs1968905-G. Combined, these three variants explained 16.4% of the total variation in CETP concentration. One  $\mu\text{g/mL}$  increase in genetically-determined CETP concentration strongly decreased high-density lipoprotein (HDL) cholesterol (-0.23 mmol/L (95% CI: -0.26, -0.20)), but only moderately increased low density lipoprotein (LDL) cholesterol (0.08 mmol/L (95% CI: 0.00, 0.16)). Also, one  $\mu\text{g/mL}$  increase in genetically-determined CETP concentration was only marginally associated with an increased risk of CAD (odds ratio: 1.08 (95% CI: 0.94, 1.23)). **Conclusion:** This is the first large study identifying independent variants that largely determine serum CETP concentration, with strong effects on HDL-cholesterol and marginal effects on LDL-cholesterol and CAD risk. In line with CETP inhibitor trials failing to show a reduction in cardiovascular events, our genetics-based study suggests that potential effects of CETP inhibition on cardiovascular disease prevention are minimal.

**A genome-wide association study identifies novel genetic signatures associated with thiazide diuretics adverse metabolic events.** M.H.

Shahin<sup>1</sup>, A. Akoluk<sup>1</sup>, S. Singh<sup>1</sup>, C.W. McDonough<sup>1</sup>, Y. Gong<sup>1</sup>, A.B. Chapman<sup>2</sup>, S.T. Turner<sup>3</sup>, J.G. Gums<sup>1</sup>, A.L. Beitelshes<sup>4</sup>, E. Boerwinkle<sup>5</sup>, R.M. Copper-DeHoff<sup>1</sup>, J.A. Johnson<sup>1</sup>. 1) Department of Pharmacotherapy and Translational Research, Center for Pharmacogenomics, College of Pharmacy, University of Florida, Gainesville, FL; 2) Department of Medicine, The University of Chicago, Chicago, IL; 3) Division of Nephrology and Hypertension, Department of Medicine, College of Medicine, Mayo Clinic, Rochester, MN; 4) Department of Medicine, University of Maryland, Baltimore, MD; 5) Human Genetics Center and Institute of Molecular Medicine, University of Texas Health Science Center, Houston, TX.

Thiazide diuretics, including hydrochlorothiazide (HCTZ) and chlorthalidone (CLT), are among the most commonly prescribed first-line classes of antihypertensives in the U.S with more than 100 million prescriptions annually. However, the use of these drugs has been associated with adverse effects, including hypertriglyceridemia. Given the heritable nature of triglyceride levels, genetics may also be influencing the adverse drug effect on triglycerides. Herein, we conducted a genome-wide association study (GWAS) to identify novel genetic biomarkers associated with changes in fasting triglyceride levels in response to thiazide diuretics. For the discovery analysis, we included 186 Caucasians treated with CLT in the Pharmacogenomic Evaluation of Antihypertensive Responses-2 (PEAR-2) study. A GWAS was conducted with adjustment for age, sex, waist circumference, baseline triglycerides, and principal components 1 and 2. Genetic signals with a p-value <1E-05 from the GWAS analysis were tested for replication in 228 Caucasians treated with HCTZ. Results from the discovery analysis revealed 12 independent signals associated with changes in triglycerides in response to CLT (at a p-value <1 E-05). From those signals, rs7877356 in Purinergic Receptor P2Y12 (*P2RY12*) was significantly replicated in the same direction of response in an independent group of hypertensive Caucasians treated with HCTZ (p=8.6E0-5). In PEAR-2, rs7877356 G/A genotype carriers had a significant increase in triglycerides compared to A/A genotype carriers (G/A=57.6 mg dl-1 vs. A/A=11 mg dl-1, p=3.3E-06). Consistently, we also found that G/A carriers had a significant elevation in triglycerides compared to A/A genotype carriers when treated with HCTZ (G/A=32.5 mg dl-1 vs. A/A=3.51 mg dl-1, p=8.6E0-5). The meta-analysis p-value of the rs7877356 between the discovery and replication cohorts reached genome-wide significance (p=1E-09). Additionally, we replicated the region in 142 African-Americans treated with CLT, where we found an association between rs4146770 and changes in triglyceride levels (p=1.5E-04). In conclusion, this study reveals a novel genetic signal, within *P2RY12*, with clinically relevant effect on the thiazide-induced changes in triglycerides. These findings may represent a novel mechanism underlying thiazide-induced adverse metabolic effects that warrant further investigation.

**Background:** Congenital heart disease is the most common congenital defect, with an estimated prevalence of 1%. Transposition of the great arteries of the dextro type (D-TGA) is one of the most critical lesions that results in neonatal death if untreated. The role of genetic factors in predisposition for D-TGA is largely unknown. Complex inheritance may account for the sporadic presentation of the disorder. In this study we conducted a case-control genome-wide association study (GWAS) to explore the role of common genetic variants in the determination of risk for D-TGA in the context of a complex inheritance paradigm. **Methods:** D-TGA cases of Western-European descent were included and genotyped on Illumina OmniExpress Beadchip or Illumina Human660W arrays. After stringent quality control 245,999 single nucleotide polymorphisms (SNPs) in 969 cases and 4,347 ethnically matched controls remained for analysis. An additional >7 million SNPs were imputed using the Haplotype Reference Consortium panel (minor allele frequency > 0.05). SNP-disease association was assessed for genotyped SNPs and imputed SNP dosages by logistic regression analysis including sex and population structure as covariates. Loci that passed a suggestive threshold of statistical significance ( $p \leq 1 \times 10^{-6}$ ) were analyzed for expression quantitative trait locus (eQTL) effects in tissue sets from the GTEx resource. Furthermore, we performed a GO enrichment analysis on genes located within the 500 Kb upstream and downstream of the association signal. **Results:** No locus reached the genome-wide statistical significance threshold of  $p < 5 \times 10^{-8}$ . Nineteen loci displayed an association signal that passed the suggestive threshold of  $p < 1 \times 10^{-6}$ . Six of these loci displayed an eQTL effect, some for genes well known to influence cardiac outflow tract formation (e.g. *WNT5A* ( $p = 1.5 \times 10^{-7}$ ) and *ALDH1A2* ( $p = 6 \times 10^{-6}$ )). GO enrichment analysis identified an over-representation of genes involved in heart development among the 151 genes at the 19 loci ( $p = 0.01$ ). **Conclusion:** This is the first study exploring the role of common variants in a large cohort of D-TGA cases. These data indicate a possible role for common genetic variation in the determination of risk for D-TGA. Additional patients are currently being genotyped to extend the dataset. This work is expected to contribute to our understanding of the genetic architecture of D-TGA and to uncover new molecular mechanisms that underlie the disorder.

**GWAS-driven pathway analyses and functional validation reveals *GLIS1* to associate with mitral valve prolapse.** M. Yu<sup>1</sup>, C. Dina<sup>2</sup>, N. Tucker<sup>3</sup>, F. Del-ling<sup>4</sup>, S. Slangenhaupt<sup>5</sup>, R.A. Levine<sup>6</sup>, A.A. Hagège<sup>7</sup>, J.J. Schott<sup>8</sup>, X. Jeunemaitre<sup>9</sup>, D. Milan<sup>3</sup>, R. Norris<sup>3</sup>, N. Bouatia-Naji<sup>1</sup>. 1) INSERM UMR 970 Paris Cardiovascular Research Center, Paris, France; 2) INSERM UMR 1087, CNRS UMR 6291, Institut du Thorax, Centre Hospitalier Universitaire (CHU), Nantes University, Nantes, France; 3) Cardiovascular Research Center, Massachusetts General Hospital, Charlestown, Massachusetts, United States; 4) Framingham Heart Study, Framingham, Massachusetts, United States; 5) Center for Human Genetic Research, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, United States; 6) Cardiac Ultrasound Laboratory, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, United States; 7) AP-HP, Department of Cardiology, European Georges Pompidou Hospital, Paris, France; 8) AP-HP, Department of Genetics, European Georges Pompidou Hospital, Paris, France; 9) Cardiovascular Developmental Biology Center, Children's Research Institute, Medical University of South Carolina, Charleston, South Carolina, United States.

Mitral valve prolapse (MVP) is the most common indication for surgical repair of mitral regurgitation. MVP is a risk factor for arrhythmia, atrial fibrillation and sudden death. We have previously performed genome-wide association study (GWAS) in 1412 MVP cases and 2439 controls that identified 6 GWASig loci for MVP. However, stringent statistical thresholds set in GWAS may exclude genuinely associated loci. Additional genetic predisposition loci and mechanisms for MVP may deserve follow-up using pathway-based analyses. We first analyzed GWAS data using iGSEA4GWAS to detect associated pathways by applying gene set enrichment analyses. We found *GLIS1*, a GLI-related Kruppel-like zinc finger transcription factor to be the best ranked gene in 8 enriched gene sets (FDR<0.05). We also investigated 355 suggestively associated SNPs ( $P < 10^{-6}$ ) using DEPICT, which uses predicted functions to prioritize causal genes and highlight systematically enriched pathways. We identified 5 enriched gene sets ( $P < 10^{-4}$ ) involved in endothelial cell migration (e.g. GO:0043542), a highly relevant mechanism to valve development. In addition, we found that 26 tissue types are enriched for MVP loci (FDR<0.05), including those part of the cardiovascular system. Interestingly, among 13 significantly highlighted loci ( $P < 0.05$ ), we found *SMG6*, *LMCD1* and *PBX1* genes already part of the 6 confirmed loci and *GLIS1*. In the GWAS, *GLIS1* located on Chr1 is significantly associated with MVP risk (best SNP rs1879734: OR=1.30,  $P = 7.1 \times 10^{-6}$ ). Follow-up analyses indicate positive replication in four additional case control studies (~1400 cases and ~6400 controls, overall OR=1.23,  $P = 1.2 \times 10^{-7}$ ). *GLIS1* is part of the Hedgehog signaling, which is an important pathway for endothelial to mesenchymal transition and cilia organization during heart development. Using immunohistochemistry we found that *Glis1* is expressed during valve morphogenesis in mice (E.13 and E.17 stages) and maintained in the adult. *Glis1* is detected in nuclei from endothelial and valvular interstitial cells. *Glis1* knockdown by morpholino caused significant atrioventricular (AV) regurgitation in zebrafish embryos. In summary, our pathway enrichment investigation of GWAS data provides new candidate genes and pathways that deserve further investigation. We also provide genetic and functional evidence supporting *GLIS1* as a new locus and candidate gene for MVP, which involved Hedgehog signaling for the first time in valve development and degeneration.

**2681T**

**A novel LDL-lowering missense variant in *B4GALT1* identifies novel biological connection between protein glycosylation and cardiovascular risk factors in human.** M. Montasser<sup>1</sup>, C. Van Hout<sup>2</sup>, G. Della Gatta<sup>3</sup>, M. Puurunen<sup>4</sup>, J. Reid<sup>5</sup>, J. Overton<sup>6</sup>, A. Baras<sup>7</sup>, A. Economides<sup>8</sup>, M. Healy<sup>9</sup>, N. Zaghoul<sup>1</sup>, C. Sztalryd-Woodle<sup>1</sup>, E. Streeten<sup>1</sup>, B. Mitchell<sup>1</sup>, S. Taylor<sup>1</sup>, J. O'Connell<sup>1</sup>, A. Shuldiner<sup>1,2</sup>. 1) Program for Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, Maryland USA; 2) Regeneron Genetics Center, Regeneron Pharmaceuticals, Inc, Tarrytown, NY USA.

Cardiovascular disease (CVD) is the leading cause of death worldwide. Elevated low density lipoprotein cholesterol (LDL) and fibrinogen are major independent risk factors for CVD. Understanding their genetic basis may identify novel therapeutic targets to lower their levels and treat or prevent CVD. Isolated founder populations can enable discovery of novel disease-associated variants enriched in these populations through genetic drift. Although very rare in the cosmopolitan populations, these novel variants can inform biology relevant to all humans. To identify novel rare drifted alleles associated with CVD risk factors, we performed whole exome ( $n = 4,725$ ) and genome sequencing ( $n = 1113$ ) on well phenotyped Amish subjects. We identified a strong novel association ( $p = 3.3E-18$ ) between a missense SNP (N352S) in *B4GALT1* and LDL. Each 352S allele is associated with a 14.7 mg/dl lower LDL, and has a frequency of 6% in the Amish while extremely rare in the general population. In addition, this SNP was associated with a 20% decreased fibrinogen ( $p = 5.0E-4$ ), a two-fold increase in aspartate transaminase (AST) ( $p = 3.0E-8$ ), and a 50% increase in creatine kinase (CPK) ( $p = 0.02$ ). These observations are consistent with coagulopathy and myopathy phenotypes reported in patients homozygous for rare protein-truncating mutations in *B4GALT1*. Notably, the 13 Amish 352S homozygotes appear to be healthy adults without any obvious phenotypic sequelae. The enzyme encoded by *B4GALT1* plays a critical role in processing of N-linked oligosaccharide moieties in glycoproteins. The N352S substitution resides very close to the catalytic site of the enzyme. Alterations in glycosylation have been reported to impair intracellular trafficking of various glycoproteins including the LDL receptor, and may also affect various circulating glycoproteins such as apolipoprotein B and fibrinogen. As expected for a missense SNP we found no difference in the protein expression between the wild type and the mutant forms expressed in cultured Cos-7 cells, however, we expect, and are currently testing, that the 352S allele will cause lower enzymatic activity. We have knocked down *B4GALT1* in zebrafish and we will assess the associated traits in the knockdown model, and also assess the impact of N352S on these traits. More functional assays are underway to fully understand the biological impact of the protein glycosylation pathway on CVD risk factors and its therapeutic opportunities.

Chagas disease, caused by the protozoan *Trypanosoma cruzi*, is endemic in Latin America and affects 10 million people worldwide. Approximately 12,000 deaths attributable to Chagas disease occur annually due to Chagas disease cardiomyopathy (CCC). Little is known about the role of epigenetic modifications in pathological gene expression patterns in CCC patients' myocardium. Whole genome DNA methylation and global gene expression were done on myocardial samples from end-stage CCC patients and control samples. 4720 genes were differentially methylated between CCC patients and controls, of which 399 were also differentially expressed. Reporter gene and in silico transcription factor binding analyses indicated promoter methylation modified expression of key genes. These analyses have shown that Sp1 is a major transcription factor for differentially methylated CpG regions. It may be a therapeutic target for restoring gene expression patterns. We found potassium channel genes *KCNA4* and *KCNIP4*, involved in electrical conduction and arrhythmia. *KCNA4* encodes the potassium voltage-gated channel Kv1.4, and *KCNIP4* is a potassium channel-interacting protein that regulates Kv4.3 potassium channel function. Both modulate the duration and shape of the cardiac action potential. Potassium channel gene expression was found to be disturbed in hearts of *T. cruzi*-infected mice. In addition, *SMOC2* gene is highly expressed during wound healing, matrix assembly and remodeling, processes associated with fibrosis in CCC. Transgenic mice over or underexpressing the *Smoc2* gene displayed increased/decreased kidney fibrosis in a kidney damage model, by modulating fibroblast proliferation and extracellular matrix deposition. *PENK* mRNA, upregulated in CCC, is expressed mainly in the brain and heart and encodes preproenkephalin. Enkephalin is a ligand of  $\delta$  opioid receptors important in pain processing.  $\delta$  opioid receptors are present in myocardium and immune cells; opioid signaling induces heart protection against ischemic injury in experimental models. Finally, *RUNX3*, interacts with transcription factor T-bet to induce maximal IFN- $\gamma$  production in T cells which are abundant in CCC myocardium. This may indicate an additional driving factor for the potent, unrestricted activation of pathogenic IFN- $\gamma$  producing T cells in CCC myocardium. Results support that DNA methylation plays a role in the regulation of pathogenically relevant genes in CCC myocardium, and identify novel therapeutic targets in CCC.

**Primary lymphedema: A novel association with 22q11.2 deletion syndrome.** M. Unolt<sup>1,2</sup>, J. Barry<sup>2</sup>, M.C. Digilio<sup>3</sup>, B. Marino<sup>1</sup>, A.S. Bassett<sup>4</sup>, E. Oechlin<sup>4</sup>, D. Low<sup>2,5</sup>, J. Belasco<sup>2,5</sup>, S. Kallish<sup>5,6</sup>, K. Sullivan<sup>2,5</sup>, E.H. Zackai<sup>2,5</sup>, D.M. McDonald-McGinn<sup>2,5</sup>, International 22q11.2DS Consortium. 1) Department of Pediatrics, "Sapienza" University of Rome, Rome, Italy; 2) Division of Human Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 3) Ospedale Pediatrico Bambino Gesù, Rome, Italy; 4) University of Toronto, Centre for Addiction and Mental Health, Toronto, Canada; 5) Perelman School of Medicine of the University of Pennsylvania, Philadelphia, PA, USA; 6) Hospital of the University of Pennsylvania, Philadelphia, PA, USA.

**BACKGROUND:** Lymphedema is an abnormal accumulation of interstitial fluid and fibroadipose tissues. Primary lymphedema (LMP) is congenital, caused by aberrant lymphangiogenesis. Classifications of LMP are based on age at presentation: congenital, precox, tarda. Although most cases are sporadic, LMP may be familial (Hereditary Primary Lymphedema - LMPH) inherited mainly in an autosomal dominant fashion with heterogeneous mutations or in association with chromosomal abnormalities/syndromic diagnoses. **METHODS:** We identified 4 patients (1 male, 3 females) with 22q11.2DS and LMP via our International 22q11.2DS Consortium: 2 congenital; 1 precox; 1 tarda. **RESULTS:** All patients underwent comprehensive clinical, laboratory and imaging assessments to rule out other causes of lymphedema including a negative next generation sequencing panel performed on the infant male with LMP. All patients had *de novo* typical deletions and family histories were negative for lymphedema. Of note, the female patient with congenital LMP developed a nodular lymphocyte predominant Hodgkin lymphoma (NLPHL) in late adolescence and another female with LMP precox had severe pre-eclampsia during pregnancy. **CONCLUSIONS:** We report the novel association of LMP with 22q11.2DS. Importantly, animal models demonstrated *Tbx1* playing a critical role in lymphangiogenesis by reducing *Vegfr3* expression in lymphatic endothelial cells. Moreover, the *VEGFR3* pathway is essential for lymphangiogenesis with mutations identified in LMPH. This is especially notable as *VEGFR3* is also involved in tumor lymphangiogenesis/metastases which may explain the NLPHL in our patient. Finally, severe pre-eclampsia results from abnormal placental angiogenesis in association with mutations in the *VEGF* family of genes, which also may explain the preeclampsia in our patient. Accordingly, our findings provide crucial insight into clinical management, as well as, a window into understanding cellular mechanisms of lymphangiogenesis disorders.

**Utilization of drugs with evidence for pharmacogenomic testing following percutaneous coronary intervention.** N. El Rouby<sup>1</sup>, A. Alrwan<sup>2</sup>, J.A. Johnson<sup>1</sup>, A.G. Winterstein<sup>2</sup>, L. Cavallari<sup>1</sup>. 1) Pharmacotherapy and Translational Research, UF, Gainesville, FL; 2) Pharmaceutical Outcomes and Policy, UF, Gainesville, FL.

Genotype informed prescribing, an important facet of precision medicine, offers great promise of optimizing drug therapy. This can be facilitated by preemptive genotyping using multi-panel testing, which may be particularly valuable for patients with polypharmacy, and whose therapy is likely to be influenced by multiple genes. The Pharmacogenomic Knowledge Base (PharmGKB) grades the level of evidence (1A>1B>2A>3>4) for the effect of genotype on drug response, and the Clinical Pharmacogenetic Implementation Consortium (CPIC) prioritizes gene-drug pairs for integration into prescribing decisions (A>B>C>D). To determine the value of preemptive genotyping, we sought to identify the incidence of drugs with high level of pharmacogenetic evidence, defined as CPIC level A or B and PharmGKB level 1A through 2A, in a population of patients with incident percutaneous intervention (PCI) initiated on clopidogrel. We focused on PCI patients because 1) PCI is one of the most common settings for clinical pharmacogenetic implementation, and 2) patients undergoing PCI represent a high risk population with multiple co-morbidities often requiring polypharmacy. The dataset was created using in- and outpatient pharmacy billing records from employer-based health plans made available in Truven MarketScan, and included patients with continuous enrollment of  $\geq 6$  months who had a clopidogrel prescription fill within 7 days of PCI (n=122,339). Data were collected up to 5 years after PCI. Among post-PCI patients who were prescribed clopidogrel and were followed for one or three years, 51% and 62% were prescribed  $\geq 1$  additional drug with pharmacogenetic evidence, respectively. Among patients followed for five years, 68% had  $\geq 1$  additional drug, and 28% were prescribed  $\geq 3$  drugs with pharmacogenetic evidence. The most commonly prescribed drugs were opiates, proton pump inhibitors, and simvastatin, representing 31%, 22%, and 21% of drugs with pharmacogenetic evidence and whose responses are influenced by variants in *CYP2D6*, *CYP2C19*, and *SLCO1B1* genes, respectively. In conclusion, these data demonstrate that panel-based pharmacogenetic testing at the time of PCI has not only the potential to inform antiplatelet therapy, but in the majority of patients, to inform therapy decisions for additional medications impacted by genotype in the first 1 to 5 years post-PCI.

**Genome-wide association study reveals novel genetic markers associated with chlorthalidone blood pressure response.** S. Singh<sup>1</sup>, Y. Gong<sup>1</sup>, C.W. McDonough<sup>1</sup>, K.R. Bailey<sup>2</sup>, A.L. Beitelshes<sup>3</sup>, E. Boerwinkle<sup>4</sup>, A.B. Chapman<sup>5</sup>, J.G. Gums<sup>1</sup>, S.T. Turner<sup>6</sup>, R.M. Cooper-DeHoff<sup>1,7</sup>, J.A. Johnson<sup>1,7</sup>. 1) Department of Pharmacotherapy and Translational Research and Center for Pharmacogenomics, University of Florida, Gainesville, Florida; 2) Division of Biostatistics, Department of Health Sciences Research, Mayo Clinic, Rochester, Minnesota; 3) College of Medicine, University of Maryland, Baltimore, MD; 4) Human Genetics and Institute of Molecular Medicine, University of Texas Health Science Center, Houston, Texas; 5) Division of Nephrology, University of Chicago, Chicago, IL, USA; 6) Division of Nephrology and Hypertension, Mayo Clinic, Rochester, Minnesota, USA; 7) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, Gainesville, Florida, USA.

Around 30% of the adult USA population suffers from hypertension, of which almost 50% of patients have uncontrolled blood pressure (BP). Interpatient variability in response to antihypertensive drugs contributes importantly to this statistic. Thiazide and thiazide-like diuretics remain among the most widely used anti-hypertensives. Although hydrochlorothiazide is the more commonly prescribed diuretic, studies show that chlorthalidone is a more potent BP lowering diuretic and may have additional benefits. However there are few data regarding the influence of genetics on variable BP response to chlorthalidone, and we sought to address this question. We conducted a genome-wide association analysis of the systolic BP (SBP) and diastolic BP (DBP) change post 8 weeks of chlorthalidone treatment in 184 European Americans from the Pharmacogenomic Evaluation of Antihypertensive Responses-2 (PEAR-2) using linear regression, adjusting for age, sex, baseline BP and principal components 1 and 2. Genes harboring the variants that met the suggestive level of significance ( $p < 1 \times 10^{-6}$ ) were further tested for differential expression using RNA sequencing data between responders and non-responders to chlorthalidone treatment. Rs13066950 in the *C3orf35* region met the suggestive level of significance and was associated ( $p$ -value= $6.57 \times 10^{-7}$ ,  $\beta=4.0$ , SE=0.806) with decreased SBP response to chlorthalidone. Furthermore this variant was an eQTL for *MLH1* (MutL Homolog1) and *GOLGA4* (Golgin A4) and was in high Linkage Disequilibrium ( $D' > 0.9$ ) with multiple missense variants of *GOLGA4*. Upon evaluating the differential gene expression between the good responders and non-responders to chlorthalidone treatment, the expression of *C3orf35* was down regulated in non-responders ( $\log_2(\text{Fold Change}) = -1.11$ ,  $q$ -value = 0.032). Further, based on the publically available GTEx dataset (n=7051), we also found that for rs13066950 in the *C3orf35*, *GOLGA4* expression was down regulated in the carriers of the alternate allele compared to non-carriers, which correlates well with our findings. *GOLGA4* is purported to play a role in the Rab6/RabGTPases pathway that has been implicated in hypertension and atherosclerosis. Our study identified novel genetic markers that may contribute to the genetic basis of the variability of chlorthalidone BP response. Further studies are warranted to understand the exact mechanisms of these genes to help advance the personalized anti-hypertensive therapy approaches.

**2686W****Exome-chip meta-analysis identifies association between variation in *ANKRD26* and platelet aggregation.**

Previous genome-wide association studies (GWAS) have identified several variants associated with platelet function phenotypes; however, the proportion of variance explained by the identified variants is small. Rare coding variants, particularly those with high potential for impact on protein structure/function, may have substantial impact on phenotype but are difficult to detect by GWAS. The main purpose of this study was to identify low frequency or rare variants associated with platelet function using genotype data from the Illumina HumanExome Bead Chip. Three family-based cohorts of European ancestry, including ~4,000 total subjects, comprised the discovery cohort, and two independent cohorts, one of European and one of African American ancestry, were used for replication. Optical aggregometry in platelet-rich plasma was performed in all the discovery cohorts in response to adenosine diphosphate (ADP), epinephrine, and collagen. Meta-analyses were performed using both gene-based and single nucleotide variant association methods. The gene-based meta-analysis identified a significant association ( $P=7.13 \times 10^{-7}$ ) between rare genetic variants in *ANKRD26* and ADP-induced platelet aggregation. One of the *ANKRD26* SNVs - rs191015656, encoding a threonine to isoleucine substitution predicted to alter protein structure/function, was replicated in Europeans. Aggregation increases of ~20-50% were observed in heterozygotes in all cohorts. Novel genetic signals in *ABCG1* and *HCP5* were also associated with platelet aggregation to ADP in meta-analyses, although only results for *HCP5* could be replicated. The SNV in *HCP5* intersects epigenetic signatures in CD41+ megakaryocytes suggesting a new functional role in platelet biology for *HCP5*. This is the first study to use gene-based association methods from SNV array genotypes to identify rare variants related to platelet function. The molecular mechanisms and pathophysiological relevance for the identified genetic associations requires further study.

**2687T****Functional fine-mapping of coronary artery disease risk variants.**

B. Liu<sup>1,2</sup>, M. Pjanic<sup>3</sup>, T. Nguyen<sup>3</sup>, S.B. Montgomery<sup>2,4</sup>, C. Miller<sup>2</sup>, T. Quertermous<sup>3</sup>. 1) Department of Biology, Stanford University, Palo Alto, CA; 2) Department of Pathology, Stanford University, Palo Alto, CA; 3) Department of Medicine - Division of Cardiovascular Medicine, Stanford University, Palo Alto, CA; 4) Department of Genetics, Stanford University, Palo Alto, CA.

Coronary artery disease (CAD) is the leading cause of death globally. Its complex etiology is influenced by both genetic and environment risk factors. Large-scale population association studies have identified over 150 risk loci, explaining ~10% of the disease heritability. Functional interpretation of the risk-associated variants has been challenging as the majority of the variants lie outside of coding regions and are predicted to be regulatory. One of the key arbiters in coronary artery disease is the human coronary artery smooth muscle cell (HCASMC). These cells constitute the majority of the coronary artery vessel wall and have been shown to give rise to ~30% of the total cells in the atherosclerotic lesion. While these cells remain differentiated in the healthy tissue, they become highly proliferative and invasive in response to vessel injury and lesion expansion. Global changes in the HCASMC transcriptome and the underlying regulatory mechanisms responsible for these disease state transitions have not been fully characterized due to limited sample availability. Here, we have generated RNA and whole-genome sequencing datasets on 52 serum-stimulated HCASMC lines (mimicking the disease state) and ATACseq on a subset of 9 lines, representing one of the largest collections of these valuable samples to date. By comparing the transcriptomes of HCASMC lines and closely related tissue types in the GTEx project, we identify upregulated pathways and HCASMC-specific genes. In addition, we identify HCASMC-specific eQTLs as compared to related GTEx tissues. Around 30% of all eQTLs overlap chromatin-accessible regions, and eQTL specificity positively correlates with chromatin specificity. As expected, CAD GWAS variants are enriched in HCASMC ATACseq regions as compared to those in other tissues, further emphasizing the disease relevance of this critical vascular cell type. By combining eQTL and ATAC-seq, we discovered 35 SNPs whose eQTL signals and GWAS signals colocalize. This study represents the first comprehensive characterization of the HCASMC transcriptome from multiple donors, ultimately revealing insights into the genetic underpinnings of CAD.

**Genetic variation in thromboxane A synthase 1 is associated with stroke risk that can be reduced by daily aspirin.** S. Zajic<sup>1</sup>, J.P. Jarvis<sup>1</sup>, M. Byrska-Bishop<sup>2</sup>, P. Zhang<sup>1</sup>, J. Leader<sup>2</sup>, A. Brangan<sup>1</sup>, K. Dent-Ferguson<sup>1</sup>, M. Ritchie<sup>2</sup>, D. Ledbetter<sup>2</sup>, M. Christman<sup>1</sup>, DiscovEHR Collaboration. 1) Coriell Institute for Medical Research, Camden, NJ; 2) Geisinger Health System, Biomedical and Translational Informatics Institute, State College, PA.

We investigated genetic and environmental factors associated with stroke risk using genetic, demographic, medical history, and medication data from 4,501 participants in the Coriell Personalized Medicine Collaborative (CPMC). Variation in metabolism-related genes was assayed using the Affymetrix DMET Plus array, a targeted set of 1931 SNPs in metabolic enzymes and transporters. We report the identification of a genetic variant of thromboxane A synthase 1 (TBXAS1) (rs8192868, c.1348G>A, p.Glu450Lys, CYP5A1\*7) as a novel risk allele for stroke. Daily aspirin use appears to reduce stroke risk associated with this variant. Risk of stroke (n = 83 cases) was significantly higher in individuals with this variant not on daily aspirin (p-value = 0.0188, odds ratio [95% CI] of 2.49 [1.20, 5.18]), with the effect of this variant on stroke risk of borderline significance (p-value = 0.0613, odds ratio [95% CI] of 1.76 [0.946, 3.27]) across the entire cohort, including daily aspirin users. This variant showed a significant association with daily aspirin use (Bonferroni-adjusted p-value = 0.00694 at a 0.05 level), consistent with the role of TBXAS1 immediately downstream of the site of action of aspirin. Heterozygous individuals were nearly twice as likely to be taking daily aspirin as compared to homozygous wild-type, with an odds ratio [95% CI] of 1.85 [1.41, 2.44]. These associations were supported by analysis of data from 40,519 individuals (including 425 stroke cases) in the exome-sequenced DiscovEHR cohort of Geisinger Health System and Regeneron Genetics Center. In that cohort, there was a significant association between stroke and this variant with p-value = 0.05 and odds ratio [95% CI] of 1.47 [1.00 – 2.17]. The genetic risk for stroke associated with this variant in non-aspirin users (odds ratio [95% CI] of 1.88 [1.07, 3.29]) was reduced in individuals on daily aspirin (odds ratio [95% CI] of 1.39 [0.856, 2.27]), consistent with the expectation that altered TBXAS1 function would be of reduced consequence in individuals taking daily aspirin, though the interaction term between this variant and daily aspirin use was not significant in the regression analysis. Genetic stroke risk associated with this variant appears to be reduced or eliminated by daily aspirin use in both cohorts. This biologically plausible association suggests personalization of daily aspirin therapy to individuals based on their genetics for primary or secondary stroke prevention.

**A longitudinal transcriptome analysis identifies novel gene expression signatures for body mass index in monocytes.** C. Müller<sup>1,2,3</sup>, M.F. Hughes<sup>4</sup>, F. Ojeda<sup>1</sup>, D. Bönnigen<sup>1,2</sup>, K.J. Lackner<sup>5,6</sup>, P.S. Wild<sup>6,7,8</sup>, D.A. Trégouët<sup>9</sup>, S. Blankenberg<sup>1,2</sup>, T. Zeller<sup>1,2</sup>. 1) Clinic for general and interventional Cardiology, University Heart Center Hamburg, Hamburg, Germany, Germany; 2) DZHK (German Centre for Cardiovascular Research) partner site Hamburg/Lübeck/Kiel, Germany; 3) Institut für Medizinische Biometrie und Statistik, Universitätsklinikum Schleswig-Holstein, Germany; 4) UKCRC Centre of Excellence for Public Health Northern Ireland, Queens University Belfast, Northern Ireland; 5) Institute of Clinical Chemistry and Laboratory Medicine, University Medical Center of the Johannes Gutenberg-University Mainz, Germany; 6) DZHK (German Centre for Cardiovascular Research) partner site Rhine Main, Germany; 7) Preventive Cardiology and Preventive Medicine, University Medical Center of the Johannes Gutenberg-University Mainz, Germany; 8) Center for Thrombosis and Hemostasis, Mainz, Germany; 9) Sorbonne Universités, UPMC, INSERM, UMR\_S 1166, ICAN Institute for Cardiometabolism and Nutrition, Paris, France.

**Background and study aims:** More than 600 million obese people worldwide are at higher risk of developing cardiometabolic disorders. Monocytes are cell types participating to cardiovascular disease progression whose regulation is affected by obesity. However, the underlying molecular mechanisms are not fully understood. We aimed to identify longitudinal gene expression changes of circulating monocytes in relation to weight gain/loss during 5 years follow-up in a large population of healthy subjects. **Methods:** mRNA was isolated from monocytes of 1,092 subjects of the Gutenberg Health Study, both at baseline study visit (BL) and at 5 years follow-up (FU). Whole-transcriptome gene expression was measured by *Illumina HT12 BeadChips*. 12,170 genes were tested for association between mRNA changes (mRNA<sub>FU</sub> – mRNA<sub>BL</sub>) and changes of body mass index (BMI<sub>FU</sub> – BMI<sub>BL</sub>) by linear regression adjusted for age, gender and BMI<sub>BL</sub>. Genes reaching a Benjamini-Hochberg based false discovery rate (FDR) ≤ 0.01 were considered as significant. Pathway and gene-set enrichment analyses were performed using *LYNX* (<http://lynx.ci.uchicago.edu/>) and by Fisher's exact test, respectively. **Results:** mRNA changes of 143 genes were significantly associated to longitudinal BMI changes. The strongest association (FDR = 1.7 × 10<sup>-6</sup>) was observed for lipocalin-2 (*LCN2*) whose decreased mRNA levels were associated with increased BMI. Significant genes were ~6-fold enriched (p < 10<sup>-16</sup>) in a signature separating classical CD14<sup>+</sup>CD16<sup>-</sup> from non-classical CD14<sup>+</sup>CD16<sup>+</sup> monocytes indicating a shift of monocyte composition during obesity development. In addition, BMI related genes were >3-fold enriched (p = 1.3 × 10<sup>-8</sup>) in a signature reflecting the age of transcriptomes. *LYNX* analyses revealed enrichment of *Gene Ontology* term *immune response* (FDR = 0.034) and – amongst others – *REACTOME* pathway *Oxidative Stress Induced Senescence* (FDR = 4.2 × 10<sup>-3</sup>). **Conclusion:** This is the first longitudinal population-based study investigating BMI changes in relation to transcriptomes in monocytes. The top gene *LCN2* is known to be involved in type 2 diabetes and cardiovascular disorders, underlining the validity of our analysis. Enrichment analyses revealed strong over-representation of aging-related genes, and suggest a shift of monocyte sub-populations towards non-classical monocytes. The latter finding is consistent with current studies reporting a shift in monocyte composition during obesity and cardiovascular disease development.

**2690T**

**Implementing genome-based predictive and preventive medicine: The GeneRISK follow-up study.** E. Widen<sup>1</sup>, J. Aro<sup>1</sup>, K. Hotakainen<sup>2</sup>, J. Partanen<sup>3</sup>, P. Pollanen<sup>4</sup>, I. Salonen<sup>4</sup>, S. Ripatti<sup>1</sup>. 1) Institute for Molecular Medicine Finland, Helsinki, University of Helsinki, Finland; 2) Mehiläinen Oy, Helsinki, Finland; 3) Finnish Red Cross Blood Service, Helsinki, Finland; 4) CAREA - Kymenlaakso Social and Health Care Services, Kotka, Finland.

While genomic strategies have resulted in successful identification of numerous genetic loci modifying the risk for common complex disorders, the use of this information for disease prevention has remained minimal, in part because the very large number of associated variants imposes a considerable interpretation and data management challenge. To facilitate the translation of recent genomic discoveries, to guide intervention, and to empower individuals to use this information and actively take care of their health, we have developed a novel interactive graphical interface for patients and doctors to utilize genome data to predict and prevent cardiovascular disease (CVD). We have also set up a prospective population-based study, GeneRISK, where 10,000 participants will use this tool to receive and interpret information on their personal disease risk, including genomic information. We initiated the study in 2015, and have hitherto enrolled 6,807 subjects from Southern Finland aged 45-65 years. The CVD risk is estimated based on traditional factors and on a genomic risk score (GRS) computed from ~ 49,000 common variants. 5,128 individuals have received their disease risk information so far. 65% had BMI >25 kg/m<sup>2</sup>, 18% were smokers, and 70% had total cholesterol >5 mmol/l. 25% of them had a high (>10%) 10-year risk for severe ischemic heart disease. 15% of subjects in the high-risk group had been reclassified from a lower risk category because of a high GRS. As many as 42% of individuals at high risk were current smokers, and only 16-18% were on lipid-lowering therapy. This suggests that both by life style and medical intervention can be applied to lower the disease risk. Follow-up visits will be initiated in 2017, aiming at monitoring changes in risk factor levels, behavior and life-style. We will additionally assess the participants' use of medication and disease outcomes prospectively by regularly linking to key nation-wide health registers containing information on hospitalization, drug purchases and causes of death. Setting up and testing comprehensive procedures to integrate genomic and traditional health information for clinical practice is expected to enhance disease prevention and treatment and lead to better life quality of patients and healthy individuals. By promoting early detection and targeted prevention of CVD in the GeneRISK-study, we aim at providing a precedent for practical targeted genome-based prevention to be adapted broadly.

**The effect of genetic variation in donors and patients on rejection after heart transplantation.** J. van Setten<sup>1</sup>, B. Chang<sup>2</sup>, N. de Jonge<sup>1</sup>, M.V. Holmes<sup>2</sup>, C.C. Baan<sup>4</sup>, O.C. Manintveld<sup>4</sup>, A.M.A. Peeters<sup>4</sup>, F. Dominguez<sup>5</sup>, K.K. Khush<sup>3</sup>, P. Garcia-Pavia<sup>2</sup>, J.W. Rossano<sup>2</sup>, R.A. de Weger<sup>1</sup>, J.H. Moore<sup>2</sup>, B. Keating<sup>3</sup>, F.W. Asselbergs<sup>1</sup> on behalf of the iGeneTRAIIn consortium. 1) University Medical Center Utrecht, Utrecht, Netherlands; 2) University of Pennsylvania, Philadelphia, USA; 3) Stanford University, Stanford, USA; 4) Erasmus MC, Rotterdam, Netherlands; 5) Puerta de Hierro University Hospital, Madrid, Spain.

**Introduction:** Heart transplantation is the best therapeutic option for selected patients with end-stage heart failure. However, the immunological barrier between the donor and recipient still limits long-term survival. Immunosuppressive drugs are needed to avoid rejection, but cause an increased incidence of cancer and infections. Besides HLA, also other genetic factors play a role in graft rejection. We aim to identify genetic variants in the patient and in the donor that are involved in rejection after heart transplantation. **Methods:** iGeneTRAIIn is a large-scale international consortium, consisting of over 30,000 solid organ transplant patients and donors. We included 1022 patients and 945 heart transplant donors from five different hospitals. A majority of samples has been genotyped on the Affymetrix Tx Array. This array is specifically tailored for the transplantation community. We tested over 10 million variants and included high-resolution data of the MHC region. We used a mixed models approach to take relatedness and ancestry into account. Donor and recipient age and sex, year of transplant, genetic distance between the donor and the recipient, and cohort were included as covariates. **Results:** Two loci, both located on chromosome 6, in the recipients DNA are significantly associated with rejection in the first year after transplantation. We did not identify novel variants for rejection after heart transplantation in the donor DNA. **Conclusion:** We identified two loci in the recipient that are associated with rejection. Our current sample of 945 did not yield novel loci in donor DNA. We aim to increase our sample of heart transplant donors and recipients in the near future. In addition, we will conduct cross-organ meta-analyses including lung, liver, and kidney transplants, maximizing statistical power to identify novel variants. We ultimately aim to translate genetic data into clinical applications such as more optimal genomic compatibility matching of D-R pairs and immune suppression therapy dosing.

Temporal measures on the electrocardiogram (ECG) assess distinct and heritable aspects of cardiac electrophysiology centrally important to cardiovascular health. The broad impact of several genetic loci across ECG segments suggests pleiotropy, although few studies have systematically evaluated evidence of shared effects. Using PAGE data on 33,967 participants (20% African American; 30% Hispanic/Latino; 50% Caucasian; 74% female), we therefore conducted a series of univariate genome-wide association studies (GWAS; 18,698,945 common variants imputed to the 1000 Genomes reference panel, phases 1 and 3), for each component of a temporally-decomposed average heartbeat: P-wave, PR-segment, QRS interval, ST-segment, T-wave and TP-segment. We then calculated combined phenotype effects using the adaptive sum of powered score tests. In univariate GWAS, we identified fifteen novel loci ( $P < 8.3 \times 10^{-9}$ , i.e.  $5 \times 10^{-6}$  ECG traits). Among them was rs3211938 for the TP-segment phenotype, a nonsense *CD36* mutation only common in African populations (minor allele frequency [MAF]=0.12), which given the variant's known ties to high-density lipoprotein cholesterol (HDL-C) may support hypothesized links between HDL-C and cardiac electrophysiology. We additionally identified two novel common loci when evaluating the six ECG traits in aggregate: rs12175748 (Global MAF=0.46), situated near *HEY2*, which has roles in cardiac development; and rs7136054 (Global MAF=0.31), in a locus near *HMGA2* with suspected ties to aortic root size. Identification of novel and population-specific loci underscore the value of GWAS in ancestrally diverse populations, and of the comprehensive evaluation of pleiotropic phenotypes.

**Putative loss-of-function (pLOF) genetic variants in arrhythmogenic cardiomyopathy-associated genes: Prevalence and EHR-based phenotype in 50,000 biobank participants.** C.M. Haggerty, A. Pulenthiran, T.N. Person, D.N. Hartzel, J.B. Leader, D.J. Carey, D.H. Ledbetter, S.A. Pendergrass, M.D. Ritchie, K. Manickam, M.F. Murray, B.K. Fornwalt on behalf of the DiscovEHR collaboration. Geisinger Health System, Danville, PA.

Arrhythmogenic cardiomyopathy (ACM) is associated with genetic variants in desmosome genes. Incidental findings of pathogenic/likely pathogenic (P/LP) variants in these genes, and select non-desmosomal genes, are recommended for clinical return; however, their prevalence and associated phenotype in the general population are not entirely known. Missense variants are relatively common, have uncertain physiologic significance (absent other data, such as curation in ClinVar), and were recently reported to demonstrate no disease phenotype in electronic health records (EHR). In contrast, pLOF variants are less common and may have a greater impact on traits and diseases. This study characterized the prevalence of ACM pLOF variants coupled with EHR data from 50,726 subjects with exome sequencing. We identified all participants from the Geisinger-Regeneron DiscovEHR Collaboration with rare (MAF $\leq$ 0.00075) variants annotated as "high" impact by Ensembl's Variant Effect Predictor in Refseq canonical transcripts, or with 2-star P/LP designation in ClinVar in the following genes: *DSC2*, *DSG2*, *DSP*, *PKP2*, *JUP*. Two-star P/LP ClinVar variants in *TMEM43* and *TGF $\beta$ 3* were also included. We excluded all variants occurring in the terminal exon, and all benign or "uncertain significance" variants in ClinVar. Phenotype data for all patients carrying variants meeting these criteria were retrieved, inclusive of EHR diagnoses, electrocardiograms (EKG), and echocardiograms. Age and sex-matched controls were selected for Bonferroni-adjusted two-sample comparisons. We identified 123 subjects carrying 1 of the 64 variants meeting the specified criteria. Distribution of variants and patients among genes is shown in the Table. Most variants resulted in a frameshift (n=24), stop gain (18), or splice donor/acceptor change (19). The subjects were 60 $\pm$ 17 years old, 63% female, and 87% alive. Based on diagnostic codes and chart review of recent physician notes, none of these individuals had a clinical diagnosis of ACM. Furthermore, comparison of available EKG and echocardiogram measures did not reveal significant quantitative differences with variant-negative control subjects. In conclusion, 1 in 412 subjects in the DiscovEHR cohort has a pLOF variant associated with ACM, but no ACM diagnoses. The phenotypic consequences remain to be determined from prospective clinical evaluation.

Distribution of ARVC variants		
	Variant count	Subject count
<i>DSP</i>	18	26
<i>DSG2</i>	13	35
<i>DSC2</i>	11	17
<i>PKP2</i>	18	34
<i>JUP</i>	3	10
<i>TMEM43</i>	1	1
<i>TGF<math>\beta</math>3</i>	0	0

## 2694F

**Breast cancer clinical trial of chemotherapy and trastuzumab: Potential tool to identify cardiac modifying variants of dilated cardiomyopathy.** *N. Norton<sup>1</sup>, D.J. Serie<sup>2</sup>, J.E. Crook<sup>2</sup>, B.M. Necela<sup>1</sup>, B.C. Axenfeld<sup>1</sup>, T.J. Dockter<sup>3</sup>, G. Colon-Otero<sup>4</sup>, E.A. Perez<sup>1</sup>, E.A. Thompson<sup>1</sup>.* 1) Cancer Biology, Mayo Clinic FL, Jacksonville, FL; 2) Health Sciences Research, Mayo Clinic, Jacksonville, FL; 3) Health Sciences Research, Mayo Clinic, Rochester, MN; 4) Hematology/Oncology, Mayo Clinic, Jacksonville, FL.

Doxorubicin and the ERBB2 targeted therapy, trastuzumab are routinely used in the treatment of HER2+ breast cancer. In mouse models, doxorubicin is known to cause cardiomyopathy and conditional cardiac knock out of *ErbB2* results in dilated cardiomyopathy and increased sensitivity to doxorubicin induced cell death. In humans, these drugs also result in cardiac phenotypes, but severity and reversibility is highly variable. We examined association of decline in LVEF at 15,204 SNPs spanning 72 cardiomyopathy genes, in 800 breast cancer patients who received combination doxorubicin and trastuzumab. For 7,033 common SNPs (MAF>0.01) we performed single marker linear regression. For all SNPs, we performed gene-based testing with SKAT, SKAT-O and SKAT-common/rare under rare variant non-burden, rare variant optimized burden and non-burden tests and combination of rare and common variants respectively. Single marker analyses identified seven missense variants in *OBSCN* ( $p=0.0045-0.0009$ , MAF=0.18-0.50) and two in *TTN* ( $p=0.04$ , MAF=0.22). Gene based rare variant analyses, SKAT and SKAT-O, performed very similarly (*ILK*, *TCAP*, *DSC2*, *VCL*, *FXN*, *DSP* and *KCNQ1*,  $p=0.042-0.006$ ). Gene-based tests of rare/common variants were significant at the nominal 5% level for *OBSCN* as well as *TCAP*, *DSC2*, *VCL*, *NEXN*, *KCNJ2* and *DMD* ( $p=0.044-0.008$ ). Our results suggest that rare and common variants in *OBSCN*, as well as in other genes, could have modifying effects in cardiomyopathy.

**APOL1 coding variants are associated with incident cardiovascular disease in community-dwelling African Americans.** *C.A. Winkler<sup>1</sup>, M. Irwin<sup>2</sup>, N. Chaudhary<sup>2</sup>, M. Cushman<sup>3</sup>, N. Zaka<sup>3</sup>, S. Limou<sup>4</sup>, N. Pamir<sup>5</sup>, A. Reiner<sup>6</sup>, R. Naik<sup>7</sup>, M. Sale<sup>8</sup>, G. Nelson<sup>1</sup>, M.M. Safford<sup>6</sup>, H. Hyacinth<sup>10</sup>, S. Judd<sup>8</sup>, O. Gutierrez<sup>11</sup>, J.B. Kopp<sup>12</sup>, Reasons for Geographic and Racial Differences in Stroke (REGARDS).* 1) National Cancer Institute, Leidos Biomedical Research Inc., Frederick National Laboratory, Frederick, MD; 2) University of Alabama at Birmingham, Birmingham, AL; 3) University of Vermont, Colchester, VT; 4) University of Nantes, Nantes, France; 5) Oregon Health and Science University, Portland, OR; 6) University of Washington, Seattle, WA; 7) Johns Hopkins University, Baltimore, MD; 8) University of Virginia, Charlottesville, VA; 9) Weill Cornell Medicine, New York, NY; 10) Aflac Cancer and Blood Disorder Center, Children's Healthcare of Atlanta, Emory University, Atlanta, GA; 11) University of Alabama School of Medicine, Birmingham, AL; 12) NIDDK, NIH, Bethesda, MD.

**Background:** *APOL1* renal risk variants are strongly associated with chronic kidney disease in African Americans (AA), but associations with incident cardiovascular disease (CVD) are conflicting. **Methods:** We determined *APOL1* genotypes for 10605 AA participants with incident coronary disease (Coronary Heart Disease (CHD),  $n=323$ ), stroke ( $n=331$ ), and combined composite CVD endpoint ( $n=500$ ) enrolled in the REASONS for Geographic and Racial Differences in Stroke (REGARDS). Analyses compared those with *APOL1* high-risk genotypes (2 risk alleles) to *APOL1* low-risk genotypes (0/1 risk alleles) in Cox models adjusted for CVD risk factors and ancestry principal components. **Results:** *APOL1* HR participants were younger and more likely to have albuminuria than low-risk participants. The risk of incident stroke, CHD, or composite CVD endpoint did not differ significantly by *APOL1* genotype in multivariable models. However, the association of *APOL1* high-risk genotype with the composite CVD outcome differed by diabetes status ( $P=0.01$ ) in fully adjusted models. This association appeared to be driven by incident stroke. In contrast, *APOL1* HR status was associated with a trend towards lower risk of CVD in diabetics. **Conclusion:** *APOL1* high-risk status is associated with higher incidence of incident stroke and CVD disease in individuals without diabetes, whereas *APOL1* HR status appeared to lower risk in patients with diabetes.

Hazard ratios (95% CI) of incident CVD in APOL1 HR vs. LR status		
Model*	N <sub>events</sub> /N <sub>at risk</sub>	HR (95% CI)
<b>No diabetes</b>		
Stroke	197/6621	2.32 (1.33, 4.07)
CHD	174/6173	1.31 (0.08, 2.10)

Lipoprotein(a), Lp(a), is a highly heritable, independent causal risk factor for coronary heart disease. Lp(a) is influenced by 5.5kb kringle IV-2 copy number repeats (KIV2-CN), and single nucleotide polymorphisms (SNPs) at the LPA locus. The distinct phenotypic consequences of KIV2-CN and SNPs at the LPA locus are unknown. Here, we address this question using a combination of deep (<30x) WGS and array genotyping data from 6,440 Finns from FINRISK study and performed genome-wide association analyses (PheWAS) of distinct LPA variant classes with 10 incident clinical outcomes and 100 metabolic biomarkers. In addition to directly genotyped KIV2-CN for 455 individuals, to impute KIV2-CN to the rest of the cohort we develop a novel LASSO-based approach to impute KIV2-CN using directly genotyped KIV2-CN from the imputation reference panel of 2,215 whole genome sequenced Finns. Genotyped and imputed KIV2-CN were highly correlated ( $r^2=0.6$ ,  $p=1.06e-9$ ) and we observed a strong negative association between Lp(a) and predicted KIV2-CN ( $-0.087$  SD per CN,  $p=5.48e-281$ ). While both KIV2-CN and SNPs in the LPA region are known to associate with Lp(a) levels individually, their effects have not been extensively compared together in a PheWAS. Here, we accomplish this by using 3 main weighted genetic components: 1) a genetic risk score (GRS) independent of KIV2-CN using 400 independent SNPs from LPA region, 2) a KIV2-CN score, and 3) a combined score (GRS+KIV2-CN) incorporating both (1) and (2). Using the 3 genetic components, Mendelian randomization was performed to infer the causality between Lp(a) and 10 incident clinical events. Interestingly, we found that the association between Lp(a) and cardiovascular disease is associated with GRS ( $p=6.46e-8$ ,  $HR=1.30$ ), but not the KIV2-CN repeats ( $p=0.6$ ,  $HR=1.03$ ). Furthermore, association of the 3 genetic components across 100 metabolites found 9 significant associations ( $p<0.0009$ ) with the GRS, 6 with the KIV2-CN and 15 with the GRS+KIV2-CN. Biomarkers associated with KIV2-CN were almost entirely blood lipid related whereas those associated with the GRS, in addition to blood lipid related biomarkers, were related to phospholipid and fatty acid metabolism. In conclusion, we observe the distinct associations of KIV2-CN and SNP GRS from the LPA region with Lp(a) as well as with other cardiometabolic biomarkers and diseases. These findings can potentially highlight the various roles Lp(a) plays in metabolism and cardiovascular diseases.

**Introduction:** Obstructive Sleep Apnea (OSA) is a common disorder characterized by recurrent episodes of upper airway obstruction causing sleep fragmentation and hypoxemia. OSA increases the risk of cardiovascular outcomes including hypertension, heart failure, coronary heart disease and all-cause mortality. Its etiology is multi-factorial, with growing evidence that abnormalities in respiratory arousal threshold contribute to disease susceptibility. Respiratory arousability can be approximated by measuring the average length of apneas and hypopneas during sleep. A recent large observational study found that shorter event duration, driven by enhanced arousability or chemoreflex, predicted mortality. High event duration heritability has been reported in both African- and European-American family studies ( $h^2=0.6$ ,  $0.4$  respectively), indicating a strong genetic basis of this trait. Despite its clinical promise, the underlying genetic etiology of event duration is still under studied. **Methods:** To search for novel genes associated with OSA, we performed a genome-wide trans-ethnic meta-analysis of event duration using polysomnography data collected from multiple large cohorts ( $N=18,420$ ): including ARIC, CFS, CHS, FHS, HCHS/SOL, JHS, MESA, and MrOS-Sleep. Imputed SNPs in individual cohorts were analyzed using a linear mixed model, adjusting for age, sex, BMI, population structure, and family/cryptic relatedness. Fixed effect meta-analysis was performed across ethnic groups. Secondary analyses stratified by sex and population (within African- and European-Americans) were also performed. Replications were conducted on an independent European-Australian clinical cohort (WASHS;  $N=1,645$ ). **Results:** Mean event duration spanned 18.5 to 26.9 seconds across cohorts. We observed shorter event duration in females than males and in African-Americans. We identified a genome-wide significant locus (led by rs204544;  $p=1.74 \times 10^{-8}$ ; chr19:44449585; ZNF229) in meta-analysis that was replicated in WASHS ( $p=4.56 \times 10^{-3}$ ). Three additional genome-wide significant associations were identified in sex-specific and population-specific analyses ( $p<5 \times 10^{-8}$ ). **Conclusion:** This is the first GWAS ever performed on apnea/hypopnea length across populations. Elucidating the genetic determinants for this physiologically-based novel endophenotype may help identify molecular mechanisms influencing respiratory control relevant to OSA and other sleep and respiratory traits.

**2698W**

**Fitness, physical activity, and cardiovascular disease: Longitudinal and genetic analyses in the UK Biobank Study.** E. Tikkanen<sup>1</sup>, S. Gustafsson<sup>2</sup>, E. Ingelsson<sup>1</sup>. 1) Stanford University, Stanford, CA; 2) Uppsala University, Sweden.

**Background:** Exercise is inversely related with cardiovascular disease (CVD), but large-scale studies of incident CVD events are lacking. Moreover, little is known about genetic determinants of fitness and physical activity, and modifiable effects of exercise in individuals with elevated genetic risk of CVD. Finally, causal analyses of exercise traits are limited. **Material and Methods:** We estimated associations of grip strength, physical activity, and cardiorespiratory fitness with CVD and all-cause death in up to 502,635 individuals from the UK Biobank. We also examined these associations in individuals with different genetic burden on coronary heart disease (CHD) and atrial fibrillation (AF). Finally, we performed genome-wide association study (GWAS) of grip strength and physical activity, as well as Mendelian randomization analysis to assess the causal role of grip strength in CHD. **Results:** Grip strength, physical activity, and cardiorespiratory fitness showed strong inverse associations with incident cardiovascular events and all-cause death (for composite CVD; HR, 0.78, 95% CI, 0.77-0.80; HR, 0.94, 95% CI, 0.93-0.95, and HR, 0.67, 95% CI, 0.63-0.71, per SD change, respectively). We observed stronger associations of grip strength with CHD and AF for individuals in the lowest tertile of genetic risk ( $P_{\text{interaction}}=0.006$ ,  $P_{\text{interaction}}=0.03$ , respectively), but the inverse associations were present in each category of genetic risk. We report 27 novel genetic loci associated with grip strength and 2 loci with physical activity, with the strongest associations in *FTO* (rs56094641,  $P=3.8 \times 10^{-24}$ ) and *SMIM2* (rs9316077,  $P=1.4 \times 10^{-9}$ ), respectively. By use of Mendelian randomization, we provide evidence that grip strength is causally related to CHD (OR = 0.56, 95% CI 0.44-0.70,  $P=1.4 \times 10^{-7}$ ). The results remained similar in sensitivity analyses **Conclusions:** Maintaining physical strength is likely to prevent future cardiovascular events, also in individuals with elevated genetic risk for CVD.

**2699T**

**Large-scale genomic study of >26,000 MyCode participants uncovers novel loci for hemostasis.** J. Backman<sup>1</sup>, S. McCarthy<sup>1</sup>, M. Puurunen<sup>1</sup>, S. Setia<sup>2</sup>, D. Carey<sup>2</sup>, D. Ledbetter<sup>2</sup>, M. Ritchie<sup>2</sup>, J. Reid<sup>1</sup>, J. Overton<sup>1</sup>, O. Gottesman<sup>1</sup>, A. Baras<sup>1</sup>, F. Dewey<sup>1</sup>, T. Teslovich<sup>1</sup>. 1) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

Venous thromboembolism (VTE), consisting of deep venous thrombosis and pulmonary embolism, is a recurrent and debilitating disease characterized by the formation of blood clots in veins. Family-based studies suggest that genetic variation is a major contributor to VTE risk. However, VTE has a complex etiology, and polymorphisms identified through GWAS account for ~5% of the heritable component of VTE, providing limited insight into genetic underpinnings of the disease. The identification of novel genetic variants that influence VTE risk may illuminate new therapeutic targets and guide the way to safer and more effective alternatives to current therapies for VTE prophylaxis and treatment. Endophenotypes such as activated partial thromboplastin time (aPTT) and the international normalized ratio of prothrombin time (INR), which are well-correlated with thrombosis and measure specific and essential components of coagulation, could be leveraged to gain a more complete understanding of the genetic components of VTE risk. In this study, we utilize exome sequences and genome-wide SNP genotypes for >26,000 MyCode participants as part of the DiscovEHR collaboration to evaluate the impact of rare and common variation on hemostatic measures ascertained from electronic health records. Single variant analysis of aPTT, an *ex vivo* measure of the intrinsic coagulation pathway, led to replication of variants in well-established coagulation loci (near *F5*, *KNG1*, *ABO*, *HLA-DQA1*, *F11*, *F12*) as well as the discovery of a novel association ( $p=1.6 \times 10^{-7}$ ) with a rare (MAF<0.01) missense variant in *SLC14A1*, a glycoprotein that may influence coagulation through modulation of serum urea levels. Gene-level tests of rare loss-of-function and missense variants also identified strong associations ( $p=2.5 \times 10^{-7}$ ) for aPTT with *SLC14A1* and a second gene with no established role in hemostasis (*TOP3B*;  $p=1.4 \times 10^{-6}$ ). Analyses of 3 additional hemostatic measures (INR, Protein C, and Protein S) replicated associations in well-known loci (near *F5*, *F7*, *F2*, *F10*, *PROZ*, *PROCR*), uncovered additional putatively novel variants within these loci, and led to the discovery of 6 novel loci associated with coagulation phenotypes. These findings have potential to improve our understanding of the mechanisms contributing to hemostasis and thrombosis, and follow-up is currently underway to independently replicate these results and extend analysis to risk of clinically-important thrombotic events, including VTE.

**2700F****Cross-exposure multivariate interaction tests.** *J. Kim, P. Kraft, H. Aschard.*

Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA.

Gene-environment (GxE) interaction has proven difficult to identify in human traits and diseases, and various strategies have been proposed to increase statistical power. Recent studies showed that using multi-SNP (single nucleotide polymorphisms) approaches, aggregating genetic information into genetic risk score (GRS) and testing for GRS-by-exposure interaction, is a promising alternative to standard single-SNP-by-exposure interaction. With increasing collection of extensive genetic, phenotypic and environmental dataset, multivariate interaction approaches could be extended in many ways. Here, we assessed performances of a range of multivariate interaction approaches through simulation and real data analysis including over 37,000 individuals. We considered three strategies, 1) an unweighted GRS, 2) a weighted GRS (wGRS) where SNPs were weighted based on the marginal effects, and 3) an omnibus test where all interaction parameters were modeled separately but tested jointly. We focused on binary outcomes, using a generalized linear model. We first assessed the robustness and power in simulation with varying parameters (e.g. number of SNP, minor allele frequency (MAF), and correlation and distribution of exposures). We applied those to a dataset comprising cohorts, the Nurses' Health Study and Health Professional Follow-up Study. We considered 4 exposures (smoking, total energy intake, physical activity, and healthy eating index), 4 diseases (obesity, type 2 diabetes, hypertension, and coronary heart disease (CHD)), and SNP identified in large-scale genome-wide association studies with the diseases. All approaches showed decreasing robustness with lower MAF, increasing correlation between exposures, and increasing number of predictors in the models. However, the decrease was minimal for GRS-based approaches but much stronger for the omnibus test when the number of SNP and exposures was large (e.g.  $N_{\text{SNP}}=100$ ,  $N_{\text{exposure}}=10$ ,  $N_{\text{sample}}=20K$ ). Overall, wGRS tended to show better robustness over unweighted GRS, and GRS-based approaches showed higher power than single SNPs analysis. Preliminary analysis considering interactions between disease-specific wGRS and the exposures (64 combinations) identified a few nominally significant associations. The strongest signal was observed for wGRS of BMI-by-smoking interaction on CHD ( $P=0.003$ ). Further stratified analysis showed a stronger effect of BMI wGRS in smokers ( $b=0.87$ ,  $P=0.00041$ ) than in non-smokers ( $b=-0.32$ ,  $P=0.11$ ).

**2701W****A Bayesian approach for detecting gene by environment interactions with common and rare variants.** *S.M. Lutz<sup>1</sup>, J.E. Hokanson<sup>2</sup>, C. Lange<sup>3</sup>.*

1) Biostatistics, University of Colorado, Anschutz Medical Campus, Denver, CO; 2) Epidemiology, University of Colorado, Anschutz Medical Campus, Denver, CO; 3) Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA.

For genetic association studies of common and rare variants, the number of genes and environmental factors is potentially large. Stratifying by environmental risks factors results in a decrease in sample size and can potentially and substantially decrease the power. A full model that includes all interactions and main effects can be unstable or non-identifiable, especially for sparse genetic data. As a result, we propose a Bayesian hierarchical mixture model that allows for all interactions to be investigated simultaneously. We propose a mixture prior with two components: a null distribution and an alternative distribution based on biological plausibility. We allow for a spike and slab prior that alternates between the two prior distributions. The proposed prior framework is very flexible and allows for substantive information to be incorporated into the analysis. Through simulation studies, we show that our Bayesian approach has an increased ability to detect gene by environment interactions for rare and common variants compared to the standard methodology which do not readily incorporate this information. We apply this approach to the COPDGene study, a case-control study of Chronic Obstructive Pulmonary Disease (COPD) in current and former heavy smokers to examine gene by gender interactions for subclinical atherosclerosis.

**StructLMM: Resolving genetic effects due to environmental sample substructure.** R. Moore<sup>1,2</sup>, F. Casale<sup>2</sup>, I. Barroso<sup>1</sup>, O. Stegle<sup>2</sup>. 1) Human Genetics, Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) European Bioinformatics Institute, Hinxton, Cambridge, United Kingdom.

Genotype-environment interactions (GxE) are common and manifest in variation of genetic effects across individuals. Accounting for interactions due to exposures, such as diet, smoking status and other lifestyle covariates, within genetic analyses can increase power and provide insights into the interplay between genetic and environmental factors. Whilst there have been numerous attempts to identify GxE effects in population cohorts, existing analysis approaches predominantly consider individual environments one-by-one, or consider discretised subgroups. These strategies entail a severe multiple-testing burden and may miss out on more subtle sample substructure. To address this, we propose StructLMM, a method based on linear mixed models that allows for integrating tens or even hundreds of continuous and/or discrete environmental variables in a joint genetic analysis of GxE. Technically, this is achieved by defining a hierarchical prior on genetic effect sizes between individuals, which allows for generalising association tests and identifying interactions. Our method is computationally efficient, facilitating the analysis of up to hundreds of thousands of samples and hundreds of environments. We first validated our model using simulations, finding increased power for detecting both association and interactions. We then applied StructLMM to 83,028 individuals from UK Biobank, testing for associations and interactions between genetic variants and a broad range of lifestyle factors, affecting BMI. In addition to recovering well-known BMI risk loci such as FTO, MC4R and TMEM18, we identify one novel association downstream of ADAMEC1 and upstream of ADAM7. Our model also retrieves significant GxE for loci that have been linked to GxE, including FTO and SEC16B, the latter has only been reported as nominally significant, and novel interaction effects for ADAM7 variants. Finally, StructLMM can be used to dissect environmental factors that drive the identified GxE signals. We find that distinct environments underlie GxE of individual loci, and consistently find that a model that combines multiple environments, better explains the data than any single-environment model. This indicates that GxE is complex and tends to involve a combination of different environmental, thereby highlighting the value of our approach, enabling the exploration of GxE in deeply phenotyped population cohorts such as UK Biobank.

**Colocalization of gene-psychosocial interactions identifies novel genomic regions for blood pressure among African Americans.** M.A. Richard<sup>1</sup>, S.K. Musani<sup>2</sup>, M. Sims<sup>2</sup>, M. Fornage<sup>1</sup> on behalf of the CHARGE Gene-Lifestyle Interactions Working Group. 1) Brown Foundation Institute of Molecular Medicine, The University of Texas Health Science Center, Houston, TX; 2) Department of Medicine, University of Mississippi School of Medicine, Jackson, MS.

Psychosocial factors are becoming recognized as risk factors for cardiovascular disease, particularly among minority populations, but it is unclear to what extent they modify genetic associations with blood pressure (BP). Depression and perceived social support are interrelated and we hypothesized that BP associations identified by accounting for genetic interaction with either depression or social support are consistent with a shared causal variant. In the CHARGE Gene-Lifestyle Interactions Working Group, depression and social support were measured in up to 14,922 individuals of African ancestry in nine cohorts. We performed one degree of freedom (df) single nucleotide polymorphism (SNP) main effect tests and joint two df tests of the SNP main effect and SNP-psychosocial interactions for systolic BP, diastolic BP, mean arterial pressure, and pulse pressure. Bayesian colocalization was performed 500 kb up and downstream of 2,950 regions at least nominally associated with BP in the analyses of individual psychosocial factors ( $P < 1E-5$  for 1df SNP main effect or 2df test). We identified 21 genomic regions with posterior probabilities (PP) favoring a colocalized gene-psychosocial interaction: 1) the 2df test had strong evidence of colocalization ( $PP_{2df} > 0.8$ ), and 2) the 2df test improved the colocalization PP beyond the main effect analysis ( $PP_{2df} - PP_{main} > 0.2$ ). Many colocalized signals map to genes previously implicated in neuropsychiatric traits, such as schizophrenia, bipolar disorder, suicide risk, and response to antipsychotic medications (*PZDZ2*, *NAV3*, *AIG1*, *EPAS1*, *NRCAM*, *SORBS1*, and *CACNA1C*). We additionally identified evidence of colocalized psychosocial interactions at known BP loci (*SLC39A13* and *L3MBTL4*) and cardiac loci (*RYR2* and *B3GAT2*). Thirteen of the colocalized regions are driven by low frequency or African-specific alleles and eight regions harbored common variation. By identifying shared genetic variants influencing BP in the context of psychosocial factors, these results may help to explain the possible biological connection between psychological and cardiovascular health. We have identified novel candidate genes for BP that may help guide the development of new treatment and prevention strategies aimed at reducing health disparities in African Americans. Supported by HL118305.

**Race, sex, and age differences in GxE association: *EBF1* gene-by-stress interaction on central obesity differs among Blacks, Whites and male, female in multiple harmonized datasets.** A. Singh<sup>1</sup>, M.A. Babyak<sup>1</sup>, M. Sims<sup>2</sup>, S.K. Musani<sup>2</sup>, B.H. Brummett<sup>1</sup>, R. Jiang<sup>1</sup>, I.C. Siegler<sup>1</sup>, E.R. Hauser<sup>1</sup>, R.B. Williams<sup>1</sup>. 1) Duke University Medical Center, Durham, NC, USA; 2) University of Mississippi Medical Center, Jackson, MS, USA.

In a precision medicine framework, it is critical to consider several factors, such as, individual's genetic and molecular makeup; complex physiological aspects of race, sex, and age; and how these factors may interact with environmental factors. In our previous study [Singh et al., *EJHG*, 2015] we identified a novel CVD risk gene *EBF1* in MESA White samples, where a common variant (rs4704963) contributed to inter-individual differences in central obesity (hip, waist, and BMI) in the presence of chronic psychosocial stress. In a subsequent study [Singh et al., *Gen Epi*, 2015], we presented an algorithm to build a synthetic measure of stress using the proxy indicators of its components (items) and replicated the *EBF1* x stress interaction in additional datasets. In the current study, we evaluated race, sex, and age differences in the *EBF1* x stress interaction on central obesity traits in nine datasets (MESA, FHS, ARIC, CARDIA, WHI, Jackson Heart Study (JHS), Family Heart Study, CATHGEN, and Duke Caregiver Study). Using a MESA-like 5-component harmonized synthetic stress measure, we replicated ( $P < 0.05$ ) the *EBF1* x stress interaction in White women of all datasets except CARDIA which was the youngest cohort (mean age 25 years). We were not able to replicate the *EBF1* x stress interaction on obesity traits in Black participants of any dataset except in JHS where we observed a significant ( $P=0.02$ ) *EBF1* x stress interaction on waist circumference in Black women using an 8-component stress measure. We hypothesized that a MESA-like 5-component stress measure might not be sufficient to capture the chronic stress in everyday life among the Black participants; and that one or more additional stress component(s) or an existing component but evaluated differently (specifically, 'racism/discrimination' and 'not meeting basic needs') may have contributed in observing the relationship between stress, *EBF1*, and central obesity. The *EBF1* interaction *P*-values for individual items 'racism/discrimination' and 'not meeting basic needs' in JHS Black women were 0.036 and 0.053, respectively, suggesting that the 5-component synthetic MESA-like measure is missing elements related to psychosocial stress in Black participants. In conclusion, this study elucidates the race, sex, and age related differences in the *EBF1* x stress interaction and demonstrates the need for careful evaluation of environmental measures in different ethnicities in cross-ethnic gene-by-stress interaction studies.

**Introduction:** Genome-wide association analysis has advanced understanding of blood pressure (BP), a major public health priority with implications for vascular conditions such as coronary heart disease and stroke. Incorporating gene-environment interactions in genome-wide analysis represents an additional route for discovery of BP loci and extending our knowledge of its genetic architecture. **Methods:** We performed genome-wide meta-analyses of systolic and diastolic BP incorporating gene-smoking interactions in up to 610,091 individuals from five ancestries. Stage 1 meta-analyses examined ~18.8 million SNPs and small insertion/deletion (indel) variants among 129,913 individuals from four ancestries (European, African, Asian, and Hispanic). Ancestry-specific meta-analyses were performed using inverse-variance weighting with the 1 degree of freedom (DF) test of interaction effect and the 2 DF joint test of genetic main and interaction effects. The ancestry-specific results were then combined through meta-analysis to obtain evidence of "trans-ancestry" association. Stage 2 analyses examined the top variants selected from Stage 1 (with  $P < 10^{-6}$ ) among 480,178 additional individuals from five ancestries. **Results:** Stage 1 meta-analyses identified 1,993 genome-wide significant ( $P < 5 \times 10^{-8}$ ) and 2,466 suggestive ( $P < 10^{-6}$ ) variants. Among these 114 genome-wide significant loci in Stage 1, 14 novel and 39 known BP loci were replicated in Stage 2 even after accounting for multiple testing. A joint meta-analysis of Stage 1 and Stage 2 results identified 69 additional novel loci and 17 additional known loci ( $P < 5 \times 10^{-8}$ ). **Conclusion:** This first large-scale multi-ancestry investigation of gene-smoking interactions validated 56 known BP loci and identified 83 novel loci. Several novel loci were identified through African ancestry analysis, highlighting the importance of pursuing genetic studies in diverse populations. The novel loci show strong regulatory features and evidence for shared pathophysiology with cardiometabolic traits and addiction traits including smoking. In addition, they highlight a role in BP regulation for biological candidates such as modulators of vascular structure and function (*CDKN1B*, *BCAR1-CFDP1*, *PXDN*, *EEA1*), ciliopathies (*SDCCAG8*, *RPGRIP1L*), telomere maintenance (*TNKS*, *PINX1*, *AKTIP*), and central dopaminergic signaling (*MSRA*, *EBF2*).

## 2706F

**GWAS of red cell distribution width identifies discovery associations at GCNT4, KCNJ3, and chr6p22.1 in admixed U.S. populations: The PAGE Study.** C.J. Hodonsky<sup>1</sup>, K.N. Loos<sup>11,12,13</sup>, B. Thyagarajan<sup>14</sup>, C.L. Wassel<sup>15</sup>, A.P. Reiner<sup>1</sup>, K.E. North<sup>1,9</sup>, C. Kooperberg<sup>7</sup>, C.L. Avery<sup>1</sup>. 1) Epidemiology, University of North Carolina Gillings School of Public Health, Chapel Hill, NC; 2) Epidemiology Department, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) Department of Biostatistics, Vanderbilt University, Nashville, TN; 4) Department of Statistics and Biostatistics, Rutgers University, New Brunswick, NJ; 5) National Institutes of Health, National Human Genome Research Institute, Office of Population Genomics, Bethesda, MD; 6) Department of Epidemiology, University of Washington, Seattle, WA; 7) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 8) Department of Biostatistics, University of North Carolina Gillings School of Public Health, Chapel Hill, NC; 9) Department of Genetics, University of North Carolina Chapel Hill, Chapel Hill, NC; 10) Department of Computer Science, University of North Carolina Chapel Hill, Chapel Hill, NC; 11) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York City, NY; 12) The Genetics of Obesity and Related Metabolic Traits Program, The Icahn School of Medicine at Mount Sinai, New York City, NY; 13) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York City, NY; 14) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 15) Department of Pathology and Laboratory Medicine, University of Vermont Larner College of Medicine, Burlington, VT.

**Background:** Red cell distribution width (RDW) is one of several heritable indices associated clinically with cardiovascular disease outcomes, including stroke and myocardial infarction, and for which large-scale genetic characterization remains incomplete. We thus conducted a genome-wide association study (GWAS) of RDW in Population Architecture using Genomics and Epidemiology (PAGE II) participants genotyped on the Multiethnic Genotyping Array (MEGA). **Methods:** The Illumina MEGA platform was designed to improve common and low frequency variant discovery and fine-mapping in global populations. Approximately 19,000 PAGE participants (19% African American, 81% Hispanic/Latino, 65% female) with RDW measurement and MEGA genotyping were available. We conducted a GWAS of inverse-normal-transformed RDW and ~30 million genotyped and imputed (1000 Genomes Phase 3) autosomal variants in PAGE II participants. For discovery, we define a locus as +/-250kb of a published lead variant. Linear regression models were adjusted for age, sex, study, study center, self-reported race/ancestry, family structure (when applicable), and ten ancestral principal components. **Results:** We identified 13 genome-wide significant ( $p < 5 \times 10^{-8}$ ) associations, including three discovery loci: *KCNJ3* (chr2q24.1, PAGE coded allele frequency [CAF]=0.002, variant specific to African haplotypes), *GCNT4* (chr5q13.3, PAGE CAF=0.28; 1000 Genomes population CAFs range from 0.02 [AFR] to 0.41 [EUR]); and an indel in the histone region (chr6p22.1, CAF=0.09). Six published RDW loci (*SLC12A7*, *SLC12A2*, *PSMB5*, *DNAJA4/WD61*, *HBA1/2*, and *TMPRSS6*) and four loci previously associated with other correlated RBC traits (*TFRC*, *HFE*, *HBS1L/ MYB*, and *HBB*) also displayed genome-wide significant associations with RDW in our study population. **Discussion:** Our identification of novel associations underscores the benefits of performing GWAS in ancestrally diverse populations, using arrays that better capture global genetic variation. This opportunity for improved discovery and fine-mapping is highlighted in allele frequency variation by ancestry of all three lead discovery variants, particularly the rare, African-specific SNP at the *KCNJ3* locus. Characterization of the *DNAJA4/WD61* locus is also merited, as *WD61* has a known role in hematopoiesis, and several variants in the *DNAJA4* coding region are trans-eQTLs for *BCL11A*, a beta-globin transcription factor. *In silico* functional characterization of all significant loci is ongoing.

## 2707W

**Cadmium exposure, MT polymorphisms and subclinical cardiovascular disease in American Indians: The Strong Heart Family Study.** R. Hou<sup>1</sup>, M. Tellez-Plaza<sup>2</sup>, G. **Background:** Exposure to cadmium (Cd) has been associated with all cause- and cardiovascular disease (CVD) mortality in the United States. The major sources of Cd exposure are food intake and cigarette smoking. Metallothioneins (MTs) play an important role as scavengers of excessive Cd, however, the effect of variant MT-encoding genes on Cd toxicity is unknown. American Indians have premature, exaggerated CVD mortality compared to the general population and have a higher Cd burden. **Aims:** To assess common genetic effects on urinary Cd (a measure of total body burden) and CVD outcomes, and to assess the association between urinary Cd and single nucleotide polymorphisms (SNPs) in MT-encoding genes in American Indian participants of the Strong Heart Family Study (SHFS). **Methods:** 2000 SHFS participants aged >14 years were stratified by study site location (Dakotas, Oklahoma or Arizona) and 19 MT gene SNPs were genotyped. Association was assessed using measured genotype analysis accounting for family relationships. We also estimated correlations between urinary Cd and subclinical CVD measured by electrocardiogram, echocardiogram and carotid ultrasound. **Results:** Significant genetic correlations were found between urinary Cd and QRS duration ( $\rho$  (SE) = 0.46 (0.22),  $p < 0.05$ ) in the Dakota and Oklahoma study centers. When stratified by sex, dietary zinc status or smoking status, the genetic correlation between urinary Cd and QRS duration was significant only in women ( $\rho$  (SE) = 0.53 (0.29),  $p < 0.05$ ) and men and women smokers ( $\rho$  (SE) = 0.54 (0.26),  $p < 0.05$ ) in the Dakotas. Significant genetic associations were found between urinary Cd and rs8044791 ( $\beta$  (SE) = 0.29 (0.09),  $p = 0.002$ ) and rs2301234 ( $\beta$  (SE) = -0.12 (0.05),  $p = 0.02$ ) in the Dakotas only. **Conclusions:** Urinary Cd is influenced by MT SNPs and is associated with prolonged QRS duration in American Indian women in the SHFS. Given that QRS duration is an independent predictor of CVD events in American Indian women, assessment of Cd exposure may be useful as a unique CVD risk factor in difficult to assess populations with a high lifetime risk of CVD.

**2708T****Genome-wide association study of mitochondrial DNA copy number: The Cohorts for Heart & Aging Research in Genetic Epidemiology (CHARGE).**

R.J. Longchamps<sup>1</sup>, J.A. Lane<sup>2</sup>, M.L. Grove<sup>3</sup>, K.S. Lawson<sup>3</sup>, E. Boerwinkle<sup>3</sup>, N. Pankratz<sup>2</sup>, D.E. Arking<sup>1</sup>, CHARGE Aging and Longevity Working Group. 1) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 3) School of Public Health, Human Genetics Center, The University of Texas Health Science Center at Houston, Houston, TX.

Mitochondria, the key organelle involved in energy production, have long been proposed to play a critical role in human disease and aging. A considerable amount of inter-individual variation exists in the number of mitochondrial genomes per individual, also known as mitochondrial DNA copy number (mtDNA CN). As an easily accessible marker for mitochondrial function, mtDNA CN provides us with the ability to assess the role of the mitochondria in disease. Recent work has found mtDNA CN declines with age and is associated with frailty, coronary artery disease (CAD), sudden cardiac death, and overall mortality. Here, we report interim results from a genome wide association study (GWAS) to identify genetic determinants of mtDNA CN, as well as efforts to determine the causality of mtDNA CN in CAD utilizing Mendelian Randomization (MR). Interim analyses consist of 41,908 individuals (18.2% Black, 2.8% Hispanic, 1.8% Chinese), with an expectation of an additional 52,310 samples by September. mtDNA CN was either estimated from microarray raw probe intensities via the Genvisis software package or from an optimized qPCR Taqman assay. Our final mtDNA CN phenotype is represented as the standardized residuals from a race stratified linear regression adjusting for location and age at which DNA was collected, sex, white blood cell (WBC) count, platelet (PLT) count as well as qPCR plate (qPCR) or PCs generated from nuclear probe intensities (microarray). GWAS were also race stratified and adjusted for age, location, sex, WBC and PLT count as well as GWAS PCs. Meta-analysis was performed using the Metal software package. Interim meta-analyses in whites (n = 32,300) identify one genome-wide significant locus (rs10432360), lying downstream of *ZEB2*, which encodes a zinc finger protein responsible for transcriptional repression. Additionally, we observe an enrichment of loci with p-values < 5e10-7 (3 expected, 6 observed). No loci reached genome-wide significance in other ethnic groups, however power was low due to our current sample size. Interim MR analysis in whites reveals no significant causal relationship between mtDNA CN and CAD (beta = -0.016, p-value = 0.17), however the direction of effect suggests increased mtDNA CN may mitigate CAD risk. Doubling of our sample size may identify additional genome-wide significant loci and further elucidate whether there is a causal relationship between mtDNA CN and CAD.

**2709F****"Genotype-phenotype in Marfan syndrome patients with causative mutations in the calcium binding region of the 43 cbEGF-like domains in fibrillin-1 gene (FBN1)".**

J.A. Aragon-Martin<sup>1</sup>, Y.B.A. Wan<sup>1</sup>, L.N.A. Belkacem<sup>1</sup>, A. Samoto<sup>1</sup>, A. Masoha<sup>1</sup>, Y. Isekame<sup>1</sup>, C.S. Gracias<sup>1</sup>, P. Mazadza<sup>1</sup>, T. Thayalacumar<sup>1</sup>, A. Chandra<sup>2</sup>, D.G. Charteris<sup>3</sup>, A. Saggarr<sup>4</sup>, M. Jahangiri<sup>5</sup>, A.H. Child<sup>1</sup>. 1) Cardiovascular and Cell Sciences Research Institute, St George's University of London, London, England, United Kingdom; 2) Southend University Hospital, Southend on Sea, United Kingdom; 3) Vitreoretinal Surgery, Moorfields Eye Hospital, London, United Kingdom; 4) Regional Genetics Unit, St. George's Healthcare NHS Trust, Cranmer Terrace, London, United Kingdom; 5) Department of Cardiothoracic Surgery, St. George's Healthcare NHS Trust, Cranmer Terrace, London SW17 0RE, United Kingdom.

**Background:** Marfan syndrome (MFS) is a phenotypically heterogeneous autosomal dominant monogenic connective tissue disorder due to mutations in *FBN1*. There are 43 cbEGF-like domains that contain a calcium binding region that is highly conserved in FBN1 protein. Calcium ions play a key role in the stability of these domains and increase resistance to proteolysis degradation. This study aims to observe a relationship between the genotype and phenotype in MFS patients. **Methods:** Patients (n=109) fulfilling the Ghent Criteria and with a mutation in the calcium binding region were entered in the study. Clinical data was obtained from a dedicated Marfan Clinic at St George's Hospital and the genotypes from the *FBN1* mutation-screening database in the Sonalee Laboratory. A genotype-phenotype database was created with this data. **Results:** This study found that MFS phenotypes may arise due to mutations in any of the calcium binding regions of the 43 cbEGF-like domains: – prevalence of TAA in all cb-Regions (p= 0.00021), cb-Region C (p= 0.00005), cb-Region Exon 52 (p= 0.06061), cb-Region Exon 61 (p= 0.02857) and cb-Region Exon 62 (p= 0.00191); and – prevalence of EL in cb-Region Exon 27 (p= 0.04762). Data showed that phenotypes found in calcium binding regions were EL (35%) and TAA (65%). Males were more likely to have TAA (59%) and Females EL (52%) phenotypes. **Conclusions:** The study shows **genotype-phenotype** relationship with mutations in **all** cb-Regions, **cb-Region C**, **cb-Region Exon 52**, **cb-Region Exon 61** and **cb-Region Exon 62** with **TAA**. When looking at **cb-Region Exon 27** the strongest genotype-phenotype is with **EL**. The variability in phenotypes arising from mutations in the calcium binding region could be due to a variable interaction between the amino acids in this region with the calcium molecule in the protein. Also, it could be due to other factors playing a role, such as environmental or gene modifiers that might increase or reduce the severity of the phenotype. Instability of the calcium binding region due to mutations in this part are more likely to express a TAA than an EL phenotype but the risk of TAA is still very high. Mutations in the cb-Region are not exclusive to either phenotype (TAA or EL) but rather a variable degree of expressions. Due to genetic and phenotypic variability in *FBN1* mutations it is essential to create an international database with single patient genotype-phenotype data to elucidate their relationship. Corresponding author: jaragon@sgul.ac.uk.

**Family based method for the discovery of rare high penetrance sequence variants.** G. Sveinbjornsson<sup>1,3</sup>, E.F. Olafsdottir<sup>2</sup>, R.B. Thorolfsdottir<sup>1</sup>, D.O. Arnar<sup>2</sup>, H. Holm<sup>1</sup>, D.F. Gudbjartsson<sup>1,3</sup>, K. Stefansson<sup>1,2</sup>. 1) DeCode Genetics/Amgen, Inc, Reykjavik, Iceland; 2) Faculty of Medicine, University of Iceland, Reykjavik, Iceland; 3) School of Engineering and Natural Sciences, University of Iceland Reykjavik, Iceland.

Recent advances in whole-genome sequencing has provided opportunities to discover rare, disease causing variants. However, current methods for testing rare variants segregating in families are insufficient. Here we describe a family-based method to test rare sequence variants for co-segregation with disease using data from the deCODE genetics sequencing study. We construct a score for each variant propagating in the pedigree based on the predicted functional effect of the variant and a likelihood ratio based on its co-segregation with the disease. Depending on the probability that an individual is affected given sex, year of birth, county of birth, and lifespan, affected carriers have a positive impact on the log likelihood ratio and unaffected carriers have a negative impact. Analogous to parametric linkage analysis, we assume an effect of the variant, but different from parametric linkage analysis we do not search for linkage with unknown linkage variants but test particular variants with a known set of carriers. To estimate the significance of a variant we use genome-wide simulations where we sample founders from a set of 30K whole genome sequenced Icelanders outside of the family. Using electronic medical records and the Icelandic genealogy we applied our method to a pedigree with a high load of individuals with dilated cardiomyopathy. We found a disease causing missense variant, p.Phe145Leu (genome-wide corrected  $P = 5.2 \times 10^{-5}$ , MAF 0.007%) in *NKX2-5*. For verification and deeper phenotyping we reviewed medical records of all individuals carrying the mutation revealing a high penetrance of a serious heart disease with variable expressivity.

**Association of genetic risk score with childhood obesity-related traits: The Santiago Longitudinal Cohort Study (SLCS).** G. Chittoor<sup>1</sup>, AE. Justice<sup>2</sup>, E. Blanco<sup>3</sup>, M. Graff<sup>4</sup>, Y. Wang<sup>2</sup>, C. Alcala<sup>4</sup>, JL. Santos<sup>5</sup>, B. Angel<sup>4</sup>, B. Lozoff<sup>6</sup>, VS. Voruganti<sup>1</sup>, KE. North<sup>2</sup>, S. Gahagan<sup>3</sup>. 1) Department of Nutrition, UNC Nutrition Research Institute, University of North Carolina at Chapel Hill, Kannapolis, NC, USA; 2) Department of Epidemiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA; 3) Division of Academic General Pediatrics, Child Development and Community Health at the Center for Community Health, University of California at San Diego, San Diego, CA, USA; 4) Department of Public Health Nutrition, Institute of Nutrition and Food Technology (INTA), University of Chile, Santiago, Chile; 5) Department of Nutrition, Diabetes and Metabolism, School of Medicine, Pontificia Universidad Católica de Chile, Santiago, Chile; 6) Pediatrics and Communicable Diseases, University of Michigan, Ann Arbor, MI, USA.

**Background:** GWAS of obesity-related traits have identified multiple single nucleotide polymorphisms (SNPs) associated with obesity, although most findings have been revealed in European descent populations (EUR). At the same time, the use of genetic risk scores (GRS) to summarize phenotype – SNP relationships for the prediction of disease and clinical evaluation is growing rapidly. Yet, the applicability and appropriateness of using EUR tag SNPs in GRS' constructed in ancestrally diverse populations is a subject of great importance. Therefore, we aim to investigate the association of body mass index (BMI; age and sex standardized BMI scores – BMIz) with GRS derived from EUR tag SNPs compared to population-specific tag SNPs selected from the 1 MB interval of these known loci in the Santiago Longitudinal Cohort Study (SLCS; N=770; Mean Age=10.03y; 52% boys). **Methods:** BMIz were calculated using the CDC reference (2007–2010) in SLCS participants. We identified the most significant SNP positioned within 1 MB of each of 15 GWAS findings for BMIz in our SLCS cohort. In addition to finding a better tag SNP at 12 of 15 loci (3 tag SNPs were exactly same as in EUR GWAS), we identified 7 independent association signals (22 SNPs total). We estimated simple-count GRS two ways: 1) GRS\_EUR: by summing the number of BMIz increasing risk alleles from the 15 known GWAS SNPs; and, 2) GRS\_SLCS: by summing the number of independent BMIz increasing risk alleles from the 22 SNPs in 15 loci in our SLCS cohort. Multiple linear regression of GRS and BMIz were performed adjusting for sex, and population substructure using principal components. **Results:** This diverse ancestry GRS, was constructed using 22 SNPs from known obesity loci (e.g. *SEC16B*, *OLFM4*, *TFAP2B*, *FTO*), with EAF ranging from 1% to 49%. Both GRS' were significantly associated with BMIz ( $p < 0.0001$ ), but with a better overall model fit for BMIz–GRS\_SLCS ( $R^2 = 13.7\%$ ) than BMIz–GRS\_EUR ( $R^2 = 4.3\%$ ). Importantly, GRS\_SLCS explained 10.08% of the total phenotypic variation in BMIz and GRS\_EUR explained only 0.54%. **Conclusion:** We constructed an ancestry specific GRS in a Chilean cohort with extensive admixture. The estimation of GRS–BMIz score associations using published tag SNPs displayed much poorer performance than using ancestry appropriate tags for our population of interest. Our study demonstrates the importance of selecting ancestry appropriate tag SNPs in future studies of disease prediction and clinical evaluation.

## 2712F

**New genetic variants unveiled using a predicted-VAT mass phenotype.** T. Karlsson, M. Rask-Andersen, W.E. Ek, A. Johansson. Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden.

**Purpose:** An excess of visceral adipose tissue (VAT) is associated with increased risk of cardiovascular diseases, type 2 diabetes, and mortality<sup>1</sup>, more so than other measures of fat mass like body-mass index and waist circumference<sup>2</sup>. However, as measurements of VAT mass, e.g., by dual energy X-ray absorptiometry (DXA), are both expensive and relatively time-consuming, no large-scale genome-wide association (GWA) study has yet been carried out. This study aims to investigate the effect of genetic variants on *predicted* VAT mass using data from the UK Biobank. **Methods:** To construct a nonlinear (interaction) multiple regression model for prediction, DXA-scan-measured VAT mass was regressed on a number of predictors, including age, menopausal status (women), body size and bioelectrical impedance measures. After stratification for sex, the models were calibrated on a training data set, including 4,198 individuals from the UK Biobank cohort. VAT mass was then predicted for all Caucasian participants in the UK Biobank. Finally, we performed GWA studies on *predicted* VAT mass, both for females and males separately and for the combined data set of 116,137 individuals with genotype data available at the time. We used linear regression, adjusted for age, sex (combined set), batch number and principal components. **Summary of results:** Female and male prediction models both had an adjusted  $R^2 = 0.76$  while the root-mean-squared-error (RMSE) of the predicted residuals (leave-one-out cross-validation) was  $RMSE = 0.28$  kg for females and  $RMSE = 0.47$  kg for males. In the GWA study of the combined data set, 38 loci were detected ( $p < 5 \times 10^{-8}$ ). As a confirmation of the prediction model, the majority of the previously reported loci were associated with BMI and/or obesity. However, *nine* loci were *not* found in the GWAS catalogue. The bulk of the potentially novel loci were found in close connection to genes, such as *RTN4RL1*, *ADARB1*, *ARNTL*, and *PAX2*. Moreover, a few gender-specific new loci were also detected, including one potential locus in *CLYBL* on chromosome 13, for which the effect on predicted VAT mass in males was in the opposite direction ( $p = 1.6 \times 10^{-7}$ ) to that in females. **Towards precision therapy in hypertension: Genome-wide association study reveals genetic variants associated with uncontrolled blood pressure on thiazide diuretic/beta-blocker combination therapy.** O. Magvanjav<sup>1,2</sup>, Y. Gong<sup>1</sup>, C.W. McDonough<sup>1</sup>, A.B. Chapman<sup>3</sup>, S.T. Turner<sup>4</sup>, J.G. Gums<sup>1</sup>, K.R. Bailey<sup>5</sup>, E. Boerwinkle<sup>6</sup>, A.L. Beitelshes<sup>7</sup>, T. Tanaka<sup>8</sup>, M. Kubo<sup>8</sup>, C.J. Pepine<sup>9</sup>, R.M. Cooper-DeHoff<sup>9</sup>, J.A. Johnson<sup>10</sup>. 1) Department of Pharmacotherapy and Translational Research and Center for Pharmacogenomics, University of Florida, College of Pharmacy, Gainesville, FL; 2) College of Medicine, University of Florida, Gainesville, FL; 3) Section of Nephrology, Department of Medicine, University of Chicago, Chicago, IL; 4) Division of Nephrology and Hypertension, Department of Medicine, Mayo Clinic, Rochester, MN; 5) Division of Biomedical Statistics and Informatics, Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 6) Human Genetics Center and Institute of Molecular Medicine, University of Texas Health Science Center, Houston, TX; 7) Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD; 8) RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 9) Division of Cardiovascular Medicine, Department of Medicine, University of Florida, College of Medicine, Gainesville, FL.

**Background:** Heart disease and stroke are the leading causes of death worldwide, and hypertension is the primary risk factor. The majority of hypertensive individuals require combination antihypertensive therapy to achieve adequate blood pressure control. Understanding the genetic underpinnings of differential response to common antihypertensive drugs may contribute to realizing the goal of precision therapy for hypertension. This study aimed to identify genetic variants associated with having uncontrolled or controlled blood pressure on combination therapy with a thiazide diuretic and a beta-blocker, two commonly prescribed antihypertensive drug classes. **Methods and Results:** A genome-wide association study of uncontrolled BP on combination therapy was conducted among 314 White participants of the Pharmacogenomic Evaluation of Antihypertensive Responses (PEAR) clinical trial. Multivariable logistic regression analysis was used. Genetic variants meeting a suggestive level of significance ( $p < 1.0 \times 10^{-5}$ ) were tested for replication in the International Verapamil SR Trandolapril Study (INVEST). We also examined genome-wide variant associations with systolic and diastolic blood pressure response on combination therapy and tested for replication. We discovered a variant, rs261316, at chromosome 15 in the gene *ALDH1A2* associated with a decreased probability of having uncontrolled BP on combination therapy (OR: 0.39, 95% CI: 0.26-0.59,  $p = 8.64 \times 10^{-6}$ ). This variant was replicated in INVEST (OR: 0.54, 95% CI: 0.39-0.74,  $p = 0.001$ ) and approached genome-wide significance in the meta-analysis of discovery and replication cohorts (OR: 0.46, 95% CI: 0.35-0.61,  $p = 8.60 \times 10^{-8}$ ). Other genes in the region surrounding rs261316 (*ALDH1A2*) include *AQP9* and *LIPC*. **Conclusion:** A variant in the gene *ALDH1A2* may be associated with a decreased probability of uncontrolled blood pressure following treatment with a thiazide diuretic/beta-blocker combination. **Clinical Trials Registration:** URL: <http://www.clinicaltrials.gov>. Unique identifiers: NCT00246519; NCT00133692.

**2714T**

**Low frequency and rare variants of *RBFOX1* are associated with blood pressure.** K.Y. He<sup>1</sup>, X. Li<sup>1</sup>, B.E. Cade<sup>2,3</sup>, J. Liang<sup>1</sup>, H. Wang<sup>2,3</sup>, X. Lin<sup>4</sup>, S. Redline<sup>2,3,5</sup>, X. Zhu<sup>1</sup>, NHLBI TOPMed BP Working Group. 1) Department of Population Quantitative Health Science, Case Western Reserve University, Cleveland, OH; 2) Division of Sleep and Circadian Disorders, Brigham and Women's Hospital, Boston, MA; 3) Division of Sleep Medicine, Harvard Medical School, Boston, MA; 4) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 5) Division of Pulmonary, Critical Care, and Sleep Medicine, Beth Israel Deaconess Medical Center, Boston, MA.

Our previous combined linkage and association analysis of exome array data in the Cleveland Family Study (CFS) and four cohorts with unrelated individuals (N = 57,234) identified rare, functional variants in *RBFOX1*, an evolutionarily conserved RNA-binding protein that regulates tissue-specific alternative splicing, to be associated with SBP and PP. In the present study, 487 European Americans (EA) and 507 African Americans (AA) from CFS have been whole-genome sequenced (WGS) as a part of the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program. We divided the low frequency and rare variants (defined as minor allele frequency < 5%) of *RBFOX1* into three groups: 1) functional coding variants that lead to an amino acid change, 2) synonymous variants, and 3) non-coding variants. The WGS identified 6 variants in group 1, 4 variants in group 2, and 163 variants in group 3 among CFS European Americans; and 12, 4, 269 variants in CFS African Americans, respectively. Using group 1 variants, gene-based analysis using linkage information verified our previous results that rare, coding variants in *RBFOX1* are associated with SBP (p-value = 0.00332), DBP (p-value = 0.0267), and PP (p-value = 0.0399) in CFS European Americans. WGS enabled us to identify 3 additional variants in EA that were previously not found in exome array. In African Americans, we detected novel association at the gene-level using functional coding variants (SBP p-value = 0.097; DBP p-value = 0.00663). However, the rare variants associated with BP traits in the two populations are mostly population-specific in this gene, suggesting that rare variant replication at a gene-level is more feasible and necessary than at a variant-level. Replication analysis of *RBFOX1* low frequency and rare variants in other TOPMed cohorts are currently underway.

**Incorporating multiple sources of biological knowledge into association analysis of whole genome sequencing data identifies novel trait-associated rare variants.** Y. Ma<sup>1,2</sup>, P. Wei<sup>1</sup>. 1) Department of Biostatistics, The University of Texas MD Anderson Cancer Center, Houston, Texas; 2) Department of Biostatistics, The University of Texas School of Public Health, Houston, Texas.

Despite the ongoing large-scale population-based whole genome sequencing (WGS) projects such as the NIH NHLBI TOPMed program and the NHGRI Genome Sequencing Program, WGS-based association analysis of complex traits remains a tremendous challenge due to the large number of rare variants, many of which are non-trait-associated neutral ones. External biological knowledge, such as functional annotations based on the ENCODE and Roadmap Epigenomics Project, may be helpful in distinguishing causal rare variants from neutral ones. However, each functional annotation can only provide certain aspect of the biological functions. Our knowledge to select the informative annotations *a priori* is limited while incorporating non-informative annotations will introduce noise and lose power. We propose an adaptive test that incorporates multiple biological annotations and is adaptive at both the annotation and variant levels, thus maintaining high power even in the presence of noninformative annotations. In addition to extensive simulations, we illustrate our proposed test using the TWINSUK cohort (n=1,718) of UK10K WGS data (Walter et al, Nature 2015) based on six functional annotations: CADD, RegulomeDB, FunSeq, Funseq2, GERP++, and GenoSkyline. We identified a genome-wide significant genetic locus on chromosome 19 near gene *TOMM40* associated with LDL, which is replicated in the UK10K ALSPAC cohort (n=1,796). This novel and replicated LDL-associated locus was missed by existing rare variant association tests that either ignore external biological information or rely on a single source of biological knowledge. We have implemented the proposed test in an R package "FunSPU".

**Low frequency and rare variants in multiple genes are associated with sleep related traits using whole genome sequencing data.** X. Zhu<sup>1</sup>, J. Liang<sup>1</sup>, B. Cade<sup>2,3</sup>, K. He<sup>1</sup>, H. Wang<sup>2,3</sup>, R. Saxena<sup>2,3,4,5</sup>, S. Sunyaev<sup>6</sup>, X. Lin<sup>7</sup>, S. Redline<sup>2,3,8</sup>, NHLBI TOPMed Sleep working group. 1) Department of Population Quantitative Health Scien, Case Western Reserve Univ, Cleveland, OH; 2) Division of Sleep and Circadian Disorders, Brigham and Women's Hospital, Boston, MA; 3) Division of Sleep Medicine, Harvard Medical School, Boston, MA; 4) Broad Institute, Cambridge, MA 02142, USA; 5) Center for Human Genetic Research and Department of Anesthesia, Pain, and Critical Care Medicine, Massachusetts General Hospital, Boston, MA 02114, USA; 6) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 7) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 8) Division of Pulmonary, Critical Care, and Sleep Medicine, Beth Israel Deaconess Medical Center, Boston, MA.

A disease trait often can be characterized by multiple phenotypic measurements that can provide complementary information on disease etiology, physiology, or clinical manifestations. We previously performed analysis on the principal components of the phenotypes (PCPs) and principal components of the heritability (PCHs) for six obstructive sleep apnea hypopnea syndrome (OSAHS) related phenotypes using the data from the Cleveland Family Study, which include both African-American and European-American families. We demonstrated that principal components generally result in higher heritability and linkage evidence than individual traits and the PCHs can be transferred across populations. We identified the largest linkage peak for the third PCH (PCH3) on chromosome 8 with a maximum LOD score of 3.7 in CFS European Americans. In this study, 487 European Americans and 507 African Americans from CFS have been whole-genome sequenced (WGS) by the NHLBI Trans-Omics for Precision Medicine (TOPMed) Program. There are 144,565 variants identified in the 20Mb linkage region in CFS European Americans. We hypothesized that low frequency and rare variants contribute to the observed linkage evidence. We divided the low frequency and rare variants (defined as MAF<5%) into three groups: 1) functional coding variants, 2) functional non-coding variants and 3) other variants. Under the linkage peak, we observed 88 and 258 genes with at least 3 functional coding and non-coding low frequency or rare variants, respectively. We observed 1.5 to 2.3 fold enrichment of genes associated with PCH3 using gene-based SKAT or burden analysis with or without adjusting for BMI. By restricting to these low frequency or rare functional coding variants that segregate within the families with family-specific LOD scores >0.1, we identified 17 genes with at least 3 low frequency or rare variants. The enrichment was further improved to 7 times and we identified 6 out of the 17 genes with SKAT  $P < 0.05$ . Three (*DLGAP2*, *CSMD1* and *ER11*) of the 6 genes were further replicated in CFS African Americans (SKAT  $P < 0.05$ ). Further replication using additional TOPMed cohorts is underway. Our study suggests that analyzing multiple traits informed by linkage evidence and interrogation of low frequency and rare variants using WGS data can be fruitful.

**Partitioning genome-wide summary statistics improves polygenic risk prediction.** S. Chun<sup>1,2</sup>, M. Imakaev<sup>1,2</sup>, N. Marziliano<sup>3,4</sup>, M.F. Notarangelo<sup>3</sup>, P.A. Merlini<sup>4,5</sup>, D. Ardissino<sup>3,5</sup>, S. Kathiresan<sup>2,6,7,8</sup>, M. Orho-Melander<sup>9</sup>, O. Melander<sup>10</sup>, N.O. Stitzel<sup>11,12,13</sup>, S.R. Sunyaev<sup>1,2,8,14</sup>. 1) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 2) Dept of Medicine, Harvard Medical School, Boston, MA; 3) Division of Cardiology Azienda Ospedaliero-Universitaria di Parma, Parma, Italy; 4) Associazione per lo Studio della Trombosi in Cardiologia, Pavia, Italy; 5) Division of Cardiology Niguarda Hospital, Milano, Italy; 6) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 7) Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA; 8) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 9) Dept of Clinical Sciences in Malmö, Lund University, Clinical Research Center, Malmö, Sweden; 10) Dept of Clinical Sciences, Diabetes and Endocrinology, Lund University, University Hospital Malmö, Malmö, Sweden; 11) Cardiovascular Division, Dept of Medicine, Washington University School of Medicine, Saint Louis, MO; 12) Dept of Genetics, Washington University School of Medicine, Saint Louis, MO; 13) McDonnell Genome Institute, Washington University School of Medicine, Saint Louis, MO; 14) Dept of Biomedical Informatics, Harvard Medical School, Boston, MA.

Traditional methods for polygenic risk prediction of complex disease have historically focused on the set of genetic markers associated with disease at a genome-wide level of significance. Newer approaches have been developed to incorporate information from all markers across the genome, however these methods typically require individual level genotypes or depend on accurately specifying the underlying genetic architecture in order to optimally apply shrinkage methods on estimated effect sizes. Here, we propose a novel partitioning-based risk prediction model to achieve non-parametric shrinkage that does not require explicitly modeling the genetic architecture. We partition markers by intervals of discovery association  $p$ -values and apply a piecewise constant interpolation of shrinkage curve by utilizing a small second cohort providing individual genotypes. Based on simulated genetic architecture of independent markers, we show that our new partitioning-based risk predictor outperforms  $p$ -value thresholding and even Bayesian shrinkage when the estimated prior deviates from the true genetic architecture. Further, we demonstrate the utility of this new approach by applying it to a myocardial infarction (MI) dataset, which is comprised of summary level data from >85,000 individuals and genotype level data from a sub-cohort ( $n=2,685$ ). We assessed the ability of this method to predict MI in a completely independent prospective population-based cohort ( $n=6,708$ ). Our new partitioning method produces significantly more accurate MI predictions compared with a genome-wide significant score (1.39-fold improvement in AUC;  $P = 0.001$ ) and a thresholding-based polygenic score (1.44-fold improvement in AUC;  $P = 0.0001$ ). Future method development in partitioning summary statistics may further improve polygenic risk prediction for common diseases like MI.

**2718F****Geographic distribution of polygenic risk of complex traits and diseases in Finland.**

Pirinen<sup>1,8,9</sup>. 1) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 2) National Institute of Health and Welfare, Helsinki, Finland; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 5) Psychiatric & Neurodevelopmental Genetics Unit, Department of Psychiatry, Massachusetts General Hospital, Boston, MA, USA; 6) Department of Neurology, Massachusetts General Hospital, Boston, MA, USA; 7) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 8) Department of Public Health, University of Helsinki, Helsinki, Finland; 9) Helsinki Institute for Information Technology HIIT and Department of Mathematics and Statistics, University of Helsinki, Helsinki, Finland.

Understanding sources of regional differences in disease incidence is important for targeting health care resources optimally. As many complex diseases have a considerable genetic component, it is important to quantify the role of genetics in geographic variation of disease risk. Genetic risk is often estimated using polygenic risk scores (PRS) derived from large GWAS meta-analyses. A challenge with this approach is that a complex interplay of population genetic differences within the target sample and the GWAS data can confound the results. Here we show that, after careful assessments of biases, PRS reveal geographic differences in genetic risk of several complex traits and diseases in Finland. We estimated polygenic risk across Finland for five diseases: Crohn's disease (CD), coronary artery disease (CAD), rheumatoid arthritis (RA), schizophrenia (SCZ) and ulcerative colitis (UC), and for three traits: waist-hip ratio (WHR), body-mass index (BMI) and height, using summary statistics of publically available GWAS meta-analyses and a geographically well-defined sample of 2,376 individuals from the FINRISK Study. By spatially smoothing PRS across the country we observed clear geographic patterns for all quantitative traits and for CAD, RA and SCZ, but not for CD or UC. We quantified these patterns using a general linear model and observed the strongest effects for longitude on height ( $P = 2E-60$ ) and WHR ( $P = 7E-20$ ) and lower but non-zero effects ( $P < 0.02$ ) on CAD, RA, SCZ and BMI. We performed several analyses to assess possible biases. First, we generated random PRS by permuting the effect sizes. Second, we assessed the geographic distribution of PRS within four risk variant bins that explained equal amount of total variance but included different numbers of variants. Third, we compared SCZ scores that were generated with and without Finnish samples included in the GWAS meta-analysis. Fourth, we tested whether the risk allele frequency differences between eastern and western Finland varied within MAF bins. In these analyses, possible biases did not explain away the geographic differences in PRS. Our work provides multiple ways to assess possible biases related to PRS and demonstrates that there are geographic differences in genetic risk of several complex traits and diseases in Finland, including CAD and SCZ. Such information is important for future use of PRS for individualized risk prediction and for targeting the health care resources optimally.

**2719W****An information theoretic approach to filtering false signals of pathogenicity across ancestrally diverse populations.** A.K. Manrai, I.S. Kohane. Biomedical Informatics, Harvard Medical School, Cambridge, MA.

Over the past several years, large catalogues of genomic variation such as the Genome Aggregation Database (gnomAD) and 1000 Genomes Project (1000G) have become mainstays of clinical genomics. These resources enable researchers and genetic testing laboratories to filter both novel variants discovered in sequencing studies as well as benign variants previously implicated as pathogenic. Recently, we have shown how these resources are critical for ancestrally diverse populations that have been understudied in the primary literature (Manrai et al., *NEJM* 2016). Although there is widespread agreement about the need to increase diversity in clinical genomics research, there remains limited precise guidance or formalism on how best to accomplish this goal. Here, we start with a popular proposal, "proportional representation," in which ancestrally diverse populations are represented in proportion to their representation in the general population. We study this proposal in the context of using moderate to large control sequence databases ( $>1,000$  to  $>100,000$  individuals) to rule out variation that is too common in the general population to be causal for a particular disease of interest. We develop an information theoretic approach that uses the diminishing returns of increases in sample size to design more efficient schemes to allocate samples amongst a set of ancestrally diverse populations. We use theoretical analyses and simulations leveraging gnomAD and 1000G to demonstrate the optimality properties as well as limitations of this approach. Finally, we apply our approach to filter a set of  $>4,000$  assertions regarding the causality of variants labeled pathogenic for the inherited heart disease hypertrophic cardiomyopathy (HCM) by at least one submitter to the ClinVar database.

**Control of ethnically-stratified vascular risk factors in modeling of intracerebral hemorrhage.** S. Marini<sup>1,2</sup>, U.K. Lena<sup>1,2</sup>, C.J. Moomaw<sup>3</sup>, F.D. Testa<sup>3</sup>, S.J. Kittner<sup>4</sup>, M.L. James<sup>5</sup>, D. Woo<sup>6</sup>, J. Rosand<sup>1,2</sup>, C.D. Langefeld<sup>6</sup>, C.D. Anderson<sup>1,2</sup>. 1) Center for Genomic Medicine, MGH, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 3) Department of Neurology, University of Cincinnati College of Medicine, Cincinnati, OH; 4) Department of Neurology, Baltimore Veterans Administration Medical Center and University of Maryland School of Medicine, Baltimore, MD; 5) Neurology, Duke University Medical Center, Durham, NC; 6) Center for Public Health Genomics and Department of Biostatistical Sciences, Wake Forest University, Winston-Salem, NC.

**Introduction:** Presence of vascular risk factors (VRFs) and their net effects vary across ethnic populations. We hypothesize that use of DNA-based ancestry informative markers (AIMs), compared with self-reported race/ethnicity, results in better prediction of VRF status in U.S. minority populations and thus provides more accuracy in attributing risk of intracerebral hemorrhage (ICH) across racial/ethnic groups. **Methods:** Using data from the Ethnic/Racial Variations of Intracerebral Hemorrhage (ERICH) study (a multi-center case-control study of ICH in whites, blacks, and Hispanics), we utilized 15 ancestry-informative single nucleotide polymorphisms (SNPs) to perform principal component (PC) analysis using PLINK v1.9 variance-standardized relationship matrix dimension reduction. Logistic regression (adjusted for age) and tests of two independent samples ( $\chi^2$  and Mann-Whitney U tests) were used to compare PC-defined with self-identified race/ethnicity in association with VRFs. Results of sub-analyses within each population were further meta-analyzed to highlight differences between self-identified classifications. Finally, we compared two logistic models for ICH risk (one with self-reported ancestry, one with the AIMs), adjusting for age and hypertension. **Results:** Among 4,935 subjects (median age 61, interquartile range 52–72; cases 43.4%) 34.7% were blacks, 35.1% white, and 30.2% Hispanic. Percentages of hypertension, hypercholesterolemia, and diabetes differed across self-identified race/ethnicity as well as PCs (all  $p < 0.001$ ). However, even within each self-reported population, PC dispersals differed among those with and without each of the VRFs ( $p < 0.001$ ). Regression of each VRF with PCs, adjusting for age, confirmed independent associations of PCs with both hypertension and diabetes exposures ( $p < 0.001$ ). Akaike information criterion (6303 vs. 6321) and Davidson-MacKinnon J test ( $p < 0.001$ ) verified that PC-defined ancestry significantly improved the ICH risk prediction model over self-identified ancestry alone. **Conclusion:** AIMs provide a more detailed assessment of risk exposures in studies employing U.S. minority populations. Particularly among Hispanics and blacks, the use of PCs derived from AIMs adds value in controlling for genetic and environmental exposures unique to these populations. This more inclusive ancestry modeling improves accuracy in risk prediction.

**Association of SELP variants and soluble P-selectin levels with type 2 diabetes mellitus: A case-control study.** R. Kaur<sup>1</sup>, J. Singh<sup>1</sup>, R. Kapoor<sup>2</sup>, M. Kaur<sup>3</sup>. 1) Department of Molecular biology and biochemistry, Guru Nanak Dev university, Amritsar, Punjab, India; 2) Carewell Heart & superspeciality hospital, Amritsar, Punjab, India; 3) Department of Human Genetics, Guru Nanak Dev, university, Amritsar, India.

**Statement of purpose:** P-selectin, an adhesion molecule, is a marker of endothelial dysfunction. Soluble P-selectin (sP-selectin) is proposed as a predictor of adverse cardiovascular events. The present study was aimed to determine SELP single nucleotide polymorphisms (SNPs) and sP-selectin levels in Type 2 diabetes mellitus (T2DM) patients. The future CVD risk, based on brachial-ankle Pulse wave velocity (baPWV), was also assessed in the patients. **Methods used:** The study subjects comprised of 100 T2DM patients and 100 age- and gender- matched healthy controls from north India. The subjects were screened for demographic as well as clinical characteristics. Two non-synonymous (ns) SNPs of P-selectin i.e. rs6136 (T715P) and rs6127 (N562D) were genotyped by PCR- RFLP. To evaluate the future mortality and CVD risk, patients were segregated on the basis of baPWV and Ankle Brachial Index. **Summary of results:** Serum P-selectin levels were significantly high in patients as compared to controls ( $P < 0.01$ ). Frequency of rs6127 polymorphism was found to be significantly high ( $p < 0.01$ ) in T2DM patients as compared to controls. The variant allele A was associated with 1.5 fold risk. For rs6136, frequency of heterozygous genotype was found to be significantly high in patients as compared to controls ( $p < 0.01$ ) and the variant allele was associated with 2.4 fold risk. Furthermore, both of these variants were in strong linkage disequilibrium ( $D' = 0.999$ ). Out of total, 22% of patients were found to have very high risk, 43% subjects with high risk, while 34% subjects have moderate risk. In conclusion, the findings of the present study indicated significant association of SELP variants with risk towards T2DM. High P-selectin levels in these patients can be correlated with chronic inflammatory condition in T2DM. Furthermore, baPWV, being a sensitive technique, can offer novel method to assess future CVD risk in these patients.

**Whole genome sequence reveals selection for muscle and cardiovascular functions in sport hunting dog breeds.** *J. Kim, F. Williams, D. Dreger, B. Davis, E. Ostrander.* Cancer Genetics and Comparative Genomics Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD.

Modern dogs are distinguished among domesticated species by the vast breadth of phenotypic variation produced by strong and consistent human-driven selective pressure. The resulting breeds reflect the development of closed populations with well-defined physical and behavioral attributes. The sport hunting dog group has long been employed in assistance to hunters, reflecting strong behavioral pressure to produce dogs that can locate and pursue quarry over great distances and variable terrain. Comparison of whole genome sequences (WGS) data between sport hunting and terrier breeds, a group that represents the end of a continuum in both form and function, reveals that genes underlying cardiovascular and muscular functions are under greatest selection in sport hunting breeds, including *ADRB1*, *TRPM3*, *RYR3*, *UTRN* and *ASIC3*, rather than genes associated with physical attributes. Among the most interesting is the positively selected allele of *TRPM3* which is significantly associated with the increased racing speed in whippets, accounting for 11.6% of variance in racing performance. We also observed strong selection for a high impact mutation in a widely-conserved site in *CDH23*, a gene associated with hearing loss and human Usher syndrome, possibly as a mechanism to control startle reflex in so called “gun” dogs. Together these results provide strong evidence that sport hunting dogs have adapted to their roles by improving endurance, cardiac function, blood fluidity, and startle reflex, demonstrating how strong behavioral selection alters physiology, over form, to create breeds with distinct capabilities.

**Heterogeneity in coronary artery disease GWAS results is associated with pan-tissue eQTL count.** *K.W. Johnson<sup>1,2</sup>, B.S. Glicksberg<sup>1,2</sup>, K. Shameer<sup>1,2</sup>, J.T. Dudley<sup>1,2,3</sup>.* 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Institute for Next Generation Healthcare, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Population Health Science and Policy, Icahn School of Medicine at Mount Sinai, New York, NY.

Results from Genome Wide Association Studies (GWAS) have primarily driven our current understanding of the contribution of genetics to coronary artery disease (CAD). Genetic characterization is most often performed via discovery of common single nucleotide polymorphisms (SNPs) in large case/control studies and results are ultimately collated with meta-analysis. Recently, a large meta-analysis (*CARDIoGRAMplusC4D Consortium*) using data from a number of genome-wide investigations was made public to enable re-analysis of CAD genomic data. In addition to identifying novel putative CAD-related loci, a central finding from the meta-analysis was the determination of between-study heterogeneity of SNP significance and effect sizes ( $I^2$ ). In a previous work, we have shown that GWAS discoveries are biased toward evolutionarily conserved genomic positions. Cis-expression Quantitative Trait Loci (cis-eQTL) are evolutionarily conserved genomic regions that regulate the expression of one or more proximal genes. Here, we demonstrate a significant association between the number of tissues in which a SNP functions as a cis-eQTL and the GWAS study heterogeneity for the given SNP. First, we combined 2213 CAD SNPs which reached genome-wide significance ( $p < 5 \times 10^{-8}$ ) with cis-eQTL results in 44 tissues from the Genotype-Tissue Expression (GTEx) consortium. Using negative binomial (NB) regression, we found the  $-\log_{10}(\text{between-study heterogeneity } P \text{ Value})$  significantly negatively predicted the number of tissues in which a SNP functions as an eQTL (NB regression,  $p < 0.025$ ). After splitting the GTEx tissues into cardiovascular related ( $n=6$ ) and non-cardiovascular related ( $n=39$ ), we also found that this relationship holds in non-cardiovascular tissues ( $p < 10^{-8}$ , NB regression) but not in cardiovascular tissues ( $p < 0.99$ , NB regression). We believe this study demonstrates the utility of making summary statistics from GWAS publically available for re-use. We plan to extend this study by investigating heterogeneity patterns from other public disease-related meta-analyses with the goal of better characterizing GWAS results. In addition, tissue-specific eQTL searches may also lead to novel genes driving pathophysiology of complex diseases.

**Origins and dynamics of the Brazilian population and sickle cell mutations reveal unexpected diversity.** Y. Guo<sup>1</sup>, B. Custer<sup>2</sup>, S. Kelley<sup>2</sup>, E. Sabino<sup>3</sup>, A.B. Proietti<sup>4</sup>, D. Werneck<sup>5</sup>, R. Afonso<sup>6</sup>, P. Loureiro<sup>7</sup>, C. Lobo<sup>8</sup>, L. Preisse<sup>9</sup>, M. Busch<sup>2</sup>, G.P. Page<sup>2</sup>, *NHLBI Recipient Epidemiology and Donor Evaluation Study-III*. 1) RTI International, RTP, NC, USA; 2) Blood Systems Research Institute, San Francisco, CA, USA; 3) Universidade de São Paulo, São Paulo, Brazil; 4) Fundação Hemominas, Belo Horizonte, Brazil; 5) Fundação Hemominas, Juiz de Fora, Brazil; 6) Fundação Hemominas, Montes Claros, Brazil; 7) Fundação Hemope, Recife, Brazil; 8) Fundação Hemorio, Rio de Janeiro, Brazil; 9) RTI International, Atlanta, GA, USA.

**Background** Sickle cell disease is relatively common in Brazil. Mutations within the HBB gene, specifically the 1 base apart Hemoglobin S mutation (HbS) and Hemoglobin C mutation (HbC), reach relatively high frequency due to balancing positive selection from the protection they appear to provide against certain types of malaria. The frequency differ markedly across Africa, with rates of HbC range from 12.5% (Burkina Faso and Ghana) to less than 1% (Angola and Mozambique) and HbS from 18% (Angola) to about 2% (other Malaria endemic regions across Africa). **Methods** The REDS-III Brazilian Sickle Cell Disease cohort (SCDC) is a cohort of ~2,800 sickle cell patients from six geographically diverse sites within Brazil which has been genotyped with a genome wide Affymetrix Axiom SNP array. The specific sickle cell mutation type was determined by both SNP and SSCP typing. Haplotypes were constructed using 1516 markers spanning >2 MB around HBB. **Results** Principal components analysis using 1000 genomes as reference support the finding that most of the African ancestry in Brazil is related to Luhya (Bantu), congruent with the slave trade data. The sites from the interior state of Minas Geras had higher rates of Native South American ancestry, while samples from Rio De Janeiro had the highest African ancestry, and Recife and Sao Paulo had the highest levels of European Ancestry. High concordance (>97%) between the SNP and SSCP calling of the HbS and HbC alleles was observed. The Bantu and Benin haplotypes accounted for over 95% of the HbS chromosome in Brazil. The Benin haplotype averages over 1.4 MB in length, the Bantu haplotype around 1.6 Mb, and the HbC around 700 kb in length. As many as 33% of the sickle cell patients in Minas Geras has a HbC mutation and the Benin HbS haplotype was 40-50%, while in Recife HbC frequency it is as low as 9% and Benin HbS haplotype only 20%. **Conclusions** The data suggest high flow of Africans from the Bite of Benin which is supported by the slave trade data which suggests people brought from there were first taken to Bahia and then into the interior. The lengths of the haplotypes suggest that the HbC is the oldest followed by the Benin and Bantu mutations. This could have implications for the spread of humans and malaria. For the first time, we can accurately call HbC and HbS mutations using SNP based markers and define specific HbS and HbC haplotypes using dense SNP markers.

**2725W**

**Integrating biological age and transcriptome markers for predicting the functional recovery potential of patients undergoing mechanical circulatory support surgery.** G. Bondar<sup>2</sup>, S. Deshmukh<sup>1</sup>, S. Ramachandrala<sup>1</sup>, M. Raghavivedha<sup>1</sup>, S.C. Cherukuri<sup>1</sup>, N. Agrawal<sup>1</sup>, M. Deng<sup>2</sup>. 1) Strand Life Sciences Pvt. Ltd, Bangalore, Karnataka, India; 2) Advanced Heart Failure/Mechanical Support/Heart Transplant, David Geffen School of Medicine at UCLA, Ronald Reagan UCLA Medical Center, 100 Medical Plaza, Suite 630, Los Angeles, CA 90095, USA.

Heart failure (HF) is a syndrome that results from a mismatch between demand and supply of oxygenated blood in turn leading to systemic organ failure. At any given chronological age and HF stage, some patients are more frail, malnourished, and immunologically compromised, while others are less so. Frail patients with HF not only have poorer outcomes on Optimal Medical Management (OMM) but also have an increased risk for organ dysfunction (OD) and death even after HF therapies such as mechanical circulatory support (MCS)-surgery. For these reasons, we believe that mortality risk does not solely depend on a patient's chronological age. Our goals were: 1. Establish the impact of various clinical variables in predisposition of patients towards mortality risk. 2. Facilitate improved clinical management of patients through pre-operative risk prediction of postoperative organ function recovery and long term survival using a combination of the most prominent preoperative clinical parameters and transcriptome data. Strand NGS, a bioinformatics software was used for alignment and analysis of the RNA Seq data. In this pilot study, a total of 29 patients undergoing MCS surgery were monitored for a period of 9 days starting from a day before the surgery. During this period, blood samples were collected along with a comprehensive set of clinical variables. Based on medical records and clinician's assessment, each of these patients was labeled as high or low risk for OD. Data from 24 patients was used for building prediction models while the remaining 5 patients data were used for validating these models. Multivariate logistic regression was used to identify the smallest set of non-redundant clinical variables that impact risk outcome. Support Vector Machine (SVM) Algorithm was used to build the model using transcriptome data. Combinatorial model was built by combining clinical information and transcriptome data. We observed that Respiratory Rate (RR) and WBC count in combination with chronological age predict the outcome of MCS surgery. The SVM model built on transcriptome data alone had a risk prediction accuracy of 92%. By incorporating RR, WBC count and age into the model, prediction accuracy increased to 96%. This pilot study indicates that the functional recovery potential of a person indicative of biological age has a more prominent role in the recovery process than isolated chronological age and should therefore be weighted for risk prediction before MCS-surgery.

**Integrated analysis using RNA-Seq and ChIP-Seq data to understand the regulation of cardiogenesis.** *M. Toufiq, S. Deshmukh, S. Ramachandrala, S.C. Cherukuri.* Strand Life Sciences Pvt. Ltd, Bangalore, Karnataka, India.

1% of all live births are affected with congenital heart disease in the west and this constitutes a major burden on public health organizations. Transcription factors like NKX2-5 and MEIS1 have been shown to play a critical role in vertebrate heart development. Identifying their expression and targets of these factors, along with the regulatory interactions will be a major step towards understanding the broader cardiac developmental processes. Numerous next-generation sequencing studies utilize multiple technologies to understand and answer complex biological questions. Here, using Strand NGS bioinformatics software, we provide an illustrative example on how to integrate data from different sources to identify differential expression profiles and infer their transcription factor binding sites (using RNA-Seq and ChIP-Seq data) in a combined analysis to define the regulation of cardiogenesis. As a part of this study, we re-analyzed publicly available datasets GSE44576. This RNA-Seq and ChIP-Seq data was generated using the Illumina platform to investigate the expression profiles and genome binding sites. Similar to the author's conclusions, we could identify the mechanism of transcriptional regulation during cardiac differentiation by successive binding of the two homeodomain transcription factors NKX2-5 and MEIS1 on *Popdc2* enhancer. ChIP-Seq helped in finding the binding domains of NKX2-5 and MEIS1, while RNA-Seq aided in finding their impact on the expression of other genes. In addition to these results, we also built architecture of pathway and NLP networks. Pathway Analysis displayed NKX2-5 playing a pivotal role in cardiogenesis and any change in its levels causing multiplying effects on heart development pathway. NLP was used to build a network with plausible interaction of genes mined from interaction DB and a proprietary database constructed by Strand using all the PubMed abstracts. Further, NLP showed that most proteins that interact with NKX2-5 are either enhancers or growth factors which might explain the mechanism of heightened impact on heart development. We intend to showcase Strand NGS as a go to tool for analyzing and interpreting multi-omics data with intuitive workflows and user friendly features.

**Disease-specific variant pathogenicity prediction using machine learning methods improves interpretation in inherited cardiac conditions.** *X. Zhang<sup>1,2</sup>, N. Whiffin<sup>1,2,3</sup>, K.L. Thomson<sup>4,5</sup>, R. Walsh<sup>1,2</sup>, R. Govind<sup>1,2</sup>, H. Watkins<sup>5,6</sup>, L. Bottolo<sup>7,8,9</sup>, J.S. Ware<sup>1,2,3</sup>.*

1) National Heart and Lung Institute, Imperial College London, London, UK; 2) Royal Brompton Cardiovascular Research Centre, Royal Brompton & Harefield Hospitals NHS Trust, London, UK; 3) MRC London Institute of Medical Sciences, Imperial College London, London, UK; 4) Oxford Medical Genetics Laboratory, Oxford University Hospitals NHS Foundation Trust, The Churchill Hospital, Oxford, UK; 5) Radcliffe Department of Medicine, University of Oxford, Oxford, UK; 6) The Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 7) Department of Medical Genetics, University of Cambridge, UK; 8) The Alan Turing Institute, London, UK; 9) MRC Biostatistics Unit, Cambridge Institute of Public Health, UK.

Accurate variant interpretation is an unmet need in clinical genetics. The ACMG-AMP guidelines provide a standardised qualitative classification framework to integrate diverse lines of evidence and support variant interpretation. While these guidelines represent an important step forward and a valuable platform for reproducible interpretation, limitations include a lack of transparent and quantitative measures of classification probability and confidence. Many bioinformatics tools have been developed to predict the functional effects of variants given multiple features and derive a likelihood-based score of pathogenicity. However, these tools are typically trained on variants across the genome and do not benefit from specific lines of evidence only available for a subset of well-characterised genes or diseases. We have previously shown that the addition of such gene and disease-specific evidence into a transparent Bayesian logistic regression framework improves variant interpretation. Here we develop a syndrome-specific variant interpretation tool to predict the probability of variant pathogenicity on three inherited cardiac conditions: long QT syndrome, Brugada syndrome and cardiomyopathies. The predictor integrates variant-level evidence, domain-level information, gene-level evidence derived from large disease cohorts and pathogenicity scores reported by various existing genome-wide variant effect predictors. Using state-of-the-art ensemble learning techniques, the prediction model was first built on a training data set of highly confident interpreted rare variants collected from ClinVar, alongside variants derived from healthy individuals confirmed by MRI scan. After training, the model was evaluated in independent disease cohorts with known causative variants and control data sets. Compared to the popular genome-wide tools, our disease-specific predictor significantly improves the classification of variants by reducing the predictive loss. In long QT syndrome, it improves at least by 45.13%. It shows the best performance in terms of the area under the curve as well as the measures of clinical relevance such as specificity and sensitivity. We present that a novel pathogenic variant classifier based on ensemble learning outperforms genome-wide methods by leveraging expert-curated gene and disease-specific data. The use of equivalent variant features and machine learning methods is highly transferable to variant interpretation in other genetic diseases.

**2728W**

**A disease-specific and automated variant annotator enables fast and accurate clinical variant interpretation.** N. Whiffin<sup>1,2,3</sup>, R. Walsh<sup>1,2</sup>, E. Edwards<sup>1,3</sup>, R. Govind<sup>1,3</sup>, M. Ahmad<sup>1,3</sup>, M. Edwards<sup>3</sup>, X. Zhang<sup>1,3</sup>, R. Buchan<sup>1,3</sup>, W. Midwinter<sup>1,3</sup>, H. Najgebauer<sup>1,3</sup>, A.E. Wilk<sup>1,3</sup>, D.J. Morris-Rosendahl<sup>1,3</sup>, P.J.R. Barton<sup>1,3</sup>, J.S. Ware<sup>1,2,3</sup>, S.A. Cook<sup>1,2,3</sup>. 1) National Heart and Lung Institute, Imperial College London, London, United Kingdom; 2) MRC London Institute of Medical Sciences, Imperial College London, London, United Kingdom; 3) Royal Brompton and Harefield NHS Foundation Trust, London, United Kingdom.

Guidelines from the American College of Medical Genetics and Genomics and the Association for Molecular Pathology (ACMG/AMP) aim to standardise variant interpretation by outlining the evidence types to be considered and how these might be weighted. Although the authors stress the importance of refining the framework for individual genes and diseases, to date disease-specific guidance is lacking. To address this shortcoming, we created CardioClassifier, an interactive web-tool that supports semi-automated variant interpretation for inherited cardiac conditions according to the ACMG/AMP guidelines. Our tool is the first to combine automation with expertly curated disease and gene-specific thresholds, using data derived from robustly refined allele frequency thresholds, regional mutational burden analyses, single variant association statistics and intricately phenotyped disease and control cohorts. To quantitatively assess the added value of incorporating gene- and disease-specificity, we compared our disease-specific CardioClassifier tool to InterVar, a semi-automated generic tool. Using a set of 219 variants validated as Pathogenic (by multiple submitters) in ClinVar, we show that the sensitivity of CardioClassifier is two-fold greater than InterVar, without a loss of specificity. Additionally, we compared the performance of CardioClassifier for 57 'gold-standard variants', previously manually-curated by the Clinical Genome Resource (ClinGen). After accounting for expected differences in *in silico* effect prediction algorithms and the availability of clinical data, we achieved perfect concordance for 53 (93%) of these variants. To further increase the utility of CardioClassifier for clinical application, we developed an associated knowledge-base, incorporating segregation and functional data manually curated from the literature. The tool can be continually refined to align with consensus disease-specific guidance emerging from community efforts such as ClinGen and to incorporate new knowledge, and will support data sharing with community resources (ClinVar). Through creation of CardioClassifier we show that using automation to guide variant interpretation markedly reduces the time needed for annotation while increasing accuracy and consistency. We demonstrate the importance of disease-specific variant interpretation and we hope this stimulates the development of similar tools for additional diseases. CardioClassifier is available at [cardioclassifier.org](http://cardioclassifier.org).

**Data mining "normal" chromosome microarrays for gene discovery.** N. Walton<sup>1</sup>, H. Nguyen<sup>2</sup>, P. Jay<sup>2</sup>. 1) Genetics and Genomic Medicine, Washington University, St Louis, MO; 2) Pediatric Cardiology, Washington University, St Louis, MO; 3) Pediatric Cardiology, Rush University, Chicago, IL.

**A chromosome microarray (CMA) is a commonly ordered clinical test to ascertain genetic etiologies of congenital heart disease (CHD). Laboratories report the CMA as "normal" if there are no deletions greater than 200kb or duplications greater than 500kb. Hundreds of smaller copy number variants (CNV's) go unreported. It is logical to think that even these unreported CNV's may be informative for research and clinical diagnosis if they overlap genes that cause CHD. We hypothesize that by using the raw data from "normal" CMA's in combination with detailed phenotypic information, that we may be able to discover new genetic causes of CHD. For this study, we analyzed data on 1,762 Patients who had a CMA performed for diagnostic purposes whose results were reported as normal. This included 319 patients with CHD and 1443 without CHD. Charts of all patients were manually reviewed and phenotyped. CHD patients were categorized into 28 different cardiac phenotypes and groups. We developed a computer algorithm that compared the number of deletions in a gene for patients with CHD phenotypes compared to patients without CHD. This algorithm was looped through every CHD phenotype in combination with 18,232 individual genes resulting in a table of 510,496 scores. The results from the analysis were then filtered based on p-value, odds ratio, CNV prevalence, and tolerance to loss of function (pLI, Shet) to produce a list of genes enriched for known CHD genes. Permutation analyses determined the number of known CHD genes that could be expected under the null hypothesis. We further assessed our results for enrichment of genes with de-novo variants in three large CHD exome sequencing cohorts and used a cohort of patients without CHD as a control. Our filtering approach produced greater than 30-fold enrichment of CHD genes that was statistically significant when compared to permuted data. Our method also produced a small set of candidate genes. We further validated our method by showing significant enrichment of genes with de-novo variants in the CHD exome cohorts while showing no significant enrichment in the control population. Candidate genes that overlap between our study and the exome cohorts may serve as good candidates for further study. Two of our "candidate" genes have since been published as CHD genes. The results of this analysis also suggests that there may be valuable diagnostic information regarding deletions in known CHD genes that goes unreported in clinical CMA's..**

**Postoperative risk prediction based on preoperative leukocyte immunobiology.** S. Ramachandral<sup>1</sup>, G. Bondar<sup>2</sup>, S. Deshmukh<sup>1</sup>, N. Agrawal<sup>1</sup>, S.C. Cherukuri<sup>1</sup>, M. Deng<sup>2</sup>. 1) Strand Life Sciences Pvt. Ltd, Bangalore, Karnataka, India; 2) Advanced Heart Failure/Mechanical Support/Heart Transplant, David Geffen School of Medicine at UCLA, Ronald Reagan UCLA Medical Center, 100 Medical Plaza, Suite 630, Los Angeles, CA 90095, USA.

Mechanical Circulatory Support (MCS) devices are a therapeutic option for Advanced Heart Failure (AdHF) patients with challenging clinical profiles. Even after MCS surgery, some patients are still at an increased mortality risk due to Multi-Organ Dysfunction (MOD) Syndrome associated with immune cell dysfunction. The ability to precisely predict postoperative risk for each AdHF-patient before surgery would therefore be paramount in clinical decision-making and management. Our goal is to use leukocyte immune-biology information to develop a preoperative test which accurately predicts postoperative outcomes in individual AdHF-patients. As a part of this pilot study, 29 patients undergoing MCS surgery were monitored for a period of 9 days starting from a day before the surgery. During this period, blood samples were collected along with a comprehensive set of clinical variables to assess MOD. Based on medical records and clinician's assessment, each of these patients was labeled as high or low risk. PBMCs were extracted from the blood samples of preoperative day and used for transcriptome, cytokine, and flow cytometry analysis. We then used this data from 23 patients to build a class prediction model that distinguished low risk patients from those of high risk; and the remaining 6 samples were set aside for testing the prediction model. Data from each platform was imported into Strand NGS, a bioinformatics software, using the most optimal data transformation and normalization options. After quality assessments and filters, high quality data points were used for statistical and fold change analysis. Feature selection methods were employed to find the features that best captured trends in the data and differentiated low-risk patients from those of high-risk. Multiple class prediction models were then built on patient data from each platform using Support Vector Machine, Neural Network, Decision Tree, and Naive Bayes algorithms. In order to leverage the potential of multi-dimensional data from different platforms, combinatorial, sequential, and weighted models were built using features from across platforms. We obtained the following prediction accuracies in classifying pre-operative patients into high or low risk. Such models when constructed using a larger cohort can be used to optimally predict the MOD risk to be faced by a new patient due to undergo MCS surgery.

SVM Model	Accuracy (%)
RNA-Seq	93
Flow Cytometry	91
Cytokines	92
Combinatorial	92

**Genetic variants in familial abdominal aortic aneurysms identified by whole genome and exome sequencing.** A. IJpma<sup>1,2</sup>, D. Heijtsman<sup>1</sup>, Y. Li<sup>1</sup>, H. Brüggewirth<sup>1</sup>, I. van den Boogert<sup>1</sup>, D. Majoer-Krakauer<sup>1</sup>. 1) Department of Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Department of Bioinformatics, Erasmus MC, Rotterdam, Netherlands.

**Introduction:** Abdominal Aortic Aneurysm (AAA) is a frequent disorder with a prevalence of 5% in the elderly population. An Abdominal Aortic Aneurysm occurs when the aorta below the renal arteries expands to a diameter of 3cm or more. In the Netherlands, approximately 5000 AAA patients are hospitalized each year and around 750 people die annually due to AAA rupture. Approximately 20% of AAA patients are familial. In non-familial AAA, genetic predisposition likely also plays a role since known cardiovascular risk factors alone do not explain the localized weakening of the aortic wall. Our goal is to identify the genes that play a role in the formation of abdominal aneurysms. **Methods:** Our study population consists of approximately 1250 AAA patients. So far we sequenced 548 of these patients of which 365 have a family history of AAA. Complete Genomics whole genome sequencing (WGS) was performed in 3 families (15 individuals) and whole exome sequencing (WES) on the illumina platform using Agilent Haloplex and CRE sureselect exome capturing technology was performed in 71 families (175 individuals) and 358 single AAA patients. Burden analysis was used to identify genes enriched in our AAA population. Prioritization of resulting variants was performed according to the following gene sets: 1. Genes in the diagnostics thoracic or syndromic aneurysms (n=25) panel as applied in the Erasmus MC. 2. All genes in the exome dataset. **Results:** We present the detailed workflow of the analysis of the genomics data, including the results so far. In 73 out of 365 families a variant with predicted pathogenicity was identified in one of the diagnostic genes. Analysis of all genes in the exome dataset led to the identification of several candidate genes that show variants with predicted pathogenicity in more than one AAA family and that have not been linked to AAA before. We will discuss several candidate genes identified such as the enrichment for pathogenic variants we identified in the COL4A2 gene. Supported by Stichting Lijf en Leven. .

**High-throughput discovery of deleterious cardiac sodium channel variants.** A. Glazer<sup>1</sup>, B. Kroncke<sup>1</sup>, K. Matreyek<sup>2</sup>, T. Yang<sup>1</sup>, D. Fowler<sup>2</sup>, D. Roden<sup>1</sup>. 1) Vanderbilt University Medical Center, Nashville, TN; 2) University of Washington, Seattle, WA.

A major challenge in genomic medicine is classifying the pathogenicity of variants in Mendelian disease genes. Coding variants in the cardiac sodium channel, *SCN5A*, are a major cause of inherited arrhythmia syndromes including Brugada Syndrome (loss of function) and Long QT Syndrome (gain of function). Although pathogenic variants in *SCN5A* are considered actionable and reportable to the patient/clinician, the pathogenicity of most *SCN5A* variants is unknown or disputed. Here we describe a program to generate high-throughput *in vitro* functional data for *SCN5A* variants. We created a pilot mutant library in a 36 base pair region of *SCN5A* (including known disease-associated mutations) and confirmed by high-throughput sequencing that all 240 possible single amino acid changes were represented. Plasmids were tagged with a random 18-mer barcode and integrated into a HEK293T "landing pad" cell line, resulting in expression of a single variant in each cell. Patch clamp electrophysiology of cells with integrated wild-type channels confirmed a high level of sodium current with typical properties. We next developed an assay to detect cells with dysfunctional sodium channels. A cocktail of three drugs (veratridine, brevetoxin, and ouabain) was used to promote sodium influx and preferentially kill cells with functional channels. This assay successfully discriminated between wild-type channels (35% fitness), a nonsense variant (97% fitness), a partial loss of function variant (71% fitness), and a gain of function variant (16% fitness). High-throughput sequencing of the pre- and post-assay pools will be used to count the prevalence of each variant and identify variants with abnormal function. These experiments demonstrate proof-of-principle methods for a high-throughput *in vitro* screen of *SCN5A* variant function. These methods will ultimately be used across all possible *SCN5A* variants, which may help identify individuals at risk for Brugada Syndrome and Long QT Syndrome.

**2733F**

**Integration of exome genetic variation into mass spectrometry peptide identification to effectively identify plasma proteome QTLs.** T. Solomon<sup>1</sup>, J.D. Lapek<sup>2</sup>, H. Matsui<sup>3</sup>, W.W. Greenwald<sup>4</sup>, K. Hindberg<sup>5</sup>, N. Latysheva<sup>5</sup>, S.B. Jensen<sup>2</sup>, S.K. Braekken<sup>6,7</sup>, D.J. Gonzalez<sup>2</sup>, K.A. Frazer<sup>3,5,7</sup>, E.N. Smith<sup>1</sup>, J-B. Hansen<sup>5,6</sup>. 1) Biomedical Science Graduate Program, University of California San Diego, La Jolla, CA; 2) Department of Pharmacology, Skaggs School of Pharmacy and Pharmaceutical Sciences, University of California San Diego, La Jolla, CA; 3) Institute for Genomic Medicine, University of California San Diego, La Jolla, CA; 4) Bioinformatics and Systems Biology Graduate Program, University of California San Diego, La Jolla, CA; 5) K.G. Jebsen Thrombosis Research and Expertise Center, Department of Clinical Medicine, UiT - The Arctic University of Norway, Tromsø, Norway; 6) Division of Internal Medicine, University Hospital of North Norway, Tromsø, Norway; 7) Department of Pediatrics and Rady's Children's Hospital, University of California San Diego, La Jolla, CA.

Identifying genetic variation associated with plasma protein levels (protein quantitative trait loci, pQTLs) can provide insight into mechanisms underlying disease. Mass spectrometry can be used to estimate protein levels in a high-throughput manner, however variant peptides are challenging to detect using mass spectrometry and this systematic loss of variant peptide information may influence pQTL identification. Our aim was to integrate known coding variation measured by exome sequencing and genotyping arrays into mass spectrometry protein level estimation in order to more effectively identify and characterize genetic variants associated with plasma protein levels. We performed exome sequencing or exome array genotyping of 170 participants from the Tromsø Study; a longitudinal, single-center, prospective study of the inhabitants of Tromsø, Norway. Additionally, plasma was isolated at study entry and profiled for protein levels using TMT-multiplexed mass spectrometry. Mass spectra were mapped to peptides and proteins using Proteome Discoverer and the Gencode protein sequence database. Mixed models were used to test for associations between common genetic variants near the protein's locus (*cis*) and peptide or protein levels. We quantified levels of 5,826 peptides that map to 693 Gencode protein IDs and 675 gene loci. We identified common genetic variation associated with 152 of the 5,826 peptides. By examining the coding impact of the most associated SNP, we found that almost 30% of the variants that were associated with peptide levels were missense mutations that disrupt the peptide sequence and cause misidentification of the peptide. In some cases, these missense mutations have known functional effects on the peptide, such as rs854560 (L55M) in paraoxonase 1 (PON1), which decreases PON1 mRNA and plasma levels, while others may not be functional and may have confounded mass spectrometry protein level estimation. We are currently incorporating common and rare nonsynonymous coding variation into the Proteome Discoverer peptide database to determine if this can prevent peptide misidentification and improve pQTL identification. In summary, we have identified *cis* common variation associated with plasma peptide and protein levels and show that genetic variation often alters mass spectrometry estimates of peptide levels and thus may be important to take into account when identifying or assaying protein biomarkers.

**Large-scale generation of iPSC-derived cardiomyocytes for functional genomic applications.** *M.K.R. Donovan<sup>1,2</sup>, A. D'Antonio-Chronowska<sup>3</sup>, P. Benaglio<sup>4</sup>, M. Cook<sup>5</sup>, K. Farnam<sup>3</sup>, M. D'Antonio<sup>3</sup>, E.N. Smith<sup>4</sup>, K.A. Frazer<sup>3,4</sup>.*

1) Department of Biomedical Informatics, University of California, San Diego, La Jolla, CA 92093, USA; 2) Bioinformatics and Systems Biology Graduate Program, University of California, San Diego, La Jolla, CA 92093, USA; 3) Institute for Genomic Medicine, University of California, San Diego, La Jolla, CA 92093, USA; 4) Department of Pediatrics, University of California, San Diego, La Jolla, CA 92093, USA.

Regulatory genetic variation associated with molecular and physiological traits often shows effects restricted to a subset of cell types. Experimentally elucidating the functional molecular underpinnings of regulatory variants is challenging because of the lack of genetically diverse human cell models. Human induced pluripotent stem cells (iPSCs) can be derived into cell types that are relevant for disease, such as cardiomyocytes, and may be an effective system for the comprehensive functional characterization of genetic variants in relevant cell types. Here we used iPSCs from the iPSCORE (iPSC Collection for Omic Research) study to derive cardiomyocytes (iPSC-CMs) from 145 different individuals, all of whom had whole-genome sequence data. This collection included 89 individuals belonging to one of 28 families (which include 6 trios and 7 MZ twin pairs) and genetically related to at least one other person, as well as 56 singletons. To achieve large-scale and robust derivations of iPSC-CM, we developed a highly-standardized protocol, which yielded up to  $5.7 \times 10^8$  iPSC-CM with an average purity of 87.5% and up to 99.5% of cTnT-positive cells measured by flow cytometry. To study how genetic variation influences molecular phenotypes in iPSC-CM lines derived from both the same and different individuals, we analyzed the transcriptome and epigenome (RNA-seq, ATAC-seq, ChIP-seq for H3K27ac) of a subset of 24 iPSC lines derived from 5 monozygotic (MZ) twin pairs. Comparison of these data to reference data revealed cell type-specific transcriptomic and epigenomic profiles that recapitulated those of fetal heart. We then examined genetic and non-genetic sources of variation in the molecular phenotypes by comparing iPSC-CM molecular phenotypes within and across the 24 iPSC lines derived from the 5 MZ twin pairs. We observed that non-genetic factors including the % of cTnT-positive cells and harvest density were associated with variability between clones from the same subject. However, genetic background accounted for most molecular variability in iPSC-CM and these genetic effects were independent of variation associated with non-genetic factors, suggesting that inherited genetic variants associated with molecular traits could be identified. Our study demonstrates that large collections of iPSC-CMs enabling molecular phenotype genetic studies can be created and supports the use of iPSC-derived cells as a model to functionally characterize regulatory genetic variants.

Large-scale collections of induced pluripotent stem cells (iPSCs) could serve as powerful model systems for examining how genetic variation affects biology and disease. Here we describe the iPSCORE resource: a collection of systematically derived and characterized iPSC lines from 222 ethnically diverse individuals that allows for both familial and association-based genetic studies. Participants were recruited to include families, twins, and individuals of diverse ethnicity to enable genetic studies investigating the segregation of traits. Using high-throughput RNA-sequencing and genotyping arrays, we show that the iPSCORE lines are pluripotent with high genomic integrity (no or low numbers of somatic copy-number variants). We differentiated a subset of iPSCs from a family to cardiomyocytes and examined how the donor's genetic background was associated with gene expression variation in derived cell lines. We show that iPSC-derived cardiomyocytes demonstrate gene expression patterns that cluster by genetic background, and can be used to examine variants associated with physiological and disease phenotypes. Finally, we examined and annotated how individuals in the iPSCORE resource carry SNPs associated with diverse genome-wide association studies (GWAS) phenotypes. The iPSCORE collection contains representative individuals for risk and non-risk alleles for 95% of SNPs associated with human phenotypes through genome-wide association studies. Our study demonstrates the utility of iPSCORE for examining how genetic variants influence molecular and physiological traits in iPSCs and derived cell lines.

**Finding biomarkers for thromboembolism leading to stroke.** *D.B. Dogini<sup>1</sup>, F.H. Menezes<sup>2</sup>, A.T. Guillaumon<sup>2</sup>, W.M. Avelar<sup>2</sup>, C.S. Rocha<sup>1</sup>, I. Lopes-Cendes<sup>1</sup>, BRAINN - Brazilian Institute of Neuroscience and Neurotechnology.* 1) Medical Genetics Dept, School of Medical Sciences - UNICAMP, Campinas, Sao Paulo, Brazil; 2) Surgery Dept, School of Medical Sciences - UNICAMP, Campinas, Sao Paulo, Brazil; 3) Neurology Dept, School of Medical Sciences - UNICAMP, Campinas, Sao Paulo, Brazil.

The world is facing an epidemic of stroke. Severe atherosclerotic tightening of the internal carotid artery is found in 20% to 30% of patients with ischemic stroke. However, features associated with a symptomatic plaque including the degree of vessel stenosis, plaque characteristics, ulceration, inflammatory cell infiltration, and others are still poor predictors for the risk of thromboembolism leading stroke. In order identify better biomarkers for carotid disease due to atherosclerotic plaque we apply microarray technology to generate gene expression profile of carotid plaques (CP). In the present pilot study we used 3 CP from patients who underwent endarterectomy and, as control we used 3 healthy extracranial vessels from patients who underwent neurological surgery. Microarray experiments were performed using the Human Genome U133 Plus 2.0 array (Affymetrix™). Data was acquired by the GeneChip Scanner 3000 (Affymetrix™) and analyzed using DNA-Chip Analyzer (dChip). Background correction, summarization and normalization were performed by RMA function and differential gene expression was analyzed using RankProd (FDR  $p < 0.05$ ). These analyses were performed in R environment. We found 4027 genes which were differentially expressed (up and down regulated) in CP as compared to controls. Some upregulated genes found are involved with negative regulation of transcription (GDF15 - growth differentiation factor 15; TCF4 - transcription factor 4; LMCD1 - LIM and cysteine-rich domains 1 and others), cell morphogenesis (NOX4 - NADPH oxidase 4; LST1 - leukocyte specific transcript 1), angiogenesis (PGF - Placental growth factor; ARHGAP24 - Rho GTPase activating protein 24; COL15A1 - collagen, type XV, alpha 1). Some downregulated genes were found to be involved with regulation of cell growth (FAM107A - family with sequence similarity 107 member A; SOCS3 - suppressor of cytokine signaling 3; IGFBP6 - insulin-like growth factor binding protein 6), vasculogenesis (HEY1 - hairy enhancer-of-split related with YRPW motif 1), blood vessel development (PPAP2B - phosphatidic acid phosphatase type 2B; FOXO1 - forkhead box O1). Our results suggest the involvement of a wide variety of biological processes in the formation and maintenance of CP, which need to be better explored in further studies.

**Danon Disease: A lysosomal hypertrophic cardiomyopathy model created by CRISPR editing LAMP2 in iPSC and fibroblasts.** *C. McKinney<sup>1,2</sup>, K. Baumgarner<sup>1,2</sup>.* 1) Genetics and Biochemistry, Edward Via College of Osteopathic Medicine, Spartanburg, SC; 2) Gibbs Research Institution, Spartanburg, SC.

Danon disease, an X-linked genetic disorder, is a dysfunction of LAMP2 protein in cardiomyocyte lysosomes. The disorder affects both sexes but more severely affects males who show an earlier onset of cardiac symptoms resulting in shorter lifespans or cardiac transplant. This disease manifests as a cardiac hypertrophy that may also affect cells of the skeletal muscle. In some patients, mild intellectual disability is also reported. Danon disease is caused by documented mutations in the LAMP2 gene with mutations resulting in frameshifts and several small and large deletions that produce LAMP2 knockouts. Cardiac cells accumulate vacuoles, also seen in the mouse LAMP2 knockout, that appear to contribute to muscle weakness in the heart. LAMP2 protein has three isoforms, differing at the exon 9 sequence, that function as lysosomal membrane proteins and also appear to participate in the cell's autophagy pathway. LAMP2A is a known participant in chaperone mediated autophagy but functional analysis LAMP2B and LAMP2C function remains ambiguous although it maybe involved with the immune system. *We hypothesized that creating cardiomyocytes lacking LAMP2 isoforms and then a specific LAMP2B knockout would allow investigation of the role of LAMP2 in these cells.* Utilizing CRISPR/Cas9 gene editing and iPSC reprogramming methods, we created a BJ fibroblast LAMP2 knockout of all three isoforms by placing an insertion early in exon 2. This is confirmed by genomic cleavage assays and Sanger sequencing of the mutant LAMP2 gene. We are reprogramming the LAMP2 KO fibroblasts to iPSC and then cardiomyocytes. Using a single stranded oligo and gRNAs, a second CRISPR introduced mutant in LAMP2 exon 9B models a KO of the LAMP2B isoform. This gives us the opportunity to decipher LAMP2B function in cardiomyocytes. We have reprogrammed the control BJ fibroblast line into cardiomyocytes and shown that they acquire a beating phenotype and express cardiac-specific biomarkers (troponin T2, GATA4 and Nkx2.5). These analyses confirm the cardiac nature of these reprogrammed cells. To further characterize defects in Danon mutated BJ cardiomyocytes compared to our isogenic control line, we plan to assess cardiomyocyte function by MEA techniques, autophagy and lysosomal/mitochondria assays. The study outcome yields two LAMP2 mutant cell lines that probe functional cardiac deficits leading to Danon disease.

**Chromosome 22q11 microdeletion: Modifiers of the cardiovascular phenotype identified by whole exome sequencing.** *G. Repetto<sup>1</sup>, B. Rebolledo<sup>1</sup>, F. Benavides<sup>1</sup>, H. Poggi<sup>1</sup>, A. Cuiza<sup>1</sup>, P. Alvarez<sup>2</sup>.* 1) Center for Genetics and Genomics, Clin Alemana- Univ Desarrollo, Santiago, Chile; 2) Hospital Dr Roberto del Rio, Santiago, Chile.

Chromosome 22q11.2 microdeletion syndrome (22q11DS) is the most common microdeletion syndrome in humans, with an estimated frequency of 1/4000. The deletion is caused by non-homologous recombination between low copy repeats (LCRs) in the region, and there are 3 common deletion sizes: 3Mb (between LCRs A-D), 2 Mb (A-C) and 1.5 (A-B). The syndrome shows marked variable expressivity, that is not associated with the deletion size or to parental origin, and suggests the presence of modifiers elsewhere in the genome. Approximately 50-60 % of patients have congenital heart disease (CHD), usually affecting the cardiac outflow tract. CHD is a feature associated with earlier diagnosis and higher case fatality rate. The aim of this study was to search for genetic modifiers of the cardiovascular phenotype in the remaining 22q11 locus or outside of the deletion region, through whole exome sequencing (WES). We included 60 patients with 22q11DS and known cardiac anatomy: 25 cases with conotruncal severe CHD: tetralogy of Fallot (TOF), TOF with pulmonary atresia (TOF+PA) or interrupted aortic arch (IAA), and 35 controls with normal cardiac phenotype. WES was performed at the Northwest Genome Center (NWGC), using Roche Nimblegen V2 Exome capture and 75 bp paired-end sequencing. After quality control, 22 cases and 33 control samples were analysed. We focused on the identification of non-synonymous variants present only in cases. Analysis of the likelihood of pathogenicity for each SNV was carried out using five standard prediction metrics : SIFT, Polyphen2 HVAR, MutationTaster, MutationAssessor and FATHMM. We found 16 variants with potential pathogenicity in cases. Among them, was a variant on KDM6B, involved in histone acetylation and one on CLTCL1, a gene located within the 22q11 deletion that participates in intracellular endosomal trafficking. Variants in histone modifier genes have been previously reported as associated both with non-syndromic and 22q11 deletion-related CHD. These results suggest that, in a small number of patients with the deletion, variants in genes in the remaining 22q11 region or elsewhere in the genome may be associated with the presence of CHD. Funded by FONDECYT Chile grant 1130392 and 1171014.

**AIF-1 in association with TLR-2 induces proinflammatory response in monocytes after ischemia reperfusion (IR).** *D.Olga. McDaniel<sup>1</sup>, AllenA. Simeone<sup>1</sup>, LarryS. McDaniel<sup>2</sup>.* 1) Department of Surgery, University Mississippi Med Ctr, Jackson, MS; 2) Department of Microbiology and Immunology, University Mississippi Med Center, Jackson MS.

Inflammatory responses fundamentally influence the short and the long term performance of cardiac allograft after transplantation. Genes associated with innate immunity are prime activators of early inflammatory responses to an allograft and that may lead to host-induced inflammation and organ dysfunction after transplantation. We hypothesized that endogenous substances or damage-associated molecular patterns (DAMPs), released after allograft ischemia-reperfusion (IR) such as allograft inflammatory factor 1 (AIF-1) by interacting with cardiac resident TLR-2 could promote activation of innate immune responses causing phenotypic switching of macrophages from the M2 to M1 subtype and in turn induces a proinflammatory response. AIF-1 and TLR-2 mRNA transcripts were significantly increased in a time-dependent manner in a rat model of the left anterior descending (LAD) artery occlusion after IR. AIF-1 was specifically detected in monocytes by the level of mRNA expression. However, a minimal level of anti-AIF-1 stain was detected by IHC. Functional activity of AIF-1 was confirmed in an *in vitro* model using human coronary vascular smooth muscle cells and monocytes, treated with IFN-g, as well as using HEK293 cells transfected with h-TLR-2 or TLR-4 in which was determined by production of proinflammatory cytokine such as IL-18. AIF-1 treated cells demonstrated 1.25 to 4.5 fold, dose dependent increase in IL-18 secretion in HEK-293 transfected cells with TLR-2. However, a significantly less increase was observed in cells transfected with TLR-4. To investigate the impact of TLR-2 on activation of human HEK293 by AIF-1, cells were incubated with a monoclonal antibody (mAb) to TLR-2 for 1 hour before treatment with AIF-1. The IL-18 production was significantly reduced with mAb to TLR2. Using AIF-1 protein sequence in a 3D protein database, we found a strong homology between domain 2 of human AIF-1 (sdi: 160028) and cardiac Troponin C (1IH0 A). It has been shown that the rate of Troponin release by cardiomyocytes after IR has direct effects on myocardial protection during cardiac allograft preservation. Thus, characterization of AIF-1 as an endogenous ligand for the TLR-2 and elucidation of the mechanisms of an induced inflammation within the myocardial cells has the potential for the development of therapeutic inhibitors for clinical application and further to improve transplantation outcomes.

**Association of rare recurrent copy number variants in next generation sequencing data from family trios with congenital heart defects.** *Y. Liu, X. Chang, A. Desai, L. Tian, Y. Guo, D. Li, P. Sleiman, H. Hakonarson.* Center for Applied Genomics CAG, The Children's Hospital of Philadelphia CHOP, Philadelphia, PA.

Congenital Heart Defects (CHD) are common, affecting approximately 1% of newborn children in the United States. A significant number of CHD defects are attributed to alter Copy Number Variation (CNV), usually loss, as reported in previous studies. In this project, we used whole exome sequencing (WES) data generated by the PGC (CHOP being one of the site), including discovery data set of 2109 individuals from 760 trios, and an independent replication set of 4940 individuals from 1770 trios. The candidate targets uncovered were further validated, using OMNI-2.5M SNP array chip data from 2099 individuals, including 922 CHD patients, as well as in whole genome sequencing (WGS) data generated on 150 individuals from 50 trios. The RNA sequencing (RNA-seq) data used were generated from cardiac tissues obtained from 57 patients, and included left/right ventricle, aorta, right atrium and papillary tissues. The genes harboring CNVs of interest were then tested for expression alternations. We identified five loci harboring CNVs in *LIMS*, *GCC2*, *RANBP2*, *TTC3*, *MAP3K7CL*, and *FXR1*. Three out of the five loci included *de novo* CNVs. Two of the CNV loci associated with developmental delays. All six genes are highly expressed in human heart/coronary/artery/aorta, and highly expressed in mouse 14.5 days embryo heart except *MAP3K7CL*. Taken together, we have uncovered five novel CNV loci all of which alter expression of the respective candidate genes involved. Raw data is publicly available through the database of genotypes and phenotypes (dbGaP).

**2741T**

**The effects of missense mutations causing PRKAG2 cardiomyopathy on expression levels of selected genes involved in AMPK pathway.** *E. Komurcu-Bayrak, M.A. Kalkan, G. Celebi, N. Coban, B. Ozsait-Selcuk, B. Vural.* Department of Genetics, Istanbul University, Aziz Sancar Institute of Experimental Medicine, Istanbul, Turkey.

Background: Missense mutations in *PRKAG2*, the gene for the gamma 2 regulatory subunit of adenosine monophosphate-activated protein kinase (AMPK), cause cardiac hypertrophy and electrophysiological abnormalities, a condition named as *PRKAG2* cardiomyopathy. In our previous study, we reported a novel *PRKAG2* missense mutation (E506K) in three generations of a family with ventricular hypertrophy with normal systolic function and ventricular pre-excitation. The mutation affects a residue in the fourth CBS (cystathionine h-synthase) domain with unknown function, although thought to alter AMPK activity. The aim of this study was to determine the expression profiles of genes involved in the AMPK signaling pathway *in vitro*. Methods: The *PRKAG2b* E506K, E506Q and R531G mutations were constructed by site-directed mutagenesis technique in pcDNA3.1/V5-His-TOPO expression vector and then transfected into HEK293 cells by lipofectamine system. The *PRKAG2* expression was determined by immunofluorescence staining with anti-His-Tag antibody in tagged wild-type and stable mutated cells. The expression of *PRKAG2*, *PRKAA2*, *PRKAB2*, *PFKM*, *SLCA5A1*, *SLCA2A4* and *PFKFB3* genes were determined by quantitative RT-PCR in wild-type and stable mutated cells. Results: We found that the expression level of *PRKAG2b* transcript variant (short form composed of 328 amino acid residues) was higher than *PRKAG2d* transcript variant (intermediate form composed of 444 amino acid residues) in the adult human heart and HEK293 cells using variant specific long PCR. Therefore, the 2b transcript encoding the short form was cloned into the expression vector. The mRNA levels of *PRKAG2*, *PRKAA2* and *PRKAB2* encoding AMPK isoforms showed no significant increase in *PRKAG2* E506K, E506Q and R531G in mutated cells compared to wild-type cells. In contrast, the mRNA expression levels of *PFKM*, *SLCA5A1*, *SLCA2A4* and *PFKFB3* were increased by 1.5–5 fold in mutated cells according to wild-type cells. And also we localized *PRKAG2* with His-tag by immunofluorescence in the cytoplasm of the mutated cells. Conclusion: In this study, we found the relationship between *PRKAG2* missense mutations and over-expressed four genes involved in AMPK signaling pathway, however further study is required to analyze the AMPK activity. This study was supported by The Scientific And Technological Research Council Of Turkey (Project number: 115S137).

**Investigation of microRNA expression in coronary artery disease.** *N. Coban<sup>1</sup>, D. Pirim<sup>2</sup>, A.F. Erkan<sup>3</sup>, F. Guclu-Geyik<sup>1</sup>, B. Ekici<sup>2</sup>, N. Erginel-Unaltuna<sup>1</sup>.* 1) Genetics, Institute for Experimental Medicine, Istanbul, Turkey; 2) Department of Molecular Biology and Genetics, Mus Alparslan University, Mus, Turkey; 3) Department of Cardiology, Medical Faculty, Ufuk University, Ankara, Turkey.

**BACKGROUND AND AIM:** Although patients with coronary artery disease (CAD) have a high mortality rate, the pathogenesis of CAD is still poorly understood. During the past decade, microRNAs (miRNAs) have emerged as new, potential diagnostic biomarkers in several diseases, including CAD. The aim of this study was to investigate the expression profiles of miRNAs in Turkish patients with CAD and controls ( $\leq 30\%$  stenosis). **METHODS:** Ninety nine patients with angina or acute myocardial infarction who underwent coronary angiography were divided into 2 groups: normal coronary arteries (coronary lesion with  $\leq 30\%$  stenosis) and critical disease ( $\geq 1$  coronary lesion with  $\geq 70\%$  stenosis). Blood samples were drawn before coronary angiography. Gensini and SYNTAX scores and myocardial blush grade (MBG) were assessed. The Agilent's microarray analyses were performed to compare plasma miRNA profile of selected individuals with CAD ( $n=12$ ) and without CAD ( $n=12$ ). MiRDB target prediction tool was utilized to identify miRNA target genes involved in atherosclerosis pathway for differently expressed miRNAs. Expressions of selected miRNAs were analyzed by using real-time PCR in 57 patients with CAD and of 42 controls. **RESULTS:** Microarray results showed 2 miRNAs (miR-26a, miR-19a) were upregulated and 3 miRNAs (miR-18a, miR-130b and miR-584) were down-regulated (fold change  $> 1.5$ ,  $p < 0.05$ ) in patients with CAD. Based on miRDB target prediction scores, we identified *TIMP2*, *ADM*, *LRP2*, *GRIA1* and *PHACTR1* genes were strong candidates (target score  $\geq 89$ ) for miR-18a, miR-26a, miR-19a, miR-130b and miR-584, respectively. Currently, expression profiles of miR-18a, miR-26a, miR-19a, miR-130b and miR-584 are being analyzed by qRT-PCR in 57 patients with CAD and of 42 controls. **CONCLUSIONS:** Our findings highlight significantly different pattern of miRNA expression in Turkish CAD patients. These miRNAs might serve as biomarkers of CAD development and progression in Turkish patients and warrant further attention.

**2743W**

**An integrated genetic-epigenetic prediction model for coronary heart disease.** *M. Dogan<sup>1,2,3</sup>, I. Grumbach<sup>5,6</sup>, J. Michaelson<sup>2,3</sup>, R. Philibert<sup>2,3,4</sup>.* 1) Cardio Diagnostics, LLC, Coralville, IA; 2) Biomedical Engineering, University of Iowa, Iowa City, IA; 3) Psychiatry, University of Iowa, Iowa City, IA; 4) Behavioral Diagnostics, LLC, Coralville, IA; 5) Internal Medicine, University of Iowa, Iowa City, IA; 6) Iowa City Veterans Affairs Healthcare System, Iowa City, IA.

Heart disease is the leading cause of death in the United States. The most common type of heart disease is coronary heart disease (CHD), which is responsible for over 300,000 deaths annually. An improved method for detecting CHD could have a substantial clinical impact given that sudden cardiac death is the initial presentation in 15% of patients with CHD. Building on the idea that systemic effects of CHD risk factors are a conglomeration of genetic and environmental factors, our study was designed to use machine learning techniques and integrate genetic, epigenetic and phenotype data from the Framingham Heart Study to build and test a Random Forest classification model for predicting symptomatic CHD. Genome-wide SNP and DNA methylation data were profiled using the Affymetrix GeneChip HumanMapping 500K and Illumina Infinium HumanMethylation450 BeadChip arrays, respectively. The training set consisted of 1545 individuals (851 females and 694 males) of Northern European ancestry. Of these individuals, 58 females and 115 males were diagnosed with CHD. The test set consisted of 142 individuals (54 females and 88 males) with 22 females and 49 males diagnosed with CHD. Our classifier built using the training dataset consisted of four DNA methylation sites, two SNPs, age and gender. This classifier was capable of predicting CHD status of the test set with an accuracy, sensitivity and specificity of 78%, 0.75 and 0.80, respectively. To determine if this integrated model may be a viable alternative to a model consisting of only conventional CHD risk factors (age, gender, systolic blood pressure, total cholesterol, HDL cholesterol, diabetes and smoking status), another Random Forest model was built on the training set and tested on the test set. In contrast, this model had an accuracy and sensitivity of only 65% and 0.41, respectively, but a specificity of 0.89 in the test set. Regression analyses of the methylation signatures of individual clinical risk factors illustrate the strong role of pathways moderated by smoking in CHD pathogenesis. These results demonstrate the capability of an integrated approach to effectively predict symptomatic CHD status. They also suggest that future studies of biomaterial collected from longitudinally informative cohorts that are specifically characterized for cardiac disease at follow-up could lead to the introduction of sensitive, readily employable integrated genetic-epigenetic models for predicting onset of future CHD.

**2744T**

**Epigenetic modulation in the pathogenesis and treatment of inherited aortic aneurysm conditions.** B.E. Kang<sup>1,4</sup>, D. Bedja<sup>2</sup>, R. Bagirzadeh<sup>1,4</sup>, H.C. Dietz<sup>1,3,4</sup>. 1) Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, MD; 2) Department of Cardiology, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 4) Howard Hughes Medical Institute, Bethesda, MD.

The transforming growth factor  $\beta$  (TGF $\beta$ ) aortic aneurysm syndromes are unified by striking clinical overlap in the craniofacial, skeletal, cutaneous and cardiovascular systems and a common mechanism, as evidenced by a uniform tissue signature for high TGF $\beta$  signaling in the aorta. Primary mutations occur in the genes encoding regulators of extracellular TGF $\beta$  bioavailability (*FBN1* or *BGN*), TGF $\beta$  ligands (*TGFB2* or *TGFB3*), TGF $\beta$  signaling effectors (*TGFBR1*, *TGFBR2* or *SMAD3*), or regulators of the TGF $\beta$  transcriptional response (*SKI*). Discordance in the predicted consequence of the underlying mutations and lack of precise pathogenic understanding has engendered ambiguity regarding the most promising treatment strategies. Shprintzen-Goldberg syndrome (SGS) shares most features of Marfan and Loeys-Dietz syndromes (MFS and LDS) with the added finding of intellectual disability. The underlying mutations in the Sloan-Kettering Institute proto-oncoprotein SKI occur in the Smad-binding domain, preventing co-recruitment of SKI to regulatory elements in TGF $\beta$  target genes, unopposed histone acetyltransferase (HAT) activity of EP300/CREB-binding protein (CBP), and an amplified TGF $\beta$  transcriptional response. Mice heterozygous for a severe SGS mutation (*Skij<sup>G34D/+</sup>*) phenocopy the human condition; conditional targeting specifically to vascular smooth muscle cells (*Skij<sup>SMC;G34D/+</sup>*) causes highly penetrant aortic root (AoR) aneurysm and dissection. This occurs in association with all of the histologic and functional hallmarks of MFS and LDS, including aortic wall thickening with collagen accumulation and elastic fiber fragmentation, an overt mRNA signature for a TGF $\beta$  synthetic repertoire (TSR), and a therapeutic response to angiotensin receptor blockers. In consideration of mechanism, we hypothesized therapeutic potential for HAT inhibitors (HATi). Remarkably, systemically-administered C646 (a selective EP300/CBP HATi) prevented aneurysm progression in *Skij<sup>SMC;G34D/+</sup>* mice in association with preservation of aortic wall architecture, prevention of excessive H3K27 acetylation (both globally and at TGF $\beta$  target gene enhancers), and normalization of the TSR. C646 also normalized TGF $\beta$  target gene expression in SGS patient fibroblasts, with comparable efficiency as a TGF $\beta$  type I receptor (*Alk5*) kinase inhibitor. These data unambiguously implicate the TGF $\beta$  transcriptional response in the pathogenesis of AoR aneurysm and highlight novel therapeutic strategies aimed at epigenetic modulation.

**Gender transcriptome signatures for congenital heart defects (CHD) children based on next generation sequencing technologies of cardiac tissues.** C. Kim, Y. Li, Y. Guo, X. Chang, L. Tian, H. Hakonarson. The Center Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA.

Congenital heart defects (CHD) are the most common form of birth defects, affecting nearly 1%, or ~40,000 children in United States annually. Previous studies show that the gender mortality rates are different, more specially, males are more likely to die from congenital heart defects than females, and that genetic factors may be associated with those differences. In this study, we compared the gender transcriptome differences using RNA sequencing based on 125 cardiac samples of seven tissue types from 113 CHD patients of European American (EA) ancestry. We identify a set of differentially expressed genes and showed tissue specific expression profiles. The target genes were examined for structural variations and if highly expressed in developing mouse heart at 14.5 days. Those signatures were further filtered by structural variations based on whole exome sequencing from 96 blood samples from CHD patients, a subset of the 113 CHD patients. Integrative analysis uncovered four genes: *ELN*, *MYH7*, *MYOM1*, and *RYR2* as the transcriptome signatures for CHD gender differences among the tissue samples evaluated. Those four genes were differentially expressed between the genders and are all highly expressed in the developing mouse heart and they are nominally associated with CHD related structural variations. We conclude that genes that are significantly differentially expressed between genders may contribute to the differences in mortality observed between genders with CHD.

**Interpreting genetic variation in coronary artery disease (CAD). I.**

Selvarajan<sup>1</sup>, M. Laakso<sup>2,3</sup>, M.U. Kaikkonen<sup>1</sup>. 1) Department of Biotechnology and Molecular Medicine, University of Eastern Finland, A.I.Virtanen Institute for Molecular Sciences, Kuopio, Itä-suomi, Finland; 2) Institute of Clinical Medicine, Internal Medicine, University of Eastern Finland, Kuopio, Finland; 3) Department of Medicine, Kuopio University Hospital, Kuopio, Finland.

Genome-wide association studies (GWAS) have identified many significant and suggestive loci for coronary artery disease (CAD). It is also known that almost 90% of the disease causing genetic variants are present at the non-coding region. It is important to interpret the variants present at the enhancer level that regulate gene expression. Analysis of enhancer activity and gene expression correlation is an important method for discovering relevant transcription factors and their specific functionality, which can be used to gain better understanding of transcriptional regulation and disease states. Hence, we aim to functionally characterize of SNPs associated with CAD by focusing our search for causal SNPs to enhancers of the disease relevant cell types, namely endothelial cells, smooth muscle cells and macrophages of the vessel wall as well as liver and adipose tissue. The enhancers of these cell types harbour 32% of all CAD-SNPs. By identifying the target genes of the candidate enhancers and establishing causal relationships between the enhancer activity and gene expression we hope to obtain a more complete picture of the gene regulatory events driving the disease progression. Shedding light into the molecular mechanisms of these variants will bring a complete picture of gene regulatory programs and causal events driving the progression of atherosclerosis and has the potential to improve risk prediction, biomarker identification and personalized medicine in the clinical practice.

Bosch<sup>6</sup>, M. Harper<sup>1,5</sup>, L. Falk<sup>1</sup>, A. Groom<sup>1</sup>, B. Nordestgaard<sup>8,9,10</sup>, A. Tybaerg-Hansen<sup>8,9,10</sup>, C. Relton<sup>1,2</sup>, S. Bojesen<sup>8,9,10</sup>, A. Mumford<sup>7</sup>, A. Poole<sup>6</sup>. 1) MRC/UoB IEU/SSCM, Bristol Univ, Bristol, United Kingdom; 2) School of Social and Community Medicine (SSCM), University of Bristol, Bristol, UK; 3) UK Centre for Tobacco and Alcohol Studies and School of Experimental Psychology, University of Bristol, Bristol, UK; 4) School of Clinical Sciences, University of Bristol, Bristol, UK; 5) School of Healthcare Science, Manchester Metropolitan University, Manchester, UK; 6) School of Physiology, Pharmacology and Neuroscience, University of Bristol, Bristol, UK; 7) School of Cellular and Molecular Medicine, University of Bristol, Bristol, UK; 8) Department of Clinical Biochemistry, Herlev and Gentofte Hospital, Copenhagen University Hospital, Herlev, Denmark; 9) Faculty of Health and Medical Sciences, University of Copenhagen, Copenhagen, Denmark; 10) The Copenhagen City Heart Study, Frederiksberg Hospital, Copenhagen University Hospital, Copenhagen, Denmark; 11) Department of Pharmacology, University of Cambridge, Tennis Court Road, Cambridge, UK.

We have used a set of complementary experiments to show that *F2RL3* hypomethylation (a robust epigenetic index of smoking) results in upregulated *F2RL3*/PAR4 expression and increased platelet responsiveness. This suggests a mechanism for the cardiovascular effect of cigarette smoke exposure. In a sample of acute myocardial infarction cases and controls from the Copenhagen City Heart Study there was evidence of association between death and methylation at *F2RL3* after adjustment using methylation at the independent locus *AHRR* as an objective measure of smoking (HR per 10% decrease in methylation: 1.21, 95%CI:1.12,1.31). In a two-step Mendelian randomization analyses using the same sample and in UKBiobank, we are able to show that smoking intensity is likely to be causal in affecting methylation at *F2RL3* and that there is evidence that differential methylation at *F2RL3* is causally associated with cardiovascular events involving thrombosis (OR per standard deviation decrease in methylation: 1.29, 95%CI:1.08,1.44). Having established a likely causal pathway we interrogated the biological mechanisms underpinning it. Cell modelling provided evidence of the effect of exposure to cigarette smoke extract on differential methylation (up to -2.3%) and expression at *F2RL3* (5.4 fold increase in *F2RL3* mRNA levels (95%CI:3.9,7.6). Functional analysis of the expression of PAR-4 supports the importance of a methylation regulated recognition site for CCAAT-enhancer binding factor (CEBP) at *F2RL3*. Recruitment and collection of fresh blood in non-smoking participants selected based on differences in methylation at *F2RL3* was undertaken and shows association between methylation and platelet function given exposure to PAR-4 specific agonists (integrin activation (EC<sub>50</sub>,  $p=0.001$ ) and P-selectin exposure (EC<sub>50</sub>,  $p=0.05$ ) high versus low methylation) and in comparison to the negative control (PAR-1). Lastly and importantly for clinical interpretation of these results, we are able to show evidence that smoking-induced hypomethylation of the *F2RL3* CpG sites is likely to persist for decades after cessation with methylation levels returning to levels similar to never smokers around 20 years after quitting. Overall, observations suggest that the epigenetic regulation of *F2RL3* could be a route between smoking and coagulation response. PAR4 antagonists are an emerging class of anti-platelet drugs able to reduce risk of thrombosis, but cause less bleeding than existing anti-platelet drugs.

**Silencing the miR-30c-5p pathway attenuates cocaine-induced increases in blood pressure and aortic stiffness.** *W. Zhu, H. Wang, J. Wei, G.C. Sartor, M. Bao, C.T. Pierce, C.R. Wahlestedt, D.M. Dykxhoorn, C. Dong.* University of Miami, Miami, FL.

**Introduction:** Cocaine abuse increases the risk of hypertension and aortic stiffness; however, the underlying molecular mechanisms remain elusive. We previously detected that cocaine exposure upregulates miR-30c-5p expression, which targets on inhibiting malic enzyme 1 (Me1) expression, leading to reactive oxygen species (ROS) acceleration in the mouse aorta. **Goal:** We aimed to test *in vivo* a functional role of the miR-30c-5p-Me1-ROS pathway in mediating the effect of cocaine on increasing blood pressure (BP) and aortic stiffness. **Methods:** C57BL/6 mice were injected (ip) daily with cocaine (20mg/kg body weight) or saline for 10 consecutive days. In parallel, mice were injected via tail vein daily for 5 days with lentiviral vectors ( $2 \times 10^5$  IU per mouse) encoding the miR-30c-5p antagonist (miR-Zip30c-5p) or no gene (vector Ctr) under driven by a smooth muscle cell-specific promoter, and subsequently exposed to cocaine. Additional mice were injected with N-Acetyl cysteine (NAC, 250mg/kg body weight), a scavenger of free oxygen radicals, one day prior and daily during cocaine injection. BP and pulse wave velocity (PWV) for aortic stiffness were measured. MiR-30c-5p and Me1 expression was determined by RT-qPCR. Superoxide ( $O_2^-$ ) was detected by dihydroethidium. **Results:** Relative to saline treatment, cocaine treatment led to a significant increase in systolic and diastolic BP over the entire treatment course. However, the cocaine-induced increases in BP were significantly reduced from day 3 to 10 in animals that were pretreated with miR-Zip30c-5p but not the vector Ctr. Treating mice with NAC was also able to largely inhibit the increase in BP seen upon cocaine exposure. Similarly, pretreatment with miR-Zip30c-5p or NAC reduced the cocaine-increased PWV by almost 20%. Concomitantly, in contrast to a significant reduction in Me1 expression upon cocaine exposure alone, pretreatment with miR-Zip30c-5p showed only a modest decrease in Me1 expression. Moreover, compared to cocaine treatment alone, pretreatment with miR-Zip30c-5p and NAC reduced the level of cocaine-induced increases in  $O_2^-$  by 56% and 45%, respectively. **Conclusion:** Blocking the miR-30c-5p-Me1-ROS pathway, either by genetically silencing the miR-30c-5p or pharmacologically impairing ROS production with NAC, suppresses the cocaine-increased BP and aortic stiffness. This miR-30c-5p-related pathway provides a novel mechanistic base for potential therapeutic interventions to treat cocaine abuse-induced CVD.

**2749W**

**Epigenome-wide association study of the previous number of strokes in participants from the Vitamin Intervention for Stroke Prevention (VISP) clinical trial.** *N.M. Davis-Armstrong<sup>1</sup>, W.M. Chen<sup>2,3</sup>, M.S. Brewer<sup>1</sup>, S.R. Williams<sup>4</sup>, M.M. Sale<sup>2,3</sup>, B.B. Worrall<sup>3,4</sup>, K.L. Keene<sup>1,5</sup>.* 1) Department of Biology, East Carolina University, Greenville, NC; 2) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 3) Department of Public Health Genomics, University of Virginia, Charlottesville, VA; 4) Department of Neurology, University of Virginia, Charlottesville, VA; 5) Center for Health Disparities, East Carolina University, Greenville, NC.

To evaluate epigenetic influences associated with recurrent stroke and related traits, we performed an epigenome-wide association study (EWAS) assessing differential methylation using DNA extracted from whole blood and Illumina HumanMethylation450 BeadChip arrays in 180 ischemic stroke patients from the Vitamin Intervention for Stroke Prevention (VISP) clinical trial. VISP was a multi-center, double-blind, randomized, controlled clinical trial designed to determine whether daily supplementation of folic acid, vitamin B6, and vitamin B12 reduced recurrent cerebral infarction. Following quantile normalization, filtering, and quality control, a total of 473,864 autosomal CpG sites were analyzed. A multiple linear regression approach was used to assess the association between the number of strokes prior to VISP enrollment and the degree of methylation (beta value), stratified by race (European descent, EA n=104; African descent, AA n=76). Two differentially methylated CpG sites exceeded genome-wide significance ( $p \leq 1.055 \times 10^{-7}$ ) in the EA stratum. A locus, cg22812874, in the ankyrin repeat and SOCS box containing 10 gene (*ASB10*) demonstrated the most significant difference in methylation ( $p = 3.4 \times 10^{-9}$ ). The second significantly associated CpG site, cg00340919, is located in intron 4 of the tetratricopeptide repeat domain 37 gene (*TTC37*;  $p = 8.74 \times 10^{-9}$ ). It was observed that a lower number of prior strokes were associated with higher methylation beta values for both CpG sites. *ASB10* is upregulated by tumor necrosis factor alpha and interleukin-1 beta cytokines, both of which contribute to neurotoxicity in rats after an ischemic event, as well as being primary inflammation markers and risk factors of ischemic stroke in humans. The *TTC37* gene product is highly expressed in vascular tissues and has been implicated in trichoheptoenteric (THE) syndrome. Platelet abnormalities, such as large platelet size and thrombocytosis are commonly observed in THE syndrome patients and have been implicated as risk factors for stroke. In conclusion, we have identified two novel epigenetic modifications that influence stroke recurrence.

## 2750T

**Enhancer signature of dilated cardiomyopathy.** D. Hemerich<sup>1,2</sup>, M. Harakalova<sup>1</sup>, J. Pei<sup>3</sup>, E. Nagyova<sup>1</sup>, I.R. Efimov<sup>4</sup>, B. Boukens<sup>1</sup>, C. Cheng<sup>3</sup>, R. Weger<sup>5</sup>, A. Vink<sup>6</sup>, V. Tragante<sup>1</sup>, M. Mokry<sup>6</sup>, F.W. Asselbergs<sup>1,7,8</sup>. 1) University Medical Center Utrecht, Utrecht, Utrecht, Netherlands; 2) CAPES Foundation, Ministry of Education of Brazil, Brasilia, Brazil; 3) Department of Nephrology, UMC Utrecht, Utrecht, NL; 4) Department of Biomedical Engineering, George Washington University, Washington DC, US; 5) Department of Pathology, University Medical Center Utrecht, Utrecht, NL; 6) Department of Pediatrics, Wilhelmina Children's Hospital, Utrecht, NL; 7) Institute of Cardiovascular Science, UCL, London, UK; 8) Durrer Center for Cardiogenetic Research, ICIN-Netherlands Heart Institute, Utrecht, NL.

Cardiovascular diseases are a leading cause of death worldwide. Dilated cardiomyopathy (DCM) is the most common type of cardiomyopathies and a major cause of heart failure and mortality. Despite the identification of multiple highly penetrant causal genes, the regulatory processes that mediate biological mechanisms of DCM remain incompletely understood. Distal regulatory sequences, such as enhancers, have been shown to act on gene activation in a cell-type specific manner. Disruption in such sequences is believed to contribute significantly to the aetiology of traits. We assessed the hypothesis that distal enhancers play a significant role in heart functions and the identification of heart enhancers in disease state can shed a light into the mechanisms of DCM. To identify enhancers and their role in progression of human heart disease, we profiled epigenomic (H3K27ac ChIP-seq) and gene expression (RNA-seq) of eight normal human heart samples and six DCM patients. Our analysis identified thousands of both hyper (10,668) and hypo-acetylated (5,951) regions. Significantly enriched biological processes and disease ontology include regulation of cardiac muscle contraction, growth and cell-differentiation, abnormal cardiac development and remodelling. Additional analysis revealed the enrichment of JNK MAPK, PDGFR $\alpha$  and Notch signalling pathways, known to be involved in cardiac remodelling and whose mutations result in heart defects. Motif analysis using public data on DNase I hypersensitive sites of left ventricle identified 274 transcription factors enriched on hypo-acetylated regions, and 143 unique motifs enriched on hyper-acetylated peaks. Further investigation on the target genes of these putative enhancers can facilitate the understanding of disease biology and the establishment of an epigenetic signature of dilated cardiomyopathy.

**Identification of eQTLs for platelet and hemostasis related genes in platelets and leukocytes within the Framingham Heart Study.** J.E. Huffman<sup>1,2,3</sup>, J.D. Eicher<sup>1,2</sup>, K. Tanriverdi<sup>4</sup>, J.E. Freedman<sup>4</sup>, C.J. O'Donnell<sup>1,2,3,5</sup>, A.D. Johnson<sup>1,2</sup>. 1) Population Science Branch, National Heart, Lung, and Blood Institute, Framingham, MA; 2) The Framingham Heart Study, Framingham, MA, USA; 3) Center for Population Genomics, Boston VA Healthcare System, Jamaica Plain, MA; 4) Department of Medicine, University of Massachusetts Medical School, Worcester, MA; 5) Cardiology Section Administration, Boston VA Healthcare System, West Roxbury, MA.

**Background:** Platelets and hemostatic factors are important in thrombosis, inflammation, and wound healing. Their functions and signaling pathways interact in the tight control of these processes. Consequently, platelets and hemostatic factor measures have been associated with cardiovascular disease, myocardial infarction, stroke, and venous thrombosis. Identifying key genetic regulators of platelets and hemostatic factors and their mechanisms are important to understanding their contribution to disease. **Aim:** To identify expression quantitative trait loci (eQTLs) for platelet and hemostatic factor associated genes. **Methods:** Platelet and/or hemostasis related transcripts were selected based on known biological function or prior GWAS findings. RNA expression levels were measured by qRT-PCR in leukocytes and platelets from ~1,600 Framingham Heart Study participants. *Cis*-eQTLs ( $\pm 1$  Mb of gene) and *trans*-eQTLs were identified corrected for age, sex, and other technical covariates using 1000Genomes imputed genotypes. A Bonferroni significance threshold was used for *cis*-eQTLs based on the number of SNPs within the *cis* region and a  $p < 5E-08$  was used for *trans*-eQTLs. eQTLs were annotated using megakaryocyte histone marks from the BLUEPRINT epigenome project, conditional analyses performed to identify independent loci, and disease associations identified using GRASP and GWAS Catalog. **Results:** Significant *cis*- and *trans*-eQTLs were identified in both leukocytes and platelets (Table 1). Of the *trans*-eQTLs, SNPs within the well-characterized *ARHGEF3* region were associated with expression of 14 transcripts including *VWF* and *FADS2*. Additionally, we observed intriguing associations of: 1) SNPs near *GP1BA*, a critical platelet receptor for vWF, with platelet *CCL5* expression and 2) SNPs in *AP2B1*, a clathrin-dependent endocytotic factor associated with platelet count in prior GWAS, with platelet *ITGA2B* expression. Significant *cis*-eQTLs were enriched for activating histone marks ( $p < 0.0005$ ) or those identifying promoters or enhancers ( $p < 0.0002$ ) in megakaryocytes from BLUEPRINT. **Conclusion:** We identified numerous *cis*- and *trans*-eQTLs of platelet and hemostatic factor related transcripts. Such insights into their regulatory architecture may help reveal how they influence thrombosis and hemostasis, and contribute to human disease.

Table 1: Summary of RNA Transcripts Investigated

	Leukocytes	Platelets	Overlapping
<b>Transcripts Analyzed</b>	138	82	77

**Characterization of experimentally validated heart disease genes using functional genomic information and 3d genome structure.** R. Gill, B. Pei, Y. Hsu. Amgen, Cambridge, MA.

**Introduction** The majority of disease-associated SNPs are present in non-coding regions, and some reside within putative regulatory elements, such as enhancers. Understanding the relationships between these enhancers and their target genes could identify genes directly relevant to disease pathophysiology, and distinguish causal variants from other disease-associated SNPs. Evidence of physical interaction between enhancers and target genes, including topological features derived from Hi-C data, are critical to delineating disease-relevant regulatory circuits, but need to be combined with histone and ATAC-seq signatures of active enhancers and promoters along with gene expression, from disease-relevant cellular contexts, in order to accurately predict regulatory relationships. **Method** We hypothesize that the cardiac fibroblast represents a heart disease-relevant cellular context, and generated functional genomic data, including high-resolution (1.6-kb) Hi-C, ATAC-seq, histone ChIP-seq, and RNA-seq data from human primary fibroblasts from the atria and ventricles. All data processing was performed on DNA Nexus. We trained a deep neural network (DNN) to integrate multiple topological and functional genomic features of 58 pairs of heart disease genes and proximal (within 100 kb) enhancers with (22 positive pairs) and without regulatory effects (36 negative pairs), based on experimental validation in E11.5 murine developing heart and blood vessels. As input, we used pairwise information from enhancers and promoters, including normalized contact frequency, signatures of active enhancers and promoters from histone marks and open chromatin, and correlation between pairs of ATAC-peaks, to learn their weighted contribution to positive and negative enhancer-gene pairs. Our prediction set consisted of genome-wide combinations of enhancers and promoters active in cardiac fibroblasts, based on ChIP-seq and ATAC-seq data. **Results and Summary** We first examined topologically associated domain (TAD) boundaries and contact frequencies between enhancer-gene pairs. As expected both positive and negative pairs of heart disease genes and enhancers resided in the same TAD, and positive pairs had increased significant interactions. The DNN will learn higher-level representations of the inputs important for classification, such as hidden features of Hi-C data predictive of regulatory relationships, while suppressing irrelevant information. We will present additional findings at the meeting.

**2753T**

**Functional analysis of  $\beta$ -globin locus control region hypersensitive site 2-associated proteins and noncoding RNA.** A. Gurumurthy, P. Wassel, S. Thakur, M. Hossain, J. Stees, K. Gavrilova, J. Bungert. UNIVERSITY OF FLORIDA, GAINESVILLE, FL.

The hemoglobin molecule is a tetramer composed of two  $\alpha$  and two  $\beta$ -globin chains. The  $\beta$ -globin locus undergoes dynamic conformational changes in differentiating erythroid cells which are thought to be important for proper globin gene expression. The Locus Control Region (LCR) consists of several DNase I hypersensitive sites (HSs) that bind to erythroid and ubiquitously expressed transcription factors and function as enhancers. In addition, RNA Polymerase II (Pol II) synthesizes non coding, enhancer RNAs (eRNA) from the LCR HSs that may regulate  $\beta$ -globin gene expression. We aim to further understand the role of LCR HS2 and its associated eRNA in regulating  $\beta$ -globin expression. We created stable HS2 eRNA knockdown cell lines and observed reductions in  $\beta$ -globin RNA levels. The data suggest that LCR-associated eRNAs may participate in long-range regulation of  $\beta$ -globin gene expression. We also found that eRNAs remain associated with the  $\beta$ -globin gene locus. Previous studies have shown that the Integrator complex is involved in processing eRNAs. We hypothesize that termination of eRNA transcription releases Pol II which is then transferred to the globin gene promoters. To study this hypothesis, we created stable INT11 knockdown cell lines. INT11 is the endonucleolytic subunit of the Integrator complex. Furthermore, to identify proteins associated with HS2 in the context of intact cells, we sought to specifically purify LCR-HS2 associated chromatin using a two-step purification strategy. We designed two zinc finger DNA-binding domains, binding to the 5' and 3' flanking region of LCR HS2, respectively. The ZF-DBDs are associated with different tags for pull-down assays. By functionally assessing LCR HS2 associated proteins and non-coding RNA, we aim to gain better insight into the regulation of the  $\beta$ -globin locus which may lead to new strategies to treat hemoglobinopathies.

**RNA-seq of human heart tissue identifies shared and divergent expression signatures of heart failure.** *M.E. Sweet<sup>1</sup>, A. Cocciolo<sup>2</sup>, D. Slavov<sup>2</sup>, S.L. Graw<sup>2</sup>, K.L. Jones<sup>3</sup>, T.B. Reece<sup>4</sup>, A.V. Ambardekar<sup>2</sup>, M.R. Bristow<sup>2</sup>, L.M. Mestroni<sup>1,2</sup>, M.R.G. Taylor<sup>1,2</sup>.* 1) Human Medical Genetics and Genomics, University of Colorado, Aurora, CO; 2) Cardiovascular Institute and Adult Medical Genetics Program, University of Colorado, Aurora, CO; 3) Department of Pediatrics, Section of Hematology, Oncology, and Bone Marrow Transplant, University of Colorado, Aurora, CO; 4) Department of Cardiothoracic Surgery, University of Colorado Hospital, Aurora, CO.

Heart failure occurs when disease or injury weakens the heart muscle and its ability to pump blood effectively. Current treatment paradigms are based on symptom-severity classification, with little regard to etiology, reflecting a lack of knowledge of underlying heart failure mechanisms and highlighting a critical barrier to more effective treatments. We used RNA-seq and pathway analysis in 64 explanted left ventricle human heart tissues to identify transcriptome signatures common to heart failure as well as unique to specific heart failure subsets. We identified differentially expressed genes (DEGs) between dilated cardiomyopathy (DCM, n=37) and non-failing controls (NF, n=14) and between ischemic cardiomyopathy (ICM, n=13) and NF. Between DCM and NF, there were 3,649 DEGs, and between ICM and NF, there were 4,150 DEGs (FDR  $\leq$  5%). These comparisons share 2,691 DEGs, all with fold-changes in the same direction for both comparisons. These genes represent the expression signature common to heart failure with reduced ejection fraction and, using Ingenuity Pathway Analysis (IPA), are enriched for pathways suggesting dysregulation of energy metabolism (Mitochondrial Dysfunction,  $p = 5e^{-16}$ ; Oxidative Phosphorylation,  $p = 2e^{-14}$ ) and apoptosis (Protein Ubiquitination,  $p = 1e^{-11}$ ). There are 688 DCM-specific genes and 1,189 ICM-specific genes. Using unsupervised hierarchical clustering, the expression of these 1,877 genes clusters the samples into their disease groups. Pathway analysis at  $p \leq 0.003$  demonstrates that the majority of pathways are disease-specific, with DCM and ICM sharing only two pathways. DCM-specific genes are enriched for pathways suggesting dysfunctional cell-cell adhesion (Germ Cell-Sertoli Cell Junction Signaling) and detoxification (NRF2-mediated Oxidative Stress Response). ICM-specific pathways are enriched for cytoskeletal (Actin Cytoskeleton Signaling, Integrin Signaling, Epithelial Adherens Junction Signaling, Rac Signaling, RhoA Signaling, Signaling by Rho Family GTPases) and immune system pathways (Antigen Presentation Pathway, CD40 Signaling, CD28 Signaling in T Helper Cells, JAK/Stat Signaling, IL-8 Signaling, and IL-6 Signaling), suggesting an immune response and fibrosis of damaged tissue. Our results demonstrate that there are both common heart failure pathways as well as disease-specific signatures in DCM and ICM that could potentially aid in development of future precision medicine treatments.

**The communal relation of MTHFR, MTR, RFC gene polymorphisms and hyperhomocysteinemia as plausible risk of congenital septal defects.**

*S.B. Sunayana<sup>1</sup>, K. Srujana<sup>1</sup>, K. Nageswara Rao<sup>2</sup>, G. Sandhya Devi<sup>3</sup>, D. Sujatha<sup>4</sup>, K. Rajender Rao<sup>4</sup>, V. Sreedevi<sup>1</sup>, M. Hema Prasad<sup>1</sup>.* 1) Environmental Toxicology, Institute of Genetics, Hyderabad, India; 2) Care Hospital, Banjara Hills, Hyderabad, India; 3) Indo American Cancer Institute, Banjara Hills, Hyderabad; 4) National Institute of Nutrition, Hyderabad, India.

**Introduction:** Congenital septal defects (CSD) are the non-infectious and highly heterogeneous developmental anomaly in newborns with genetically complex traits, involving both the genetic and environmental factors. The present study is aimed to investigate the contribution of genetic determinants in severity of disease. Cytogenetic analysis using fluorescence in situ hybridization (FISH) and comet assay were performed to identify the microdeletions in chromosome 22 and to measure the oxidative DNA damage in the lymphocytes, respectively. Single nucleotide polymorphisms (SNPs) of Methylenetetrahydrofolate reductase (MTHFR) (677C>T), methionine synthase reductase (MTRR; 66 A>G) and reduced folate carrier (RFC) (80 A>G) were analyzed to identify the role of folic acid and homocysteine metabolism in CSD children. **Methods:** One hundred and sixty two children with non-syndromic CSD, were studied with age matched controls. Blood samples were collected from the Department of Pediatric Cardiology, Care Hospital, Hyderabad, with prior clearance from the Institutional Ethics Committee and written consent from the parents. The lymphocytes were isolated from fresh blood for comet assay as well as for the identification of 22q11.2 microdeletions, using specific FISH probes on G-Banded glass slides. Plasma and red blood cells (RBCs) were used for the estimation of homocysteine and folic acid. Genomic DNA was isolated for PCR and restriction fragment length polymorphism analysis of SNPs 677C> T, A66G and A80G genes. **Results:** The mean values of RBC folate are less in patients ( $225.5 \pm 146.5$  ng/ml) compared to controls ( $368.5 \pm 130.9$  ng/ml). An increased comet tail length was observed patients ( $4.3 \pm 1.5$   $\mu$ m) compared to the controls ( $2.74 \pm 1.2$   $\mu$ m), demonstrating the severity of oxidative DNA damage. Microdeletions of 22q11.2 and significant DNA damage were observed in CSD patients. An increased frequency of MTHFR 677C> T, MTRR 66 A>G and RFC 80A> G gene polymorphisms were observed in CSD children when compared to controls. **Conclusions:** Increased homocysteine, low RBC folate levels and genetic polymorphism have shown increased oxidative DNA damage in children with congenital septal defects.

**Fibulin-4a inhibits vascular and enhances cardiac cell fate by inhibiting transforming growth factor beta signaling.** Z. Urban, S.M. Khatri. Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Fibulin-4 (FBLN4) mutations cause autosomal recessive cutis laxa type 1B, a disease characterized by arterial tortuosity, aneurysms, developmental emphysema, bone fragility and loose, inelastic skin. To study the developmental functions of FBLN4, we used zebrafish as a model. Zebrafish have two fibulin-4 genes, *fbln4a* and *fbln4b*. This study focused on *fbln4a*, which is more similar to human FBLN4 than *fbln4b*. Gene expression studies showed that *fbln4a* mRNA was expressed in the adaxial cells adjacent to the notochord during somite formation, and in the myosepta, head and the heart at later stages. Knockdown of *fbln4a* by an antisense morpholino oligonucleotide (MO) caused pooling of blood at the caudal vein plexus or around the heart, vascular hemorrhage in the head, reduced circulation and heart rate, bent notochord, rounded somites and reduced embryo length. All of these features were rescued by co-injection of *fbln4a* mRNA with MO. Early cardiac and vascular progenitor markers showed an expansion of the heart field and reduction of the vascular/blood fields in the anterior lateral plate mesoderm in knockdown embryos. These early developmental changes led to a randomization of heart laterality, and variably reduced or enlarged heart size. The lumens of both the segmental and axial blood vessels were irregular. Inhibition of transforming growth factor beta receptor 1 (Tgfb1) kinase activity with a small molecule rescued all of the cardiovascular and connective tissue anomalies in knockdown embryos. By varying the period of treatment, we identified late gastrulation and early segmentation as the critical periods of rescue by Tgfb1 inhibition. Simultaneous knockdown of transforming growth factor 2 (*tgfb2*) or 3 (*tgfb3*) with *fbln4a* also rescued the knockdown phenotype. We conclude that Fbln4a inhibits Tgfb2 and/or Tgfb3 signals emanating from the notochord to determine the size of cardiac and vascular progenitor pools during late gastrulation and early segmentation. These results identify a previously unrecognized function of fibulin-4 in addition to its well-known role in elastic fiber assembly.

**Genetic causes of heterotaxy identified by whole exome sequencing.** A. Sridhar<sup>1</sup>, J. Lajiness<sup>1</sup>, C. Crawford<sup>1</sup>, L. Elmore<sup>1</sup>, M. Tariq<sup>2</sup>, S. Ware<sup>1</sup>. 1) Indiana University School of Medicine, Indianapolis, IN; 2) University of Tabuk, Tabuk, Kingdom of Saudi Arabia.

Heterotaxy (HTX) is a rare congenital anomaly syndrome accompanied by thoracic and/or abdominal situs abnormalities resulting from abnormal left-right patterning in the developing embryo. Although multiple inheritance patterns have been described in conditions that share features with HTX such as isolated congenital heart defects (CHD) and Primary Ciliary Dyskinesia (PCD), the genetic basis of HTX syndrome is rarely identified in a clinical setting. The purpose of this study is to define the frequency of pathogenic variants in genes known to affect laterality as well as identify novel candidate genes using whole exome sequencing in a large HTX cohort. We analyzed whole exomes of 285 subjects with HTX-spectrum disorders of which 37 (13%) had positive family history. In order to investigate potential pathogenic variants, we evaluated 172 genes compiled from various HTX, PCD and laterality defect clinical panels. Nearly 11% of the cohort had molecular findings that were likely or definitely pathogenic for PCD (5.6%), ciliopathies (3.2%, including multiple individuals with Bardet-Biedl syndrome), or other genetic syndromes (2.1%, including multiple participants with Oculo-Facio-Cardio-Dental syndrome). *DNAH5*, *DNAH11* and *GPR98* showed highest counts with more than 40 rare heterozygous variants. We also analyzed 5 trio samples utilizing an inheritance-pattern based analysis to identify novel candidate genes. We identified 20 genes that had recessive, compound heterozygous or de novo mutations. Of these genes, *SPIRE1* and *FMN2*, involved in the dorso-ventral axis formation, and *SYNE1* and *PKD1*, involved in ciliogenesis/cilia function, are interesting candidates for functional studies. This study highlights the utility of whole exome studies using inheritance-based models to identify novel genes and variants that begin to elucidate the mechanisms of a complex congenital disorder such as heterotaxy.

**2758W****A mutation in the *LMOD1* actin-binding domain segregating with disease in a large British family with thoracic aortic aneurysms and dissections.**

We describe a mutation in *LMOD1*, which predisposes individuals to thoracic aortic aneurysms and dissections in a large multi-generation British family. Exome variant profiles for the proband and two distantly related affected relatives were generated and a rare protein-altering, heterozygous variant was identified, present in all the exome-sequenced affected individuals. The allele c.1784T>C, p.(V595A) in *LMOD1* is located in a known actin-binding WH2 domain and is carried by all living affected individuals in the family. *LMOD1* was further assessed in a consecutive series of 98 UK TAAD patients and one further mutation was found, yielding an incidence of ~2% in our study group. Assessment of *LMOD1* in international TAAD cohorts discovered nine other missense variants of which three were assessed as likely pathogenic. Validation of *LMOD1* was undertaken using a zebrafish animal model. Knock-down of both *lmod1a* and *lmod1b* paralogs using morpholino oligonucleotides showed a reproducible abnormal phenotype involving the aortic arches. Injection of the human *LMOD1* c.1784T>C, p.(V595A) mutation demonstrated a likely dominant negative effect and illustrated a loss of function cause. Mutations found in the WH2 actin-binding domain of *LMOD1* may delay actin polymerization and therefore compromise actin length, dynamics and interaction with myosin in the smooth muscle contraction pathway.

**2759T**

**Homozygous *EEF1A2* mutation causes dilated cardiomyopathy, failure to thrive, global developmental delay, epilepsy and early death.** P.B. Agrawal<sup>1</sup>, S. Cao<sup>1</sup>, L.L. Smith<sup>1</sup>, S.R. Padilla-Lopez<sup>2</sup>, B.S. Guida<sup>2</sup>, E. Blume<sup>1</sup>, C.A. Brownstein<sup>1</sup>, A.H. Beggs<sup>2</sup>, M.C. Kruer<sup>2</sup>. 1) Boston Children's Hospital, Boston, MA.02115, USA; 2) Barrow Neurological Institute, University of Arizona College of Medicine, Phoenix, AZ 85013 USA.

Eukaryotic elongation factor 1A (*EEF1A*), the second most abundant protein in the cell, is encoded by two distinct isoforms, *EEF1A1* and *EEF1A2*; whereas *EEF1A1* is expressed almost ubiquitously, *EEF1A2* expression is limited such that it is only detectable in skeletal muscle, heart, brain and spinal cord. Currently, the role of *EEF1A2* in normal cardiac development and function is unclear. There have been several reports linking *de novo* *EEF1A2* mutations to neurological issues in humans. We report a pair of siblings carrying a homozygous missense mutation p.P333L in *EEF1A2* who exhibited global developmental delay, failure to thrive, dilated cardiomyopathy and epilepsy, ultimately leading to death in early childhood. A third sibling also died of a similar presentation, but DNA was unavailable to confirm the mutation. Functional genomic analysis was performed in *S. cerevisiae* and zebrafish. In *S. cerevisiae*, there was no evidence for a dominant-negative effect. Previously identified putative *de novo* mutations failed to complement yeast strains lacking the *EEF1A* ortholog showing a major growth defect. In contrast, introduction of the mutation seen in our family led to a milder growth defect. To evaluate its function in zebrafish, we knocked down *eef1a2* expression using translation blocking and splice-site interfering morpholinos. *EEF1A2*-deficient zebrafish had skeletal muscle weakness, cardiac failure and small heads. Human *EEF1A2* wild-type mRNA successfully rescued the morphant phenotype, but mutant RNA did not. Overall, *EEF1A2* appears to be critical for normal heart function in humans, and its deficiency results in clinical abnormalities in neurologic function as well as skeletal and cardiac muscle defects.

**Isoforms and eQTLs of the myocardial infarction gene *PHACTR1*.** V. Codina-Fauteux<sup>1,2</sup>, M. Beaudoin<sup>1</sup>, G. Lettre<sup>1</sup>. 1) Montreal Heart Institute, Montreal, Canada; 2) Université de Montréal, Montreal, Canada.

Coronary artery disease (CAD), including myocardial infarction (MI), is the major cause of death and disability worldwide. Traditional risk factors include: sex, age, smoking, hypertension, diabetes, dyslipidemia, etc. Genetic variation also influences the risk to develop CAD/MI. Large GWAS have identified >60 SNPs associated with this disease, including an intronic SNP (rs9349379) in *PHACTR1* located on chromosome 6. We previously showed that this SNP is an expression quantitative trait locus (eQTL) for *PHACTR1* expression in human right coronary artery (hRCA) – a result since then replicated in the GTEx resource – and that it abrogates a MEF2 binding site (Beaudoin et al., ATVB, 2015). Here, we present our effort to define the different *PHACTR1* isoforms in various human cells and tissues. Specifically, we explored which isoforms are expressed in brain, heart, hRCA, and several other cells (HUVEC, HCAEC, HAEC, teloHAEC, HCASMC, THP-1) using a combination of RT-PCR, 5' and 3' Rapid Amplification of cDNA Ends (RACE), as well as long molecules sequencing (PacBio). Integration of these results led to the identification of four isoforms expressed from the same open reading frame and that share the same stop codon. We note, however, that these isoforms all contain multiple possible alternative initiation codons. In the brain, we found one major "long" isoform that encodes a protein of 580 amino acids. We also identified two ubiquitously expressed "intermediate" isoforms (488/557 amino acids), differentiated by alternative splicing of a 207-bp exon. Finally, we found in THP-1, heart, hRCA and brain a "short" isoforms (144 amino acids) that starts at exon 14 of the long isoform, a result consistent with a recent report (Reschen et al., Atherosclerosis, 2016). We then tested if genotypes at rs9349379 are associated with the expression of the two intermediate and short *PHACTR1* isoforms in 36 hRCA (the long isoform is not expressed in this tissue). Genotypes were associated with the intermediate + alternative exon isoform ( $r^2=0.164$ ,  $P=0.014$ ) but not with the other two transcripts (intermediate – alternative exon ( $r^2=0.064$ ,  $P=0.135$ ); short isoform ( $r^2=0.003$ ,  $P=0.733$ )). This result suggests that *PHACTR1*-rs9349379 is unlikely to mediate its effect on CAD/MI risk by regulating the expression of the immune-specific short isoform in hRCA.

**2761W****Integration of GWAS and local genetic effects on gene expression**

**(eQTL/ASE) highlights genes with kidney function and disease.** C. Qiu<sup>1</sup>, S. Huang<sup>1</sup>, J. Park<sup>1</sup>, Y. Ko<sup>1</sup>, Y. Park<sup>2</sup>, M. Palmer<sup>2</sup>, C. Boustany<sup>2</sup>, S. Pullen<sup>2</sup>, C. Brown<sup>2</sup>, K. Susztak<sup>3</sup>. 1) Department of Medicine, Renal Electrolyte and Hypertension Division, University of Pennsylvania, Philadelphia, PA; 2) Department of Genetics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA; 3) Pathology and Laboratory Medicine at the Hospital of the University of Pennsylvania, Philadelphia, PA; 4) Boehringer Ingelheim Pharmaceuticals, Inc. Ridgefield, CT 06877, USA.

Chronic kidney disease (CKD) is a common complex disease affecting 10% people of the population. Genome-wide association studies (GWAS) have identified more than 100 genomic regions that are significantly and reproducibly associated with kidney function. Identifying genetic variations associated with quantifiable cellular phenotypes such as gene expression levels (eQTLs) is a powerful approach to identify functional variants. We have earlier generated eQTL data for 96 whole kidney samples and integrated these results with GWAS signals and identified 7 potential target genes. Here we examined whether we can improve upon our GWAS target gene identification by generating kidney compartment specific eQTL and allele-specific expression (ASE) datasets. Human kidney tissue samples and associated clinical data were collected from unaffected portion of nephrectomies and manually microdissected into key kidney compartments, glomerulus and tubule fractions. Whole transcriptome sequencing was performed separately and genotyping was done using Affymetrix arrays. Histological analysis and in silico cell type composition analysis was performed to assure consistency of cell type composition of the analyzed samples. Finally 121 of samples that were of European descent were used for the analysis. We identified cis-eQTLs and associated ASE regions variation in kidney compartments and compared our results with publicly available 44 human tissue data from Genotype Tissue Expression consortium to test kidney-specificity. Then we integrated CKD-GWAS and eQTL findings by multiple genetic colocalization methods, including Coloc and RTC. We identify 4081 eGenes in the tubule compartment and 4913 in glomeruli, the list of eGenes showed 91% overlap. The eSNPs were enriched on kidney specific regulatory regions such as promoters and enhancers. By overlapping kidney eGenes with the GWAS catalogue, we found statistically significant enrichment for blood metabolite and kidney specific traits. Using meta-analysis method, we have identified 507 kidney tissue specific eGenes, which were enriched for kidney function and disease traits. By integrating kidney compartment specific eQTL and ASE and kidney disease GWAS variants, we identified 17 likely GWAS target genes. Integration of GWAS data with compartment-specific eQTLs and ASE analysis can improve upon identification for potential causal genes for kidney function and disease when compared to whole tissue samples.

**2762T****Contribution of AMD risk variants to the genetic architecture of choroidal thickness in the Amish.**

N. Restrepo<sup>1</sup>, Y. Song<sup>1</sup>, R. Laux<sup>1</sup>, L. Adams<sup>2</sup>, D. Fuzzell<sup>1</sup>, L. Caywood<sup>2</sup>, V. Horst<sup>2</sup>, T. MacKay<sup>2</sup>, D. Dana<sup>3</sup>, M. Nittala<sup>4</sup>, S.V. Sadda<sup>4,5</sup>, W. Scott<sup>2</sup>, . Stambolian<sup>3</sup>, M.A. Pericak-Vance<sup>2</sup>, J. Haines<sup>1</sup>. 1) Population & Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 2) Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Departments of Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA; 4) Doheny Image Reading Center, Doheny Eye Institute, Los Angeles, CA; 5) Department of Ophthalmology, University of California –Los Angeles, CA.

**Purpose:** To understand the role that genetics plays in risk and progression of AMD. Parsing AMD into quantitative endophenotypes, each with a distinct genetic basis, will improve prediction of risk and increase our understanding of the genetic architecture of AMD. Here we assess the contribution that known AMD risk SNPs contribute to the genetics of choroidal thickness (CT) in an Amish cohort. **Methods:** We sampled 579 related individuals from Amish families with early/intermediate AMD cases in Pennsylvania, Ohio, and Indiana. Individuals underwent a health history and ophthalmologic exam including color fundus photography and SD-OCT scans. Individuals were genotyped for 52 known AMD risk-associated SNPs. We performed a genetic association study of individuals from AMD pedigrees ascertained because at least one individual was diagnosed with AMD. CT was treated as both a continuous and a dichotomous trait (thin vs. normal). Tests were performed with R-Package “GWAF” assuming an additive genetic model and a Wald chi-square test for right, left, and mean eye measures. Continuous CT was analyzed under a Generalized Linear Mixed Effects model (GLMM) and dichotomous CT under Generalized Estimating Equations (GEE) model. **Results:** Of the SNPs tested, two were consistently identified across statistical algorithms and across models. Rs1142 on chr. 7 is located in the 3' UTR of the *SRSF protein kinase 2 (SRPK2)* gene. When considering CT as a dichotomous trait, rs1142 is statistically significant ( $p < 0.001$ ) across GLMM and GEE regardless of AMD status. Modeling CT as a continuous trait, rs1142 is significant ( $p = 0.005$ ) only after excluding AMD cases from the pedigrees. Rs2230199 is a missense variant in *complement component 3 (C3)* and is significantly associated with CT as a dichotomous trait under the GEE model and with nominal associations in GLMM ( $p < 0.05$ ). **Conclusions:** The association of a known AMD-risk variant in *C3* with CT suggests that the CT endophenotype shares pathophysiology with AMD. Additionally, variants in *C3* (i.e., rs2241394) are associated with risk of polypoidal choroidal vasculopathy, which shares characteristics of wet AMD, in the Japanese. The.

**Type 1 diabetes progression is correlated with changes in the co-expression relationships of immune response genes.** *I. Braenne, R. Chen, A.W. Manichaikul, S. Onengut-Gumuscu, S.S. Rich, W. Chen, C.R. Farber, TEDDY Study Group.* Center of Public Health Genomics, University of Virginia, Charlottesville, VA.

Type 1 diabetes (T1D) is an autoimmune disease caused by destruction of beta-cells in the pancreas. The etiology of T1D is unknown, but likely due to effects of multiple genetic and environmental factors. The Environmental Determinants of Diabetes in the Young (TEDDY) study aims to identify factors influencing T1D through the long-term monitoring of children at high genetic risk of T1D. Here, we applied Weighted Gene Co-expression Network Analysis (WGCNA) to whole blood gene expression profiles taken every 3-6 months from TEDDY participants with the goal of identifying network alterations influencing T1D progression. We generated a co-expression network using gene expression profiles collected approximately six months before T1D diagnosis (N=60). From this network, we identified two co-expression modules whose behavior was highly associated with T1D progression. The first module contained 1437 genes and its eigengene was positively correlated with age at T1D diagnosis (slower progression) ( $r=0.50$ ,  $p=6 \times 10^{-9}$ ). This module was enriched for "immune response" genes ( $p=5 \times 10^{-27}$ ) and the pathway "Reactome neutrophil degranulation" ( $p=2.15 \times 10^{-38}$ ). The second significant module contained 36 genes and its eigengene was negatively correlated with age at T1D diagnosis (faster progression) ( $r=-0.54$ ,  $p=1 \times 10^{-6}$ ). This module was enriched for the KEGG pathway "B-cell signaling" ( $p=3 \times 10^{-6}$ ). Over time, we observed significant dynamic changes in the strength of gene-gene relationships (connectivity). In particular, we observed consistent increases in connectivity at time points preceding T1D onset. These network changes were not due to differences in individual gene expression levels or apparent blood cell composition. The hub genes exhibiting the largest changes in connectivity as a function of time were *CXCR5*, *MMP25* and *IFIT3*. *CXCR5* belongs to the chemokine receptor family and is a putative biomarker for T1D. *MMP25* is a matrix metalloproteinase known to play a role in immune system function. *IFIT3* is related to the interferon gamma signaling pathway, a pathway suggested to play a role in T1D progression. The results of this study suggest that changes in gene connectivity play a role in the etiology of T1D. Further dissection of network changes may identify specific factors and mechanisms influencing T1D progression.

**Understanding progression and subtypes of prediabetes with metabolomics and genomic profiling in Starr County Mexican Americans.** *G. Jun<sup>1</sup>, C. Evans<sup>2</sup>, G. Bell<sup>3</sup>, C. Burant<sup>2</sup>, C. Hanis<sup>1</sup>.* 1) Human Genetics Center, UTHealth School of Public Health, Houston, TX; 2) University of Michigan; 3) University of Chicago.

Biological and metabolic changes occur long before the diagnosis of type 2 diabetes (T2D). Understanding the metabolic landscape in the early stages is important to understand progression to and subtypes of diabetes. Currently there are three different criteria defining prediabetes: fasting glucose, 2-hr glucose, and HbA1c. All three predict diabetes but they differ in underlying biological and metabolic mechanisms. In Starr County, only 12.3% of those with prediabetes meet all three criteria. It has been long known that branched-chain amino acids play an important role in insulin regulation and glucose metabolism and recent studies show that metabolomics profiling provide important information about diabetes and its progression. Metabolomic and lipidomic profiles were assayed on 155 samples from 127 unrelated females as a pilot analysis at the University of Michigan. 28 individuals were profiled at two time points 10 years apart with selection based on BMI change profiles. Results show distinctive amino acid signatures in normal and prediabetic individuals. Moreover, we observed differences in amino acid levels between subtypes of prediabetes. Average arginine levels of individuals with prediabetes by impaired fasting glucose were much higher than normal, but arginine levels in prediabetes by impaired glucose tolerance (2-hour glucose) was noticeably lower than normal. Next we tested for quantitative associations of metabolites with glucose phenotypes. The top metabolites associated with fasting glucose and HbA1c were from amino acids including lysine, tryptophan, arginine, and isoleucine, while 2-hr glucose associated signals were mainly from fatty acids including palmitate, palmitoleic acid and oleic acid. We performed genetic association analyses of these metabolites and found genome-wide significant signals for kynurenine (rs2973808) and elaidic acid (chr11:61602453:D). We also observed additional signals for unknown metabolites that are highly correlated with prediabetes-associated metabolites. We also performed multi-dimensional discriminant analyses to take full advantage of the untargeted metabolomics data. K-nearest neighbor imputation was done on 3,560 metabolites with  $\leq 30\%$  missing rates and 78 metabolites were selected by Elastic Net with multi-response Gaussian model. Discriminant analyses on selected metabolites show clear separation between subtypes of prediabetes, suggesting that metabolomic profiles help identifying subtypes of prediabetes.

**2765T**

**Preliminary evidence suggests that a 6.7 kb deletion polymorphism in *LILRA3* is associated with Type 1 Diabetes.** C. Maroteau<sup>1</sup>, M.K Siddiqui<sup>1</sup>, P. Appelby<sup>2</sup>, C.N.A Palmer<sup>1</sup>. 1) Division of Molecular and Clinical Medicine, University of Dundee, Dundee, ANGUS, United Kingdom; 2) Health Informatics Centre (HIC) / FARR Scotland, Ninewells Hospital and Medical School, Dundee, ANGUS, United Kingdom.

The 6.7 kb deletion polymorphism in *LILRA3* is well characterized in the East Asian population and shows evidence of natural selection. The deletion has known associations with autoimmune traits such as multiple sclerosis, Sjorgen's syndrome, Systemic Lupus Erythematosus. We examine exome sequence data from 1,373 individuals to determine the frequency of the deletion, and to identify variants strongly associated with the deletion in a European population. Finally, we perform a PheWAS on a sub-population for whom detailed clinical data was available. We find the deletion occurs in 63% of our population, as opposed to Northeast Asian populations where the frequency is variable, but often above 75%. Previous studies in Northeast Asian populations have also found variants in neighbouring *LILRB2* to be in total linkage with the deletion, however we observe that the  $R^2$  is 0.24. Further examination of variants associated with the deletion showed a SNP in *HLA-DRB5* (rs41559420) was strongly associated. This locus has known associations with the development of Type 1 diabetes. A preliminary PheWAS showed a strong association between the deletion and insulin use ( $n = 212$ ), but no other diabetic medication, suggesting a type 1 diabetic phenotype. We present evidence that suggests *LILRA3* might play a role in the etiology of Type 1 diabetes. The relationship between *LILRA3*, *HLA-DRB5* and Type1 diabetes is worthy of further exploration. Furthermore, disease profiles of autoimmune traits juxtaposed with the *LILRA3* deletion frequency should be examined across populations that show diverse frequency.

**Smoking-by-genotype interaction in type 2 diabetes.** P. Wu<sup>1</sup>, D.V. Rybin<sup>1</sup>, J.G. Wilson<sup>2</sup>, M. Feitosa<sup>3</sup>, N. Franceschini<sup>4</sup>, J. Dupuis<sup>1,5</sup>, J.B. Meigs<sup>6,7,8</sup>, J.L. Vassy<sup>9,10,11</sup>, C.T. Liu<sup>1</sup> on behalf of the CARE Consortium and the CHARGE Gene-Lifestyle Interactions Consortium. 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS; 3) Division of Statistical Genomics, Washington University in St. Louis, St. Louis, MO; 4) Department of Epidemiology, The University of North Carolina at Chapel Hill, Chapel Hill, NC; 5) Framingham Heart Study, National Heart, Lung, and Blood Institute, Framingham, MA; 6) Department of Medicine, Harvard Medical School, Boston, MA; 7) Division of General Internal Medicine, Massachusetts General Hospital, Boston, MA; 8) Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge, MA; 9) Division of General Medicine and Primary Care, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 10) VA Boston Healthcare System, Boston, Massachusetts, USA; 11) Harvard Medical School, Boston, Massachusetts, USA.

**Background:** Smoking is an important behavioral risk factor for type 2 diabetes (T2D), but not all smokers develop T2D. It is unknown whether genotypes explain some of this variability. We performed a genome-wide gene-by-environment interaction study (GEWIS) to identify SNPs that exhibit interaction with baseline smoking status (ever vs. never) on incident T2D.

**Method:** We performed ethnicity-stratified analyses using Cox proportional hazards model to evaluate whether SNP-by-smoke interactions additionally contributing to the incident T2D. We implemented several strategies and determined that there was an association if a SNP was significant in one of 3 scenarios: (1) SNP-by-smoking interaction, (2) joint test of interaction and main effect, excluding SNPs with significant main effects (3) SNP effect in only one smoking status-stratified analysis. In the discovery stage, we conduct cohort-specific association analysis and performed inverse variance weighted fixed-effect meta-analysis to analyze 5 cohorts, including 17,823 European American and 4,820 African American, from Candidate-gene Association Resource (CARE) Consortium and evaluated the association for the SNPs from the gene centric IBC 50k. We then followed up 701 candidate SNPs ( $p$ -value  $< 10^{-3}$  in one of three scenarios) from the discovery stage in 14 cohorts from the CHARGE Gene-Lifestyle Interactions Consortium ( $N_{\text{European}}=35831$ ,  $N_{\text{African}}=2690$ ). We selected  $2 \times 10^{-6}$  as the chip-wide significance threshold for the combined analysis. **Results:** We identified and replicated four loci significantly associated with incident T2D. Two loci, *RTN4* (EA) and *FBN1* (AA), were identified in joint analysis. Four loci reached chip-wide significance threshold in smoke-stratified analysis: *RTN4* (EA) in never smokers, *TCF7L2* (EA), *FBN1* (AA) and *CUBN* (AA) in ever smokers. *TCF7L2* has been associated with T2D and fasting glucose. Genetic variation in the cubilin (*CUBN*) has been associated with albuminuria, chronic kidney disease and end-stage renal disease in blacks. Prior study also showed that hyperinsulinaemia/hyperglycaemia-induced the changes of mRNA expression of Fbn1 in rat. And *FBN1* has been found to be responsible for cardiovascular disease. **Conclusion:** We have identified loci that could have been detected only in a stratified analysis. Our findings provide evidence for genetic interactions of smoking exposure on the risk of on genes that may explain some of the T2D genetic risk heterogeneity.

**2767W**

**Genome-by-environment interactions have a major impact on obesity.** C. Amador<sup>1</sup>, C. Xia<sup>1</sup>, R. Nagy<sup>1</sup>, A. Campbell<sup>2,3</sup>, D. Porteous<sup>2,3</sup>, C. Hayward<sup>1</sup>, P.K. Joshi<sup>4</sup>, J.F. Wilson<sup>1,4</sup>, P. Navarro<sup>1</sup>, C. Haley<sup>1,5</sup>. 1) MRC Human Genetics Unit, Institute of Genetic and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; 2) Centre for Genomic and Experimental Medicine, Institute of Genetic and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom; 3) Generation Scotland, Centre for Genomic and Experimental Medicine, Institute of Genetic and Experimental Medicine, University of Edinburgh, Edinburgh, United Kingdom; 4) Centre for Global Health Research, Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, United Kingdom; 5) Roslin Institute and Royal (Dick) School of Veterinary Studies, University of Edinburgh, Edinburgh, United Kingdom.

Obesity has a large genetic component: estimates from twin studies for the heritability of BMI are in the range of 48-60%. Large-scale genome-wide association studies have now identified many genetic variants associated with BMI, but almost all the detected individual variants have a very small effect on BMI. Non-genetic variation is attributed to environmental causes, with factors such as lack of exercise and a high-calorie diets often blamed for the obesity epidemic. Several studies have shown that specific genetic variants have an effect on BMI that depends on interactions with such lifestyle variables. However, the proportion of the trait variation that is explained by interactions with individual genetic variants is even smaller than the direct effects of the variants themselves, making them very difficult to detect. Here we take a new approach and study the overall contribution of interactions between the genome and environment, by estimating the total variance that genome-by-environment interactions (GxE) explain. To do this, we constructed separate similarity matrices for individuals based on their genomes and their lifestyles, and we combined those two matrices to create a joint similarity matrix reflecting the genome-by-environment interactions. This novel method measures the effect of sharing both genes and lifestyles, over and above their separate effects. Using 15,000 genotyped subjects from the Generation Scotland cohort, we estimated that GxE explains up to 15% of the observed variance for obesity related traits. This GxE variance is in addition to the previously detected variance explained by genetics and common environment. We replicated some of the results in UK Biobank (with 150,000 genotyped individuals). GxE is a potential source of phantom heritability measured in twin studies and our work suggests the effect is substantial and explains a large part of the long standing missing heritability problem. Even more importantly, better analysis of the interactions between genes and environment improves our understanding of trait architecture and will lead to enhanced methods of disease prediction that will facilitate more effective interventions to tackle obesity.

**Pleiotropic associations of adiposity-related genetic risk scores.** Z. Fairhurst-Hunter<sup>1,3</sup>, C.M. Lindgren<sup>2</sup>, M. McCarthy<sup>1</sup>, Z. Cheng<sup>3</sup>, R. Walters<sup>3</sup>, M. Holmes<sup>3</sup>, China Kadoorie Biobank Collective and UK Biobank. 1) Wellcome Trust Centre for Human Genetics, Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom; 2) The Big Data Institute, Li Ka Shing Centre for Health Information and Discovery, University of Oxford; 3) Clinical Trial Service Unit & Epidemiological Studies Unit (CTSU), Nuffield Department of Population Health, University of Oxford.

**Aim:** To assess, in 2 different ancestries, how genetic risk scores (GRSs) for adiposity traits associate with various measures of adiposity and body shape. **Methods:** Externally weighted GRSs were constructed for the adiposity traits: body mass index (BMI); waist and hip circumferences (WC, HC); waist-hip ratio (WHR); and BMI-adjusted WC, HC and WHR (WCadjBMI, HCadjBMI, WHRadjBMI), using published SNPs associated with the respective adiposity trait at  $P < 5 \times 10^{-8}$ . Residuals for each adiposity trait, derived from adjustment for: age, sex, and population stratification, were tested for association with each GRS, in 32,211 individuals from China Kadoorie Biobank (CKB) and 118,727 individuals from UK Biobank (UKB). **Results:** All scores were significantly associated with their corresponding adiposity trait, but these associations were consistently stronger in Europeans (EUR) than in East Asians (EAS). In EUR, a unit increase in each GRS was associated with an increase in the corresponding trait of 0.81 SDs or greater. By contrast, in EAS the only GRS to attain an effect size greater than 0.8 with the corresponding trait was the GRS for BMI ( $\beta = 0.84$ ). Despite limited overlap between the GRSs in terms of loci (average overlap 16%), each GRS was associated with multiple other adiposity traits. In the extreme the GRSs for HC, WHRadjBMI and WCadjBMI were significantly associated ( $P < 5 \times 10^{-8}$ ) with every adiposity trait tested. Furthermore, GRSs often had effects on non-corresponding traits similar to or greater than the effect on their corresponding trait. For example, a unit increase in the GRS for WC was associated with an increase in WC of  $\beta = 0.73$  in CKB and  $\beta = 0.84$  in UKB, but had slightly stronger effects on BMI of  $\beta = 0.76$  in CKB and  $\beta = 0.89$  in UKB. **Summary:** GRSs for individual adiposity traits showed pleiotropic effects across multiple traits. This may hamper interpretation of studies using such scores to assess the relationship of different adiposity traits with disease risk. In order to assign risk to a certain adiposity distribution, the pleiotropic effects of the scores should be addressed. Additionally, reduced performance of many of the GRSs in EAS suggests differences in genetic architecture for body shape between EUR and EAS, highlighting the importance of performing GWAS in diverse populations.

## 2769F

**Investigation of the association between ITLN1 gene A326T polymorphism and in subjects with type 2 diabetes mellitus and obese: In the TARF study.** F. Geyik<sup>1</sup>, A. Onat<sup>2</sup>, G. Can<sup>3</sup>, N. Coban<sup>1</sup>, E. Komurcu-Bayrak<sup>1</sup>, N. Erginel-Unaltuna<sup>1</sup>. 1) Department of Genetics, Aziz Sancar Institute of Experimental Medicine, Istanbul University, Istanbul, Turkey; 2) Department of Cardiology, Cerrahpasa Medical Faculty, Istanbul University, Istanbul, Turkey; 3) Department of Public Health, Cerrahpasa Medical Faculty, Istanbul University, Istanbul, Turkey.

**Background:** Omentin is a novel adipokine expressed predominantly in visceral adipose tissue. Plasma omentin levels are negatively correlated with obesity, insulin resistance, and type 2 diabetes (T2DM). The aim of the study is to evaluate the frequency of ITLN-1 (intelectin 1) gene A326T polymorphism and assessment of its relation with serum omentin level, obesity, T2DM and other biochemical parameters in a large cross-sectional population-based random sample of Turkish Adults (TARF Study). **Methods:** Genotyping was performed using LightSNiP assay (TIB Molbiol) in 2291 adult individuals (mean age 51.9 ± 11.7; 49.1% men). Analyses were performed in men and women separately. Stratified analysis according to T2DM and obesity, was performed. **Results:** The frequency of ITLN1 rare allele (T) was 27.9%, and the genotype distribution was in Hardy-Weinberg equilibrium. In both genders, A326T polymorphism T allele carriers were not at increased risk for obesity and T2DM. When the study population was stratified according to T2DM, homozygotes for T allele were strongly associated with elevated fasting triglyceride ( $p=0.025$ ) and C-reactive protein levels ( $p=0.029$ ) in diabetic men. Non-diabetic men with homozygote T allele had elevated serum omentin levels ( $p=0.033$ ). ITLN1 A326T polymorphism was related to triglyceride ( $p=0.022$ ) and lipoprotein(a) ( $p=0.014$ ) levels in obese women. **Conclusion:** The ITLN1 A326T polymorphism is associated with serum omentin levels in a sex- and diabetes-specific manner. Presence of obesity in women and diabetes in men seems to be required for A326T polymorphism to induce markedly elevated triglycerides.

**Fine-mapping and characterization of GWAS loci harboring extensive allelic heterogeneity.** C. Spracklen<sup>1</sup>, A.U. Jackson<sup>2</sup>, A. Iyengar<sup>1</sup>, S. Vadlamudi<sup>1</sup>, H.M. Stringham<sup>3</sup>, Y. Wu<sup>1</sup>, M.E. Cannon<sup>4</sup>, M. Civelek<sup>5</sup>, K. Currin<sup>1</sup>, C. Fuchsberger<sup>1</sup>, A.E. Locke<sup>6</sup>, R. Welch<sup>7</sup>, P.S. Chines<sup>8</sup>, N. Narisu<sup>9</sup>, A.J. Lusis<sup>1</sup>, J.K. Kuusisto<sup>9</sup>, F.S. Collins<sup>6</sup>, M. Boehnke<sup>2</sup>, M. Laakso<sup>8</sup>, K.L. Mohlke<sup>1</sup>. 1) Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics and Center for Statistical Genetics, School of Public Health, University of Michigan, Ann Arbor, MI; 3) Center for Public Health Genomics, University of Virginia, Charlottesville, VA; 4) Center for Biomedicine, European Academy of Bozen/Bolzano (EURAC), University of Lubeck, Bolzano, Italy; 5) McDonnell Genome Institute, Washington University School of Medicine, Saint Louis, MO; 6) National Human Genome Research Institute, National Institutes of Health, Bethesda, MD; 7) Department of Medicine, University of California, Los Angeles, Los Angeles, CA; 8) Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Interpreting GWAS loci can be challenging if multiple functional variants exist. Using adiponectin levels, a complex trait, we sought to fine-map loci containing multiple signals. In a GWAS of 19M variants in 9,262 nondiabetic individuals from the Metabolic Syndrome in Men (METSIM) study, we identified 3 significant loci, *CDH13*, *ADIPOQ*, and *IRS1*. At each locus, we performed stepwise conditional analyses to identify additional signals. Distinct signals were defined as  $P_{\text{cond}} < 1 \times 10^{-5}$  within 1 Mb of the index variant with pairwise linkage disequilibrium (LD) between variants  $r^2 > .01$ ; signals were defined as independent if  $r^2 \leq .01$ . We annotated signals using eQTLs in adipose tissue from 770 METSIM subjects, ATAC-seq data from adipose tissue of 3 subjects and SGBS preadipocyte cells, and Epigenomics Roadmap adipose nuclei data. Two adiponectin-associated loci (*CDH13*, *ADIPOQ*) contained 2 and 8 distinct signals, respectively, 2 and 4 of which are independent. Joint conditional analyses were performed with GCTA for comparison, identifying 2 (*CDH13*) and 6 (*ADIPOQ*) of the signals from the stepwise approach. At *CDH13*, the 1<sup>st</sup> previously-identified signal contained the lead adipose eQTL variant for *CDH13*, as well as a proposed functional variant and a methylation QTL. Within the new 2<sup>nd</sup> *CDH13* signal, we examined a candidate regulatory element containing rs4782722 and rs12444113 and observed >1.6 fold allelic differences ( $P=0.001$ ) in transcriptional reporter activity. At *ADIPOQ*, each of the 8 distinguishable signals consisted of 1-15 variants ( $r^2 > 0.8$ ), including rs62625753, a coding variant (G90S;  $P_{\text{int}}=3 \times 10^{-3}$ ,  $P_{\text{cond}}=6 \times 10^{-4}$ ) predicted to be deleterious (SIFT) and probably damaging (PolyPhen). The lead adipose eQTL for *ADIPOQ* was the 8<sup>th</sup> ranked signal (rs35469083;  $P_{\text{int}}=1 \times 10^{-44}$ ,  $P_{\text{cond}}=2 \times 10^{-9}$ ). The trait-raising alleles of signals 1 & 2 and of signals 1, 4 & 8 share haplotypes with frequency >0.37 ( $D' \geq 0.94$ ;  $r^2=0.05-0.33$ ), which may explain the strength of signal 1. All 8 signals contain  $\geq 1$  variant in a putative enhancer. Additional independent eQTL signals ( $\text{FDR} < 1\%$ ) were identified for *CDH13* and *ADIPOQ* that were not coincident with the other GWAS signals. Accounting for multiple signals resulted in a 1.6-fold increase in variance explained over the lead signals alone (5.9 vs 9.4%). Taken together, fine-mapping, annotation, and experimental validation identified multiple distinguishable association signals, including potentially novel coding and functional variants.

## 2771T

**Gender-, genotype- and ethnic-specific effects of sugar-sweetened beverages on serum uric acid concentrations.** X. Zhang, B. Mass, R. Hou, V.S. Voruganti. Nutrition, University of North Carolina at Chapel Hill, Nutrition Research Institute, Chapel Hill, NC.

Increased consumption of sugar-sweetened beverages (SSB) has been associated with elevated serum uric acid (SUA) concentration, which in turn increases the risk for gout, kidney and cardiovascular disease. However, it is not clear whether an individual's response in SUA to SSB is dependent on one's genotype and ethnicity. The aim of this study was to investigate the acute effects of SSB on SUA in adults, aged 30-50yrs, of Caucasian (C), African-American (A) or Hispanic (H) descent and determine whether the SUA response is dependent on their gender, genotype and ethnicity. After an overnight fast, 61 subjects (C=37, A=20, H=4) consumed SSBs containing 60 grams of fructose and 15 grams of glucose. Blood samples were collected at 0-, 30-, 60-, 120- and 180-minute post-baseline for the analysis of SUA. Six single nucleotide polymorphisms (SNPs) from uric acid transporters, rs2231142 of *ABCG2*, rs1183201 of *SLC17A1* and rs16890979, rs737267, rs6449213 and rs3775948 of *SLC2A9*, were genotyped. Baseline SUA levels were significantly higher in men (6.2 (0.3) mg/dL) than in women (5.2 (0.1) mg/dL,  $p < 0.01$ ). Following SSB consumption, SUA increased 0.65 mg/dL within 30 minutes and then gradually returned to the baseline concentration by 180 minutes. The changes in SUA throughout five time points were significantly different between men and women ( $p < 0.009$ ). Genotype-specific analysis showed that rs3775948 was significantly associated with changes in SUA at all time points between GG and GC ( $p = 0.03$  (0min);  $p = 0.03$  (30min);  $p = 0.01$  (60, 120 and 180min) and between GC and CC ( $p = 0.04$  (60min),  $p = 0.02$  (120min and 180min) genotypes in women but not in men. Ethnic-specific analysis showed that baseline SUA was similar in all ethnicities [(C-5.6 (0.21) mg/dL); A-5.4 (0.4) mg/dL; H-5.2 (0.24) mg/dL,  $p = 0.31$ ]. However, significant differences were found between C and A post SSB consumption [(0-30min,  $p < 0.05$ ) (30-60min,  $p < 0.05$ ), (60-120 min,  $p < 0.05$ ), (120-180min,  $p < 0.05$ )]. The present pilot data demonstrate that SUA response to SSB depends on individual genders, genotypes and ethnicity and they need to be confirmed in larger population studies. Overall, our work underscores the importance of gender, genotype and ethnic-specific responses to dietary challenges in intervention studies.

**Long-term response to oral eliglustat in treatment-naïve adults with Gaucher disease type 1: Final efficacy and safety results from a phase 2 clinical trial after 8 years of treatment.** H. Lau<sup>1</sup>, E. Lukina<sup>2</sup>, N. Watman<sup>3</sup>, M. Dragosky<sup>4</sup>, E. Avila Arreguin<sup>5</sup>, H. Rosenbaum<sup>6</sup>, Y. Wu<sup>7</sup>, S.J.M. Gaemers<sup>7</sup>, M.J. Peterschmitt<sup>7</sup>. 1) New York University School of Medicine, New York, NY; 2) National Research Center for Hematology, Moscow, Russia; 3) Hospital Ramos Mejia, Buenos Aires, Argentina; 4) IMAI-Research, Buenos Aires, Argentina; 5) Instituto Mexicano del Seguro Social Hospital de Especialidades, Col. La Raza, Mexico; 6) Rambam Medical Center, Haifa, Israel; 7) Sanofi Genzyme, Cambridge, MA.

**Background:** We report final long-term efficacy and safety results of a Phase 2 trial (NCT00358150, Sanofi Genzyme) in previously untreated adult patients with Gaucher disease type 1 (GD1) after 8 years of treatment with eliglustat, an oral substrate reduction therapy. **Methods:** Adult GD1 patients who had splenomegaly with thrombocytopenia and/or anemia received 50 or 100 mg eliglustat tartrate (equivalent to 42 or 84 mg eliglustat) twice daily, dosed by plasma trough levels. Efficacy outcomes included changes in hemoglobin, platelets, spleen and liver volumes, disease-related biomarker levels, skeletal manifestations, and achievement of therapeutic goals for anemia, thrombocytopenia, splenomegaly, and hepatomegaly (Pastores. *Semin Hematol.* 2004; Lukina. *Blood.* 2010). **Results:** Of 26 enrolled patients, 19 completed the trial and 7 withdrew: 2 due to asymptomatic nonsustained ventricular tachycardia detected during 36-hour ECG safety monitoring on Day 1 (plasma drug levels were undetectable); 1 after 1 year due to progression of a bone lesion retrospectively identified at baseline; 1 administrative withdrawal after 2 years; and 3 due to pregnancy. After 8 years of eliglustat, mean±SD hemoglobin and platelet count increased by 2.1±1.7 g/dL (from 11.3±1.6 to 13.4±1.3 g/dL) and 110% (from 67.5±21.1 to 130.7±59.8 ×10<sup>9</sup>/L), respectively. Mean spleen and liver volumes decreased by 68% (from 17.3±10.4 to 5.1±3.5 multiples of normal [MN]) and 31% (from 1.6±0.5 to 1.1±0.3 MN), respectively. All patients met ≥3 of 4 long-term therapeutic goals (spleen, 100% of patients; liver, 100%; hemoglobin, 93%; platelets, 53%) by 7–8 years. Median chitotriosidase levels decreased by 84%, CCL-18 by 82%, and glucosylsphingosine by 88%; plasma GL-1 normalized. Total mean lumbar spine bone mineral density increased by 0.12 g/cm<sup>2</sup>; mean Z-score increased by 0.88 (from -1.27±1.02 to -0.39±1.13) and mean T-score by 0.95 (from -1.64±1.07 to -0.69±1.31). Eliglustat was well-tolerated. All quality of life measures (SF-36, fatigue severity score, Gaucher disease severity score) showed improvement over time. Most adverse events in this long-term trial were mild or moderate in severity (98%, 342/348) and considered unrelated (94%, 328/348) to treatment. No new safety concerns emerged. **Conclusion:** Clinically meaningful improvements in hematologic, visceral, biomarker, and bone parameters continued or were maintained in previously untreated GD1 patients treated with eliglustat for 8 years.

**Long-term results of ENGAGE: A phase 3, randomized, double-blind, placebo-controlled, multi-center study investigating the efficacy and safety of eliglustat in adults with Gaucher disease type 1.** P. Mistry<sup>1</sup>, E. Lukina<sup>2</sup>, H. Ben Turkia<sup>3</sup>, S. Shankar<sup>4</sup>, H. Baris Feldman<sup>5</sup>, M. Ghosn<sup>6</sup>, A. Mehta<sup>7</sup>, S. Packman<sup>8</sup>, H. Lau<sup>9</sup>, M. Petakov<sup>10</sup>, S. Assouline<sup>11</sup>, M. Balwani<sup>12</sup>, S. Danda<sup>13</sup>, E. Hadjiev<sup>14</sup>, A. Ortega<sup>15</sup>, Y. Wu<sup>16</sup>, S.J.M. Gaemers<sup>16</sup>, M.J. Peterschmitt<sup>16</sup>. 1) Yale University School of Medicine, New Haven, CT; 2) National Research Center for Hematology, Moscow, Russia; 3) Hôpital La Rabta, Tunis, Tunisia; 4) Emory University, Atlanta, GA; 5) Rabin Medical Center, Petach Tikvah, and Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel; 6) Hôtel-Dieu de France University Hospital, Beirut, Lebanon; 7) The Royal Free Hospital, London, England; 8) University of California, San Francisco, School of Medicine, San Francisco, CA; 9) New York University School of Medicine, New York, NY; 10) Clinical Center of Serbia, University of Belgrade School of Medicine, Belgrade, Serbia; 11) Jewish General Hospital, Montreal, Quebec, Canada; 12) Icahn School of Medicine at Mount Sinai, New York, NY; 13) Christian Medical College, Vellore, India; 14) University Hospital Alexandrovska, Sofia, Bulgaria; 15) OCA Hospital, Monterrey, Mexico; 16) Sanofi Genzyme, Cambridge, MA.

**Background:** Eliglustat, an oral substrate reduction therapy, is a first-line treatment for adults with Gaucher disease type 1 (GD1) who have poor, intermediate, or extensive CYP2D6-metabolizer phenotypes (>90% of patients). ENGAGE (NCT00891202, Sanofi Genzyme), a randomized, double-blind, placebo-controlled, Phase 3 trial, investigated efficacy and safety of eliglustat in untreated adults with GD1. In the 9-month primary analysis period (PAP), all visceral and hematologic efficacy parameters improved significantly in eliglustat-treated but not placebo-treated patients (Mistry, *JAMA*. 2015). **Methods:** Of 40 patients in the PAP, 39 entered the open-label extension phase, during which all received eliglustat. Long-term efficacy and safety data were analyzed with respect to time on eliglustat (including the PAP), which varied from 2.3 to ≥4.5 years depending on when randomization occurred (randomization spanned 2 full years), initial randomization group (placebo or eliglustat), and protocol-mandated switches to commercial eliglustat when it became available. **Results:** Overall, 7 patients were switched to commercial eliglustat, 2 discontinued due to pregnancy, and 4 chose to withdraw. Among the 14 patients with 4.5 years of data, mean spleen and liver volumes decreased by 66% and 23%, respectively, and mean hemoglobin level and platelet count increased by 1.4 g/dL and 87%, respectively. With regard to long-term therapeutic goals for these 4 parameters (Pastores, *Semin Hematol*. 2004), among the 33 patients with ≥2.5 years of data, the majority met all 4 goals, and 91% met at least 3 goals. Mean spine T-score increased by 21%, and median levels of the biomarkers glucosylceramide, glucosylsphingosine, chitotriosidase, and MIP-1β decreased by 79%, 84%, 82%, and 71%, respectively. Eliglustat was generally well-tolerated; 99% of all 559 adverse events (AEs) and all 7 serious AEs were mild or moderate; 83% were considered unrelated to treatment. No patients discontinued due to AEs, and there were no new safety concerns.

**Conclusions:** In summary, final and complete results of the ENGAGE trial demonstrated continuation and maintenance of improvements in hematologic, visceral, biomarker, and bone measures after 4.5 years of treatment with eliglustat. Eliglustat was generally well-tolerated with no AE-related withdrawals. These results are consistent with the 4-year results of the eliglustat open-label Phase 2 trial in treatment-naïve patients (Lukina, *Blood Cells Mol Dis*. 2014).

**2774T**

**Diagnostic of a worldwide cohort of Gaucher patients: Glucosylsphingosine levels in blood reflects the severity of GBA mutations.** A. Rolfs<sup>1,2</sup>, A.K. Giese<sup>1</sup>, S. Zielke<sup>1</sup>, S. Eichler<sup>2</sup>, C. Cozma<sup>2</sup>. 1) Albrecht-Kossel-Institute, University of Rostock, Rostock, Germany; 2) Centogene AG, Rostock, Germany.

Gaucher disease (GD) is an autosomal recessive, rare genetic disorder characterized by a deficient beta-glucocerebrosidase that leads to deposition of glucocerebroside in cells especially of the macrophage-monocyte system. Gaucher phenotypes vary widely among affected individuals from perinatal lethal form to an asymptomatic type. The rate of proper early diagnosis of GD patients is low. Standardized, simple and highly reproducible workflows for the diagnosis are crucial, especially since more than 15 years a highly effective treatment is available. We have developed and systematically validated a high-throughput workflow for the simple testing of GD patients: beta-glucocerebrosidase enzymatic activity, glucosylsphingosine (lyso-Gb1) quantification in DBS followed by GBA gene sequencing from the sample blood sample. Here, we report data from over 1,000 GBA variants in over 640 Gaucher individuals. Determination of lyso-Gb1 is performed by LC/MRM-MS. Lyso-Gb1 was investigated in three GBA cohorts comprising: (A) 133 homozygotes GBA cases; (B) 226 compound heterozygotes GBA patients and (C) 201 Gaucher carriers. The lyso-Gb1 levels found Gaucher patients were clinically divided in: very mild (12 ng/ml -25.0 ng/mL), mild (25.1 - 50 ng/mL), moderate (50.1 - 200 ng/mL) and severe (>200 ng/mL). Lyso-Gb1 was proven to have a sensitivity and a specificity of 100%. The clinical severity of the mutations and their location could be correlated with the lyso-Gb1 in the homozygous cases, e.g. c.1295G>T is correlated with mild lyso-Gb1 values while c.1060G>A and c.518C>A with extremely high lyso-Gb1 values (> 600 ng/mL). The most common mutations: were c.1226A>G (30.1%) and c.1448T>C (24.7%). c.1448T>C is a severe mutation correlating to a massive increase of lyso-Gb1 up to 1,250 ng/mL. lyso-Gb1 for c.1226A>G can vary from very mild to moderate. Lyso-Gb1 concentrations in blood can be used for the easy and early diagnosis of Gaucher patients and for treatment monitoring. Literature: Rolfs et al., 2013.

**Obesity is a systemic regulatory outcome and mainly controlled by several tissues.** R. Hao, T. Yang, Y. Rong, S. Yao, S. Dong, Y. Guo. School of Life Science and Technology, Xi'an Jiaotong University, Xi'an, China.

**Abstract** It is normally believed that the abnormal or excessive accumulation of adipose tissue is the direct reason for obesity. With the growing evidence that other tissues, apart from adipose, could have essential effects on the incidence of obesity, it is necessary to comprehensively understand the roles of other tissues in affecting obesity. Here, we included 549 participants with 20 different tissue types to find the different importance of each tissue in affecting obesity. Firstly, in each tissue, we employed both Spearman's correlation test and weighted correlation network analysis (WGCNA) to identify genes with expression changes along with BMI distribution. Subsequently, we performed enrichment analyses with obesity-associated genes and pathways to see different regulation patterns among tissues. In addition, we compared obesity genes identified by genome-wide association studies (GWAS) with BMI-related genes to find the overlapping proportion in each tissue. Finally, we integrated preceding results to indicate 4 categories to represent varying degrees of effect on obesity. Statistical analyses revealed diverse BMI-related gene numbers and enrichment patterns among tissues. Comparison between all the BMI-related genes and GWAS findings showed over half overlap. Ultimately, 5 tissues showed abundant numbers of both BMI-related genes and enriched obesity-associated pathways, and successfully enriched with obesity-associated genes and prominently embraced GWAS genes. We further refer them as strong obesity-associated tissues, including adipose, brain, esophagus, muscle and pituitary. The BMI-related genes in these 5 tissues together could recognize 53.89% of GWAS identified obesity genes. In conclusion, our research suggests tissue-specific functions in pathogenesis of obesity. Also, we propose that 5 tissues could play the central roles in contributing to obesity development.

**Genetic polymorphism of APOA5 gene is associated with metabolic syndrome in Koreans.** S.W. Oh<sup>1</sup>, E. Shin<sup>2</sup>, H. Kwon<sup>3</sup>, EK. Choe<sup>1</sup>, SY. Choi<sup>1</sup>, SH. Choi<sup>1</sup>, CH. Lee<sup>1</sup>. 1) Healthcare System Gangnam Center, Seoul National University Hospital, Seoul, South Korea; 2) DNA Link, Inc., Seoul, South Korea; 3) Seoul National University Hospital, Seoul, South Korea.

**Background/Aims:** Metabolic syndrome (Mets) which is caused by obesity and insulin resistance, is well known for its predictive capability for the risk of diabetes mellitus and cardiovascular disease. The development of Mets is associated with multiple genetic factors, environmental factors and lifestyle. **Methods:** We performed a genome-wide association study to identify genetic factors related to Mets in large Korean population based samples of 1,362 subjects with Mets and 6,061 controls using the Axiom® Korean Biobank Array 1.0. We replicated the data in another sample including 502 subjects with Mets and 1,751 controls. **Results:** After adjusting for age and sex, rs662799 located in the APOA5 gene, a locus previously reported, was validated in our population ( $p = 2.85 \times 10^{-10}$  in the discovery set and  $p = 3.19 \times 10^{-3}$  in the replication set). We investigated the regional plotting for SNPs which were aggregated regionally with distances less than 100 base pair apart and had P value less than  $10^{-3}$ . 3 SNPs (rs8139657, rs5998275 and rs6518762) in the RFPL2 and C22orf42 gene were in strong linkage disequilibrium (LD) ( $R^2 = 0.966, 0.983$  and  $0.963$ ) and showed significant associations with Mets in the replication set ( $p = 1.5 \times 10^{-2}$ ,  $p = 7.77 \times 10^{-3}$  and  $p = 1.90 \times 10^{-2}$ ). **Conclusions:** We confirmed that the APOA5 gene is associated with Mets in Korean. Additional studies for investigating the association of RFPL2 and C22orf42 gene and Mets are necessary.

**2777T**

**Gene-level differential methylation analysis.** *H. Xu<sup>1</sup>, S. Li<sup>1</sup>, X. Xu<sup>2</sup>, X. Wang<sup>2</sup>, X. Wang<sup>2</sup>, S. Su<sup>2</sup>, V. George<sup>1</sup>.* 1) Dept Biostatistics & Epidemiology, Augusta University, Augusta, GA; 2) Georgia Prevention Institute, Department of Pediatrics, Augusta University, Augusta, GA.

DNA methylation is an important mechanism involved in many complex diseases. The biological and clinical significance results in increasing interests in the methods for differential methylation analysis in genome-wide association studies. Gene-level differential methylation analysis aims to identify differential methylated genes between groups. Limited statistical approaches are available for gene-level differential methylation analysis. We developed a statistical approach for gene-level differential methylation analysis based on clustered data analysis. This approach allows potential correlations between methylation levels from CpG sites within the defined genes. We compared our approach with IMA using two Illumina 450k methylation data sets, our own data on obesity and GSE54503. Analyses of these data indicate that our approach not only enables the identification of promising genes but also controls false positive rate efficiently.

**2778F**

**Newborn screening for six lysosomal storage diseases in a cohort of Mexican patients: Three-year findings from a screening program in a closed Mexican health system.** *J.I. Navarrete<sup>1</sup>, A.E. Limón<sup>1</sup>, M.J. Gaytán<sup>1</sup>, J. Reyna<sup>1</sup>, G. Wakida<sup>1</sup>, R. Delgado<sup>2</sup>, C. Cantú<sup>3</sup>, H. Cruz<sup>3</sup>, D. Cervantes<sup>1</sup>.* 1) Hospital Central sur de Alta Especialidad Petroleos Mexicanos, Mexico City, Mexico; 2) Hospital Regional de Villahermosa Tabasco Petróleos Mexicanos; 3) Laboratorio Genomik Monterrey Nuevo León, México.

To evaluate the results of a lysosomal newborn screening (NBS) program in a cohort of 20,018 Mexican patients over the course of 3 years in a closed Mexican Health System (Petróleos Mexicanos Pemex Health Services). Using dried blood spots (DBS), we performed a multiplex tandem mass spectrometry enzymatic assay for six lysosomal storage disorders (LSDs) including Pompe, Fabry, Gaucher, Mucopolysaccharidosis type I, Niemann-Pick Type A and B and Krabbe disease. Screen positive cases were confirmed using leukocytes enzymatic activity and DNA molecular analysis. Results From July 2012 to April 2016, 20,018 patients were screened; 20 patients were confirmed to have an LSD phenotype (99.9 in 100,000 newborns) final distributions included 11 Pompe disease, 5 Fabry disease, 2 MPSI and 2 Niemann Pick type A/B. We did not find any Gaucher or Krabbe patients. A final frequency of 1 in 1001 LSD newborn phenotypes was established. Discussion NBS is a major public health achievement that has decreased the morbidity and mortality of inborn errors of metabolism. The introduction of NBS for LSD presents new challenges. This is the first multiplex Latin American study of six LSDs detected through NBS.

## 2779W

**Obesity revisited: Evidence of genetic predisposition for metabolically healthy obesity.** L.O. Huang<sup>1</sup>, R.J.F. Loos<sup>2,3,4,5</sup>, T.O. Kilpeläinen<sup>1,5</sup>. 1) Section for Metabolic Genetics, Novo Nordisk Foundation Center for Basic Metabolic Research, København Ø, København, Denmark; 2) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, New York, United States of America; 3) The Genetics of Obesity and Related Metabolic Traits Program, The Icahn School of Medicine at Mount Sinai, New York, New York, United States of America; 4) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai, New York, New York United States of America; 5) Department of Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York, New York, United States of America.

Obesity has evolved into a global pandemic, which constitutes a major threat to public health. The majority of obesity-related health care costs are due to cardiometabolic complications, such as insulin resistance, dyslipidemia, and hypertension, which are risk factors for type 2 diabetes and cardiovascular disease. However, many obese individuals, often called metabolically healthy obese (MHO), seem to be protected from these complications. Recent large-scale genomic studies have provided evidence that some genetic variants show an association with increased adiposity but a favorable cardiometabolic profile, an indicator for the genetic basis of MHO. We want to identify genetic variants that are strongly associated with the MHO phenotype, defined by a range of trait pairs. We carried out cross-phenotype bivariate genome-wide meta-analyses on pairs of adiposity trait, measured by body fat percentage (BFP) and BMI, and cardiometabolic trait such as high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), triglycerides (TG), fasting insulin (FI), fasting glucose (FG), and systolic blood pressure (SBP), to confirm association pattern reminiscent of MHO. In the preliminary analysis of the BFP-HDL pair, we replicated some known loci, such as *IRS1*, *GRB14*, *CCDC92/DNAH10*, *TOMM40/APOE*, *FAM13A*, and *KFL14*, from previous GWAS. Furthermore, we identified additional loci using this approach, including *ABCA1*, *UBASH3B*, and *PCIF1*, which do not have genome-wide significant univariate p-values, but yielded genome-wide significant bivariate p-values. The bivariate analysis on the BFP-HDL trait pair has identified 85 independent loci exhibiting the MHO feature. Similarly, BFP-LDL, BFP-TG, BFP-FI, BFP-FG, and BFP-SBP trait pairs implicated over 150 loci, which include shared loci, *IRS1*, *CCDC92/DNAH10*, and *TOMM40/APOE*, with BFP-HDL, and additional ones, such as *SARS*, *CELSR2*, and *PPARG*. Analysis on BMI-associated trait pairs identified over 300 loci, some coincide with BFP-pair implicated loci, while others are novel. Many of these known and novel loci could locate in or near effector genes that implicate pathways involved in adipogenesis, fat distribution, insulin signaling, and insulin resistance. These important findings will likely contribute to the better understanding of the genetic aspects of the mechanisms that underpin MHO, which is crucial to define appropriate public health action points and to develop effective intervention measures.

**Socioeconomic deprivation amplifies genetic susceptibility to obesity and its comorbidities.** K.A. Kentistou<sup>1,2</sup>, P.K. Joshi<sup>1</sup>, J.F. Wilson<sup>1,3</sup>. 1) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, EH8 9AG, UK; 2) Centre for Cardiovascular Sciences, Queen's Medical Research Institute, University of Edinburgh, Edinburgh, EH16 4TJ, Scotland; 3) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, EH4 2XU, UK.

Obesity's rapid inflation to epidemic proportions has often been attributed to a complex interplay between environmental and genetic factors<sup>1</sup>. It is associated with increased morbidity mediated by predisposition to type 2 diabetes, cardiovascular disease and various cancers. Body mass index (BMI) is a clinically important surrogate of obesity and is a representative measure of body fat composition. Thus far, genome-wide association studies (GWAS) have linked thousands of variants to obesity and its proxies<sup>2</sup>. Using the GIANT GWA meta-analysis<sup>3</sup>, we constructed a polygenic risk score (PGRS) for BMI using all independent SNPs ( $p < 1$ ) from 118,214 UK Biobank participants, to investigate the way in which the effect of genetic susceptibility to obesity might differ by socioeconomic stratum. We observed that low socioeconomic status increased the effect of the PGRS on BMI by 25% (+/-0.05), between the top and bottom strata, beyond any effects of scale ( $p < 2.2e-16$ ). Although the size of the PGRS effects were stronger in women, their overall amplification was similar for both sexes. The effect of the genetic instruments on self reported prevalence of heart disease in the same cohort in the most socioeconomically deprived tertile was more than double that of the least deprived one (118% increase, +/-0.16,  $p=0.08$ ), although no difference was observed between the two sexes. Even though non-significant, we also found a substantial increase in the effect of the PGRS on diabetes prevalence of 58% (+/-0.34,  $p=0.115$ ). Our findings suggest that gene-environment interactions have the potential to explain a significant proportion of trait variance in obesity and its comorbidities, and highlight the potential efficacy of targeted interventions and public health policies. 1. **Effects of the interaction between a *CREBRF* missense variant and body mass index on type 2 diabetes risk in Samoans.** E.M. Russell<sup>1</sup>, N.L. Hawley<sup>2</sup>, G. Sun<sup>3</sup>, H. Cheng<sup>3</sup>, T. Naseri<sup>4</sup>, M. Sefuiva Reupena<sup>5</sup>, I. Miljkovic<sup>6</sup>, R. Deka<sup>7</sup>, D.E. Weeks<sup>1,7</sup>, S.T. McGarvey<sup>8</sup>, R.L. Minster<sup>1</sup>. 1) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Department of Epidemiology (Chronic Disease), School of Public Health, Yale University, New Haven, CT; 3) Department of Environmental Health, College of Medicine, University of Cincinnati, Cincinnati, OH; 4) Ministry of Health, Government of Samoa, Apia, Samoa; 5) Bureau of Statistics, Government of Samoa, Apia, Samoa; 6) Department of Epidemiology, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 7) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 8) International Health Institute, Department of Epidemiology, School of Public Health, Brown University, Providence, RI; 9) Department of Anthropology, Brown University, Providence, RI.

Studying genetically isolated groups, such as Samoans, may provide insight into the etiology of common complex diseases. Obesity and type 2 diabetes (T2D) are highly prevalent in Samoans (41% of men, 65% of women and 16% of men, 18% of women, respectively, in our cross-sectional sample). The minor allele of a missense variant in *CREBRF*, rs373863828 (c.1370G>A, p.Arg457Gln), is associated with increased body mass index (BMI) in the Samoan population. This variant is common in Samoans (minor allele frequency [MAF]=0.259), but is rare in other non-Pacific Islander populations (MAF < 0.0001). While BMI is a risk factor for T2D, the A allele is associated with lower than expected odds of T2D. We hypothesized that, in addition to main effects, there is a statistical interaction between the *CREBRF* variant and BMI affecting T2D odds. After log transforming BMI, we first used logistic regression to test this hypothesis. The interaction between genotype and BMI was not significantly associated with T2D ( $p=0.830$ ); however, both BMI and genotype were significantly associated with T2D as main effects in an analysis that did not include an interaction term ( $p=8.31 \times 10^{-9}$  and  $p=1.97 \times 10^{-8}$ , respectively). To further explore the relationship, we divided the sample into three genotype-specific subgroups (GG, GA, AA), and we used logistic regression to test for association between BMI and T2D within each subgroup. There was an association between BMI and T2D in the GG ( $n=1513$ ) and GA ( $n=1116$ ) subgroups ( $p=3.68 \times 10^{-5}$ , OR=4.749; and  $p=3.23 \times 10^{-5}$ , OR=8.234, respectively); however, in the AA subgroup ( $n=232$ ) there was no significant association between BMI and T2D ( $p=0.619$ , OR=1.773). This may suggest that the AA subgroup has a weaker association between BMI and T2D risk; however, this could also be the result of low power due to the small sample size of this subgroup. We used path analysis to further model the relationship between age, sex, the *CREBRF* variant and BMI. Our model indicates that sex has a moderate effect on BMI ( $p < 0.001$ , path coefficient ( $P_{\text{BMI,Sex}}$ )=-0.260) while genotype (Gt) and age have small effects ( $p < 0.001$ ,  $P_{\text{BMI,Gt}}=0.128$ ; and  $p < 0.001$ ,  $P_{\text{BMI,Age}}=0.103$ , respectively). Age has a moderate effect on T2D ( $p < 0.001$ ,  $P_{\text{T2D,Age}}=0.281$ ) while genotype and BMI have small effects ( $p < 0.001$ ,  $P_{\text{T2D,Gt}}=-0.102$ ; and  $p < 0.001$ ,  $P_{\text{T2D,BMI}}=0.108$ , respectively). These analyses suggest that the *CREBRF* variant does not synergistically alter the effect of BMI on the odds of T2D.

**Genetic determinants of glycemic response to metformin in the Million Veteran Program.** C. Roumie<sup>1,6</sup>, A. Giri<sup>2</sup>, C. Kovessy<sup>7</sup>, D.R. Velez Edwards<sup>1,2,3</sup>, J. Hellwege<sup>1,2,5</sup>, O. Wilson<sup>1,4</sup>, E. Torstenson<sup>1,2,5</sup>, K.A. Birdwell<sup>4</sup>, C. Chung<sup>1</sup>, E. Siew<sup>1,4</sup>, M. Matheny<sup>1,6</sup>, T. Edwards<sup>8</sup>, A. Hung<sup>1,4</sup> on behalf of the VA Million Veteran Program. 1) Tennessee Valley Healthcare System Nashville VA; Nashville, TN; 2) Vanderbilt Genetics Institute, Vanderbilt University Medical Center Nashville TN; 3) Department of Obstetrics and Gynecology, Vanderbilt University Medical Center; 4) Division of Nephrology & Hypertension, Vanderbilt University Medical Center; 5) Division of Epidemiology, Department of Medicine Vanderbilt University Medical Center; 6) Department of Bioinformatics, Vanderbilt University medical Center; 7) Nephrology Section, Memphis VA Medical Center, Memphis TN; 8) Department of General Internal Medicine and Public Health Vanderbilt University Medical Center, Nashville TN.

Glycemic response to metformin, the first line therapy for type-2 diabetes, is variable and heritable. Only two genome-wide significant loci have been identified to date. A better understanding of the genetic architecture may help differentiate non-responders from responders. We used data from 8,282 veterans [6,553 self-reported European Americans (EA) and 1,729 self-reported African Americans (AA)] enrolled in the Million Veteran Program (MVP) to perform a trans-ethnic genome-wide association study (GWAS) of glycemic response to metformin. Adults with normal kidney function, who initiated and took metformin for at least 180 days and had available pre (baseline) - and on-metformin treatment Hba1c measures were included in the study. The lowest recorded on-treatment Hba1c measures within 18-months of baseline Hba1c were considered for each individual. Glycemic response to metformin was computed as absolute reduction in Hba1c (baseline minus on-treatment), and relative reduction in Hba1c (absolute change divided by baseline). Linear regression models were used to evaluate the association between markers imputed to the 1000 Genomes cosmopolitan reference panel and response to metformin-Hba1c traits while adjusting for important clinical covariates and 5 principal components. We report two novel genome-wide significant loci, one for relative reduction in EAs (rs55755349: intron in *FAM107B*, 0.39% reduction for allele T,  $P=1.4 \times 10^{-6}$ ) and another for absolute reduction in trans-ethnic meta-analysis (rs4253564; 0.17 unit reduction for allele GT;  $P=2.4 \times 10^{-6}$ ). Variants within 10KB of rs55755349 have been associated with platelet function. Large platelet aggregation is characteristic in hyperglycemia. Rs4253564 lies within 500KB of well-known type-2 diabetes associated gene, *ZMIZ1*. Previously reported GWAS significant SNP rs8192675 at *SLC2A* was also nominally significant with consistent direction of effect in AAs ( $P=0.02$ ), but not in EAs. Interaction with BMI was also observed at this SNP in AAs, with largest effect in obese AAs ( $P$ -value=0.009). We also identify another SNP rs11309000 ( $P=4.9 \times 10^{-6}$ ) within <500Kb of rs8192675. We identify several other suggestive loci ( $P < 1 \times 10^{-6}$ ) with ties to type-2 diabetes and Hba1c. This trans-ethnic GWAS finds two novel loci associated with glycemic response to metformin in a well-defined cohort of EA and AA veterans. We further extend evidence for previously reported main- and interaction- effects at *SLC2A* to AAs as well.

**Principal component-based prediction of complex traits by using support vector machine approach.** X. Li, X. Zhu. Department of Population and Quantitative Health Science, Case Western Reserve University, School of Medicine, Cleveland, OH.

The use of genetic information for predicting complex disease risk has played a major role in precision medicine. In this work, we have developed a technique for genetic risk prediction using GWAS data. Our method, a two-step principal component based support vector machine approach, focuses on relaxing the assumption on the effect to accommodate different genetic architecture and takes into account linkage disequilibrium. Unlike traditional prediction approaches, such as the genetic risk score which relies on pruning and setting an arbitrary P-value threshold, the linear mixed model which assumes that the SNP effects follow a normal distribution or the Bayesian approach that requires specifying a prior, the major benefit of such an approach is that we no longer need to make assumptions on the distribution of the input data. We compared our method with the best linear unbiased predictor (BLUP) and demonstrated the improvement in risk prediction performances through Welcome Trust Case Control Consortium (WTCCC) data. Area under the ROC curve (AUC) are 75% for type 1 diabetes, 66% for rheumatoid arthritis, 64% for Coronary Artery Disease and 61% for Crohn's disease, consistently higher than 67%, 61%, 57% and 60% from BLUP, respectively. Our proposed method can substantially increase the accuracy of risk prediction across a range of diseases with different genetic architecture.

**Trans-ethnic meta-analysis of rare variants in sequencing association studies.** J. Shi, S. Lee. Biostatistics, University of Michigan, MI.

The rapid technological advances in high-throughput sequencing platforms have made it possible to test for rare variant associations to accelerate our knowledge of complex trait genetics. A practical approach to identify rare variants is to aggregate studies that have already been conducted through a trans-ethnic meta-analysis, as it aims to include samples from as many studies as possible, even if they come from different ancestries. With the increased sample size, trans-ethnic meta-analysis is expected to be more powerful at detecting novel loci. Unfortunately, under the presence of genetic effect heterogeneity among participating studies in multiethnic meta-analysis, existing approaches may be unsatisfactory because they only assume varying genetic effects between studies, but do not take into consideration that studies from the more closely related ancestries can be more homogeneous than those that are more distinctly related. To fully take advantage of the strengths of multi-ethnic meta-analysis, we propose a unified score test under a modified random effects model framework for rare variants associations. The proposed method is capable of not only accounting for the expected heterogeneous genetic effects among studies, but also flexibly modeling varying levels of heterogeneity according to the relatedness between the populations. Specifically, we adopt the kernel regression framework to construct the modified random effects model, and incorporate the genetic distances across ancestry groups into modeling the heterogeneity structure of the genetic effect coefficients. In addition, we use the adaptive variance component test to achieve robust power regardless of the degree of heterogeneity. The copula method is employed to approximate the asymptotic distribution of the proposed test, which enables rapid estimation of p-values without the need for Monte Carlo simulations. To evaluate performance of our proposed method, we conducted a series of simulations with varying assumptions on genetic effect heterogeneity. Results show that our proposed method controls type I error rates at stringent significance levels and improves power over existing approaches under the presence of heterogeneity. We will further apply our method to the Type 2 Diabetes Genetic Exploration by Next-generation sequencing in multi-Ethnic Samples (T2D-GENES) consortia data, a multiethnic sample of 12,940 individuals which focuses on exome sequence variations.

**A novel approach to analyze the mediation model when the mediator is a censored variable.** *J. Wang<sup>1</sup>, S. Shete<sup>1,2</sup>*. 1) Dept Biostatistics, UT MD Anderson Cancer Ctr, Houston, TX; 2) Dept Epidemiology, UT MD Anderson Cancer Ctr, Houston, TX.

A mediation model is a widely used statistical method which studies the direct and indirect effects of an initial variable on an outcome by including one or more mediators. In realistic studies, investigators might observe censored data instead of the complete data. The most current approaches for analyzing mediation models with censored variables focus on the censored outcome variable. However, the mediator in mediation model can also be a censored variable. In this study, we proposed a novel approach to analyze the mediation model when the mediator is a censored variable, where we suggested using the accelerated failure time (AFT) model to evaluate the effect of the initial variable on the censored mediator and a multiple imputation approach to assess effects of the initial variable and mediator on the outcome variable. We also adapted a measure of the indirect effect for the mediation model with a censored mediator, which can assess the indirect effect at both the group and individual levels. We conducted simulation studies to investigate the performance of the proposed approach and compared it to that of the existing approaches, including a naïve approach, complete-case analysis, and the Tobit mediation model. The proposed approach, based on AFT and the multiple imputation approach, accurately estimates the coefficients of different paths, indirect effects and percentages of the total effects mediated; while the existing approaches provided biased estimations. We applied the existing and proposed approaches to investigate the indirect effect of the age at menopause on the association between SNPs and type-2 diabetes. Our findings showed that there was no statistically significant indirect effect of age at menopause on the association between SNPs and type-2 diabetes.

**Genome-wide association analysis in the UK Household Longitudinal Study offers insights into the genetic architecture of health-related biomarkers.** *K. Kuchenbaecker<sup>1</sup>, B. Prins<sup>1</sup>, Y. Bao<sup>2</sup>, M. Smart<sup>2</sup>, D. Zabaneh<sup>3</sup>, G. Fatemifar<sup>4</sup>, J. Luan<sup>5</sup>, N. Wareham<sup>5</sup>, R. Scott<sup>5</sup>, J. Perry<sup>5</sup>, C. Langenberg<sup>5</sup>, M. Benzeval<sup>5</sup>, M. Kumari<sup>5</sup>, E. Zeggini<sup>1</sup>*. 1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) Institute for Social and Economic Research, University of Essex, Wivenhoe Park, Colchester, Essex, UK; 3) MRC Social, Genetic & Developmental Psychiatry Centre, IoPPN, KCL, London; 4) Institute for Health Informatics, UCL and the Farr Institute of Health Informatics, London, UK; 5) MRC Epidemiology Unit, University of Cambridge and Clinical Medicine, Institute of Metabolic Science, Cambridge, UK.

Levels of serum biomarkers can reflect health status and are associated with complex diseases, such as cardiovascular, metabolic and auto-immune disorders. We aimed to gain additional insights into the genetic architecture of biomarker traits and identify novel genetic associations. We performed genome-wide association analyses for a panel of twenty serum biomarkers involved in liver and kidney function, and reproductive health. A total of 9,961 individuals from the UK Household Longitudinal Study were genotyped using the Illumina CoreExome array and variants imputed to a dense reference panel of 1000 Genomes Project and UK10K haplotypes. The association analyses were carried out using linear mixed models to account for relatedness and betas estimated per biomarker standard deviation. Heritability and genetic correlations were estimated using GREML as implemented in GCTA. We demonstrate polygenic heritability of the majority of biomarkers included in this study. Alkaline phosphatase and testosterone had the highest array heritability estimates with  $h^2=27.7\%$  (standard error (SE): 0.040) and  $h^2=27.1\%$  (SE: 0.084), respectively. The lowest estimate was observed for ferritin ( $h^2=6.1\%$ , SE: 0.037). We identify previously unreported genetic correlations between several of the biomarkers. Polygenic factors for triglyceride levels were negatively correlated with the ones for dihydroepiandrosterone sulphate (DHEAS), a precursor to sex-hormones (genetic correlation  $r_g=-0.53$   $p=4.0 \times 10^{-4}$ ). There was a positive genetic correlation between C-reactive protein and fibrinogen levels ( $r_g=0.60$   $p=3.2 \times 10^{-8}$ ), which could be due to shared inflammation pathways. The genetic correlation between creatinine and urea ( $r_g=0.56$   $p=1.2 \times 10^{-5}$ ) is a highly biologically plausible finding as both markers are increased in blood when glomerular filtration rate declines, reflecting impaired kidney function. We also identify five novel, replicating associations at stringent genome-wide significance with levels of alanine transaminase, an indicator of liver damage, with DHEAS, and with glycated haemoglobin (HbA1c) levels, a biomarker used to diagnose and manage type 2 diabetes. Our study offers insights into the genetic architecture of both well-known and less well-studied biomarkers.

**2787F****PLEIOVAR, testing for association between multiple traits and multiple variants.** O. Meirelles<sup>1</sup>, D. Schlessinger<sup>1</sup>, L. Ferrucci<sup>2</sup>, F. Cucca<sup>3</sup>, J. Ding<sup>1</sup>.

1) Laboratory of Genetics, National Institute on Aging, 251 Bayview Blvd. Baltimore, MD, 21224, USA; 2) Longitudinal Studies Section, National Institute on Aging, 251 Bayview Blvd. Baltimore, MD, 21224, USA; 3) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Cittadella Universitaria di Cagliari - 09042 Monserrato CA Sardegna, Italy.

Genome-Wide Association Studies (GWAS) explore associations between DNA variants, usually single nucleotide polymorphism (SNPs), and a trait. Recently, analyses have been extended to assess association between multiple SNPs and a trait, or between a single SNP and multiple traits. We add an assessment of pleiotropic effects of groups of SNPs, from regions defined by each gene and the DNA in close proximity. PLEIOVAR, the assessment program, is based on principal component analysis of SNPs and traits. The level of association is measured by a summary statistic whose significance is evaluated using a Chi-squared distribution. We applied the program to trait values in 5,715 individuals in the SardiNIA population study. For lipids -- LDL, HDL and triglycerides -- and for glycemic traits -- fasting glucose, fasting insulin and HBA1c -- PLEIOVAR identified both previously reported pleiotropic associations and additional signals of moderate effect size that had not been seen with standard GWAS. The analysis yields a candidate set of novel joint associations with multiple traits for studies of underlying functional interactions. We have replicated our results applied to the same traits in 1,206 individuals in the InCHIANTI study cohort.

**2788W****Gene-depressive symptoms interactions identify novel lipid loci in multi-ethnic cohorts.** S.K. Musani<sup>1</sup>, M.A. Richard<sup>2</sup>, A.R. Bentley<sup>2</sup>, M. Brown<sup>3</sup>, M. Sims<sup>1</sup>, M. Fornage<sup>2</sup>, CHARGE Gene-Lifestyle Interactions Working Group.

1) Jackson Heart Study, University of Mississippi Medical Center, Jackson, MS; 2) Department of Epidemiology, Human Genetics, and Environmental Sciences, University of Texas Health Science Center, Houston, TX; 3) Center for Research on Genomics and Global Health, NHGRI, NIH, Bethesda, MD.

**Background:** Genetic and psychosocial factors, such as depression and depressive symptoms, are known to contribute independently to variation in cardiovascular traits including plasma lipids, but little is known about interactions between genetic and psychosocial factors. We hypothesized that depressive symptoms modulate the effect of genetic variants on plasma lipids. Hence, we performed a trans-ethnic genome-wide meta-analysis using 1000G imputed single nucleotide polymorphisms (SNP) and interaction with the presence of depressive symptoms on 3 plasma lipids: fasting high density lipoproteins (HDL), fasting low density lipoproteins (LDL) and fasting triglycerides (TG).

**Methods:** Presence of depressive symptoms was defined using standard screening questionnaires. Our analyses represented 4 ancestries: 46,177 (European); 14,499 (African); 4,453 (Hispanic) and 2,592 (Asian). In the interaction analyses, each study calculated the joint 2 degree-of-freedom (df) test of the SNP effect and the SNP × depression symptoms interaction effect, as well as the 1 df SNP × depressive symptom interaction effect. **Results:** In trans-ancestry meta-analyses we replicated over 43 known lipid loci and identified 10 novel loci where variants were significantly ( $p < 5 \times 10^{-8}$ ) associated with HDL (LOC105375070, *WAC*, *MACROD2*); LDL (*CREB5*, *CREB3L2*, *TRIM5*, *TRIM6*, LOC105370312, *ZAN790-AS1*) and TG (LOC105375070) using the 2df joint test. Variants in the *MACROD2* locus also showed significant ( $p < 5 \times 10^{-8}$ ) interaction with depressive symptoms using the 1 df test. African Ancestry specific meta-analyses identified 2 additional loci: variants in *KNCIP* and LOC105370312 were significantly associated with LDL while European specific meta-analyses identified 3 additional loci (*GABBR2*, *MAF* and *PIK3R2*) associated with all three lipid traits. Each of these ancestry-specific loci were identified using the 2 df test. Some of these genes have been reported to be associated with cancer metastasis (*CREB5*, *MAF*); neurocognitive phenotypes (*WAC*, *MACROD2*, *KNCIP4*), regulation of calcium concentration (*GABBR2*) and risk of HIV infection (*TRIM5*, *TRIM6*). Further work is ongoing to validate these loci and to understand the biological mechanisms underlying each of the associations.

## 2789T

**Targeted sequencing of 109 genes in the eMERGEseq panel uncovers novel variants and genes influencing triglyceride levels.** X. Fan, M.S. Safarova, K. Ding, J.E. Olson, S.N. Thibodeau, D.J. Schaid, I.J. Kullo. Mayo Clinic, Rochester, MN.

**BACKGROUND:** Triglyceride (TG)-rich lipoprotein levels increase the risk of coronary heart disease. We investigated whether rare variants and genomic regions (sets of variants) in 109 medically relevant genes included in the eMERGE (electronic MEDical Records and GENomics) sequencing panel, influence TG levels. **METHODS:** We performed targeted sequencing in 2,547 individuals participating in the Return of Actionable Variants Empirical (RAVE) study. We excluded 5 individuals without a lipid panel and 16 non-European ancestry individuals based on principal component analyses. The mean age was 52±9, 57% were female, mean body mass index (BMI) was 30±6 kg/m<sup>2</sup>, mean TG level was 265±274 mg/dL and 813 (35%) individuals had TG levels > 250 mg/dL. Variant and gene associations with log(TG) adjusted for age, sex, BMI and the first two principal components were conducted using linear regression in PLINK and kernel regression in sequence kernel association test (SKAT). **RESULTS:** Five missense variants passed a genome-wide threshold of significance ( $P < 5 \times 10^{-8}$ ) (Table): rs3135506 (*APOA5*) and rs1260326 (*GCKR*) were both common variants previously known to be associated with TG; a rare variant (chr20:44540064C>A) in *PLTP* that inhibits VLDL lipidation; chr16:15802684T>C (*MYH11*) and rs200652865 (*CORIN*) were novel loci. At the gene level, *APOA5*, *CORIN* and *KCNQ1* were also significantly associated with TG. The lead variants (variant with the lowest *P*-value in each gene) in *APOA5* and *CORIN* were significant at variant level. Two intronic variants in *KCNQ1* were reported to be associated with TG in a Chinese cohort. Minor allele frequency (MAF) stratified analyses indicated that rare variants in *CORIN* and *KCNQ1* drove the signal. *CORIN* remained associated with TG after removing the lead variant in conditional analysis. In contrast, after removing the lead variants in *APOA5* and *KCNQ1*, these loci were not associated with TG. **CONCLUSIONS:** In this large-scale targeted sequencing study, we found five variants and three genes to be associated with TG levels including two variants and *CORIN* that have not been reported previously to be associated with TG. These findings suggest that TG levels are influenced by multiple variants in different genes.

Summary of significant variants associated with TG levels				
Variant	Gene	MAF	Beta	P-value

Timpson<sup>1</sup>. 1) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom; 2) Computational Medicine Research Group, Institute of Clinical Medicine, University of Oulu, Finland; 3) Centre for Life Course Epidemiology, Institute of Health Sciences, University of Oulu, Finland; 4) National Institute for Health and Welfare, Helsinki, Finland; 5) Public Health Genomics, Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 6) Department of Clinical Chemistry, University of Tampere, Finland; 7) The Department of Clinical Physiology and Nuclear Medicine, Turku University Hospital, Finland.

**Background** Circulating vitamin D is associated with skeletal health, cancer risk and progression and cardio-metabolic diseases but intervention studies give conflicting results. Few epidemiological studies have investigated vitamin D associated intermediates that could elucidate causal pathways to disease. This study aims to identify and estimate the size of causal associations between serum vitamin D concentration and 158 metabolic measures independent of confounders and reverse causality using Mendelian randomization. **Participants and methods** 20,650 participants from 6 population-based cohorts were included in the study. 158 metabolic measures were obtained from a nuclear magnetic resonance platform and where available, serum 25 hydroxyvitamin D (25OHD) concentrations were measured using a blood assay. Genetic variants reliably associated with 25OHD concentrations were extracted from genome wide association data. Two-sample Mendelian randomization using participant-level genetic and metabolite data for the second stage regressions was conducted. Observational 25OHD – metabolic measure associations were assessed using linear regression. **Results** In observational analyses, a one standard deviation (SD) unit increase in log-25OHD was associated with a decrease in larger subclasses of very-low-density lipoprotein (VLDL) (e.g. very large VLDL particle concentration: -0.05 SD (95% CI: -0.06, -0.03)  $P=9 \times 10^{-9}$ ). Mendelian randomization showed consistent but imprecise estimates in support of a causal relationship in the same direction (very large VLDL particle concentration: -0.04 SD (95% CI: -0.11, 0.03)  $P=0.3$ ). Serum 25OHD concentration was strongly associated with degree of fatty-acid unsaturation, omega-3 and docosahexaenoic acid concentration in observational analyses but not in causal analyses. Observational associations between serum 25OHD and amino acids were small or absent but suggestive inverse causal associations were identified between 25OHD and several amino acids, including branched-chain amino acids (Leucine: -0.07 SDs (95% CI: -0.14, -0.01)  $P=0.02$ ). **Conclusions** Mendelian randomization estimates are consistent with previous findings that vitamin D reduces VLDL. Associations of vitamin D with healthy fatty acid profiles are unlikely to be causal. Novel potentially causal inverse associations between vitamin D and branched-chain amino acids may have therapeutic potential where branched-chain amino acids are causally related to health outcomes.

**Enriched loss-of-function variants associating with lipids in Finns.** P. Helkkula<sup>1,2</sup>, I. Surakka<sup>1,2</sup>, V. Salomaa<sup>3</sup>, S. Ripatti<sup>1,2,4</sup>. 1) Institute for Molecular Medicine Finland, Helsinki, Finland; 2) Unit of Public Health Genomics, National Institute for Health and Welfare, Helsinki, Finland; 3) Department of Health, National Institute for Health and Welfare, Helsinki, Finland; 4) Wellcome Trust Sanger Institute, Hinxton, Cambridge, United Kingdom.

Population isolates, such as Finland, show an enrichment of loss-of-function (LoF) variants with potential impact on phenotypes and disease risk. Previous examples include two LoF variants in *LPA*, causing marked reductions in lipoprotein(a), and show more than tenfold enrichment in Finns compared to non-Finnish Europeans (NFEs). We considered protein-truncating and splice site variants associated with lipids in Finland. Our study consisted of 20,643 autosomal LoF and splice site variants, with 8,353 with minimum twofold enrichment in Finns. We tested their association with LDL-C, HDL-C and triglycerides in population-based FINRISK cohort (N=23,975) which has been genotyped and imputed with a whole-genome and high-coverage Finnish-specific imputation reference panel. We found five LoF variants with strong effects on lipids. A protein-truncating variant (*rs760351239*; MAF=0.0015) in *ANGPTL8* is strongly associated with lower triglyceride levels (TG-effect=-0.613,  $P=2.46e-08$ ). The variant is more than 80 times enriched in Finns compared to NFEs. It was also associated with other lipids (HDL-effect=0.603,  $P=1.92e-08$ ; non-HDL-effect=-0.539,  $P=1.414e-06$ ; LDL-effect=-0.416,  $P=2.51e-04$ ; TC-effect=-0.296,  $P=9.04e-03$ ) and protective of T2D (OR=0.29,  $P=0.036$ ). *Angptl8* is a feeding-induced hepatokine with an essential role in postprandial triglyceride trafficking, due to its lpl-inhibiting action. Hypotriglyceridemia has previously been observed in murine *ANGPTL8* knockouts. We also observed three LoF variants with substantial HDL-increasing effects in genes *LIPG* (*rs200435657*, MAF=0.0017, effect=0.638,  $P=4.69e-11$ ), *SLC12A3* (*rs765555468*, MAF=0.0013, effect=1.00,  $P=1.51e-17$ ) and *CETP* (*rs751916721*, MAF=0.0014, effect=1.09,  $P=3.11e-20$ ). The variants are over 200, 50 and 47 times enriched in Finns, respectively. *LIPG* encodes endothelial lipase, which hydrolyzes triglycerides and phospholipids, but especially HDL-C. *SLC12A3* is the target of thiazide diuretics used for treating high blood pressure, but the way it influences HDL-C levels is unknown. *CETP* mediates reverse cholesterol transport, exchanging cholesteryl ester in HDL for triglycerides in ApoB lipoproteins. These examples illustrate the potential in using population isolates to discover downstream health effects of enriched variants interrupting protein coding. These types of findings may also point to potential intervention targets.

**Do blood lipid levels influence bone mineral density? Findings from a Mendelian randomization study.** J. Zheng<sup>1</sup>, M.J. Brion<sup>2</sup>, J. Kemp<sup>3</sup>, N. Warington<sup>2</sup>, C. Borges<sup>1</sup>, G. Hemani<sup>1</sup>, T.G. Richardson<sup>1</sup>, Z. Qiao<sup>2</sup>, P.C. Haycock<sup>1</sup>, G. Davey Smith<sup>1</sup>, J.H. Tobias<sup>1,3</sup>, D.M Evans<sup>1,2</sup>. 1) Medical Research Council (MRC) Integrative Epidemiology Unit, School of Social & Community Medicine, University of Bristol, Bristol, United Kingdom; 2) University of Queensland Diamantina Institute, Translational Research Institute, Brisbane, Queensland, Australia; 3) Musculoskeletal Research Unit, University of Bristol, Bristol, UK.

Treatment with statins is associated with increased bone mineral density (BMD) and reduced fracture risk. Previous laboratory studies suggest that direct effects of statins on osteoblasts and osteoclasts underlie this relationship. However, few studies have investigated an alternative possibility that the beneficial effects of statins on bone might also be mediated by lowering levels of low density lipoprotein cholesterol (LDL-C). In order to investigate the relationship between plasma lipids and BMD, we performed a two-sample Mendelian randomization (MR) study. We utilized 184 single nucleotide polymorphisms (SNPs) robustly associated with plasma lipid levels and 239 SNPs associated with heel BMD derived from quantitative ultrasound in 142,487 individuals from the UK Biobank Study as genetic instruments. We performed univariate MR analyses on LDL-C, high density lipoprotein cholesterol (HDL-C) and triglyceride levels, and multivariable MR to account for genetic pleiotropy among the different lipid fractions. To test whether the effect of statins on BMD was mediated by lowering lipid levels, MR was repeated with and without SNPs in the *HMGCR* region, which was used to mimic the effects of statin use. We also performed bi-directional MR to examine reverse causality between BMD and blood lipids. Analyses were conducted using the MR-Base R package (<https://github.com/MRCIEU/TwoSampleMR>). Univariate MR using SNPs associated with LDL-C, HDL-C or triglyceride levels provided evidence for a causal effect of LDL-C on BMD ( $\beta=-0.077$ ;  $P=2 \times 10^{-6}$ ; SD change in BMD per SD change in LDL-C) and the results were robust to pleiotropy. Multivariable analysis suggested that the effect of LDL-C on BMD was independent of HDL-C and triglycerides. MR analyses involving SNPs in the *HMGCR* region were consistent with a causal effect of LDL-C on BMD ( $\beta=-0.110$ ;  $P=0.016$ ) as were MR analyses excluding these SNPs ( $\beta=-0.102$ ,  $P=3 \times 10^{-6}$ ). Bidirectional MR analyses provided no evidence for a causal effect of BMD on blood lipids. We are following up these results in the full Biobank sample to ensure that they are free from possible biases due to ascertainment. Our results suggest lower LDL-C is causally related to increased BMD. This suggests the effect of statins on BMD is at least partly due to their LDL-C lowering effect. Further studies are justified to explore the mechanisms by which lower LDL-C improves BMD, and to examine the potential role of modifying blood lipids in treating osteoporosis.

**Adaptive multi-trait association test using GWAS summary data.** *B. Wu, B. Guo.* Division of Biostatistics, University of Minnesota, Minneapolis, MN.

Genetics hold great promise to precision medicine by tailoring treatment to the individual patient based on their genetic profiles. Toward this goal, many large-scale genome-wide association studies (GWAS) have been performed in the last decade to identify genetic variants associated with various traits and diseases. They have successfully identified tens of thousands of disease-related variants. However they have only explained a small proportion of the overall trait heritability for most traits and are of very limited clinical use. This is partly owing to the small effect sizes of most genetic variants, and the common practice of "testing association between one trait and one genetic variant at a time" in most GWAS, even when multiple related traits are often measured for each individual. There is increasing evidence showing that many genetic variants can influence multiple traits simultaneously, and we can gain great power by testing association of multiple traits simultaneously. Ideally we can reanalyze those existing GWAS genetic and phenotype data using the multi-trait association approach. However due to privacy concerns and various logistical considerations, it is generally very hard to access the individual-level GWAS phenotype and genotype data, which creates a barrier to use these existing data to further identify novel genetic variants. We discuss several of our recently developed statistical methods for adaptive multi-trait association test that only needs summary association statistics publicly available from most GWAS. We first show that the principal component (PC) based association test can be readily reconstructed from the summary statistics. PC based test has optimal power when the underlying multi-trait signal can be captured by the first PC, and otherwise it will have suboptimal performance. We then construct an adaptive test by optimally weighting the PC based test and the omnibus chi-square test to achieve robust performance under various scenarios. A class of novel tests explicitly accounting for potential pleiotropy effects are also developed. We develop efficient numerical algorithms to compute the analytical p-value for all our proposed adaptive tests without the need of resampling or permutation. We illustrate the competitive performance of proposed methods through application to several GWAS meta-analysis summary data.

**Genetic variation associated with telomere length in African American children with and without asthma.** *M. White<sup>1</sup>, A. Zeiger<sup>1</sup>, J. Witonsky<sup>1</sup>, M. Contreras<sup>1,2</sup>, O. Risse-Adams<sup>1,3</sup>, C. Eng<sup>1</sup>, D. Hu<sup>1</sup>, S. Huntsman<sup>1</sup>, S. Oh<sup>1</sup>, E. Burchard<sup>1,4</sup>.* 1) Department of Medicine, University of California, San Francisco, San Francisco, CA; 2) SF BUILD, San Francisco State University, San Francisco, CA; 3) Lowell Science Research Program, Lowell High School, San Francisco, CA; 4) Department of Bioengineering and Therapeutic Sciences, University of California, San Francisco, CA.

Telomere length is a biomarker of biological aging and has been associated with the progression and presence of several chronic diseases including asthma. Telomere length varies by race/ethnicity with African Americans having shorter average telomeres compared to European-descent individuals. Genome-wide association studies (GWAS) have identified several genetic variants associated with telomere length; however, these studies have been largely limited to adult populations of European descent. Genetic associations discovered in European populations do not always translate to other populations and it is possible that there may also be both population-specific and age-specific genetic determinants of telomere length that have been overlooked. It is also possible that individuals with asthma may have unique genetic associations with telomere length compared with healthy controls. Our aim was to address this gap in knowledge by providing insights and preliminary results on the genetic determinants of telomere length in African American children with and without asthma. Absolute telomere length was measured using qPCR using DNA isolated from whole blood collected from 1442 African American children with and without asthma (asthma = 879, controls = 563) and available GWAS data. Linear regression models were adjusted for age, percentage of African ancestry, maternal education level, and insurance status. Analyses were stratified by asthma case control status as well as by gender. We evaluated polymorphisms previously associated with telomere length in adults as well as performed a discovery-only GWAS and meta-analysis in our pediatric African American study population. The previously reported GWAS-identified variants in adults were not associated with telomere length in our pediatric sample. Several novel polymorphisms in various genes were found to be genome-wide significant ( $p$ -value  $< 5 \times 10^{-8}$ ) in our discovery-only GWAS and meta-analysis. Our study of the genetic determinants of telomere length in African American children revealed several novel associations between telomere length and genetic polymorphisms from multiple genes that were genome-wide significant. Further large-scale studies of children from multiple populations will be needed to determine if our findings are population-specific or age-specific.

**Genome-wide haplotype-based association study reveals novel non-HLA susceptibility loci for primary biliary cirrhosis in Japanese cohorts.** C. Im<sup>1</sup>, Y. Sapkota<sup>2</sup>, M. Nakamura<sup>3</sup>, K. Tokunaga<sup>4</sup>, Y. Yasui<sup>1,2</sup>. 1) School of Public Health, University of Alberta, Edmonton, Alberta, Canada; 2) Department of Epidemiology and Cancer Control, St. Jude Children's Research Hospital, Memphis, TN; 3) Clinical Research Center, National Hospital Organization, Nagasaki Medical Center, Nagasaki, Japan; 4) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan.

Primary biliary cirrhosis (PBC) is a chronic, progressive autoimmune disease of the liver with a strong hereditary component. While robust PBC susceptibility loci have been discovered through single SNP association testing, exploration of the joint effects of SNPs organized on the same chromosome, or haplotypes, on PBC pathogenesis is warranted. Haplotype investigations may be more powerful in mapping disease loci and can reflect *cis*-interactions that regulate gene expression. To this end, we conducted a gene-based search of haplotype SNP patterns associated with PBC risk in a cohort of 1,937 Japanese individuals (901 cases, 1,036 controls) and replicated selected signals in an independent Japanese cohort (480 cases, 469 controls). Haplotype phase was computationally estimated using SHAPEITv2.79 for unphased, genome-wide SNP genotype data. After mapping SNPs to RefSeq genes and corresponding 500-kb windows at 5'/3' ends, our analysis included ~272K SNPs mapped to 15,105 gene regions. We identified gene-based haplotype patterns consisting of 3 SNPs associated with PBC using logic regression, an adaptive regression methodology that detects best combinations of predictors associated with an outcome. We then applied a permutation-based selection statistic to 53 HLA (human leukocyte antigen) and 8,878 non-HLA unique haplotype patterns, selecting patterns with the top 1% of selection statistics for replication. A total of 24 haplotype patterns met Bonferroni-corrected p-value thresholds in replication ( $P < 0.05/\#$  of selected haplotypes). Replicated haplotype signals not only corroborated previous GWAS signals, but also implicated additional SNPs with regulatory functions in relevant cell types. For example, *TNFS15-TNFSF8* is an important PBC susceptibility locus in Japanese cohorts. One of the strongest non-HLA haplotype signals involved 3 intergenic SNPs residing near *TNFSF15* (9q32-9q33.1; OR=1.7,  $P=3.0 \times 10^{-21}$ , combined sample), each overlapping with promoter and enhancer histone mark peaks in liver and immune cell epigenomes; 2 SNPs were significantly associated with *TNFSF8* expression in whole blood. A novel non-HLA haplotype signal involving SNPs mapped to *UMAD1* introns (7p21.3; OR=15.2,  $P=3.9 \times 10^{-9}$ , combined sample) includes SNPs overlapping enhancer histone peaks in liver and memory T<sub>H</sub> cells. In summary, our study demonstrates the utility of haplotype association analyses in characterizing PBC susceptibility loci.

**Precisely controlled differential gene expression system to investigate the effect of eQTL.** X. Lu<sup>1,2</sup>, X. Chen<sup>1</sup>, C. Schroeder<sup>1</sup>, C. Forney<sup>1</sup>, J. Harley<sup>1,2,4</sup>, M. Weirauch<sup>1,3</sup>, L. Kottyan<sup>1,2</sup>. 1) Center for Autoimmune Genomics and Etiology (CAGE), Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Immunobiology Graduate Program, University of Cincinnati College of Medicine, Cincinnati, OH; 3) Divisions of Biomedical Informatics and Developmental Biology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) US Department of Veteran Affairs Medical Center, Cincinnati, OH.

Genome-wide association studies and large-scale sequencing studies identify many non-coding genetic variants that increase disease risk. At least 60% of these loci have been associated with genotype-dependent expression of nearby genes. It remains to be determined that 50-100% expression differences are biologically relevant in specific immune cell types. Here, we developed a system combining the Clustered regularly interspaced short palindromic repeats (CRISPR) Homology-directed Repair technique with Tet-inducible Controlled Gene Expression technique to precisely control gene expression. This system allows us to mimic the differential gene expressions caused by genetic variants. We focus on the expression quantitative trait loci (eQTL) at the ETS1 lupus-risk locus. Patients with lupus have 50% less peripheral blood mononuclear cell mRNA expression of ETS1 than people without SLE, and people with the risk haplotype at the ETS1 locus have 50% less mRNA expression than people with the non-risk haplotype. Since ETS1 is a transcription factor, differential ETS1 expression could have easily measurable consequences on transcription factor binding and downstream gene expression. There are nearly 800 genes that are known to be dysregulated in subjects with SLE. Our analyses of these genes using publicly available ChIP-seq data sets from B cell line GM12878 and epithelial cell line K562 indicates that 191 and 151 of these genes, respectively, have ETS1 binding sites proximal to the transcription start site (enrichment of 3-4 fold compared to randomly chosen gene sets,  $p < 10^{-46}$ ). We hypothesize that these changes in ETS1 levels are important in 1) ETS1 binding throughout the genome, 2) expression of ETS1 downstream target genes (such as BLIMP1), and 3) immunological dysfunction and hyperactivity of B cells. We test these hypotheses by analyzing the binding of ETS1 (ChIP-seq) and the changes to the transcriptome of cells with 2-fold differences in ETS1 expression (RNA-seq). The investigation of the ETS1 eQTL will allow us to make important progress in the field of human genetics and especially complex genetic disease etiology.

**2797W**

**Transcriptional risk scores link GWAS to eQTL and predict complications in Crohn's disease.** *U.M. Marigorta<sup>1</sup>, L.A. Denson<sup>2</sup>, J.S. Hyams<sup>3</sup>, S. Kugathasan<sup>4</sup>, G. Gibson<sup>1</sup>, RISK Consortium.* 1) Center for Integrative Genomics, Georgia Institute of Technology, Atlanta, GA; 2) Division of Pediatric Gastroenterology, Hepatology, and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 3) Division of Digestive Diseases, Hepatology, and Nutrition, Connecticut Children's Medical Center, Hartford, CT; 4) Division of Pediatric Gastroenterology, Emory University School of Medicine, Atlanta, GA.

Differential gene expression profiling can be used to uncover the mechanisms by which GWAS associations contribute to pathology. Given that most GWAS hits are regulatory in nature and transcript abundance is in a sense closer to the phenotype, we hypothesize that risk scores based on gene expression could constitute an alternative to classical genetic risk scores (GRS). While GWAS have been very successful in identifying thousands of genetic variants associated with disease, the predictive performance of GRS is limited by the amount of heritability they explain, which is usually low. Intuitively, summation of the z-scores of risk-allele associated gene expression, namely a Transcriptional Risk Score (TRS), should provide a more accurate estimate of disease risk. We integrate summary-level GWAS and eQTL data with RNA-Seq from the RISK study, an inception cohort of pediatric Crohn's disease (CD) designed to identify factors that increase risk of a complicated course of disease. Ileal biopsies from 215 complication-free CD patients and 35 controls were profiled at diagnosis with RNA-Seq. After careful monitoring for 3 years, 27 of the CD patients progressed to stricturing or penetrating disease. We show that TRS based on genes regulated by IBD variants not only outperform GRS in distinguishing CD from healthy samples, but also serve to identify patients who in time will progress to complicated disease. Furthermore, our dissection of eQTL effects may be used to distinguish genes whose association with disease is either through promotion or protection, thereby linking statistical association to biological mechanism. The TRS approach constitutes a potential strategy for personalized medicine that enhances inference from static genotypic risk assessment.

**HLA-DQ variants interact with pregnancy to modify risk of multiple sclerosis among women of European ancestry.** *C. Adams<sup>1</sup>, X. Shao<sup>1</sup>, H. Quach<sup>1</sup>, S. Bos<sup>2</sup>, H. Harbo<sup>2</sup>, I. Brorson<sup>2</sup>, L. Alfredsson<sup>3</sup>, T. Olsson<sup>3,4</sup>, I. Kockum<sup>3</sup>, P. Strid<sup>5</sup>, A. Langer-Gould<sup>6</sup>, C. Schaefer<sup>6,7</sup>, L.F. Barcellos<sup>1,6,7</sup>.* 1) School of Public Health, Division of Epidemiology, University of California, Berkeley, Berkeley, CA; 2) Department of Neurology, Oslo University Hospital, Oslo, Norway; Institute of Clinical Medicine, University of Oslo, Oslo, Norway; 3) Department of Clinical Neuroscience and Center for Molecular Medicine, Karolinska Institutet at Karolinska University Hospital, Stockholm, Sweden; 4) Centre for Occupational and Environmental Medicine, Stockholm County Council, Stockholm, Sweden; 5) Kaiser Permanente, Southern California, Department of Research & Evaluation and Southern California Permanente Medical Group, Los Angeles Medical Center, Neurology Department; 6) Kaiser Permanente Division of Research, Oakland, CA; 7) Research Program on Genes, Environment and Health, Kaiser Permanente, Oakland, CA.

Multiple sclerosis (MS [MIM 126200]) is a demyelinating autoimmune disease with unknown etiology. Genetic and environmental risk factors have been identified, but their mechanisms are not understood. Human leukocyte antigen (HLA) genes contribute substantially to MS risk, and previous genome-wide association studies have established 110 non-HLA genetic variants associated with MS risk. MS predominantly affects women and first symptoms typically appear during childbearing years. Pregnancy is known to affect MS progression, but its role in MS etiology is unknown. It is hypothesized the immunologic changes which occur during pregnancy contribute to the risk of MS, however, studies of the marginal effect of pregnancy on MS risk have mixed results. Gene-environment (GxE) interactions can provide insight into the unexplained heritability of MS and complex pathways involving genes and exposures. This study investigated the interaction between MS genetic risk factors and pregnancy on MS risk among women using a case-only GxE study design. We hypothesized interactions between established MS genetic risk factors and pregnancy are associated with MS risk. All cases were adult females with confirmed disease selected from Kaiser Permanente California (KP), Norwegian, and Swedish populations (n=2,500). Pregnancy exposure was defined as first live-birth pregnancy before onset of first MS symptoms. Genotype data were obtained through whole-genome profiling and imputation. The case-only study design allows for estimation of GxE interaction effects when control data are not available, but cannot estimate marginal effects. Generalized linear mixed models with a logit link function were used to test for interaction between pregnancy exposure and genetic risk variants with random effects for population of origin, correcting for multiple tests ( $q < 0.2$ ). Initial results demonstrated evidence for interaction between pregnancy and *HLA-DQ* variants. Among women who were pregnant prior to MS onset, each *HLA-DQA1\*01:01* allele and *HLA-DQB1\*04:02* allele increased risk of MS 1.57-fold (95% CI: 1.22-2.11) and decreased risk of MS 0.77-fold (95% CI: 0.65-0.92), respectively. Our results provide evidence that biologic pathways for MS risk include the interaction between class II HLA genes and pregnancy. Further studies are needed to investigate genetic interaction with additional reproductive factors and MS risk as well as possible biologic mechanisms linking pregnancy and genetic risk.

**Trans-ethnic GWAS identifies genetic variants associated with white blood cell counts in the Population Architecture using Genomics and Epidemiology (PAGE) Study.** K.K. Nishimura<sup>1</sup>, M. Graff<sup>2</sup>, J. Haessler<sup>1</sup>, C. Hodonsky<sup>2</sup>, R. Tao<sup>3</sup>, S. Bien<sup>1</sup>, C. Schurmann<sup>4</sup>, G. Nadkarni<sup>4</sup>, S. Buyske<sup>5</sup>, C. Haiman<sup>6</sup>, L. Le Marchand<sup>7</sup>, R.J.F. Loos<sup>4</sup>, T. Matise<sup>8</sup>, K.E. North<sup>2</sup>, U. Peters<sup>1</sup>, C.S. Carlson<sup>1</sup>, A.P. Reiner<sup>1</sup>, C.L. Avery<sup>2</sup>, C. Kooperberg<sup>1</sup>. 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Epidemiology, University of North Carolina Chapel Hill, Chapel Hill, NC; 3) Vanderbilt University Medical Center, Nashville, TN; 4) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Department of Statistics and Biostatistics, Rutgers University, New Brunswick, NJ; 6) Department of Preventive Medicine, Keck School of Medicine, University of Southern California, Los Angeles, CA; 7) Cancer Research Center, University of Hawaii, Honolulu, HI; 8) Department of Genetics, Rutgers University, New Brunswick, NJ.

**Background:** White Blood Cell (WBC) counts are often used by clinicians to understand the nature of an ongoing inflammatory process. WBC counts are moderately heritable, yet can also be highly variable between healthy individuals. Some of this variability has previously been linked to certain genetic ancestral backgrounds. We conducted a large, multi-ethnic genome-wide association study (GWAS) in the Population Architecture using Genomics and Epidemiology (PAGE) Study to gain a deeper understanding of ancestry-specific genetic variants associated with WBC phenotypes. **Methods:** 28,534 PAGE individuals of African American, Hispanic/Latino, Asian, Native American, or Other ancestry with WBC measurements were genotyped on the Multiethnic Genotyping Array (MEGA) and subsequently imputed into the 1000 Genomes Phase 3 data. WBC outliers ( $\pm 4$  standard deviations) were excluded, and WBC counts were log transformed. Linear regression models were run using the SUGEN software, and adjusted by age at WBC measurement, sex, BMI, study, current smoking status, self-identified race/ethnicity, study center (where applicable), family/household membership (where applicable), and 10 ancestral principal components (PCs). Additional analyses including race-ethnicity stratified, conditional analyses using previously reported known loci, and SNPxPC interaction models were also conducted. **Results:** We identified a new independent signal in the known locus 13q21.33/*DACH1* (rs17088512,  $P=6.94E-09$ , PAGE coded allele frequency (CAF)=0.12), which remained genome-wide significant after conditioning on all previously known loci on the chromosome ( $P$ -conditional=3.64E-08). The PAGE lead variant is rare in 1000 Genomes Europeans (CAF=0.01), but common in those with African (CAF=0.32) and Admixed American (CAF=0.04) ancestry, populations which comprise the majority of the PAGE study population ( $P$ -African American=1.17E-05;  $P$ -Hispanic/Latino=4.13E-04). **Discussion:** For traits that show variability by genetic ancestry, it is especially important to perform GWAS in ancestrally diverse study populations. Trans-ethnic GWAS studies can identify genetic traits that are linked to certain genetic ancestries, such as the rs17088512 variant, which is frequent in both African Americans and Hispanic/Latinos. Additional analyses including rare variant and gene burden tests, fine mapping, and GWAS of WBC subtypes are ongoing to gain a deeper understanding of WBC phenotypes in non-European populations.

**Finding genomic variants regulating the exon-skipping.** R. Liu<sup>1,2,3</sup>, A. Byrnes<sup>1,2</sup>, M. Yu<sup>2</sup>, M. Daly<sup>1,2</sup>, H. Huang<sup>1,2</sup>. 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston MA, USA; 2) The Broad Institute, Cambridge, MA, USA; 3) Huazhong Agricultural University, Wuhan Hubei, China.

Multiple different mature mRNA isoforms can be generated from a single gene locus through alternative splicing. Abnormality in alternative splicing has been linked to many human disorders. To date, the extent to which genomic variations are involved in regulating the alternative splicing has not been systematically evaluated. Here, using RNA-seq data from GTEx, we present a study to find genomic variants regulating exon-skipping and isoform balance in a genome-wide fashion. We examined RNA-seq reads crossing each splice junction in the genome and looked for high quality exon-skipping events by comparing the number of the exon-skipping and non-exon-skipping reads. For each sample, we tested the imbalance of different RNA isoform levels using the binomial test, and converted the resulting p-values to z-scores. To find variants regulating the exon-skipping, we tested the association between the z-scores and variant genotypes across individuals. All variants within 1Mbp around the exon junction were tested. We applied this approach to the RNA-seq data from the EBV-transformed lymphocytes cell from the GTEx project (sample size: 83). We only considered exon-skipping events that have  $>1$  junction read from each isoform in  $>25\%$  samples. The initial analysis identified 44,016 such events, among which 919 events are significantly associated with at least one regulatory variant ( $p < 10^{-10}$ , threshold determined as  $0.05 / 44,016$  events / 10,000 variants tested per event). One interesting example is the *SP140* exon 7 skipping event. We found rs28445040 to be the most significantly associated SNP with this skipping event ( $p = 1.19 \times 10^{-11}$ ). This observation is consistent with an earlier exon splicing assay which also found rs28445040 regulating the skipping of *SP140* exon 7 (Matesanz et al., Human Molecular Genetics, 2015). In addition, the *SP140* locus has been implicated by GWAS as a risk factor for the inflammatory bowel diseases (IBD). A recent IBD fine-mapping study mapped this association to a credible set of 31 variants including rs28445040, suggesting that the skipping of exon 7 in *SP140* could be the disease-causing mechanism. In summary, we have designed a novel approach and demonstrated its utility to identify variants regulating exon-skipping events. Results from this approach could potentially help to interpret the functional mechanism of non-coding disease associations.

**Variance component selection with microbiome taxonomic data.** *J. Zhou<sup>1</sup>, J. Zhai<sup>1</sup>, J. Kim<sup>2</sup>, H. Zhou<sup>2</sup>.* 1) University of Arizona, Tucson, AZ; 2) University of California, Los Angeles.

Pulmonary complications remain a major cause of morbidity in subjects infected with Human Immunodeficiency Virus (HIV). The fundamental question raised recently was whether respiratory microbiome plays a role in these complications. In order to identify the bacterial taxa that are associated with a response, e.g., lung function, microbiome data are summarized as the counts or composition of the bacterial taxa at different taxonomic levels. Previous methods consider variable selection of taxonomic data in regression analyses and taxonomic data at different levels are considered as fixed covariates. Due to high-dimensional features of metagenomic information, different penalization schemes have been adopted. On the other hand, the association of microbiome composition and clinical phenotypes was assessed by testing the nullity of variance components, where phylogenetic tree information and distances measures between communities can be incorporated into the model. By combining these two methods, in this paper, we consider regression analysis by treating bacterial taxa at different level as multiple random effects. We propose a variance component selection scheme of high-dimensional taxonomic clusters with Lasso penalization. Our methods seamlessly coupled different distance measures with associated taxonomic selection. Extensive simulations demonstrate the superiority of our methods vs existing methods. Finally, using a longitudinal HIV lung microbiome cohort, We identify two interesting genera associated with Forced Vital Capacity (FVC), which shed lights on biological mechanisms.

**Genome-wide association study identifies susceptibility loci for primary non-response to anti-TNF therapy in patients with inflammatory bowel disease.** *T. De<sup>1</sup>, C. Alarcon<sup>1</sup>, E. Smithberger<sup>2</sup>, M. Horvath<sup>2</sup>, S. Kwan<sup>2</sup>, M. Young<sup>2</sup>, S. Adhikari<sup>2</sup>, J. Kwon<sup>2</sup>, M. Perera<sup>1</sup>.* 1) Department of Pharmacology, Northwestern University, Chicago, IL; 2) Department of Medicine, University of Chicago, Chicago, IL.

**BACKGROUND:** Tumor necrosis factor (TNF)  $\alpha$  is one of the major pro-inflammatory cytokines in the underlying pathogenesis of mucosal inflammation in inflammatory bowel disease (IBD), and are the primary therapeutic target for IBD. Anti-TNF drugs have been shown to induce clinical response in 60% of the patients, and long-term maintenance of remission in a large number of patients that respond to the drug. However, approximately 30% of the patients fail to respond to anti-TNFs (primary non-responders). Individual genetic differences could contribute to lack of efficacy. We therefore conducted the first genome-wide association study to identify the genetic variants associated with underlying differences in response to anti-TNFs. **METHODS:** The Discovery Cohort comprised of 109 cases that were primary non-responders, and 504 controls that responded to anti-TNF therapy. Population stratification was investigated through principal component analysis and only Caucasian patients were considered for this study. Association between each SNP and non-response to anti-TNFs was tested by logistic regression analysis using SNPTEST v2.5.2. **RESULTS:** Among the clinical covariates, combination or symptomatic therapy with azathioprine ( $p = 0.007$ ), methotrexate ( $p = 0.007$ ) and antibiotics ( $p < 0.0001$ ) were found to influence the response to anti-TNFs. Therefore, the association analysis was carried out after adjusting for these covariates, and the first principal component. A variant on chromosome 5 was found to be significantly associated with non-response to anti-TNFs (OR: 2.07, 95% CI: 1.46-2.94,  $p = 2.43E-07$ ). Bioinformatics analysis showed the variant to be an expression quantitative trait loci (eQTLs) for *MFAP3* and *FAM114A2* genes, in blood and duodenum mucosa. The findings from this study will be replicated in an independent Cohort of 63 cases and 339 controls. **CONCLUSION:** Our study may identify a clinically significant variant that can be used to tailor drug therapy to those patients that are most likely to gain benefit from the therapy and reduce the drug related risks in those that are unlikely to respond to anti-TNF drugs.

**Testing for colocalization of causal variants underlying obstructive sleep apnea and immune-related phenotypes.** S. Akle<sup>1,2</sup>, S. Chun<sup>2,3</sup>, B. Cade<sup>4</sup>, R. Saxena<sup>4,5</sup>, S. Redline<sup>4</sup>, S. Sunyaev<sup>2,3</sup>. 1) Organismic and Evolutionary Biology, Harvard University, Cambridge, MA; 2) Division of Genetics, Brigham and Women's Hospital, Boston, MA; 3) Division of Medical Sciences, Harvard Medical School, Boston, MA; 4) Division of Sleep and Circadian Disorders, Brigham and Women's Hospital, Boston, MA; 5) Center for Human Genetic Research and Department of Anesthesia, Pain, and Critical Care Medicine, Massachusetts General Hospital, Boston, MA.

Obstructive Sleep Apnea (OSA) is a complex genetic disease manifested by the loss of upper airway patency during sleep. The causal pathways and mechanisms underlying OSA have not been fully understood. Recently, genome-wide association studies on OSA have uncovered multiple genetic loci and suggested that immune-related genes may play a pleiotropic role in its etiology. To examine this hypothesis further, we applied Joint Likelihood Mapping (JLIM) to test for colocalization of genetic association signals between OSA and previously published immune-related cell count traits in blood of healthy individuals. Specifically, JLIM contrasts the likelihood of shared pleiotropic causal effect from that of distinct causal effects for two traits. To minimize the possibility of ancestry mismatch between cohorts, we restricted the analyses to only Caucasian subjects (n=1463) and controlled for age, sex and population structure covariates. Among 1796 previously known genome-wide significant associations to 14 non-compound immune related blood cell traits in myeloid and lymphoid lineages, 729 had nominal association to the Apnea-Hypopnea Index (AHI), the mostly widely used clinical indicator of OSA, in 200-kb windows ( $P < 0.01$ ). We ran JLIM to colocalize AHI and each of the 14 immune related blood traits in 729 tests. At nominal JLIM P-value threshold of 0.01, we find significant colocalization between OSA and 2 blood cell traits. Although we could not find any individually significant hits after multiple-testing correction, we can find signal of colocalization between AHI and two blood cell traits ( $P = 0.038$ ). The blood cell count traits that colocalize with AHI are: monocyte count and neutrophil count. This lends credence to previous suggestions that inflammation and other immune related processes might have a pleiotropic role to play in sleep related pathologies. .

**Association study of *R3HDM1* variants with aspirin exacerbated respiratory disease and FEV1 decline after aspirin provocation.** J. Kim<sup>1</sup>, Y. Cho<sup>2</sup>, C. Park<sup>3</sup>, H. Shin<sup>1,4</sup>. 1) Research Institute for Basic Science, Sogang University, Seoul, Republic of Korea; 2) Endocrine Institute, Yonsei University, Seoul, Republic of Korea; 3) Division of Allergy and Respiratory Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Republic of Korea; 4) Department of Life Science, Sogang University, Seoul, Republic of Korea.

Aspirin exacerbated respiratory disease (AERD) is a rare clinical condition characterized by a severe decline in forced expiratory volume in one second (FEV1) when taken with non-steroidal anti-inflammatory drugs (NSAIDs) including aspirin. Our previous genome-wide association study has identified several candidate genes, including *R3HDM1* (*R3H domain containing 1*), as potential susceptibility loci for AERD. To validate the potential association of *R3HDM1* variants with AERD and FEV1 in asthmatic patients, we performed an extended study using additional single nucleotide polymorphisms (SNPs), different genetic models, and haplotype analysis in a larger cohort. In the logistic analysis, *R3HDM1* polymorphisms showed potential association signals for the development of AERD ( $P = 0.01$ ). In additional linear regression analysis, *R3HDM1* polymorphisms and haplotype showed potential associations with FEV1 decline after aspirin provocation in asthmatics. Although further replications in other populations and functional evaluations are required, our findings suggest that *R3HDM1* polymorphisms might be associated with AERD and FEV1 decline, or its related symptoms.

**Statistical framework for biological interpretation and improvement of genetic association studies.** *M. Artomov<sup>1</sup>, A.A. Sergushichev<sup>2,3</sup>, A.A. Loboda<sup>2</sup>, M.N. Artyomov<sup>3</sup>, M.J. Daly<sup>1</sup>.* 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 2) Computer Technologies Department, ITMO University, Saint Petersburg, 197101, Russia; 3) Department of Pathology & Immunology, Washington University in St. Louis, St. Louis, MO 63110, USA.

Analysis of the genetic risk factors provides only unstructured pieces of information about the biology of a disorder. Generally, after identification of the associated loci massive follow-up studies are required to, first, prove the causal relationship, and, most importantly, understand the molecular mechanism of causality. Which locus should be prioritized for protein-level studies is currently determined based on empirical knowledge of protein function. Integration of the experimentally proven individual proteins functionality is then aimed to identify pathways affected by disease. Alternatively to this extensive approach, we developed a statistical framework that integrates genetic association data from multiple sources (GWAS, RVAS, etc.) and finds the protein-protein network returning the best cumulative association score. Using Bayesian model association results are then refined with evidence of the specific gene appearance in the best network. Our method provides a ranked list of genes prioritized based on both association strength and integration in the functional pathway. Such approach is essential for understanding biology of the disorders where it is impossible to build adequate animal model – autism, schizophrenia and other neuropsychiatric diseases. We used ranked list of genes from focal segmental glomerulosclerosis (FSGS) study (PMID: 26901816) to test our approach. None of the genes originally reached significance threshold for genetic association ( $0.05/1642$  genes represented in reference interactome =  $3 \times 10^{-5}$ ). Resulting most associated network consists of five genes – *WNK4*, *COL4A4*, *DLG5*, *KAT2B*, *UBC*. We used two schemes of permutation to estimate probability of each of these genes to appear in the best scoring network. According to our approach - posterior p-values of genetic association were calculated. Two genes became significant – *COL4A4*, *WNK4* and had more than 10 fold improvement in association signal: *COL4A4* – is a known risk gene for FSGS; mouse model (PMID: 26901816) demonstrated that mice with non-functional *WNK4* develop histologically confirmed FSGS, thus proving its causal role. At the same time mouse model ruled out *DLG5* and *KAT2B* as causal genes. Our model successfully predicts functionally-relevant genes from genetic association studies and could also be applied for identification of functional candidates in polygenic GWAS loci.

**Integrated clinical genome database on hepatitis B-related diseases for genome-wide association: Project goals and utilization of materials and genomic information in the ToMMo biobank.** *S. Teraguchi<sup>1</sup>, N. Nishida<sup>2</sup>, M. Sugiyama<sup>2</sup>, K. Kojima<sup>1</sup>, Y. Kawai<sup>1</sup>, H. Kudo<sup>1</sup>, R. Yamashita<sup>1</sup>, N. Minegishi<sup>1</sup>, K. Tokunaga<sup>3</sup>, M. Nagasaki<sup>1</sup>, M. Mizokami<sup>2</sup>.* 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Miyagi, Japan; 2) Genome Medical Sciences Project, National Center for Global Health and Medicine, Chiba, Japan; 3) Department of Human Genetics, The University of Tokyo, Tokyo, Japan.

Hepatitis B is an infectious disease caused by the hepatitis B virus (HBV), which affects the liver. Chronic hepatitis B infection, as well as hepatitis C infection, is known to lead to liver cirrhosis, and eventually to liver cancer. While hepatitis C can be well treated with the recent innovative drugs, effective drugs are lacking for hepatitis B. This lack of effective treatment for hepatitis B is partially due to the diversity of the disease, depending on virus genotypes and host genotypes; understanding of such diversity is urgent for the development of effective treatments against HBV. To this end, we are constructing an integrated clinical genome database on hepatitis B-related diseases under “the program for an integrated database of clinical and genomic information” of the Japan Agency for Medical Research and Development. A number of hospitals and biobanks in Japan, including the Tohoku Medical Megabank Organization (ToMMo) of Tohoku University, are involved in this project. Here, we present recent advances on this project, with particular focus on the utilization of the biobank materials and genomic information of the ToMMo biobank. ToMMo developed highly accurate Japanese population reference panels based on whole-genome sequences of healthy Japanese individuals. Using these reference panels, we imputed the genome-wide SNVs from SNP array data from healthy and HBV-infected individuals. We also performed genome wide association analysis for the imputed data. These results will be registered in the integrated clinical genome database regarding hepatitis B-related diseases. ToMMo also provided serum samples from two thousand volunteers for this project. HBV antigen/antibody tests were performed on these samples to refine the clinical information. We performed integrated analysis with the resulting HBV status and the associated WGS data of these volunteers.

**Trans-ethnic Bayesian meta-analysis detects novel replication evidence for multiple loci for inflammatory bowel disease in African Americans.**

R.Y. Cordero<sup>1</sup>, S. Kugathasan<sup>2</sup>, D.P.B. McGovern<sup>3</sup>, S.R. Brant<sup>4</sup>, C.L. Simpson<sup>1</sup>. 1) Department of Genetics, Genomics, and Informatics, University of Tennessee Health Science Center, Memphis, TN; 2) Department of Pediatrics and Department of Human Genetics, Emory University School of Medicine, Atlanta, GA; 3) F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, CA; 4) Meyerhoff Inflammatory Bowel Disease Center, Department of Medicine, School of Medicine and Department of Epidemiology, School of Public Health, Johns Hopkins University, Baltimore, MD.

**Background:** Inflammatory bowel disease (IBD) is an immune-mediated chronic intestinal disorder with major phenotypes; ulcerative colitis (UC) and Crohn's disease (CD). Multiple studies have identified over 240 IBD susceptibility loci. Recently, trans-ethnic analyses have gained ground in detecting additional loci. However, most studies have centered on European (EUR) and East Asian (EAS) populations. The prevalence of IBD in non-EUR including African Americans (AAs) has risen in recent years. Here we present the first attempt to identify loci in AAs using a trans-ethnic Bayesian approach. **Methods:** We conducted trans-ethnic meta-analysis using GWAS and ImmunoChip data from EUR meta-analysis of 38155 IBD cases and 48485 controls; EAS ImmunoChip study of 2824 IBD cases and 3719 controls, and our recent AA IBD GWAS of 2345 cases and 5002 controls. To account for heterogeneity in allelic effects between diverse ancestry groups while allowing for similarity in allelic effects between closely related populations, we adopted a Bayesian model as implemented in MANTRA. We employed a  $\log_{10}$  Bayes' factor (BF) threshold of 20 as strong evidence for association in AAs. **Results:** We identified IBD loci at *IL23R* (BF 59.8) and *PTGER4* (BF>31.8), and at *CARD9*, *NKX2-3*, *BRWD1*, *ZNF365* and *MST1* with  $20.1 < \text{BF} < 27.1$ . We identified strong signals for CD again at *IL23R* and *PTGER4*, but also *ATG16L1* (BF 34.7). However, there was evidence of heterogeneity in allelic effect for *ATG16L1*, demonstrating that unlike in the GWAS analysis, which did not find evidence for association with this gene, variants in *ATG16L1* do have some effect on risk of disease, albeit much smaller than in EUR. For UC we identified loci at *RNF186* (BF 26.2) and *IL23R*. A comparison of AA with the much smaller EAS cohort identified BF>20 loci only for CD at *TNFSF15* (BF 33.8). Only the *IL23R*, *PTGER4* and *TNFSF15* loci had significant evidence for locus replication in our parent IBD GWAS in AAs. **Conclusion:** Our Bayesian trans-ethnic analysis identified strong replication evidence for multiple IBD loci in AAs with the majority of these loci demonstrating no compelling evidence for locus replication in the parent GWAS. In particular, for *ATG16L1*, prior replication studies only showed minimal association evidence. These results highlight the value of using prior association evidence from much larger studies in other populations to enable strong evidence for replication in smaller cohorts of understudied diverse populations.

Chronic kidney disease (CKD) is a common health concern throughout the world, as well as in Japan. The majority of genome-wide association studies (GWAS) for renal traits have conducted in European populations with a few studies in an East Asian population. Furthermore, clinical relevance of combination of CKD risk factors including genetic information remains unclear. Therefore, we investigated a cross-sectional relationship of clinical and genetic factors and prevalence of CKD in a Japanese cohort study. Clinical and genetic information were the part of the Japan Multi-Institutional Collaborative Cohort (J-MICC) Study, which is one of the largest cohort studies in Japan. The present study consists of 14,539 randomly selected participants from 12 J-MICC Study sites (Chiba, Sakuragaoka, Shizuoka-Daiko, Okazaki, Aichi, Takashima, Kyoto, Tokushima, Fukuoka, Kagoshima and Kyushu-KOPS). The study protocol and procedure was approved by the Ethics Committee of Nagoya University Graduate School of Medicine and all participating institutions. Written informed consent was obtained from all participants. Genotyping was performed using the Illumina OmniExpressExome Array. After a quality check, genotype imputation was conducted based on the 1000 Genomes reference panel. A total of 11,184 participants and 7,094,228 variants was available for our analyses. Estimated glomerular filtration rate (eGFR) was calculated based on serum creatinine, age, and sex using the Japanese equation. Participants in stages 3–5 CKD (eGFR < 60 ml/min/1.73 m<sup>2</sup>) was defined as case in this study. We computed a genetic risk score (GRS) based on 36 eGFR-associated SNPs identified by the present population-based GWAS in Japanese. The mean age (SD) of this population was 54.9 (9.3), and the proportion of men was 45.9%. The frequency of individuals with CKD was 8.5%, which was relatively low comparing with other studies in Japan. In multivariable analysis, the odds ratio (OR) of having stage 3-5 CKD was observed as 10 GRS increased (OR: 1.16, 95% confidence interval: 1.10-1.23). The C-statistic was significantly increased in the adjusted model with GRS, comparing with the model without GRS (0.719 vs. 0.724,  $P_{\text{difference}} < 0.01$ ). We confirmed that increment of GRS was associated with increased risk of CKD and GRS significantly improved the discrimination of CKD. Further studies with longitudinal datasets are needed to assess clinical utility of GRS for predicting onset and prognosis of CKD.

Tromp<sup>10</sup>, M. Smith<sup>1</sup>, R.L. Chisholm<sup>1</sup>, M.G. Hayes<sup>1</sup>, A.N. Kho<sup>1</sup>. 1) Northwestern University, Chicago, IL; 2) Vanderbilt University, Nashville, TN; 3) Kaiser Permanente Washington, Seattle, WA; 4) Marshfield Clinic, Marshfield, WI; 5) Geisinger Health System, Danville, PA; 6) Mayo Clinic, Rochester, MN; 7) Weill Cornell Medical College, New York, NY; 8) VA San Diego Healthcare System, San Diego, CA; 9) University of Utah Health, Salt Lake City, UT; 10) Stellenbosch University, Stellenbosch, South Africa.

Diverticulosis is one of the most common functional gastrointestinal disorders affecting almost half of all Americans before the age of 60. Its pathogenesis is unknown, but if untreated, it can develop into diverticulitis with life-threatening complications such as peritonitis or colonic perforation. As part the Electronic Medical Records and Genomics (eMERGE) network, we performed a genome-wide association study (GWAS) to identify common variants associated with diverticular disease and a phenome-wide association study (PheWAS) of the top variants to identify potential pleiotropic effects. We developed and validated an electronic health record (EHR)-based phenotyping algorithm to identify cases and controls for diverticulosis and diverticulitis using EHR data from all adult eMERGE subjects. (n=38,828) We identified two associations with diverticulosis approaching genome-wide significance: rs12935426 (G allele, OR=0.86, P=1.2E-7) in *PHLPP2*, in European ancestry (EA) participants and rs12428560 (G allele, OR=3.61, P=8.5E-8) near *LINC00448* in African ancestry (AA) participants. Three genome-wide significant variants were associated with diverticulitis: chr2:80804829:1 (G insertion, P=3.7E-8) near *CTNNA2* in EA, rs6016299 (T allele, OR=0.51, P=2.5E-8) between *LINC01370* and *MAFB* in AA, and rs11062710 (allele G, MANTRA Bayes factor = 5.28) in *PRMT8* in a meta-analysis of EA and AA. We selected the top 12 SNPs associated with diverticulosis and diverticulitis for PheWAS, in which we identified several clinical traits associated with these variants, including and eye and skin disorders; such as cataract (rs10423674, p=8.8E-05), glaucoma (rs10423674, p=2.4E-04), disorders of optic nerve and visual pathways (rs6028974, p=1.5E-03; rs6016299, p=2.1E-03), degenerative skin conditions and other dermatoses (rs10423674, p=1.6E-03) atopic/contact dermatitis (rs10423674, p=4.30E-03), and skin cancer (chr2:80804829.i, p=1.1E-02), suggesting pleiotropy of these variants with diverticular disease and the nervous and integumentary systems. These associations, combined with the observation of calcium metabolism related genes (e.g. *COMP*, *CRA-CR2A*, *RYR3*) among the most significantly associations, suggests that signal transduction of the central nervous system, interruption of the neural cell growth in the colon, and malfunction of the collagen component of the epithelial membrane may play a role in the development of diverticular disease.

**Gene-based pathway analysis for osteoporosis: Insights from genom-**

**ic-wide association.** K.J. Su<sup>1,2</sup>, W. Zhu<sup>2</sup>, C. Xu<sup>1,2</sup>, H. Shen<sup>1,2</sup>, H.W. Deng<sup>1,2</sup>. 1) Global Biostatistics and Data Science, Tulane University, New Orleans, LA; 2) Center for Bioinformatics and Genomics, Tulane University, New Orleans, LA.

**Background:** Osteoporosis is a chronic human complex disease with decreased bone strength and increased risk of fractures, which has been characterized by low bone mineral density (BMD). To date, genome-wide association studies (GWASs) have successfully identified a large number of susceptibility loci associated with low BMD. However, these identified loci only explain a small proportion of the BMD variation and provided limited insights into the pathophysiological mechanisms of osteoporosis. To further explore the pathologic mechanism of osteoporosis, we performed gene-based pathway analyses for BMD based on the largest meta-analysis of GWASs in the bone field. **Methods:** First, we examined BMD-associated genes by analyzing the summary statistics of the sequencing project of the GENetic Factors for Osteoporosis Consortium (GEFOS.seq) with BMD of the femoral neck (FN-BMD), lumbar spine (LS-BMD), and forearm (FA-BMD), respectively. To improve the robustness of the identified candidate genes, we selected significant genes identified by two different gene-based association analysis strategies (the all-SNP test and the best-SNP test). Next, these BMD-associated genes were subject to pathway analysis through Enrichr and annotated by Gene Ontology (GO) enrichment analysis. Additionally, to gain detailed information of pathway analysis, we integrated a transcriptomic data from bone biopsy and conducted a differential expression analysis (DEA) to identify key mechanism of genes within each pathway. **Results:** We identified 709 genes nominally significantly associated with FN-BMD, 693 genes with LS-BMD, and 463 genes for FA-BMD. The pathway analysis revealed a total of 16 significant pathways (FDR < 0.05) for BMD, such as Wnt signaling pathway, RANKL/RANK signaling pathway, and Hedgehog signaling pathway. Three bone-related biological processes terms were identified on both the FN-BMD and LS-BMD (FDR < 0.05), including skeletal system development, ossification, and bone development. Notably, the difference in the expression of BMD associated genes in bone biopsy showed a gene *JUN* which could potentially provide valuable clues for the significant functional pathways. **Conclusion:** This study not only identified several known bone-related pathways, but also explored more potential risk pathways that may provide new insights into the pathological mechanism of osteoporosis.

**Integrated pediatric bone density phenotypes and genetic regulation of the developing skeleton.**

*J.A. Mitchell*<sup>1,2</sup>, *A. Ches*<sup>3</sup>, *S.E. McCormack*<sup>2,4</sup>, *D.L. Cousminer*<sup>5</sup>, *H.J. Kalkwarf*<sup>6</sup>, *J.M. Lappe*<sup>6</sup>, *V. Gilsanz*<sup>7</sup>, *S.E. Oberfield*<sup>8</sup>, *J.A. Shepherd*<sup>9</sup>, *A. Kelly*<sup>2,4</sup>, *B.S. Zemel*<sup>1,2</sup>, *S.F.A. Grant*<sup>2,3,4</sup>. 1) Division of Gastroenterology, Hepatology and Nutrition, The Children's Hospital of Philadelphia, Philadelphia; 2) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia; 3) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia; 4) Division of Endocrinology and Diabetes, The Children's Hospital of Philadelphia, Philadelphia; 5) Division of Gastroenterology, Hepatology and Nutrition, Cincinnati Children's Hospital Medical Center, Cincinnati; 6) Division of Endocrinology, Department of Medicine, Creighton University, Omaha; 7) Department of Radiology, Children's Hospital Los Angeles, Los Angeles; 8) Division of Pediatric Endocrinology, Diabetes, and Metabolism, Department of Pediatrics, Columbia University Medical Center, New York; 9) Department of Radiology, University of California San Francisco, San Francisco.

**Background** Osteoporosis is a complex disease with potential developmental origins in childhood. Common and low frequency variants have been associated with pediatric areal bone mineral density (aBMD), but phenotyping approaches used thus far have considered skeletal sites in isolation. We therefore aimed to determine if genetic variants associate with principal component (PC)-derived pediatric aBMD loading scores that integrate information across four skeletal sites. **Methods** Our sample comprised 1,293 children of European ancestry enrolled in the Bone Mineral Density in Childhood Study (52% female). Participants underwent dual energy X-ray absorptiometry for up to 7 annual study visits. Sex and age-specific aBMD Z-scores, adjusted for height, were calculated for total hip, femoral neck, spine and distal radius. PC analysis generated new integrated aBMD phenotypes by transforming the four correlated bone Z-scores into linearly uncorrelated variables (PC loading scores). Linear mixed effects models, adjusted for age, pubertal status, BMI-Z, dietary calcium and physical activity, were used to test associations between genetic score (percentage aBMD-lowering alleles carried at 63 GWAS-implicated loci) and loading scores. GWAS was applied to baseline data to identify loci associated with loading scores. **Results** Four principal components (PC1-PC4) were identified that explained 68.1%, 18.6%, 10.5%, and 2.8% of the variance, respectively. Higher PC1 loading score indicated higher bone Z-scores across all four sites. Genetic score was associated with lower PC1 loading score ( $\beta = -0.05$ ,  $P = 3.9 \times 10^{-10}$ ); from GWAS, rs114260199 (*LMO2/CAPRIN1*,  $P = 3.9 \times 10^{-8}$ ) and rs75321045 (*ZMAT4*,  $P = 2.5 \times 10^{-8}$ , females) were associated with PC1. Higher PC2 loading score indicated higher distal radius-Z only. Genetic score was not associated with PC2; from GWAS, rs67991850 (*CPED1*,  $P = 2.5 \times 10^{-11}$ ) was associated with PC2. Higher PC3 loading score indicated higher spine-Z only. Genetic score was not associated with PC3; from GWAS, rs58649746 (*RAB11FIP5*,  $P = 4.8 \times 10^{-9}$ , females) was associated with PC3. **Conclusion** We identified non-site-specific (PC1), distal radius-specific (PC2) and spine-specific phenotypes (PC3) in children. An established genetic score associated with the non-site-specific phenotype only. Novel variants near *LMO2/CAPRIN1*, *ZMAT4*, and *RAB11FIP5* associated with non-site specific or spine specific phenotypes. These genetic variants may ultimately provide insight into childhood bone accrual.

## 2812W

**Penalized regression for detecting rare variant effects under extreme phenotype sampling for continuous traits.**

*C. Xu*<sup>1,2</sup>, *J. Fang*<sup>1,3</sup>, *H. Shen*<sup>1,2</sup>, *Y.P. Wang*<sup>1,3</sup>, *H.W. Deng*<sup>1,2</sup>. 1) Center of Genomics and Bioinformatics, Tulane University, New Orleans, LA; 2) Department of Global Biostatistics and Data Science, Tulane University School of Public Health and Tropical Medicine, New Orleans, LA; 3) Department of Biomedical Engineering, Tulane University, New Orleans, LA.

Rare variant (RV) association study is a method to identify SNPs with minor allele frequency  $< 0.01$ , which may contribute to specific disease. The method is expected to play an important role in explaining the missing heritability in GWAS and uncovering novel gene-phenotype relationships. However, the detection and association power for RV is low in random samples. Several recent studies have shown that extreme phenotype sampling (EPS) is beneficial for the RV detection studies. By enriching the causal variants in the extreme phenotypic samples within the top and bottom percentiles, EPS can boost the study power compared to random sampling with the same sample size. Currently, there are two types of statistical methods for RV study in EPS: case-control method, which ignores the quantitative data of the extreme samples and tests the genes/regions individually in case/control groups; and likelihood method, which models the non-normality for the quantitative data but still tests the association individually. However, many disorders are caused by multiple genetic factors. Therefore, it is desirable to simultaneously model the joint effects of genetic markers, which may increase the power of current genetic association studies and identify novel disease-associated genetic markers under EPS. The challenge of the simultaneous analysis is: the number of genetic markers (e.g.,  $p \sim 10,000$ ) is typically greater than the sample size (e.g.,  $n \sim 1,000$ ) in a study. The standard linear model would be inappropriate for this  $p > n$  problem due to the rank deficiency of the design matrix. An alternative solution is to apply a penalized regression method – the least absolute shrinkage and selection operator (LASSO). The application of LASSO to genetic association study under random sampling has been widely studied. Here, we investigated a penalized regression model (LASSO-HT) by combining LASSO hypothesis testing with rare variant collapsing to jointly detect genes/regions carrying RV effects under EPS. Our comprehensive simulation study indicates LASSO-HT outperforms other state-of-the-art methods with the correct type I error and relative low FDR. Both simulation and real data analysis of bone mineral density show the power of LASSO-HT is comparable with, even better than, under certain conditions, existing methods. The comparison of area under receiver operating characteristic curve demonstrates the overall performance of LASSO-HT exceeds or tightly matches others for most cases.

**Background:** Responding to a 2012 Presidential Initiative to fight Alzheimer's disease (AD), the National Institute on Aging (NIA) and National Human Genome Research Institute (NHGRI) jointly developed a project to analyze the genomes of well-characterized individuals with or without clinical AD using NINCDS-ADDA criteria. This effort, the Alzheimer's Disease Sequencing Project (ADSP) has the overarching goals of identifying new (1) genes involved in AD, (2) genomic variation contributing to AD risk or protection, and (3) potential avenues for therapies and AD prevention. This presentation highlights findings from the ADSP Discovery Phase Case-Control Study, which analyzed whole exome sequence (WES) variation from unrelated participants of the Alzheimer's Disease Genetics Consortium (ADGC) and Cohorts for Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium. **Methods:** We selected European-ancestry cases and dementia-free controls based on age, sex, APOE genotype, and pathology, along with additional unrelated cases from AD families and Caribbean Hispanic controls to enrich the risk profile and diversity of the study. We analyzed individual common variants (minor allele count > 10) using logistic regression and aggregated rare (minor allele frequency < 5%) variants into genes using SKAT-O with filters based on predicted functional impact or loss-of-function. All models included adjustment for sequencing center and population structure. Sensitivity analyses adjusted for age, sex, and APOE genotype. Analyses were performed separately by ancestry and were combined using seqMeta/R. Statistical significance was established using a Bonferroni correction. **Results:** After QC, the analysis included 5,740 cases and 5,096 controls (218 cases and 177 controls were Hispanic) and approximately 1.5 million SNVs and 50,000 indels. Significant associations from single variant and gene-based tests included common and rare variants in several AD risk genes (*TREM2*, *MS4A6A*, *ABCA7*, *PILRA*), as well as potentially novel findings in *GAS2L2*, *OPRL1*, *ZNF655*, *NSF* and a long non-coding RNA. Some findings show preliminary evidence of replication in ongoing efforts among independent WES and imputed datasets. **Conclusions:** WES association analyses of ADSP case-control data replicated several known AD genes and identified novel associations; efforts to replicate these findings and characterize the biological mechanisms of the identified genes in AD are currently underway.

## 2814F

**Tissue-specific genetic regulated expression in late-onset Alzheimer's disease: The Alzheimer's Disease Genetics Consortium (ADGC).** H.-H. Chen<sup>1</sup>, the ADGC<sup>2</sup>, Y. Zhao<sup>3</sup>, S. van der Lee<sup>4</sup>, K. Hamilton-Nelson<sup>5</sup>, L. Petty<sup>1</sup>, B. Kunkle<sup>3</sup>, A. Partch<sup>3</sup>, O. Valladares<sup>3</sup>, C. Reitz<sup>6</sup>, G. Beecham<sup>3</sup>, E. Martin<sup>3</sup>, L.-S. Wang<sup>3</sup>, J. Haines<sup>7</sup>, R. Mayeux<sup>6</sup>, L. Farrer<sup>6</sup>, M. Pericak-Vance<sup>3</sup>, G. Schellenberg<sup>3</sup>, W. Bush<sup>7</sup>, A. Naj<sup>8</sup>, J.E. Below<sup>1</sup>. 1) School of Medicine, Vanderbilt University, Nashville, TN, USA; 2) the Alzheimer's Disease Genetics Consortium; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, USA; 4) Erasmus University Medical Centre, Rotterdam, Netherlands; 5) Miller School of Medicine, University of Miami, Miami, FL, USA; 6) Columbia University, New York, NY, USA; 7) School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 8) School of Medicine, Boston University, Boston, MA, USA.

As average life expectancy has increased, so has the global prevalence of Alzheimer's disease (AD) which is the leading cause of dementia in the United States. AD is highly heritable (estimated  $h^2=0.4-0.94$ ), with 19 confirmed common susceptibility loci, and multiple rare loci including *TREM2* recently identified. Little is known about how these and other genetic factors influence expression patterns, which may influence AD etiology. To improve understanding of the functional genetic etiology of AD we collected 25 GWAS datasets including 13,042 cases and 13,674 controls from the Alzheimer's Disease Genetics Consortium, imputed to ~39M variants as rare as MAF=0.0004 with the HRC r1.1 reference panel using Minimac3. High quality variants with MAF>0.05 and imputation  $R^2>0.8$  were used to predict gene expression in 45 different tissues using PrediXcan, an approach that infers the genetically regulated portion of gene expression from common expression quantitative trait loci identified in the Genotype-Tissue Expression Project (GTEx). Logistic regression was applied to test the association between each tissue-specific predicted gene expression level and AD with adjustment for sex age, and ancestry-based principal components. Meta-analysis across all studies was performed using METAL and identified 47 unique genes across all tissues (17 genes showed cross-tissue effects). These signals reached Bonferroni-corrected genome-wide significance ( $P<2.5\times 10^{-6}$ ) and include APOC1 ( $\beta = -1.931$ ,  $p\text{-value}=2.3\times 10^{-61}$ ), GEMIN7 ( $\beta = 0.91$ ,  $p\text{-value}=1.0\times 10^{-32}$ ), and AMMECR1L ( $\beta = 3.78$ ,  $p\text{-value}=2.1\times 10^{-19}$ ). We further adjusted models using nearby previously-reported sentinel risk variants for AD. Across all tissues, 44 unique genes reached genome-wide significance after correction for known signals, and 16 of them located outside of known APOE region. In conclusion, multiple novel and known genes show predicted expression that associates with AD in ADGC, illustrating that gene regulatory models may be useful in the discovery of new AD loci.

**2815W****Convergent evidence for *LRP2BP* in resilience to Alzheimer's disease.**

D. Felsky<sup>1,2</sup>, R. Cheng<sup>3</sup>, J.A. Schneider<sup>4,5</sup>, D.A. Bennett<sup>4,5</sup>, J.H. Lee<sup>3</sup>, P.L. De Jager<sup>1,2</sup>. 1) Center for Translational and Systems Neuroimmunology, Department of Neurology, Columbia University Medical Center, New York, NY; 2) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 3) Sergievsky Center and Taub Institute, Columbia University Medical Center, New York, NY; 4) Department of Neurological Sciences, Rush University Medical Center, Chicago, IL; 5) Rush Alzheimer's Disease Center, Rush University Medical Center, Chicago, IL.

Early-onset familial Alzheimer's disease (eFAD) commonly results from mutations in *PSEN1* and is characterized by onset before age 65. To date, the contribution of common genetic variation to the clinical and pathological trajectories of those with *PSEN1* mutations is not well known. We implemented an integrative approach to identifying and characterizing the molecular-genetic modifiers of cognitive decline in *PSEN1* eFAD families. First, genetic linkage and association analyses in 45 *PSEN1*-G206A mutation carrier families with total 305 members found 12 candidate loci linked and associated with AD and age at onset of AD. These loci were carried forward for multi-omics analyses in two large aging cohorts: The Religious Orders Study and Memory and Aging Project (ROS/MAP). Cognition was measured longitudinally before death and autopsy was performed postmortem for AD neuropathology. Of 1,291 subjects with postmortem data, 1,116 had genome-wide genotype data, and 599 had RNA-sequencing performed on postmortem brain. Variants within 100kb of each candidate gene were evaluated against pathology and cognitive decline. Multiple SNPs tagging four haplotypes near *SNX25* were associated with cognitive decline and AD pathology at nominal significance ( $1 > p > 1.3 \times 10^{-3}$ ). Interestingly, the top statistical signal for this region fell in proximity to the transcription start site of the adjacent gene *LRP2BP* rather than within *SNX25* itself. After FDR correction, RNA expression of *LRP2BP* but not *SNX25* was significantly associated with neuritic plaque ( $p_{\text{FDR}} = 1.3 \times 10^{-4}$ ), PHF-tau ( $p_{\text{FDR}} = 0.0019$ ), and neurofibrillary tangle ( $p_{\text{FDR}} = 4.6 \times 10^{-3}$ ) burdens. eQTL analyses were then performed in ROS/MAP and validated using GTEx. In ROS/MAP, the top pathology-associated *LRP2BP* variant was strongly associated with *LRP2BP* expression after correction ( $p = 8.6 \times 10^{-14}$ ,  $p_{\text{FDR}} < 0.0001$ ). In GTEx, this same variant is an eQTL for *LRP2BP* in subcutaneous adipose ( $p = 3.0 \times 10^{-6}$ ), tibial nerve ( $p = 3.3 \times 10^{-6}$ ), and thyroid ( $p = 1.6 \times 10^{-6}$ ). Consistently, the same allele associated with higher *LRP2BP* expression was associated with lower levels of neuropathology, and higher *LRP2BP* expression was associated with lower levels of neuropathology and slower cognitive decline. *LRP2BP* binds LRP2, which is important for axonal regeneration and clearance of  $\beta$ -amyloid across the blood brain barrier. Our results suggest that genetically-determined levels of *LRP2BP* modulate pathological load in eFAD and may be a novel target for intervention.

**2816T****Cell free single stranded DNA concentration in CSF as biomarker to**

**diagnose Alzheimer's disease status.** J.D. Gonzalez Murcia<sup>1</sup>, L.A. Stanley<sup>1</sup>, M. Ferrel<sup>1</sup>, M.T.W. Ebbert<sup>2</sup>, H. Zetterberg<sup>3</sup>, J.S.K. Kauwe<sup>1</sup>. 1) Biology, Brigham Young University, Provo, UT; 2) Mayo Clinic, Jacksonville; 3) University College London, London.

Alzheimer's disease (AD) is a fatal neurodegenerative condition and is the leading cause of dementia in the elderly (Jonsson et al., 2013). AD is identified as a proteopathic disease due to the extensive accumulation of amyloid plaques and neurofibrillary tangles (Guerreiro et al., 2013; Jonsson et al., 2013). Currently there is not adequate treatment or prevention. It has been postulated that earlier and more accurate diagnosis of AD could be a key to better therapeutic development. The aim of this study is to evaluate if the concentration of cell free single stranded DNA (cfssDNA) is correlated with the diagnosis of AD. The study was performed by obtaining 30 CSF non-demented control samples from Sweden and 30 CSF samples of AD cases from Sweden. All samples were clinically ascertained following established protocols for AD diagnosis. We proceed to extract single stranded DNA from all CSF samples and measured using Qubit assay technology. During this process we screened for dsDNA, RNA, and ssDNA. We then proceeded to analyze measurements using a T test pair analysis, a nominal regression analysis, and then a Receiver Operating Characteristic (ROC) curve. Result from Qubit assay shows detectable concentration only for ssDNA. In addition, we observed from paired T-test analysis, that cfssDNA concentration in AD samples is significantly lower than non-demented control samples. (2 tail p-value 0.0011). Nominal regression analysis shows that cfssDNA concentration can predict AD status and the power of prediction increases when age included in the model (p-value < 0.0001). Finally, ROC curve has an area under the curve of 0.82. We conclude that cell free single stranded DNA concentration in CSF is significantly lower in AD cases than non-demented controls among Swedish samples. Because of this finding cell free single stranded DNA can be added as a possible biomarker for AD.

**Genome-wide search for genetic loci perturbing gene co-expression networks in Alzheimer's disease.** L. He<sup>1,2</sup>, Y. Park<sup>1,2</sup>, L. Hou<sup>1,2</sup>, D. Jose<sup>1,2</sup>, M. Kellis<sup>1,2</sup>. 1) MIT, Cambridge, MA; 2) Broad institute, Cambridge, MA.

Genome-wide association studies (GWAS) have successfully identified thousands of single nucleotide polymorphisms (SNPs) associated with human complex diseases. However, the underlying biological and pathological mechanisms of the majority of these SNPs are still elusive. Gene co-expression network structure is an important intermediate phenotype that has the potential to improve our understanding of bridging the relationship of genetic variations and complex diseases. Expression quantitative trait loci (eQTLs) have shown local genetic effects on differential expression of single genes; however, it is yet to be examined how SNPs globally affect disease-related gene co-expression networks. In this work, we develop statistical methods to genome-widely identify SNPs that significantly perturb the co-expression structure of a gene module of interest, termed as netQTLs. We applied the proposed method to genotype and gene expression datasets from the ROS/MAP project to detect which SNPs perturb Alzheimer's disease (AD)-related gene modules and which modules are perturbed by AD-related GWAS loci. In addition to the confirmation of well-controlled type I error rate, we identified novel SNPs affecting the co-expression structure of AD-related gene modules. We found that many SNPs have large effects on the overall module structure, but are not necessarily show significant marginal association with single gene expression. We also identified multiple gene modules in immune systems and circadian clock pathways that are significantly associated with both AD and AD-related GWAS loci. Our results suggest that other than eQTLs, the investigation of genetic effects on the overall module perturbation using netQTLs may provide additional insights into the relationship between genetics and gene expression.

**Genome-wide rare variant imputation and tissue-specific transcriptomic analysis identify novel rare variant candidate loci in late-onset Alzheimer's Disease: The Alzheimer's Disease Genetics Consortium (ADGC).** A.C. Naji<sup>1</sup>, J.E. Below<sup>2</sup>, Y. Zhao<sup>3</sup>, H.-H. Chen<sup>2</sup>, S.J. van der Lee<sup>3</sup>, K.L. Hamilton-Nelson<sup>4</sup>, L. Petty<sup>5</sup>, B.W. Kunkle<sup>6</sup>, A. Kuzma<sup>1</sup>, O. Valladares<sup>1</sup>, C. Reitz<sup>5</sup>, G.W. Beecham<sup>6</sup>, E.R. Martin<sup>4</sup>, L.-S. Wang<sup>7</sup>, J.L. Haines<sup>6</sup>, R. Mayeux<sup>5</sup>, L.A. Farrer<sup>7</sup>, M.A. Pericak-Vance<sup>1</sup>, G.D. Schellenberg<sup>1</sup>, Alzheimer's Disease Genetics Consortium. 1) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, USA; 2) Vanderbilt University Medical Center, Nashville, TN, USA; 3) Erasmus University Medical Centre, Rotterdam, Netherlands; 4) University of Miami, Miami, FL, USA; 5) Columbia University, New York, NY, USA; 6) School of Medicine, Case Western Reserve University, Cleveland, OH, USA; 7) School of Medicine, Boston University, Boston, MA, USA.

The International Genomics of Alzheimer's Project (IGAP) GWAS identified 19 susceptibility LOAD loci in addition to *APOE*, however the majority of these were common (minor allele frequency (MAF)>0.05). The Haplotype Reference Consortium (HRC) released a dense reference panel (64,976 haplotypes/39,235,157 SNPs) allowing imputation of rare variants (MAF>0.00008). ADGC imputed 33 GWAS datasets to HRC to identify novel rare variant associations and genetically-regulated gene expression patterns contributing to LOAD. We imputed 14,743 cases and 15,871 controls to the HRC r1.1 reference panel using Minimac3 on the University of Michigan Imputation Server. Logistic regression on individual variants with MAF>0.01 was performed in PLINKv1.9 (GLMM/R for family-based variants) using imputed genotype probabilities and meta-analyzed in METAL, while variants with MAF≤0.01 were analyzed using score-based tests and meta-analyzed in the SeqMeta/R package; both analyses adjusted for age, sex, and population substructure. Gene-based association was performed using SKAT-O and gene-based testing of expression regulation in LOAD was performed using PrediXcan. Preliminary analyses of ~39.2 million genotyped or imputed SNVs identified single variant associations of  $P < 5 \times 10^{-8}$  in 5 known IGAP LOAD candidate loci (*APOE*, *BIN1*, the *MS4A* region, *PICALM*, and *CR1*), and multiple suggestive associations ( $P < 10^{-6}$ ) at each of 13 additional loci: rs13155750 in *MEF2C* (OR(95% CI): 1.13(1.08,1.20);  $P=5.09 \times 10^{-6}$ ) and rs755951 in *PTK2B* (OR(95% CI): 1.11(1.06,1.16);  $P=5.61 \times 10^{-6}$ ) [known IGAP locus]. Novel associations include signals at *LILRA5* (19:54821819; OR(95% CI): 1.14(1.08,1.20);  $P=4.84 \times 10^{-7}$ ), involved in innate immunity pathways; and at *SMOX* (rs1884732; OR(95% CI): 1.11(1.06,1.17);  $P=5.17 \times 10^{-6}$ ), involved in catabolism of polyamines, levels of which are altered in AD brains. Rare variant and gene-based analyses demonstrated significant *APOE* and *TREM2* associations, while gene-based testing identified strong but marginal association for *SORL1* ( $P=5.55 \times 10^{-6}$ ). PrediXcan analyses identified significant strong genetically-regulated gene expression in LOAD for *MS4A4A* ( $Q=4.26 \times 10^{-26}$ ), *BIN1* ( $Q=1.70 \times 10^{-18}$ ), and *FBXO46* ( $Q=4.25 \times 10^{-6}$ ). Several novel candidate loci for LOAD have been identified using high-quality imputation of low-frequency variants in ADGC, reinforcing the utility of high-density imputation panels, and providing a resource to newly identify genes with perturbed expression in LOAD.

## 2819T

**Complex disease prediction: A framework to integrate SNP and imaging**

**data.** B. Zhao<sup>1</sup>, J. Yang<sup>1</sup>, J. Zhang<sup>1</sup>, Y. Shan<sup>1</sup>, C. Huang<sup>1</sup>, T. Li<sup>2</sup>, J. Ibrahim<sup>1</sup>, H. Zhu<sup>2</sup>. 1) Department of Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Department of Biostatistics, University of Texas MD Anderson Cancer Center, Houston, TX.

**Introduction:** In many recent complex disease studies, both whole genome single nucleotide polymorphism (SNP) data and imaging data have been used to help identify subjects at risk and predict disease progression. It is of a great practical interest to explore how to integrate the genetics and imaging information into one prediction model. **Methods and Results:** We propose a flexible framework to predict disease using both SNPs and brain volumetric data. We assess the performance of framework using more than 1100 subjects with Alzheimer's disease (AD), mild cognitive impairment (MCI), as well as healthy controls (NC) from the Alzheimer's Disease Neuroimaging Initiative (ADNI) database. We compare the integrating model with models only with either SNPs or brain volumes via cross validation. Both binary outcome (AD, NC) and three-level outcome (AD, MCI, NC) cases are considered and several types of prediction models are applied, including generalized linear model, random forest, support vector machine, and Xgboost. We show that additional prediction accuracy can be achieved through integration, but the improvement might be limited. As an illustration, we use the ADNI-1 dataset to predict the outcomes of subjects in the ADNI-GO/2. The integration can improve the prediction accuracy from 80% to 82% in binary outcome prediction, and from 54% to 61% in three-level outcome prediction. In addition, we illustrate that unobserved batch effects may exist in multi-phase multi-site brain volumetric datasets. We propose a tool to detect and control these hidden effects when testing and estimating the primary variable(s) (such as disease status, polygenic risk score). In ADNI study, the brain regions frequently reported to be associated with Alzheimer's disease (Left/Right Hippocampus, Left/Right Entorhinal, and Left/Right Amygdala) can clearly stand out from other regions after adjusting for the unobserved batch effects. **Conclusion:** We have proposed a framework to predict complex disease by integrating both SNPs and brain volumetric data. It can be widely used for disease prediction in large-scale neuroimaging and genetics studies.

## 2820F

**Mitochondrial variants associated with increased risk of late-onset**

**Alzheimer's disease.** T.J. Zhou<sup>1</sup>, X. Zhang<sup>1,2</sup>, J.J. Farrell<sup>3</sup>, J. Chung<sup>3</sup>, A.C. Naj<sup>3</sup>, K.L. Lunetta<sup>1</sup>, L.A. Farrer<sup>1,2</sup>, Alzheimer's Disease Genetics Consortium (ADGC). 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA, USA; 2) Section of Biomedical Genetics, Boston University School of Medicine, Boston, MA, USA; 3) Department of Biostatistics, Epidemiology, and Informatics; Department of Pathology and Laboratory Medicine, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, USA.

**Background:** Alzheimer's disease (AD) is a neurodegenerative disease with complex, multifactorial etiology. Mitochondrial (MT) dysfunction has been implicated in AD. However, the association between the total array of MT variants and AD has not been fully explored in large datasets. **Methods:** The Alzheimer's Disease Genetics Consortium (ADGC) recently genotyped 8,706 AD cases and 7,002 healthy controls of European ancestry from five cohorts using the Illumina Exome-Chip 1.0 which contains 226 MT variants. Each cohort was analyzed separately for variants with minor allele count (MAC)  $\geq 10$  and call rate  $\geq 0.95$  (94 variants on average), and the results were meta-analyzed using the seqMeta/R package. In gene-based tests, only single nucleotide variants (SNVs) with minor allele frequency (MAF)  $< 0.05$  were considered, and genes with  $\geq 2$  SNVs and cumulative MAC  $\geq 10$  were tested. Associations with AD status were tested using single variant (GLM) and gene-based (SKAT-O) tests in seqMeta, controlling for age, sex, and principal components of ancestry. Bonferroni-corrected thresholds were used to determine statistical significance for single variant ( $\alpha = 8.6 \times 10^{-4}$ ) and gene-based ( $\alpha = 4.5 \times 10^{-3}$ ) associations. **Results:** The single variant analyses resulted in only one significant association between increased AD risk and a missense variant (rs2853826/Thr114Ala; OR = 1.043; P =  $2.5 \times 10^{-4}$ ; MAF = 0.22) in the gene *MT-ND3*, which encodes NADH dehydrogenase 3 involved in oxidative phosphorylation of ATP. No genes passed the Bonferroni-adjusted significance level in the gene-based analysis, however *MT-TP* yielded the most significant association (P =  $7.9 \times 10^{-3}$ ). **Conclusion:** This study identified one common MT variant significantly associated with an increased risk of AD. A replication study of independent cohorts from the International Genomics of Alzheimer's Project (including datasets from the Heart and Aging Research in Genomic Epidemiology (CHARGE) Consortium, the European Alzheimer's Disease Initiative (EADI), and the Genetic and Environmental Risk in Alzheimer's Disease (GERAD) Consortium) is currently underway. Additionally, a pathway-based aggregation test is also underway to elucidate potential biological mechanisms.

**2821W**

**Genetic association study on white matter microstructure by integrating multiple neuroimaging datasets.** J. Zhang<sup>1</sup>, T. Li<sup>2</sup>, C. Huang<sup>1</sup>, J. Yang<sup>1</sup>, Y. Wang<sup>1</sup>, J.G. Ibrahim<sup>1</sup>, H. Zhu<sup>1,2</sup>. 1) Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Biostatistics, University of Texas MD Anderson Cancer Center, Houston, TX.

**Introduction:** In recent decades, a number of large-scale neuroimaging cohort studies have been launched to improve our understanding of the structure and function of human brain. Studying the environmental and genetic influences is an essential topic to unravel the biological basis for brain development and degeneration, which could eventually inspire novel inventions in neuropsychiatric disease preventions, diagnoses and clinical treatments. **Method:** In this study, we conducted a genome-wide association analysis of diffusion tensor image using the tract-based spatial statistics (TBSS) of 17 brain regions by merging data from two studies of comparable age group, the Philadelphia Neurodevelopmental Cohort (PNC) study (8-21yrs) and the Pediatric Imaging Neurocognition and genetics study (3-21 yrs). The integration allows us to improve the statistical power to detect genetic variants with relatively weak effect. Previous analysis has confirmed the consistency of the TBSS data structure as well as the covariate effect across studies. Factor analysis is performed on the merged TBSS data and one common factor is extracted as outcome. Subsequently, GWAS analysis and gene-level analysis are performed on the common factor for European ancestry and African American ancestry respectively. **Results:** No single variant reached the genome-wide significance level in European ancestry. In gene-level analysis, the Tetraspanin2 (TSPAN2) gene remains significant after adjusting for multiple comparisons, which is known to be involved in the process of brain development. For African American ancestry, 6 LD independent loci exceeded the conventional GWAS p-value threshold of 5E-08. The top variant rs2624415 (chr5:17221636) is of particular interest, as it is located within the BASP1 gene, a brain abundant membrane attached signal protein coding gene that plays an important role in regulating the neurite growth and the maturation of the neural synapses.

**Investigating the underlying genetic basis of the co-occurrence of epilepsy and psychiatric disorders.** H.O. Heyne<sup>1,2</sup>, F.K. Satterstrom<sup>1,2</sup>, J. Kosmicki<sup>1,2</sup>, E. Wigdor<sup>1,2</sup>, A.D. Børglum<sup>3,4,5</sup>, T.M. Werge<sup>3,6,7</sup>, P.B. Mortensen<sup>3,4,8</sup>, E. Robinson<sup>1,2</sup>, D. Lal<sup>1,2</sup>, M.J. Daly<sup>1,2</sup>, iPSYCH consortium. 1) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, US; 2) Broad Institute, Stanley Center for Psychiatric Research, Cambridge, MA, US; 3) iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Aarhus, Denmark; 4) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 5) Centre for Integrative Sequencing, Aarhus University, Aarhus, Denmark; 6) Mental Health Centre Sct. Hans, Institute for Biological Psychiatry, Capital Region of Denmark, Roskilde, Denmark; 7) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 8) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark.

Individuals with neurodevelopmental disorders (NDDs), such as intellectual disability and autism are frequently comorbid with epilepsy. Vice versa, individuals with epilepsy display more neurodevelopmental or psychiatric comorbidities than individuals from the general population. Here, we investigated, whether this phenotypic co-occurrence is reflected by shared rare and common genetic variants. We screened for genes enriched for de novo variants (DNV) in comparison to expectation by a mutational model (Samocho et al., 2015) in ca. 10,000 individuals ascertained for having an NDD of developmental delay, autism, intellectual disability or epileptic encephalopathy. In a subset of ca. 1,300 individuals with NDDs comorbid but not ascertained for epilepsy, the spectrum of de novo variants was strongly enriched for genes associated with epilepsy syndromes. A lower but significant de novo burden in known epilepsy genes was also present in NDDs without epilepsy but not observed in individuals without NDDs. We confirmed similar patterns with ultra-rare variant burden analyses in the Danish population iPSYCH study - comparing ca. 11,000 individuals diagnosed with autism, ADHD, schizophrenia or bipolar/affective disorder to ca. 5,200 matched controls. Epilepsy but also intellectual disability independently predicted the presence of damaging ultra rare variants in genes associated with epilepsy. Next, we moved from rare to common variants and investigated whether individuals with autism overinherited common variants (pTDT) associated with epilepsy from their parents (n= 4003). Finally, we further describe the phenotypic spectrum of individuals carrying genes shared between epilepsy and other neuropsychiatric disorders.

**Small posterior fossa in Chiari malformation affected families is significantly linked to 1q43-44 and 12q23.** A. Musolf<sup>1</sup>, S.C.W. Ho<sup>2</sup>, K.A. Long<sup>1</sup>, P. Zhuang<sup>2,3</sup>, H. Sun<sup>1,4</sup>, B.A. Moiz<sup>1</sup>, E.G. Mendeleovich<sup>2</sup>, E.I. Bogdanov<sup>2</sup>, J.E. Bailey-Wilson<sup>1</sup>, J.D. Heiss<sup>2</sup>. 1) National Human Genome Research Institute, National Institutes of Health, Baltimore, MD; 2) Surgical Neurology Branch, National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD; 3) Neuro-Oncology Branch, National Cancer Institute, National Institutes of Health, Bethesda, MD; 4) Laboratory of Medical Genetics, Harbin Medical University, Harbin, China; 5) Department of Neurology & Rehab, Kazan State Medical University, Kazan, Russia.

The posterior fossa is a cranial cavity at the base of the skull. When it is small, it causes the cerebellum and brainstem to be pushed downward, resulting in a Chiari malformation. Chiari malformations cause neck pain, balance issues, decreased motor skills and headaches in those affected. We have posterior fossa measurements and whole exome sequence data on individuals from 9 extended families from the United States and Russia that have a family history of Chiari malformations. We performed parametric linkage analyses using an autosomal dominant inheritance model with a disease allele frequency of 0.01 and penetrance for small posterior fossa of 0.8 for carriers and 0.1 for non-carriers. Single variant two-point linkage analysis and collapsed haplotype pattern (CHP) two-point linkage analysis were performed. CHP two-point linkage analysis used rare variants (MAF  $\leq$  0.05) to create multi-allelic pseudo-markers that correspond to a gene or section of a gene. This gene-based test can improve power in the presence of allelic heterogeneity. Our results found a genome-wide significant linkage on chromosome 1q43-44 (HLOD = 3.5) and 12q23 (HLOD = 3.3) in both sets of linkage analyses. Most interesting was that both signals were driven by a single (different) family. Both regions contain several linked exonic variants including rare variants located in good candidate genes. In conclusion, we have located two significantly linked regions for small posterior fossa that are driven by linked variants in 1 family each and are potentially causal. Further laboratory work is needed to confirm these candidate genes.

**Genetics of age-related cognitive decline and relationship to Alzheimer's and other neurodegenerative diseases.** M.P. Reeve<sup>1,4</sup>, M. Alanne-Kinnunen<sup>4</sup>, H. Mattson<sup>4</sup>, H. Laivuori<sup>4</sup>, S. Koskinen<sup>5</sup>, T. Paajanen<sup>6</sup>, K. Estrada<sup>5</sup>, J. Hutz<sup>1</sup>, A. Mitchell<sup>1</sup>, D. Diogo<sup>7</sup>, C. Whelan<sup>8</sup>, M. Perola<sup>9</sup>, A. Palotie<sup>4,2,10</sup>, M. Daly<sup>2,3</sup>, S. Ripatti<sup>1</sup>. 1) Eisai, 4 Corporate Drive, Andover, MA 01810; 2) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital, Richard B. Simches Research Building, 185 Cambridge St, CPZN-6818, Boston, MA 02114; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, P.O.Box 20, FI-00014 University of Helsinki, Finland; 5) Biogen, 225 Binney St, Cambridge, MA 02142; 6) Pfizer, 1 Portland St, Cambridge, MA 02139; 7) Merck, 33 Avenue Louis Pasteur, Boston, MA 02115; 8) Finnish Institute of Occupational Health Helsinki, Uusimaa, Finland; 9) National Institute for Health and Welfare (THL), Mannerheimintie 166, Helsinki, Finland; 10) The Stanley Center for Psychiatric Research and Program in Medical and Population Genetics, The Broad Institute of MIT and Harvard, Cambridge, MA, USA.

GWAS studies of Alzheimer's disease (AD) and other neurodegenerative diseases have identified numerous genetic associations, but as yet the biological pathways leading to disease are not well understood, nor is the impact of these variants throughout life. We aimed to study how genetic polymorphisms associated with AD might be related to general age-related cognitive decline (for instance, whether the APP variant A673T is protective not only for AD, but also general cognition) or whether they speak specifically to the pathology of AD and potentially related dementias. We sought to address these and other questions using a Finnish population-based cohort (Health 2000) of more than 7703 middle-aged adults (mean age 55) who were given a battery of health and cognitive tests in 2000 and then again in 2011 – enabling unique opportunities to examine the genetics of age-related cognitive decline in the general population. We performed genome-wide association on the rate of change of cognitive function as assessed by CERAD and other standard tools, and aligned these data to the individual hits and polygenic risk scores from the largest published AD meta-analysis to date (Lambert *et al.*, 2013). By integrating these data with Finnish Health Registry data, we identified more than 500 individuals who were assessed in the year 2000 or later who received a diagnosis of AD or dementia, in addition to a total of nearly 1400 AD patients who had died before 2014. These data enabled the assessment of which cognitive tests were most correlated to future AD or dementia risk, and permitted the creation of a joint predictor (using proportional hazards model) of AD risk that includes age, specific CERAD results, and polygenic risk scores – providing a substantially improved risk predictor which derives power through an integration of pre-existing genetic risk and current cognitive status. Specific cognitive test results (e.g. word list recall) were highly significant predictors of AD and dementia ( $p < 5e-7$ ) independent of APOE genotype. Our findings add substantial value to the definition of cohorts at high risk for AD. This approach is particularly promising in Finland, where in addition to rich genetic data, there exists national registries for health care, hospitalization, prescription medications, social care and deaths, and these registries are available for research and cross-linking using unique electronic identifiers to create custom endpoints.

**2825T****Gene-gene interaction tests for genetic-imaging data analysis.** *W.*

*Peng<sup>1</sup>, N. Lin<sup>2</sup>, X. Wu<sup>1</sup>, M. Xiong<sup>2</sup>.* 1) School of Public Health, Bengbu Medical College, Bengbu, Anhui Province, China, Anhui, China; 2) School of Public Health, University of Texas Health Science Center at Houston.

Investigating the gene-gene and gene-environment interaction effects in genetic-imaging data analysis provide important information to achieve deep understanding of the complex genetic structures of neuroimaging. However, due to high dimension of imaging data, very few statistical methods have been developed for testing gene-gene and gene-environment interaction in the genetic-imaging data analysis. A key issue for high dimensional gene-gene and gene-environment interaction analysis is to effectively extract informative internal representation and features from high dimensional genotype and imaging data. To explore correlation information of imaging signal and genetic variants, effectively reduce data dimensions, and overcome critical barriers in advancing the development of novel statistical methods and computational algorithms for gene-gene and gene-environment interaction tests in genetic-imaging data analysis, we proposed a new statistic method referred to as a quadratically regularized functional CCA (QRFCCA) for gene-gene interaction analysis which combines three approaches: (1) quadratically regularized matrix factorization, (2) functional data analysis and (3) canonical correlation analysis (CCA). We extend CCA from association analysis to gene-gene and gene-environment interaction analysis and propose to use QRFCCA as a unified framework for testing gene-gene and gene-environment interaction analysis with next-generation sequencing and imaging data. To evaluate performance, the QRFCCA is applied to the Neurodevelopmental Genomics studies of Complex Phenotypes in which 8, 841,087 rare variants were collected from 854 individuals with DTI images. We identified 879 pair-wise interactions between genes.

**2826F****Low-rank structure based brain connectivity GWAS study.** *Z. Zhu<sup>1</sup>, F.*

*Zhou<sup>1</sup>, L. Yang<sup>2</sup>, Y. Shan<sup>1</sup>, J. Zhang<sup>1</sup>, J. Ibrahim<sup>1</sup>, H. Zhu<sup>1,3</sup>.* 1) Biostatistics, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Statistics and Operations Research, University of North Carolina at Chapel Hill, Chapel Hill, NC; 3) Biostatistics, The University of Texas MD Anderson Cancer Center, Houston, TX.

**Introduction:** The genetic basis of brain connectivity, which reveals brain structure and brain functions, has not been well studied. It is thought that brain connectivity is affected by only a few seeds, thus yielding a low-rank structure. Existing methods for dealing with brain connectivity data usually ignore the low-rank structure, and will incur biased results for genetic analysis and the high dimension of the original connectivity will bring much burden for statistical computing. **Methods and Results:** In this paper, we propose a new method for doing connectivity GWAS based on spectral clustering to detect the low-rank structure of brain connectivity and also overcome the drawback of the high dimensionality. In the first step, we perform a spectral clustering algorithm to detect the low rank structure of brain connectivity, and thus extracting only a few features for analysis. The second step is to perform multidimensional phenotype GWAS analysis on the features extracted in the first step. In simulation studies, we show that our method will produce more accurate results compared to using the original correlation matrices. Also, our method also outperforms other existing methods in true positive rate. We applied the method to PNC and PING datasets, which contains both typical brain imaging and genetic information. From the results, using different number of features to be selected, we identified SNPs on 16 different genes in PNC dataset, and most of the significant SNPs are on gene MOV10L1 on chromosome 22 and gene CTB.30L5.1 on chromosome 7. For PING data, we identified SNPs from 15 genes that are significantly associated with brain connectivity, with the most on gene RAB39A on chromosome 10. Our results indicates brain connectivity is significantly associated with several genes, but the association might be different in populations with different diseases. **Conclusion:** We proposed an efficient method for detecting genetic association in brain connectivity. Our method can enhance both prediction accuracy and computation efficiency by recovering the low-rank structure of brain connectivity.

**Genetic causes of death in US infants: Findings from the National Center for Health Statistics.** C. Lally<sup>1</sup>, C.C. Jones<sup>2</sup>, S.F. Cook<sup>2</sup>, W. Farwell<sup>2</sup>, J. Staropoli<sup>2</sup>, W.D. Flanders<sup>1</sup>. 1) Emory University, Atlanta, GA; 2) Biogen, Cambridge, MA; 3) Epidemiology Associates LLC, Chapel Hill, NC.

**Background:** The discovery of the genetic causes of many diseases and subsequent development of approaches to modify or ameliorate the associated morbidity and mortality of some genetic diseases warrant a re-examination and quantification of the burden of infant mortality from these causes. We examined the relative frequency of the leading genetic causes of infant mortality in the United States. **Methods:** We quantified infant mortality from the most common genetic causes. This included single gene disorders and chromosomal abnormalities. We compiled a comprehensive list of genetic causes of death and their associated ICD-10 codes from the National Human Genome Institute and linked these disorders to the Orphanet website to identify genetic causes with age of onset in infancy or listed as "any age". Using data from the National Center for Health Statistics we obtained a count of the number of deaths from each of the identified causes of death. Data were queried by ICD-10 codes using the Centers for Disease Control and Prevention, National Center for Health Statistics Underlying Cause of Death 2014 on the CDC WONDER Online Database. Infant deaths following a live birth in 2014 were queried for age 1-364 days by single cause of death based on the identified ICD-10 codes. **Results:** There were 23,215 infant deaths among 3,988,076 live births in 2014. Among these, 1,120 (4.8%) deaths were from genetic causes of death; the most frequent were: 463 (41.3%) deaths from Edwards syndrome (Trisomy 18), 246 (22%) from Patau syndrome (Trisomy 13), 95 (8.5%) from holoprosencephaly (commonly associated with three copies of chromosome 13), 70 (6.2%) from Down syndrome, and 62 (5.5%) from spinal muscular atrophy (SMA). Edwards syndrome, Patau syndrome, holoprosencephaly, and Down syndrome, all chromosomal abnormalities, are the four leading genetic causes of death. SMA is the leading cause of death from a single gene disorder. **Conclusion:** Chromosomal abnormalities make up the largest percentage of infant deaths due to genetic causes. When considering deaths from a single-gene disorder, SMA is the leading cause of infant death. This study was funded by Biogen. C.L., S.F.C., and W.D.F. are consultants to and C.C.J., W.F., and J.S. are employees and shareholders of Biogen.

**2828T**

**Rare coding mutations in Alzheimer Disease.** D. Patel<sup>1,2</sup>, J. Chung<sup>1,2</sup>, X. Zhang<sup>2,3</sup>, J. Haines<sup>2</sup>, M. Pericak-Vance<sup>4</sup>, G. Schellenberg<sup>6</sup>, K. Lunetta<sup>3</sup>, L. Farrer<sup>1,2,3,4,5,6</sup>. 1) Bioinformatics Graduate Program; 2) Departments of Medicine (Biomedical Genetics); 3) Biostatistics; 4) Neurology; 5) Ophthalmology; 6) Epidemiology, Boston University School of Medicine, Boston, MA; 7) Case Western Reserve University School of Medicine, Cleveland, OH; 8) University of Miami Miller School of Medicine, Miami, FL; 9) University of Pennsylvania, Philadelphia, PA.

**Background:** Much of the unexplained heritability of Alzheimer disease (AD) may be due to rare variants whose effects are not captured in most GWAS. Because very large samples are needed to observe statistically significant associations with rare variants in genome-wide approaches, we applied a strategy that focused on rare variants occurring only in cases or controls.

**Methods:** The Alzheimer's Disease Sequencing Project performed whole-exome sequencing on a sample including non-Hispanic whites (5617 AD cases, 4594 controls). Minor alleles in 110 genes previously associated with AD or dementia were tabulated for rare variants occurring only in AD cases or controls. Top findings were further explored with bioinformatics analyses and protein homology modeling. **Results:** *NOTCH3* SNP rs149307620 had the largest number of rare alleles in AD cases (n=10) and no controls. Multiple *NOTCH3* mutations (not including this variant) have been associated with CADASIL, a diagnostically distinct disorder marked by severe headaches in young adulthood followed by stroke and dementia later in life. A genetic link between AD and *NOTCH3* has not been established, except for an unproven report of a distinct *NOTCH3* mutation shared by several AD-affected members of a single family. 7 subjects with the rs149307620 mutation and available clinical or autopsy data display classic symptoms of AD with progressive loss of memory, and no vascular risk factors or evidence of stroke. The mutation is found in the EGF protein domain near the JAG1-NOTCH3 binding site. Previous studies have shown JAG1-Notch signaling and subsequent hippocampal neurogenesis and astrogenesis to be regulated by BACE1, one of the most promising AD drug targets. Other previously unreported mutations observed only in AD cases include *PSEN1* SNP rs375376095 (n=5) which is 2779 bp from the known AD-associated rs63749824 SNP, and a high-impact splice site *ABCA7* SNP (rs376824416). A novel protective variant in *GLIS3*, found in 4 controls but not in cases, is 3010 bp from rs514716, a common intronic variant previously associated with CSF tau protein level. **Discussion:** We identified several novel rare variants predicted to have high impact on protein structure which may alter AD risk and be useful for future studies aimed at improving our understanding of the basis of AD and developing novel therapeutic targets. We are currently extending this strategy genome-wide and attempting to replicate findings in independent samples.

**Comparison of methods for multivariate gene-based association analysis using common variants for complex disease.** J. Chung<sup>1</sup>, GR. Jun<sup>1,6</sup>, J. Dupuis<sup>2</sup>, LA. Farre<sup>1,2,3,4,5,6</sup>. 1) Department of Medicine (Biomedical Genetics), Boston University Medical Campus, Boston, MA; 2) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 3) Department of Neurology, Boston University School of Public Health, Boston, MA; 4) Department of Ophthalmology, Boston University School of Public Health, Boston, MA; 5) Department of Epidemiology, Boston University School of Public Health, Boston, MA; 6) Neurogenetics and Integrated Genomics, Andover Innovative Medicines Institute, Eisai Inc, Andover, MA.

**Background.** Complex diseases are usually associated with multiple correlated phenotypes, and the analysis of composite scores or disease status may not fully capture the complexity (or multidimensionality) of a disease. Joint analysis of multiple disease-related phenotypes in genetic tests could potentially increase power to detect SNPs (or genes) associated with a disease. Gene-based tests are designed to detect genes with multiple risk variants with weak association with a univariate trait. **Methods.** In this study, we combined three multivariate association tests (O'Brien method, TATES, and MultiPhen) with two gene-based association tests (GATES and VEGAS), and compared performance (type I error and power) of six multivariate gene-based methods using simulated data. We simulated data (N=2,000) for genetic sequence and correlated phenotypes by varying causal variant proportions and phenotype correlations for various scenarios. We applied these gene-based association methods to a GWAS dataset from the Alzheimer Disease Genetics Consortium containing three neuropathological traits related to Alzheimer disease (AD) including neuritic plaque, neurofibrillary tangles, and cerebral amyloid angiopathy measured in 3,500 autopsied brains. **Results.** Our simulation study showed that the two multivariate association tests (TATES and MultiPhen, but not O'Brien) paired with VEGAS have inflated type I error in all scenarios, while the three multivariate association tests paired with GATES have correct type I error. MultiPhen paired with GATES has higher power than competing methods if the correlations among phenotypes are low ( $r^2 < 0.55$ ). We identified gene-level significant evidence ( $P < 2.7 \times 10^{-6}$ ) in a region on chromosome 2 containing three contiguous genes (*TRAPPC12*, *TRAPPC12-AS1*, and *AD11*) using O'Brien and VEGAS. The results for these three genes using other approaches (O'Brien with GATES and TATES with GATES) were less significant ( $P < 7.0 \times 10^{-6}$ ). Gene-wide significant associations with these genes were not observed in a univariate gene-based test of each neuropathological trait. **Conclusions.** Our comparison of multivariate gene-based association methods showed noticeable differences among the methods, dependent on the various scenarios. Overall, MultiPhen with GATES performed best for most tested scenarios, but we also suggest O'Brien with VEGAS or TATES with GATES as alternative method because MultiPhen requires raw data (genotypes and phenotypes).

**2830W**

**Relationship between essential tremor and Parkinson's Disease.** A.A. Gosch<sup>1</sup>, J.C. Denny<sup>2</sup>, M.F. Davis<sup>1</sup>. 1) Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

**Introduction:** Essential tremor (ET) is a neurological disorder characterized by symmetrical tremor of the upper limbs without other neurological defects. Parkinson's disease (PD) is also characterized by tremor, with a key difference: ET tremor is mostly seen during action, while PD tremor is more prevalent while at rest. PD is also characterized by problems with walking and balance, while tremor is the primary outcome of ET, without balance problems. Lewy body dementia is an umbrella disorder which covers both Parkinson's disease dementia and dementia with Lewy bodies (DLB). The genetic relationship between these three disorders has been investigated, but remains unclear. Cross-sectional studies analyzing the prevalence of ET in a subset of PD patients suggest a prevalence from 5.9 to 7.1%. The prevalence of ET has been compared in other diseases, like migraines, in large scale datasets but the prevalence of PD development in ET patients in a prospective large scale analysis has yet to be performed. In this study, we compared the prevalence of PD development in ET patients to age matched population controls obtained from the Vanderbilt University Synthetic Derivative (SD) database to better understand the risk of developing PD in patients with a previous diagnosis of ET. **Methods:** We identified ET patients from the Vanderbilt University Medical Center's Synthetic Derivative database to examine the prevalence of PD in ET patients compared to the prevalence of PD in age and gender-matched controls. We also compared the prevalence of DLB. Criteria for diagnosis of ET for a patient was determined by the presence of an ICD9 or ICD10 billing code in their medical records (333.1 & G25.0, respectively). Patients were then identified to see if they also had an occurrence of PD or DLB in the same fashion using their respective billing codes (PD - 332 & G20; DLB - 331.82 & G31.83). **Results:** A two-sample Student's T-test for proportion was used to compare the proportion of individuals diagnosed with PD in the ET and control populations ( $p < 0.0001$ ). An odds ratio of 18.34 was calculated from the proportion of individuals diagnosed with PD in our ET dataset compared to the individuals diagnosed with PD in the control population. These data strongly suggest PD is significantly more prevalent in patients with ET than in controls. Additional analyses to investigating the shared genetic risk factors between the two diseases is ongoing.

**Multivariate genome-wide association study for volumes of structural MRI regions of interest measures via a genetic correlation network modular analysis.** J. Liang, X. Zhu, *Alzheimer's Disease Neuroimaging Initiative*. Population Quantitative Health Science, Case Western Reserve University, Cleveland, OH.

Challenges in imaging genetic studies are the high dimensionality, multi-modality and high noise data with relative small sample size in conjunction with increased evidence of polygene and pleiotropy. Multivariate and network approaches, which can accommodate correlated traits, are powerful to identify potentially weak complex effects buried in high dimensional datasets and extract independent components or modules in both imaging and genetic data analysis. We calculated the pairwise genetic correlations among 145 baseline structural MRI regions of interest (ROIs) from GWAS summary statistics of volumes of ROIs in ADNI1 participants (230 cognitively normal individuals, 200 Alzheimer's patients, and 410 patients with Mild cognitive impairment). The genetic correlation was used to define a brain imaging genetic correlation network. In this network, the nodes are 145 baseline structural MRI ROIs spanning the entire brain, while edges are genetic correlation estimated by LDSC method reflecting the correlation between genetic influences on ROIs traits. We adapted a weighted gene co-expression network analysis (WGCNA) framework and used the method of topological overlap matrix (TOM) elements in hierarchical clustering to identify module structures. We next performed multivariate GWAS using cross-phenotype association analysis (CPASSOC) program to combine GWAS summary statistics of all ROIs as well as within each of identified module. We observed two variants in genes *SGCZ* and *TOMM40* (region harboring *APOE* gene) significantly associated with ROIs of volumetric measures of occipital pole and right/left hippocampus ( $P < 5 \times 10^{-8}$ ). In the within-module CPASSOC analysis, we observed 10 independent variants in 7 loci (*TOMM40/APOE*, *APCS*, *APOC1*, *ADGRL3*, *CLSTN2*, *PSD3*, *SSBP2*) with  $P < 5 \times 10^{-8}$ , in which three of them (*TOMM40/APOE*, *APCS*, *SSBP2*) reached experimental wide significance ( $P < 2.27 \times 10^{-8}$ ) after adjusting for multiple tests. Among the identified loci, three genes (*TOMM40/APOE*, *APCS*, *APOC1*) have been reported associated with Alzheimer's Disease. Our results suggest that incorporating a brain genetic correlation network and multivariate analysis of GWAS summary statistics of brain structural imaging ROIs improves power to detect genes in imaging GWAS.

***SORBS2* is associated with extended Alzheimer disease related phenotypes in *PSEN1* mutation carriers in Puerto Rico.** R. Cheng<sup>1,2</sup>, B. Vardarajan<sup>1,2</sup>, G. Tosto<sup>1,2</sup>, R. Lantigua<sup>1,3</sup>, D. Reyes-Dumeyer<sup>2</sup>, M. Medrano<sup>5</sup>, IZ. Jimenez-Velazquez<sup>6</sup>, R. Mayeux<sup>1,2,3,4</sup>, JH. Lee<sup>1</sup>. 1) Taub Inst, Columbia Univ, New York, NY; 2) Department of Neurology, Columbia University Medical Center, New York, NY; 3) Department of Medicine, Columbia University Medical Center, New York, NY; 4) Department of Psychiatry, Columbia University Medical Center, New York, NY; 5) School of Medicine, Pontificia Universidad Catolica Madre y Maestra, Santiago, Dominican Republic; 6) Department of Internal Medicine, University of Puerto Rico School of Medicine, San Juan, Puerto Rico.

We previously reported that variants in *SORBS2* modified the expression of *PSEN1* in carriers of the G206A founder mutation based on a small set of early onset Alzheimer disease (AD). This gene is located in 4q35.1 where we observed the strongest linkage signal from our earlier study. This SH3-binding domain gene transcribes a brain-specific splice variant known as nARGBP2, and this variant has been reported to influence the integrity of f-actin in the dendritic spines of neurons. Others have reported overexpression of nARGBP2 in mice caused aggregation of f-actin bundles in dendritic spines and may influence phenotypic expression, thereby possibly altering age at onset by affecting dendritic spine morphologic and subsequent neurodegenerative processes. Here, we present the findings from our 2-stage genome study. Extending the earlier study, we examined 305 individuals from 45 families in Puerto Rico with at least one G206A mutation carrier to determine whether the association between variants in *SORBS2* and AD related phenotype, namely AD, age at onset of AD (AAO), memory performance. We performed whole genome sequencing (WGS) on a subset of family members and imputed WGS sequence onto the genome wide SNPs in family members who were not sequenced. We first examined whether *SORBS2* was associated with the above phenotypes, and then we examined the SNPs within *SORBS2*. Subsequently, to confirm the findings from the G206A carrier families, we examined the variants in the *SORBS2* in a set of late onset familial AD in Puerto Rican and Dominican families. In G206A carrier families, gene-based analysis revealed that *SORBS2* was significantly associated with the AAO ( $p=0.0021$ ); however, those of *SORBS2* for global memory or delay recall were not significant. When we examined the cohort with late onset AD (EFIGA), we observed that 15 SNPs within *SORBS2* were associated with AD ( $p$  ranging from 0.0056 to 0.05), and they localized to 186.52Mb-186.82Mb. Further, we observed 18 SNPs associated with the AAO ( $p$  ranging from 0.0014 to 0.05), and the locations overlapped. Two SNPs were associated with both phenotypes. Interestingly, a number of other 'SH3' family of genes (*SH3BP5L*, *SH3RF2*, *SH3RF3*, *SH3BP4*, *SH3TC1*, *SH3PXD2B* and *SH3BGRL2*) were also associated with the AAO. Our analysis of *SORBS2* in Caribbean Hispanics revealed that *SORBS2* is a candidate genetic modifier of the age at onset of AD in both familial EOAD and familial LOAD among our Caribbean Hispanics cohorts.

**Polygenic risk scores applied to UK Biobank data highlight the interplay between behaviour and psychiatric disorders.** *P.F. O'Reilly, J. Maxwell.* SGDP Centre, IoPPN, King's College London, London, United Kingdom.

**Polygenic risk scores (PRS) are commonly used to infer shared genetic aetiology across phenotypes. Here we construct PRS for autism and schizophrenia and test their relationship with 17 behavioural and mood-related traits in the UK Biobank ( $N = 135\,726$ ). Genetic burden for autism and schizophrenia in the *healthy population* is associated with numerous behavioural and mood-related traits, including positive correlations between autism PRS and educational attainment ( $P = 2 \times 10^{-20}$ ) and cognition ( $P = 1 \times 10^{-7}$ ), and schizophrenia PRS and risk-taking ( $P = 4 \times 10^{-26}$ ). Self-reported risk-taking is associated with UK-based migration in terms of distance-moved ( $P = 2 \times 10^{-67}$ ) and increasing population density ( $P = 4 \times 10^{-73}$ ), and thus part of schizophrenia aetiology may be the genetics of risk-taking, leading to migration, urbanicity or drug-taking – known risk factors for schizophrenia. We also gain insights into the effects of disease onset and medication by contrasting the trends of behaviour observed with increasing genetic load in healthy individuals to that of medicated and non-medicated diagnosed individuals. .**

**2834T**

**Severity modifiers in autism spectrum disorder: WGS perspective.** *S.P. Smieszek, J.L. Haines, R. Igo.* Department of Population and Quantitative Health Sciences Case Western Reserve University, Cleveland, OH.

Autism Spectrum Disorder (ASD) comprises a complex of neurodevelopmental disorders primarily characterized by deficits in verbal communication, impaired social interaction and repetitive behaviors. The genetic architecture has proved to be complex and encompasses profound clinical heterogeneity, which poses challenges in understanding its pathophysiology. We conducted a large-scale association analysis of the MSSNG whole genome sequencing data to elucidate potential modifiers of ASD severity. Using the additive linear model method (PLINK) we have directly tested the associations between 6,198,166 SNPs (Quality Control: MAF > 0.05, HWE  $P < 1 \times 10^{-6}$ , Mendelian errors, removal of samples with dis-concordant sex status, twins, samples with unreported relatedness) and Vineland Adaptive Behavior Scores. Interestingly, the top variants direct us to an 850kb region containing 21 variants within 3 genes on Chromosome 2: *LYPD1* a member of the Lynx family of neurotransmitter receptor-binding proteins implicated in anxiety, *NCKAP5* previously implicated in autism (CNV, 2 cases) and *GPR39*, a product of which has been implicated in depression. Some other interesting loci include *CACNA2D2* ( $P < 1 \times 10^{-7}$ , 16 markers) encoding a subunit of the voltage-dependent calcium channel complex and axon guidance receptor gene, *DCC* ( $P < 1 \times 10^{-7}$ ). Furthermore, to leverage the size of the data we conducted a pathway enrichment analysis of the set of highly significant results ( $P < 1 \times 10^{-6}$ ) using PARIS and DAVID software. The most significant category is tobacco use disorder, with  $P < 1 \times 10^{-5}$ , with 28% of genes contributing to the significance, followed by the brain development and structural component of myelin sheath pathways. Genes categorized a neurological, developmental and immune-related constitute 65% of all the genes contributing in these pathways. We took variants from contributing genes from significantly overrepresented categories to test how much variability in the VABS scores can be explained by the variants. The cumulative effect of the single top pathway enrichment alone on affection status is 2% ( $P = 6.34 \times 10^{-6}$ ). We detect a region that may be a hallmark of severity in ASD. As genetic predisposition may be different for almost every ASD individual, understanding the common mechanisms for endophenotypes may help elucidate ASD causal mechanisms.

**Diagnostic changes leading to ASDs' prevalence increase altered the disorders' average genetic architecture.** *E.M. Wigdor<sup>1,2</sup>, W.K. Thompson<sup>3</sup>, J.A. Kosmicki<sup>1,2,4</sup>, J. Grove<sup>5,6,7</sup>, J. Taylor<sup>1,2</sup>, T.M. Werge<sup>8,9</sup>, A.D. Børglum<sup>5,7</sup>, P.B. Mortensen<sup>5,7,10</sup>, E. Agerbo<sup>5</sup>, M.J. Daly<sup>1,2,4</sup>, E.B. Robinson<sup>1,2</sup>.* 1) Stanley Center for Psychiatric Research and Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 3) Department of Psychiatry, University of California, San Diego, La Jolla, CA, USA; 4) Department of Medicine, Harvard Medical School, Boston, MA, USA; 5) iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Aarhus, Denmark; 6) iSEQ, Centre for Integrative Sequencing, Aarhus University, Aarhus, Denmark; 7) Department of Biomedicine, Aarhus University, Aarhus, Denmark; 8) Mental Health Centre Sct. Hans, Institute for Biological Psychiatry, Capital Region of Denmark, Roskilde, Denmark; 9) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 10) National Centre for Register-based Research, Aarhus University, Aarhus, Denmark.

The estimated prevalence of Autism Spectrum Disorders (ASD) has significantly increased in the United States over the last several decades, from an estimated 0.01% in 1970 to 1.46% in 2012 (Fombonne, JARID 2005; ADDM CDC, 2012). This increase is predominantly a function of diagnostic changes; the fraction of ASD cases with Intellectual Disability (ID), for example, has simultaneously decreased (Braun et al., PLoS ONE 2015). Because ASD cases are now more heterogeneous, this period is often referred to as one of 'diagnostic expansion.' This study aimed to investigate the impact of the diagnostic expansion on ASDs' average genetic architecture, specifically on the rate of *de novo* variants within ASD cases. We conducted a literature review to estimate the change in average ID rate among ASD cases over the last several decades. In parallel, we examined the change in epilepsy rate among all ASD cases born in Denmark between 1981 and 2005. Using sequencing results from the Simons Simplex Collection (SSC) and Boston Autism Consortium (BAC), we then simulated the impact these changes would have on ASDs' average genetic profile. In our review, we found a decrease in average ID rate from 67.8% in studies published prior to 1990 to 32.8% in studies published by the US Centers for Disease Control after 2008. In the Danish National Patient Registry, we found that, within ASD cases diagnosed by age 5, the rate of epilepsy declined from 21.5% in cases born before 1990 to 6.6% in cases born after 2000 (OR=0.26 p=9.84e-09). The same trend was observed in ASD cases diagnosed at older ages (e.g. 5-10, OR=0.33, p=3.75e-11). In the SSC&BAC, both ID (p=0.002) and a history of seizures (p=0.003) were associated with rate of *de novo* constrained protein truncating variants (CPTVs), defined as PTVs in genes intolerant of heterozygous loss of function variation (Lek et al., Nature 2016). In our simulation analysis, the estimated change in ID rate would result in a 17.8% decline in the percent of ASD cases with a CPTV. Similarly, the observed change in epilepsy rate in the Danish data would result in an approximate 11.7% decline in the percent of ASD cases, diagnosed by age 5, with a CPTV. These results suggest that diagnostic trends can substantially impact the average genetic architecture of neuropsychiatric disorders.

**CNVs among Japanese individuals with neuropsychiatric diseases effect dosage sensitivity in ohnologs and genes expressions.** *M. Yamasaki<sup>1,2</sup>, T. Makino<sup>3</sup>, S.S. Khor<sup>3</sup>, K. Tokunaga<sup>3</sup>.* 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Biostatistics Section, Department of Data Science, Clinical Science Center, National Center for Global Health and Medicine, Tokyo, Japan; 3) Department of Ecology and Evolutionary Biology, Graduate School of Life Sciences, Tohoku University, Sendai, Japan.

Copy number variants (CNVs) have been reported to be associated with various diseases, traits and evolution. However, when it comes to clinical applications, several issues still remain. For an example, CNVs often spanned a few mega bases and covered several genes, and this makes it hard to determine which gene should be prioritized for downstream functional experiments if the particular CNV is rare. In this study, dosage sensitivity of genes and expression was applied to individual CNVs in five different neuropsychiatric diseases, in order to overcome this issue. A hypothesis of two round whole genome duplication (2R-WGD) was proposed by Susumu Ohno in 1970, and subsequently the hypothesis was confirmed in the past decade. Studies of ohnologs, which existed at age of 2R-WGD, revealed that a pattern of retained ohnologs was not random and that current ohnologs were undergoing gene balance selection. In this study, CNVs of individuals with five different neuropsychiatric diseases were analyzed in order to assess the burden of dosage sensitive ohnologs on these diseases. Effects of CNVs on genes expressions were recently reported. Copy number variations were calculated to contribute to 17~99% of genes expressions. Integration of GWAS and eQTL data was widely applied nowadays; however, it is hard to estimate influence of CNVs on expression in whole-genome CNV studies. Oftentimes, both whole-genome data and transcript for targeted sample-set were required to assess effects of CNVs on expression. Therefore, we utilized open-access data from The Genotype-Tissue Expression (GTEx) project in order to assess the burden of whole-genome CNVs on genes expressions. Affymetrix Genome-Wide SNP Array 6.0 was used to detect CNVs by PennCNV and CNV Workshop. After quality controls for population stratification, family relationship and CNV detection, 287 narcolepsy, 133 essential hypersomnia, 380 panic disorders, 164 autism, 784 Alzheimer and 1,280 healthy individuals remained for enrichment analysis. Overall, significant enrichment of dosage sensitive genes was found across individuals with narcolepsy, essential hypersomnia, panic disorders and autism. Particularly, significant enrichment of dosage sensitive genes in duplications was observed across all diseases except for Alzheimer disease. Significant enrichments of genes with expression sensitivity in brain were observed in subjects with panic disorder and autism.

**2837T**

**Testing the moderation of quantitative gene by environment interactions in unrelated but dependent individuals.** *R. Tahmasbi<sup>1</sup>, L. Evans<sup>1</sup>, E. Turkheimer<sup>3</sup>, M. Keller<sup>1,2</sup>.* 1) Institute for Behavioral Genetics (IBG), Boulder, CO; 2) Department of Psychology and Neuroscience, University of Colorado, Boulder, CO; 3) Department of Psychology, University of Virginia, Charlottesville, VA.

The environment can moderate the effect of genes – a phenomenon called gene–environment (GxE) interaction. There are two broad types of GxE modeled in human behavior – qualitative GxE, where the effects of genes differ depending on some environmental moderator, and quantitative GxE, where the additive genetic variance changes as a function of an environmental moderator. Tests of heritability and GxE have traditionally relied on comparing the covariances between twins and close relatives, but recently there has been much interest in testing such models on unrelated individuals measured on genome-wide data. However, to date, there has been no ability to test quantitative GxE effects in unrelated individuals; e.g., the ability to do this using the popular GCTA software does not exist because such models require solving nonlinear constraints. Here, we introduce a maximum likelihood approach with parallel constrained optimization to fit such models. We use simulation to estimate the accuracy, power, and type I error rates of our method and to gauge its computational performance, and then apply this method to IQ data measured on 40,172 individuals with whole-genome SNP data from the UK Biobank. We found that the additive genetic variation of IQ tagged by SNPs increases as SES decreases, opposite the direction found by Turkheimer et al. (2003) and several other twin studies conducted in the U.S., but consistent with several studies from Europe and Australia (Tucker-Drob & Bates, 2016).

**2838F**

**Improved prediction of genetic predisposition to psychiatric disorders using genomic feature best linear unbiased prediction models.** *P.D. Rohde<sup>1,2,3</sup>, D. Demontis<sup>2,3,4</sup>, A.D. Børglum<sup>2,3,4</sup>, P. Sørensen<sup>1</sup>, iPSYCH-Broad Consortium.* 1) Molecular Biology and Genetics, Aarhus University, Tjele, Tjele, Denmark; 2) iPSYCH, The Lundbeck Foundation Initiative for Integrative Psychiatric Research, Aarhus, Denmark; 3) iSEQ, Center for Integrative Sequencing, Aarhus University, Aarhus, Denmark; 4) Department of Biomedicine, Aarhus University, Aarhus, Denmark.

Accurate prediction of unobserved phenotypes from observed genotypes is essential for the success in predicting disease risk from genotypes. However, the performance is somewhat limited. Genomic feature best linear unbiased prediction (GFBLUP) models separate the total genomic variance into components capturing the variance by a genomic feature (e.g. GO term) and the remaining genomic variance by differential weighting of the genetic variants within the two groups. Previously we have demonstrated (on pigs and fruit flies) increased predictive ability when the genomic feature is enriched for causal variants. Here we apply the GFBLUP model to a small schizophrenia case-control study to test the promise of this model on psychiatric disorders, and hypothesize that the performance will be increased when applying the model to a larger ADHD case-control study if the genomic feature contains the causal variants. The schizophrenia study consisted of 882 controls and 888 schizophrenia cases genotyped for 520,000 SNPs. The ADHD study contained 25,954 controls and 16,663 ADHD cases with 8.4 million imputed genotypes. The predictive ability for schizophrenia for the null model (all SNPs weighted equally) was low (0.07). Few GO terms did show a tendency of increased predictive ability; e.g. GO:0008645 had a predictive ability of 0.11 (unadjusted t-test p-value =  $7.4 \times 10^{-6}$ ), and explained 9% of the genomic variance, and 1.5% of the total phenotypic variance (0.6% for the null model). The improvement in predictive ability for schizophrenia was marginal, however, greater improvement is expected for the larger ADHD data.

**Quantifying the effect of copy-number variants on general intelligence in unselected populations.** G. Huguet<sup>1,2</sup>, C. Schramm<sup>1,2,3</sup>, E. Douard<sup>1,2</sup>, L. Jiang<sup>2</sup>, A. Labbe<sup>4</sup>, JB. Poline<sup>5</sup>, E. Loth<sup>6</sup>, R. Toro<sup>7,8</sup>, G. Schumann<sup>9</sup>, P. Conrod<sup>1,2,6</sup>, Z. Pausova<sup>9</sup>, C. Greenwood<sup>3,10</sup>, T. Paus<sup>11,12</sup>, T. Bourgeron<sup>6,7,13</sup>, S. Jacquemont<sup>1,2</sup>, IM-AGEN Consortium. 1) Université de Montréal, Montreal, QC, Canada; 2) CHU Sainte-Justine, Montreal, QC, Canada; 3) Lady Davis Institute for Medical Research, Jewish General Hospital, Montreal, QC, Canada; 4) Département de Sciences de la Décision, HEC, Montreal, QC, Canada; 5) Berkeley University, Berkeley, CA, USA; 6) Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, UK; 7) Institut Pasteur, Paris, France; 8) CNRS URA 2182 "Genes, synapses and cognition", Paris, France; 9) The Hospital for Sick Children, University of Toronto, Toronto, ON, Canada; 10) McGill University, Montreal, QC, Canada; 11) Rotman Research Institute, University of Toronto, Toronto, ON, Canada; 12) Child Mind Institute, New York, NY, USA; 13) Université Paris Diderot, Sorbonne Paris Cité, Paris, France.

**Introduction:** Detection of Copy Number Variants (CNVs) are routinely performed in patients with neurodevelopmental disorders (NDs) and "Clinically significant" CNVs, defined as rare and large CNVs contributing to disease, are identified in 10-15% of these patients. Effects of these clinically significant CNVs on cognitive traits have been studied for only a small number of recurrent CNVs. In addition, case-control studies are impossible to perform for > 75% of CNVs that are non-recurrent. As a result, their effects on neurodevelopment are neither characterized nor understood. **Objectives:** To examine the effect of CNVs on measures of Performance and Verbal Intelligence Quotient (PIQ and VIQ) in general populations. To model and predict the effect of CNVs using variables that characterize gene content and non-coding regions involved in CNVs. **Method:** We called CNVs from genotyping data with Pen-CNV and QuantiSNP on two cohorts drawn for the general population: Imagen ( $n=1804$ ) and the Saguenay Youth Study ( $n=968$ ). Rare ( $<1/1000$ ) CNVs  $\geq 50\text{kb}$  were validated by visual inspection. Gene and regulatory content were annotated for all CNVs based on scores of intolerances to mutation, temporal and tissue expression, as well as gene function. We tested several models to select the independent variables most predictive of CNV effect on IQ using information based criteria. **Results:** We identified rare deletion and duplications larger than 250kb in 10% of individuals. Both the size and gene content of rare deletions decrease IQ, eg. deletions  $\geq 250\text{Kb}$  decrease IQ by 6 points ( $p=2.10^{-3}$ ). We were unable to detect a significant effect of rare duplications on IQ. For estimating the effect of all deletions on IQ, a stepwise linear model procedure converged on a model including mutation intolerance scores ( $p\text{value} < 10^{-4}$ ). To validate our model which is built mainly on rare non-recurrent deletions, we compared its predictions to empirical measures of IQ loss from the literature for 12 known recurrent CNVs. The Intraclass Coefficient Correlation shows that predictions reliably match known IQ losses ( $\text{ICC} > 80\%$ ,  $p \leq 2.10^{-3}$ ). **Conclusion:** Our results suggest that the effects of deletions on general intelligence can be reliably modeled and represent a new perspective for the study of non-recurrent CNVs. Results will help clinicians estimate the impact of CNVs on cognition in their patients.

**Genome-wide association study of dental treatment-related fear and anxiety nominates novel genes.** J.R. Shaffer<sup>1</sup>, J.M. Chernus<sup>1</sup>, C.L. Randall<sup>2</sup>, C.D. Wright<sup>2</sup>, D.W. McNeil<sup>2</sup>, R.J. Crout<sup>2</sup>, R.J. Weyant<sup>1</sup>, M.L. Marazita<sup>1</sup>. 1) University of Pittsburgh, Pittsburgh, PA; 2) West Virginia University, Morgantown, WV.

**Motivation:** Fear and anxiety related to professional dental treatment is associated with avoidance of dental healthcare services, which, in turn, contributes to poorer oral health. About 40% of adults in the USA acknowledge some apprehension related to dental treatment, and 10-20% report significant levels of dental fear. Like other forms of fear and anxiety, the etiology of dental fear and anxiety includes a substantial genetic component, although few specific genes have been identified to date. Therefore, we performed a genome-wide association study (GWAS) of dental fear to nominate susceptibility genes.

**Methods:** Dental fear and anxiety was measured on 990 adults and adolescents from north central Appalachia using the Dental Fear Survey, which yields a total score and sub-scales pertaining to avoidance, physiological arousal, and dental treatment-specific stimuli. Participants were genotyped on the Illumina Human610-Quad\_v1\_B array and imputed to the 1000 Genomes Project phase 1 (June 2011) reference. GWAS scans were performed for the dental fear and anxiety total score and each of the three sub-scales using a mixed model approach while adjusting for age, sex, education, household income, and genetic sharing. **Results:** For the dental fear and anxiety total score, the most significantly associated locus was at 10q26.11 ( $rs12412905$ ;  $p=5.1E-8$ ), which included variants in and upstream of *SLC18A2*, a vesicular monoamine transporter implicated in multiple neuropsychiatric disorders. This locus was also significantly associated with the avoidance subscale ( $p=2.0E-8$ ) and showed suggestive evidence for the physiological arousal subscale ( $p=1.1E-7$ ). Additional significant loci were observed for dental fear subscales, including 12q13.13 (upstream of *MUC1*;  $p=7.5E-9$ ) for avoidance, and 13q21.1 (intergenic;  $p=1.1E-8$ ) and 22q13.1 (intronic of *NPTXR*;  $p=3.0E-8$ ) for physiological arousal. *NPTXR*, a neuronal pentraxin receptor, is notable given that pentraxins are involved in excitatory synapses, and a previous large GWAS of neuroticism implicated a gene that ubiquitinates *NPTXR*. **Conclusion:** We nominate these new gene candidates for future investigation into the biological basis of dental fear and anxiety. Understanding the etiology of dental fear and anxiety may lead to better strategies for breaking the fear-avoidance cycle, thereby improving oral health quality of life. U01-DE018903, R01-DE014899, R03-DE024264, F31-DE023493, T32-GM081741, and U54-GM104942.

**A penalized parametric bootstrap approach for self-contained pathway analysis of gene-environment interaction.** *B.J. Coombes<sup>1</sup>, J. Biernacka<sup>1,2</sup>*  
 1) Department of Health Sciences Research, Mayo Clinic, Rochester, MN; 2) Department of Psychiatry and Psychology, Mayo Clinic, Rochester, MN.

Understanding the interplay between genes and environments can give us insight into disease etiology. Gene-environment (GE) interaction can be investigated using a Genome Environment Wide Interaction Study (GEWIS) analysis. However, detection of interactions usually requires around four times the sample size to maintain power compared to testing for main effects. Additionally, the multiple testing burden of a GEWIS further reduces power to detect interaction. Thus, researchers have begun studying GE interactions at the gene or pathway. For a gene-level GE interaction test, we can calculate principal components (PCs) for the variants in a gene and test for interaction between the top PCs and the environment. To extend to a self-contained pathway analysis, we can combine the gene-level p-values using Fisher's method to obtain a pathway-level p-value. However, due to correlation of genes within the same pathway, the pathway-level tests can have inflated type I error. Permutation approaches are commonly used in pathway analyses if we are testing for main effects, but for GE interaction, it is typically not possible to construct an exact permutation test. At the gene-level, it has been shown that the parametric bootstrap is a viable alternative to permutation. A parametric bootstrap simulates null test statistics by simulating data from the null model. For a gene-level analysis of interaction, the null model includes only the main effects of the genetic variants in a gene and the environment. While the number of main effects can be large in this setting, the number of main effects at the pathway-level is considerably larger. In order to estimate the large number of main effects, we propose to fit the null model for a pathway using either a ridge or lasso penalty on the genetic main effects. We can then simulate null data from this model in order to generate pathway-level p-values simulated under the null to compare to our observed p-value. We show that this penalized parametric bootstrap approach can correctly maintain type I error for pathway analysis. We apply our method to test whether bipolar disorder is associated with the interaction between BMI and genetic variation in the WNT signaling pathway.

**Identification of novel genetic variants of DSM-5 alcohol use disorder: Genome-wide association study in NESARC-III.** *J. Jung, H. Zhang, B. Grant, P. Chou.* Epidemiology and Biometry Branch, NIH/NIAAA, Rockville, MD.

Alcohol use disorder (AUD) is a complex psychiatric disorder that affects about 32% of European Americans (EA) and 22% of African Americans (AA). Moderate to severe DSM-5 AUD and DSM-4 alcohol dependence (AD) are similarly influenced genetically with heritability of 50-65% and genetic correlation of 95%. We analyzed data from the National Epidemiologic Survey on Alcohol and Related Conditions-III (NESARC-III) to perform a genome-wide association study of alcohol use disorder with moderate to severe symptoms (AUD  $\geq 4$ ). EA and AA in NESARC-III samples were genotyped by Affymetrix Axiom Exome Chip 319K and 100K additional customized SNPs. EA samples composed of 2,465 cases without any illicit substance dependence, and 6,599 controls with exposure of alcohol but no illicit substance dependence, and AA samples of 543 cases and 2583 controls were similarly identified. A single SNP-based analysis with common variants (minor allele frequency (MAF)  $\geq 0.01$ ) was performed to test association with moderate to severe AUD using an additive model. Moreover, a gene based analysis with a combined rare and common variants was conducted using Sequence Kernel Association Test after controlling for sex, age, family income, marital status, education, 7 major psychiatric disorders, and 2 population stratification scores. In a gene-based analysis, we identified 3 novel genes (*PPP2R2D*, *SPX*, *TRIM13*) in EA and 3 novel genes (*PPIP5K1*, *TSPAN8*, *BCAS4*) in AA with p-value  $< 2.5e-6$  of a gene level threshold, and *GABRP* was detected in both EA ( $7.8e-3$ ) and AA ( $6.4e-4$ ). Based on a single SNP analysis, we identified 7 novel SNPs in *TSPYL5* (rs34070970), *RBM11* (rs7280643), *IL23R* (rs924080), *PLCD1* (rs61755441), *PTPRD* (rs72614092, rs10958948), and *KANK3* (rs11260079), with p-value  $< 0.01$  in both EA and AA. Given that *GABRP* was detected in EA, we replicated the results in AA from a gene-based analysis. With the SNP based approach we further found that among the newly discovered 7 genes in EA and AA, 4 SNPs were associated with either alcohol-related phenotypes or psychiatric disorders. In summary, in our EA and AA samples we were able to confirm previous findings that *GABRP* was associated with alcohol dependence. Our study results identified novel associations which provided evidence and rendered promises for greater understanding of the etiology of AUD.

**Allelic heterogeneity across psychotic disorders and related phenotypes.** *T. Polushina*<sup>1,2</sup>, *V. Steen*<sup>1,2</sup>, *O. Andreassen*<sup>3</sup>, *S. Le Hellard*<sup>1,2</sup>. 1) NORMENT - K.G.Jebsen Center, Department of Clinical Science, University of Bergen, Bergen, Norway; 2) Dr. Einar Martens Research Group for Biological Psychiatry, Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 3) NORMENT- KG Jebsen Centre, Institute of Clinical Medicine, University of Oslo, Oslo, Norway.

**Background** Major mental illnesses have been shown to overlap at the clinical and genetic levels. The genetic overlaps have been so far explored at the single genetic variants level, but very few studies have explored how independent variants within a locus could contribute to the genetic overlaps. In our study, we intend to increase the information captured from GWASs by focusing on allelic heterogeneity, i.e. the contribution of several independent markers within one genetic locus, within a trait and across related traits. **Methods** Using summary statistics from GWASs of traits related to mental illnesses: psychotic disorders, cognitive traits and brain volumes, we first selected independent genomic regions associated in each traits after conditional regression (Yang et al.[1]). All the genetic variants in LD with the associated signal were included in the genomic regions. We then first explored the overlaps in the regions within traits and across traits. We also scored each genomic region in each of the traits, using the Brown score for each bin, and explored the overlap in the significant regions. **Results** We observed allelic heterogeneity within and across traits. For instance: 147 genomic regions were associated with independent markers (not in LD) across several traits. We have established a map of genetic overlaps for these clusters across psychiatric disorders and relevant phenotypes (brain volumes, cognitive and personality traits). We have established a pipeline for identification of allelic heterogeneity across different phenotypes. Several of the GWAS included were too limited in power to provide significant hits yet, and will need bigger samples to yield more significant results. **Discussion** We identify allelic heterogeneity across traits, demonstrating that some genetic regions harbor independent associations with related phenotypes. Our approach is complementary to studies that explore genetic overlap at the single marker level. This improves our understanding of the impact of genetic factors in main psychotic disorders and related phenotypes, and could help to direct functional studies later. [1] Yang J. et al. Nat. Genet. 2012.

**2844F**

**Meta-analysis of *de novo* variants from 9246 probands finds that genes previously associated with autism spectrum disorder harbor more *de novo* variants in probands with intellectual disability/developmental delay without autism.** *J.A. Kosmicki*<sup>1</sup>, *L. He*<sup>2</sup>, *K.E. Samocha*<sup>1</sup>, *E.B. Robinson*<sup>1</sup>, *J.C. Barrett*<sup>2</sup>, *M.J. Daly*<sup>1</sup>. 1) Analytic and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA 02114, USA; 2) Wellcome Trust Sanger Institute, Wellcome Genome Campus, Hinxton, UK.

Studies of *de novo* variation, which is identified by exome sequencing parent-offspring families, have successfully identified over 100 genes associated with neurodevelopmental disorders, most notably intellectual disability / developmental delay (ID/DD) or autism spectrum disorders (ASDs). Mutations in the genes first discovered in *de novo* studies of ASD were specifically enriched in those ASD individuals with comorbid ID/DD, and these genes were commonly assumed to affect both traits. As such, some criticized these studies for failing to separate ID/DD genes from those genes that confer risk to ASD without ID/DD. Winner's curse suggests the effect size for these genes would be greatest in ASD (i.e., the trait it was first discovered in). Through a meta-analysis of *de novo* variants from 3982 probands ascertained for ASD (892 with comorbid ID/DD) and 5264 probands ascertained for ID/DD (503 with comorbid ASD) we show that, in fact, the reverse is true: previously associated ASD genes are more often mutated in individuals with ID/DD who do not have ASD. To identify disease associated genes, we compared the number of observed *de novo* missense and protein-truncating variants (PTVs) to the number expected from a null mutational model across three sets: ASD+ID/DD, ASD only, and ID/DD only. This yielded a total of 98 significant genes. The contribution of evidence towards each gene's association is overwhelmingly provided by ID/DD compared to ASD (4.9-fold excess;  $P < 9e-58$ ), with only 8 of the 98 genes possessing more *de novo* missense and PTVs in ASD cases than expected by chance; the remaining 90 genes are associated with ID/DD. Of the 8 ASD-associated genes, only 3 genes, *ANK2*, *DSCAM*, and *CHD8*, are significantly more strongly associated with ASD than ID/DD, with the *de novo* variants in *DSCAM* observed solely in ASD probands. *De novo* missense and PTVs in the remaining 5 ASD-associated genes are observed 2.9 times more in 4789 probands with ID/DD who do not have ASD ( $P < 7e-7$ ). This same finding extends to prior published ASD gene lists (1.8-fold excess in ID/DD;  $P < 0.002$ ), indicating that most ASD-associated genes from previous *de novo* studies are more strongly associated with ID/DD. Therefore, researchers should be cautious with using published lists of ASD genes for follow-up functional studies, especially if the goal is to learn about the genetic etiology of core ASD features in the absence of cognitive impairment - namely social and behavioral impairments.

## 2845W

**Smoking and neuroticism: Using Mendelian randomization to investigate causality.** H. Sallis<sup>1,2</sup>, G. Davey Smith<sup>2</sup>, M. Munafò<sup>1,2</sup>. 1) School of Experimental Psychology, University of Bristol, Bristol, United Kingdom; 2) MRC Integrative Epidemiology Unit, University of Bristol, Bristol, United Kingdom.

Smoking is one of the leading modifiable risk factors for disability, disease and death. There is a well-documented association between smoking and neuroticism, with smokers reporting increased levels of neurotic symptoms. However, much of this data comes from observational studies and we are unable to make any causal inference regarding this relationship. Mendelian randomization (MR) is a method of assessing causality using observational data through the use of genetic instrumental variables for modifiable risk factors. Recent GWAS have identified variants robustly associated with both smoking phenotypes and neuroticism. This enabled us to use a range of MR methods to attempt to unpick this relationship. We use publicly available summary statistics from these studies in addition to data from UK Biobank to investigate whether there appears to be a causal link between smoking and neuroticism. We found evidence of a modest genetic correlation between smoking initiation and neuroticism ( $r_g = 0.124$ ,  $p=0.008$ ). However, we found no strong evidence of a causal relationship in either direction when using 2-sample MR or when looking at individual level data in UK Biobank. Within UK Biobank it was possible to stratify on smoking status, which meant that in addition to smoking initiation, we were able to look at the association between smoking heaviness and neuroticism. We found some evidence of a causal relationship from neuroticism to increased smoking heaviness ( $\beta=0.198$ ,  $p=0.014$ ). In conclusion, although much of the observed association between smoking and neuroticism appears to be non-causal, we found evidence of a modest genetic correlation, suggesting some shared genetic aetiology. We also found some evidence of a causal relationship from neuroticism to smoking heaviness, which would lend support to the self-medication hypothesis.

Bipolar disorder (BD) is a heritable mood disorder with 1% lifetime prevalence in general population. To expand research resources for BD genetics, we seek to leverage electronic health records (EHR) database combined with genome-wide data. As part of the International Cohort Collection for Bipolar Disorder (ICCBD), we developed automated phenotyping algorithms that can identify BD patients using codified data and concepts extracted by natural language processing (NLP) from clinical narratives. We identified BD cases and healthy controls in the Partners HealthCare system with the algorithms and genome-wide genotyped these samples. We previously showed that these algorithms have high positive predictive value using a gold standard of in-person structured interviews (Castro et al. *Am J Psychiatry*, 2015). Here, we attempted to genetically validate the EHR-based BD cases and controls by estimating SNP-based heritability ( $h^2_g$ ) and genetic correlation ( $r_g$ ) between EHR-based BD and BD cases using traditional ascertainment (diagnosis/interview) in genome-wide analyses by Psychiatric Genomics Consortium (PGC) and ICCBD. We evaluated European ancestry BD cases identified using 4 EHR-based algorithms: an "NLP-based algorithm", and 3 rule-based algorithms using codified EHR with decreasing levels of stringency – "coded-strict", "coded-broad", and "coded-broad based on a single clinical encounter" (coded-SV). We used LD score regression to estimate  $h^2_g$  and  $r_g$ . The analytic sample comprised 862 NLP, 1968 coded-strict, 2581 coded-broad, 408 coded-SV BD cases, and 3952 controls. The estimated  $h^2_g$  were 0.24 ( $p=0.015$ ), 0.09 ( $p=0.064$ ), 0.13 ( $p=0.003$ ), 0.00 ( $p=0.591$ ) for NLP, coded-strict, coded-broad and coded-SV BD, respectively. The  $h^2_g$  for all EHR-based cases combined was 0.11 ( $p=0.006$ ). These  $h^2_g$  were lower than those observed by the PGC/ICCBD (0.23,  $p=3.17E-80$ , total  $N=33181$ ). However, the  $r_g$  between PGC/ICCBD BD and the EHR-based cases were high for NLP (0.66,  $p=3.69E-5$ ), coded-strict (1.00,  $p=2.40E-4$ ), and coded-broad (0.74,  $p=8.11E-7$ ). The  $r_g$  between EHR-based BDs ranged from 0.90 to 0.98. These results provide the first genetic validation of automated EHR-based phenotyping for BD and suggest that this approach identifies cases that are highly genetically correlated with those ascertained through conventional methods. High throughput phenotyping using the large data resources available in EHRs represents a viable method for accelerating psychiatric genetic research.

**Detecting tissue-specific genetic correlation between complex psychological disorders using GWAS summaries.** Q. Fan, F. Zhang, W. Wang, A. He, J. Hao, Y. Wen, L. Liu, X. Liang, Y. Du, P. Li, C. Wu, S. Wang, X. Wang, Y. Ning, X. Guo. Key Laboratory of Trace Elements and Endemic Disease, Xi'an Jiaotong University, Xi'an, Shaan Xi, China.

Genetic correlation analysis of complex diseases can provide novel clues for pathogenetic and therapeutic studies of complex diseases. Complex diseases generally implicated in various tissues. Incorporating tissue-specificity into genetic correlation analysis has the potential to improve the performance of genetic correlation analysis. In this study, we proposed an analysis framework for tissue-specific genetic correlation analysis utilizing GWAS summary and eQTLs datasets. Our approach was applied to large-scale GWAS summary datasets of schizophrenia (SCZ), bipolar disorder (BIP), autism spectrum disorder (ASD), major depressive disorder (MDD) and attention deficiency disorder (ADD). The eQTLs datasets of ten brain tissues were driven from the Genotype-Tissue Expression database. Linkage disequilibrium score regression (LDsc) was used to detect genetic correlation between the five disorders. Without considering tissue specificity, we observed significant genetic correlation between bipolar disorder, schizophrenia and major depressive disorder. Further tissue-specific analysis detected significant genetic correlation in cerebellum ( $P$ -value= $6.98 \times 10^{-6}$ ), cortex ( $P$ -value= $1.50 \times 10^{-3}$ ) nucleus accumbens ( $P$ -value= $2.00 \times 10^{-2}$ ) and putamen ( $P$ -value= $4.07 \times 10^{-2}$ ) between schizophrenia and bipolar disorder. Additionally, although correlation analysis without considering tissue-specificity did not detect significant correlation between bipolar disorder and autism spectrum disorder, further tissue-specific analysis observed significant genetic correlation in cerebellar hemisphere ( $P$ -value= $3.80 \times 10^{-2}$ ). Our method may provide new clues for elucidating the mechanism of genetic correlation among various complex diseases.

Post-traumatic stress disorder (PTSD) is a debilitating psychiatric disorder occurring in individuals exposed to trauma. To date, little is known about the genetic aetiology of the disorder, although the latest GWAS (carried out by the PGC-PTSD working group) demonstrates that genetic heritability is in line with other psychiatric disorders. PTSD development involves multi-systemic dysregulation in multiple brain regions and diverse peripheral tissues. Some peripheral systems are particularly interesting since epidemiologic evidence suggests that PTSD patients commonly have cardiovascular, metabolic and immune dysregulation. Transcriptomic Imputation approaches use machine-learning methods to impute gene expression from large genotype data using curated eQTL reference panels. These offer an exciting opportunity to compare gene associations across neurological and peripheral tissues. Here, we apply CommonMind Consortium (CMC) and Genotype-Tissue Expression (GTEx) derived gene expression prediction models to the PGC-PTSD data (9,245 cases/ 24,285 controls). Models included 12 brain regions, five cardiovascular tissues, 2 endocrine tissues, the tibial nerve, adipose tissue and whole blood. We identified 24 significant gene-tissue associations, of which 5 were in peripheral tissues (adrenal gland, heart atrial appendage, tibial artery, tibial nerve). We stratified analyses according to trauma type (civilian vs. combat trauma), sex, and self-defined ancestry. Our three strongest associations were identified in military cohorts only, which supports the hypothesis that there is substantial genetic heterogeneity between civilian and combat PTSD risk. We used the PsychENCODE neuronal and non-neuronal reference map for two histone marks associated with transcription and open chromatin (3-trimethyl-lysine 4, H3K4me3; H3-acetyl-lysine 27, H3K27ac) to understand patterns of histone modification among our PTSD-associated genes. Preliminary analyses indicate a significant correlation between prediXcan  $p$ -values and the presence of histone marks (highest correlation: H3K4me3 mark in neurons, Pearson  $R=0.87$ ,  $p=3.99 \times 10^{-6}$ ). We will expand this analysis to include a wider range of histone modification marks. We will further expand these analyses to identify tissue specific gene clusters and enriched pathways across tissues or in specific tissues. Finally, we will use neuroimaging data and physiological cardiovascular data to functionally validate our results.

**Whole genome sequencing in families with bipolar 1 disorder implicates cysteine transport process and synaptic neurotransmission pathway.** A. Parrado<sup>1</sup>, T. Lovenberg<sup>2</sup>, Q. Lj<sup>3</sup>. 1) Discovery Sciences, Janssen Pharmaceutical R&D, Spring House, PA; 2) Neuroscience Drug Discovery, Janssen Research & Development, LLC, 3210 Merryfield Row San Diego, CA; 3) Neuroscience Therapeutic Area, Janssen Research & Development, LLC, 1125 Trenton-Harbourton Road, Titusville, NJ.

Our endeavor was to discover novel gene variants that co-segregate or confer statistical association with Bipolar 1 Disorder (BP-I) to nominate as potential drug targets to prevent, diagnose or treat BP-I. We hypothesize that rare variants within and across genes and families collectively contribute to BP-I. In this research study we generated whole-genome sequencing for 32 BP-I patients, 5 Schizophrenia patients and 27 unaffected relatives, among fourteen Bipolar 1 disorder families and 1 Schizophrenia disorder family. We took a two-prong analysis approach assuming allelic and locus heterogeneity in our families. Since BP-I is a highly heritable disorder we hypothesize that rare variants would be shared among affected relatives in either a dominant or recessive mode of inheritance and would not be observed in the remainder of the study subjects and in subjects not diagnosed with Bipolar or Schizophrenia from other studies. Furthermore, to discover novel common variants that confer risk or protective association across families we performed transmission disequilibrium tests (TDT) to access linkage disequilibrium with a disease predisposing-locus. We identified six variants (missense, deletions, and intronic) that co-segregate with disease status in six genes reported in OMIM to have a phenotype-gene relationship with neuronal disorders (i.e. Schizophrenia, Depression, and Amyotrophic Lateral Sclerosis). Although our study was not highly powered for statistical testing, three variants approached a genome-wide significant association level ( $P < 1 \times 10^{-6}$ ) in our TDT analysis. The most promising variants from our co-segregation analysis are in genes involved in transmembrane transport, short term memory, transmission of nerve impulse, and neuropeptide receptor activity. One exonic variant is located in a gene that is part of the G protein-coupled receptor family and plays a role in the synaptic neurotransmission pathway.

**Gene interaction between DRD4 and DAT1 Loci is a ADHD-risk factor in females of Chilean ancestry.** G. Pathak<sup>1</sup>, R. Chakraborty<sup>1</sup>, F. Rothhammer<sup>2</sup>. 1) Institute of Molecular Medicine, University of North Texas Health Science Center, Fort Worth, TX; 2) Instituto de Alta Investigación, Universidad de Tarapacá, Arica, Chile.

**Background** Attention-deficit/hyperactivity disorder (ADHD) is a common neurological disorder characterized by hyperactivity, inattention, and impulsivity. ADHD is mostly diagnosed in children, but it often persists into adulthood. In this study, we investigated the interaction between genes coding for dopamine receptors and transporters - dopamine receptor 4 (DRD4) and dopamine transporter 1 (DAT1) in ADHD affected individuals of Chilean ancestry. **Methods** We analyzed pedigree data, disease status and genotype data of DRD4 and DAT1 in 51 Chilean families consisting of 172 individuals, consisting of 125 cases and 72 controls. For DRD4, we grouped genotypes as Heterozygous-7, 7-allele present, and absence of 7-repeat. For DAT1 loci, we grouped individuals as Homozygous-10 R allele, Heterozygous-10 R allele, and Presence of 10-R allele. The two loci, DRD4 and DAT1 are considered simultaneously, and each combination is tested versus all other genotype grouped together, in a 2x2 contingency table between cases and controls using Fisher's exact tests. Each of these significant combinations of genotype frequencies of DRD4 and DAT1 conditions was further evaluated with kinship coefficient derived from the pedigree data for males and females separately using chi-square correction for allelic association testing. **Results** The genotype frequencies of DRD4 7- R heterozygous allele with DAT1 10-repeat homozygous was found to be significantly higher in female cases ( $p = 0.0061$ ), and presence of 7-R allele (2/7, 4/7, 7/7) with DAT1 10-R homozygous allele (10/10) was also found to be significantly higher in female cases ( $p = 0.0002$ ). None of the conditions were found to be significant in males. **Conclusion** The corrected chi-square test for allelic associations uses kinship coefficient to account for cryptic relatedness between cases and controls in a family-based study. Together with the higher prevalence of ADHD in males than females, our study observes a strong allelic association between the simultaneous occurrence of both DRD4 and DAT1 genotypes with ADHD pathogenesis in Chilean females than in males. The simultaneous presence of DAT1/10-repeat homozygosity and DRD4 7-repeat heterozygosity and homozygosity indicate a low level of dopamine owing to increased transporter activity and a reduced response of the DRD4 7-repeat receptor to dopamine, provides a plausible explanation in Chilean females with ADHD.

**Proper joint and conditional meta-analysis of sequence data in the presence of missing summary association statistics.** *D. Liu.* Department of Public Health Sciences, Penn State University, Hershey, PA.

Meta-analysis of genetic association studies plays a pivotal role in understanding the genetic architecture of complex traits. After significant associations are identified, it is of interest to estimate their joint and conditional effects in order to dissect independent novel associations and pinpoint causal variants. In practice, the summary statistics may only be available in a subset of the contributing studies, which makes it challenging to utilize studies with missing data for conditional analysis. Existing meta-analysis methods either replace missing summary statistics with zero or discard studies with missing data. These naïve approaches can bias genetic effect estimates and lead to seriously inflated type-I or II errors for conditional analysis. To address this widespread issue, we develop a method to borrow strength across participating studies and consistently estimate the joint effects for candidate and known variants. Based on the consistent estimator, we propose a pseudo-score statistic for conditional analysis of single variant and gene-level associations. Through the extensive analysis of simulated and real data, we showed that the new method produces well-calibrated type I errors and is substantially more powerful than existing approaches. We illustrated the effectiveness of the proposed methods in a large-scale meta-analysis of nicotine addiction phenotypes.

**Joint analysis of rare and common variants with the adaptive combination of Bayes factors method.** *W. Lin<sup>1,2</sup>, W. Chen<sup>1,2,3,4</sup>, C. Liu<sup>5</sup>, H. Hwu<sup>1,5</sup>, S. McCarroll<sup>6,7,8</sup>, S. Glatt<sup>9</sup>, M. Tsuang<sup>10,11</sup>.* 1) Institute of Epidemiology and Preventive Medicine, National Taiwan University, Taipei, Taiwan; 2) Department of Public Health, College of Public Health, National Taiwan University, Taipei, Taiwan; 3) Institute of Brain and Mind Sciences, College of Medicine, National Taiwan University, Taipei, Taiwan; 4) Genetic Epidemiology Core Laboratory, Division of Genomic Medicine, Research Center for Medical Excellence, National Taiwan University, Taipei, Taiwan; 5) Department of Psychiatry, College of Medicine and National Taiwan University Hospital, National Taiwan University, Taipei, Taiwan; 6) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 7) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA, USA; 8) Department of Genetics, Harvard Medical School, Boston, MA, USA; 9) Departments of Psychiatry and Behavioral Sciences and Neuroscience and Physiology, Medical Genetics Research Center, SUNY Upstate Medical University, Syracuse, New York, USA; 10) Center for Behavioral Genomics, Department of Psychiatry, University of California San Diego, La Jolla, California, USA; 11) Institute for Genomic Medicine, University of California San Diego, La Jolla, California, USA.

Both rare and common variants contribute to the etiology of complex diseases. Some specialized arrays such as PsychChip were designed for the detection of both rare and common variants. There is a need to develop a powerful statistical method for this purpose. To exclude neutral variants from a gene, previous gene-based methods remove variants with larger  $P$ -values. However, a  $P$ -value carries no information from the alternative hypothesis and power, which varies with minor allele frequencies (MAFs). Another summary measure, Bayes factor (BF), is defined as the ratio of the probability of the data under the alternative hypothesis and that under the null hypothesis. It quantifies the “relative” evidence in favor of the alternative hypothesis. We show here that BF is superior to  $P$ -value in removing neutral variants when both rare and common variants are under consideration. We therefore propose an “adaptive combination of Bayes factors” (“ADABF”) method that can be directly applied to variants with a wide spectrum of MAFs. Comprehensive simulations show that ADABF is more powerful than single-nucleotide polymorphisms (SNP)-set kernel association tests and burden tests. Moreover, we applied the method to 1,109 case-parent trios from the Schizophrenia Trio Genomic Research in Taiwan, and found that the *MAP2K7* gene was associated with schizophrenia ( $P$ -value =  $1.7 \times 10^{-6}$ ). Our ADABF method is applicable to analyses of case-parent trios or unrelated subjects (allowing covariate adjustment). The R code to implement this method can be downloaded from <http://homepage.ntu.edu.tw/~linwy/ADABF.html>.

**Flipping GWAS on its head: A statistical approach to identify genetically distinct disease subphenotypes.** A. Dahl<sup>1</sup>, C. Na<sup>2,3</sup>, J. Flint<sup>4</sup>, N. Zaitlen<sup>1</sup>. 1) Department of Medicine, University of California San Francisco, San Francisco, CA; 2) Wellcome Trust Sanger Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK; 3) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK; 4) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA.

GWAS have found many associations by comparing genotypes to pre-defined diseases. But standard GWAS ignore many known complexities of disease, including misdiagnosis, biologically and medically distinct subtypes, and genetic variants that may act differently in different samples. For example, psychiatric diseases, like bipolar disorder and schizophrenia, are often confused; diseases once considered homogeneous, like breast cancer, have genetically distinct subtypes with drastically divergent prognoses and treatments; and many are actively seeking novel subphenotypes in diseases from cancer to major depressive disorder (MDD). These complications all decrease GWAS power, hamper downstream interpretation, and prevent precision clinical treatment. To address these concerns, we develop a statistical approach that reverses GWAS: we use known GWAS hits to partition traits into distinct, latent, and heritable architectures. Our EM algorithm iterates between dividing samples into latent subphenotypes and estimating genetic effects for each subphenotype. The inferred latent factors are then used in a standard interaction test for genetic heterogeneity in the subphenotypes. Our supervised approach identifies phenotypically relevant latent factors without prior knowledge. In particular, it can be used in datasets without direct measurements of subphenotypes, which dramatically eases replication of subphenotype associations. Finally, our multitrait method provides a principled decomposition of disease correlations. The method runs in minutes for tens of thousands of samples and tens of SNPs and traits; can incorporate arbitrary covariates; and can exploit penalization. We show in simulations that our method controls the false positive rate and has power to detect heterogeneity at published GWAS SNPs. By collecting more traits or samples or increasing main genetic and environmental effects, our power approaches an oracle interaction test that uses the true subphenotypes. We apply our method to breast cancer data to recover SNPs with effects known to depend on estrogen receptor status. We then study notoriously-complex psychiatric traits using the CONVERGE MDD dataset, which measured tens of risk factors and related disorders. These precise phenotypes provide a unique opportunity to characterize our inferred subphenotypes post hoc. We then analyze depression in the UK Biobank and explore the detected heterogeneous SNPs by studying their phenotypic segregation in CONVERGE.

**2854W**

**FOLD: A method to optimize power in meta-analysis of genetic association studies with overlapping subjects.** E. Kim<sup>1</sup>, H. Buhm<sup>1,2</sup>. 1) Asan Institute for Life Sciences, Seoul, South Korea; 2) Department of Convergence Medicine, University of Ulsan College of Medicine, Seoul, South Korea.

**Motivation:** In genetic association studies, meta-analyses have been widely used to increase the sample size and achieve sufficient statistical power by aggregating summary statistics from multiple studies. In meta-analyses, participating studies often share the same individuals due to the public availability of control data, accidental recruiting of the same subjects, or utilizing the same controls for meta-analysis. Particularly, a repeated use of the same controls is prevalent in cross-disease meta-analyses where one combines association results of multiple diseases to uncover pleiotropic loci. As such overlapping subjects induce correlations between studies and thus can inflate false positive rate, overlapping subjects are traditionally split in the studies prior to meta-analysis, which requires access to genotype data and is not always possible. Fortunately, recently developed meta-analysis methods can systematically account for overlapping subjects at the summary statistics level. **Results:** We identify and report a phenomenon that these methods for overlapping subjects can yield low power. For instance, in our simulation involving a meta-analysis of five studies that share 20% of individuals, the traditional splitting method achieved 80% power, whereas the power of the other new methods was less than 32%. This low power results from the unaccounted differences between shared and unshared individuals in terms of their contributions towards the final statistics. Here, we propose an optimal summary-statistic-based method termed as FOLD (Fully-powered strategy for OverLapping Data) that increases the power of meta-analysis involving studies with overlapping subjects. In this method, we categorize subjects based on their contributions to the final statistic and then calculate the summary statistic for each category. We analytically show that the FOLD estimator achieves smaller variance than the current methods. Moreover, we apply our method to the cross-disease meta-analysis design using the Psychiatric Genomics Consortium (PGC) data and show that FOLD outperforms other competing methods. **Availability:** Our method is available at <http://software.buhmhan.com/FOLD>.

**2855T**

**Integrating eQTL data with GWAS summary statistics identifies novel genes and pathways associated with schizophrenia.** C. Wu, W. Pan. Division of Biostatistics, University of Minnesota, Minneapolis, MN.

The largest genome-wide association study (GWAS) of schizophrenia (SCZ) to date has identified 108 risk loci; however, the biological mechanism underlying these associations is not well understood. Some new gene-based methods, such as transcriptome-wide association study (TWAS) (Gusev et al. 2016, *Nature Genetics* 48: 245-252), have been proposed to boost statistical power and offer biological insights by imputing gene expression with reference eQTL dataset. We first note that TWAS is simply a weighted Sum test with the weights determined by the reference eQTL data. By noting some well-known shortcomings of the (weighted) Sum test, we propose adopting other more powerful gene-based tests while integrating a reference eQTL dataset to further boost power. Specifically, we applied and compared TWAS and an adaptive association test called aSPU (Pan et al. 2015, *Genetics*, 197: 1081-1095) with eQTL datasets drawn from brain, blood, and adipose tissues and two SCZ GWAS summary association datasets, denoted SCZ1 and SCZ2, based on 20,000 and 80,000 subjects respectively. 90% of the significant genes identified by the SCZ1 data set were confirmed to be significant by the SCZ2 data set, validating the high reproducibility of the proposed methods. For SCZ2, TWAS and aSPU identified 152 and 242 significant genes, respectively, showcasing much improved statistical power of applying our proposed aSPU test. In the end, we identified 59 novel SCZ genes, of which 41 have not yet been reported. Noting that causal genes of the same disease may share biological function, next we propose a pathway-based association analysis integrating pathway annotations, a reference eQTL dataset, and a GWAS summary association dataset. The basic idea is to impute the gene expression for each gene in a pathway, then adaptively test for association between imputed expression levels of the genes and a GWAS trait. We applied our proposed approach with the KEGG and GO pathways to the eQTL datasets and the SCZ1 and SCZ2. Most of the significant pathways identified by analyzing the SCZ1 were confirmed by the SCZ2. Importantly, we identified 31 novel significant pathways associated with SCZ, such as GO:0007158 (Neuron Cell Adhesion), which could not be uncovered by the gene-based TWAS or aSPU analysis. Our results showcase the power of incorporating reference gene expression data for GWAS. The newly identified genes and pathways provide insights into the mechanism underlying SCZ.

**Identifying highly damaging missense mutations in over 10,000 developmental disorder trios using a regional missense constraint metric.** K.E. Samocha<sup>1,2,3,4</sup>, J.A. Kosmicki<sup>2,3,4</sup>, K.J. Karczewski<sup>2,3</sup>, A.H. O'Donnell-Luria<sup>2,3,5</sup>, J. McRae<sup>1</sup>, G. Gallone<sup>1</sup>, E. Pierce-Hoffman<sup>2,3</sup>, J.C. Barrett<sup>1</sup>, D.G MacArthur<sup>2,3</sup>, B.M. Neale<sup>2,3</sup>, M.J. Daly<sup>2,3,4</sup>, *Deciphering Developmental Disorders*. 1) Wellcome Trust Sanger Institute, Hinxton, United Kingdom; 2) Massachusetts General Hospital, Boston, USA; 3) Broad Institute of Harvard and MIT, Cambridge, USA; 4) Harvard Medical School, Boston, USA; 5) Boston Children's Hospital, Boston, USA.

Given the increasing numbers of patients who are undergoing exome or genome sequencing, it is critical to establish tools and methods to interpret the impact of genetic variation. This has specifically arisen in the study of *de novo* (newly arising) variants, which have an important role in the genetic architecture of neurodevelopmental disorders. While the largest excess has been found for *de novo* protein-truncating variants (roughly 2-fold enriched over expectation), there is a significant, but more modest (1.3-fold), enrichment of *de novo* missense variants in cases with a neurodevelopmental disorder. Unfortunately, the ability to interpret missense variation remains particularly challenging since missense variants can have drastically different effects depending on both the precise location and specific amino acid substitution of the variant. Previous tools used to predict the deleteriousness of missense variation have relied primarily on sequence conservation across species (e.g. SIFT), structural features of the protein (e.g. PolyPhen-2), or combinations of these metrics (e.g. CADD). Few metrics have yet to take advantage of the knowledge of constrained genes and regions where natural selection most aggressively removes variation within the human population. In order to better evaluate missense variation, we combined information about the local depletion of missense variation with variant-level metrics to create a novel missense deleteriousness metric named MPC (for **M**issense badness, **P**olyPhen-2, and **C**onstraint). We applied MPC to *de novo* missense variants from over 10,000 trios with a neurodevelopmental disorder and identified a category of *de novo* missense variants with the same impact on risk for developing a neurodevelopmental disorder as truncating variants (rate ratio = 5.8,  $p < 10^{-50}$ ). Furthermore, we showed that MPC vastly outperforms three other metrics that predict missense pathogenicity (PolyPhen-2, CADD, and M-CAP) and provide MPC scores of all potential missense variants in the 18k transcripts studied as a resource for the community.

**2857W**

**Genotype-phenotype study of *OPHN1* and *IL1RAPL2* genes mutations in children with intellectual disability.** Y.M. Khimsuriya<sup>1</sup>, N. Kharod<sup>2</sup>, J.B. Chauhan<sup>1</sup>. 1) P. G. Department of Genetics, ARIBAS, SPU, Anand, Gujarat, India; 2) H. M. Patel Academic Centre, Karamsad, Anand, Gujarat, India.

**Background:** Intellectual disability (ID), a generalized neurodevelopmental disorder defined by significantly underdeveloped intellectual and adaptive skills. The sign and symptoms of ID are mainly behavioral. Genetic analysis of such children helps to understand the genetics aspects of ID. The present study was undertaken to correlate phenotypic and genetic features in two genes *OPHN1* and *IL1RAPL2*, known to cause non-specific X-linked intellectual disability. **Materials & methods:** The PCR-RFLP method was used for genotyping of rs199985543 in *OPHN1* and rs9887672 in *IL1RAPL2* genes in 140 children with ID and 100 normal children of the Indian population. The clinical features of patients were recorded, statistically analyzed and correlated with genotype data. The Multifactor dimensionality reduction (MDR) analysis carried out by GMDR software to predict gene-gene interaction for both selected genes mutation. **Results:** In the present study, genotype frequencies of rs199985543 and rs9887672 were significant and increased disease risk compared to the normal children ( $\chi^2= 15.22$  &  $14.32$ ;  $P= 0.005$  &  $0.0001$ ;  $OR= 32.56$  &  $30.56$ ;  $CI= 1.94-545.08$  &  $1.821-512.76$  respectively). Our study population has 70% males that were most probably due to XLID genes mutations as per reported studies. Interestingly, statistical data of reported clinical features revealed that majority of XLID features were correlated with both the selected mutations. The MDR model also revealed that both mutations have epistasis interactions ( $p=0.001$  and cross-validation consistency= 10/10).

**Conclusion:** The study was statistically significant for selected polymorphism in West Indian population but we may not say that these polymorphisms are only responsible for such phenotypes. Our clinical features data demonstrated that the ID affected group have the majority of X-linked phenotypic appearance but due to the limitation of genotyping study we cannot identify the all possible genetic mutations. .

**Global developmental delay: Genetic causes in a group of Mexican patients.** M.L. Arenas-Sordo, LL. Flores-García, EP. Linares-Mendoza. Genetics, Instituto Nacional de Rehabilitación "Luis Guillermo Ibarra Ibarra", Av Mexico-Xochimilco 289. Arenal de Guadalupe, 14389 Tlapan, Mexico City, Mexico City, Mexico.

**Introduction.** Global developmental delay (GDD) is defined as delay in two or more developmental areas: gross motor, fine motor, language, cognition and social or daily living activities. The delay needs to be more than 2 ST (McDonald et al. 2006). This term is used only in children 5 years old or less. This condition has high prevalence, around 1% to 3%, but it could be higher (Moeschler et al. 2006). The causes of GDD are many but if we grouped them, the most important group is the genetic one (Srouf et al. 2006). In some studies is as high as 50%. Development of language and speech is considered by experts as a useful indicator of cognitive abilities and global development of a child (Riou et al. 2009; Spiel et al. 2001; Shevell et al. 2003; Gooch et al. 2015; Busari and Weggelaar 2004). **Methods.** An observational clinic investigation was carried out, retrospective, transversal and descriptive, revising patients' files of those who had gone for the first time to the Genetic Service. From 154 files only 92 complied with the inclusion criteria: To have global developmental delay and complete file. **Results.** Most patients were between the ages of 2 to 4 yrs. The great majority of them (87%) presented affectation of the 5 neurodevelopmental areas. We found 33 different syndromes as a cause of the GDD. We reached the etiological diagnosis in 64 (69%) **Conclusions.** To conclude we can say the patients were studied in an adequate and carefully way. We reached the etiological diagnosis in 69% of the cases, the same percentage mentioned in the literature with the diagnosis tools we used. The patients referred to the Genetic Service are in general, persons with diseases which compromise many cerebral areas. .

Westmeath, Ireland.

Inborn errors of metabolism (IEM) comprise heterogeneous and rare genetic diseases with overlapping and/or unspecific phenotype. They are caused by a significant block in a metabolic pathway resulting either in accumulation of substrate or deficiency of product. These disruptions can generally be assessed biochemically through the detection of metabolites in biological fluids allowing the diagnosis. However, biomarkers are not always available especially in new emerging, extremely rare and complex IEM. Moreover, the specificity and sensitivity of some of these biomarkers are not always high. All these considerations make the diagnosis of IEM challenging. Here, we evaluate the contribution of WES strategy combined to reverse clinical and biochemical phenotyping in the diagnosis of complex IEM, in a series of patients of all ages. They presented with unspecific phenotype of developmental delay (DD) and/or congenital malformations and were referred for exome sequencing after negative diagnosis workup. The genetic diagnosis was achieved in 32% of patients (177/550), among them 15 were rare IEM, identified in 19 unrelated patients, including the identification of a novel gene *SLC13A5*. They were first misdiagnosed mainly because of atypical or mild presentations or unspecific symptoms. Moreover, specific and reliable biomarkers in the blood or urines were not available in at least 10 disorders. In this series, despite the absence of clinical or biochemical suspicion of IEM, the diagnosis rate was 3.6%. It represented 11% of all genetic diagnosis. This study highlights the value of WES strategy in the diagnosis of complex IEM which is important for appropriate patient genetic counselling and treatment. Indeed, at least two (*GLUT1* and *SPR* deficiency) of these disorders have specific therapy.

Mitochondrial DNA (mtDNA) copy number is a cellular phenotype which can be estimated directly from whole-genome sequence data. Here, we investigate mtDNA copy number variation in diverse populations using whole-genome sequence data from Phase 1 of the NHLBI Trans-Omics for Precision Medicine (TOPMed) program, which has sequenced blood-derived DNA samples for 18,526 individuals. We have estimated mtDNA copy number from short-read sequence data in 13,648 individuals (8 studies) by comparing the average sequence coverage of mitochondrial and autosomal genomes. The estimates in 13,648 participants average 148.9 mitochondrial genomes per cell, with 80% of the samples between 89.0 and 224.3. We observe differences in mtDNA copy number distribution between studies as a result of different strategies for extracting and processing DNA. We see a modest decrease in mtDNA copy number due to sex and age effects. On average, males have 5.1 fewer mitochondrial genomes per cell than females; for each additional 10 years of age, individuals have on average 4.3 fewer mitochondrial genomes per cell. An apparent strong positive association is found between mtDNA copy number and the Duffy null blood group variant on Chromosome 1 (*rs2814778*) (effect size: 0.321 standard deviation per allele,  $p=1.1 \times 10^{-39}$ ). This signal is also found in male-only and female-only association studies ( $p=1.0 \times 10^{-20}$  and  $4.3 \times 10^{-20}$  respectively). This result is driven by the high frequency of the Duffy null allele, which causes ethnic neutropenia in persons of African Ancestry. Indeed, reduced neutrophil count alone predicts mitochondrial copy number more accurately than the Duffy genotype. In 1,000 Genomes sequence data, the non-reference allele at this locus is present at 0.6% in 1,006 samples of European ancestry and 96% in 1,322 samples of African and African American ancestry. This finding highlights the value of incorporating ethnic diversity included in the TOPMed sequencing program.

**Targeted sequence analysis of human mitochondrial DNA using an IDT xGen® Lockdown® probe panel.** R. Lopez, N. Downey. Integrated DNA Technologies, Coralville, IA, USA.

Mitochondria play an essential role in producing energy for cells. In humans, 80% of the ~17 kb mitochondrial genome encodes RNA, in contrast to the nuclear genome where <2% codes for proteins and up to 80% codes for RNAs that feed into the complex systems of a cell. Hence, if the smaller mtDNA chromosome incorporates a random mutation in mitochondrial DNA (mtDNA) it is much more likely to have direct functional consequences compared to mutations in the nuclear genome. Human mtDNA is also maternally inherited, thus tracking mutations in the mtDNA hypervariable regions over generations can be used in population genetic studies. In addition, cells in tissues that have higher energy demands (i.e., need more ATP) also have higher copy numbers of mtDNA than cells with lower energy requirements which lends itself to coverage depth challenges when analysis is done in conjunction with nuclear genomic DNA. To facilitate studies of the mitochondrial genome and its potential disease contributions, IDT has developed the xGen® Human mtDNA Research Panel, which consists of 138 synthesized xGen Lockdown® Probes that provide reliable coverage for the entire mitochondrial genome. The ability to detect single nucleotide polymorphisms (SNPs) that lead to functional or metabolic disorders was measured using a Leber Optic Atrophy cell line, which contains a G>A transition in the NADH dehydrogenase subunit 4 gene (Coriell NA10744). Three generations of CEPH/Utah pedigree 1463 were used to demonstrate inheritance of variants in the hypervariable region of the mitochondrial genome. IDT xGen panels are modular, so the xGen Human mtDNA Research Panel may be used as a spike-in to other larger panels (e.g., xGen Exome Research Panel or AML Cancer Panel) to evaluate mitochondrial mutations and/or copy number for cancer research. Here, the mitochondrial panel was used as a spike-in with a custom xGen Lockdown panel of 508 probes and the larger Exome Research Panel across a broad dynamic range of mtDNA copies to assess the relative coverage. Together these data demonstrate the utility of the xGen Human mtDNA Research Panel for disease and cancer research.

**Association study for common and rare genetic variation contributing to exfoliation syndrome.** R.P. Igo<sup>1</sup>, J.N. Cooke Bailey<sup>1</sup>, J.H. Kang<sup>2</sup>, P. Kraft<sup>3</sup>, R. Allingham<sup>4</sup>, M. Houser<sup>5</sup>, J. Fingert<sup>6</sup>, R. Ritch<sup>7</sup>, A. Sit<sup>8</sup>, R. Lee<sup>9</sup>, M.A. Pericak-Vance<sup>10</sup>, W. Scott<sup>11</sup>, L.R. Pasquale<sup>11</sup>, J.L. Haines<sup>1</sup>, J.L. Wiggs<sup>11</sup>. 1) Population and Quantitative Health Sciences, Case Western Reserve Univ, Cleveland, OH; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 3) Program in Genetic Epidemiology and Statistical Genetics, T.H. Chan Harvard School of Public Health, Boston, MA; 4) Ophthalmology, Duke University Medical Center, Durham, NC; 5) Medicine, Duke University Medical Center, Durham, NC; 6) Ophthalmology, University of Iowa, College of Medicine, Iowa City, IA; 7) Einhorn Clinical Research Center, Department of Ophthalmology, New York Eye and Ear Infirmary of Mt. Sinai, New York, NY; 8) Ophthalmology, Mayo Clinic, Rochester, MN; 9) Bascom Palmer Eye Institute, University of Miami Miller School of Medicine, Miami FL; 10) Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 11) Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA.

Exfoliation syndrome (XFS), characterized by proteinaceous deposits within the eye, is a major risk factor for glaucoma, and therefore an important cause of blindness. *LOXL1*, a well-characterized risk locus, accounts for much of the heritable variation for XFS. Two missense variants in *LOXL1* are strongly associated with XFS, but the risk allele of each is reversed in some populations, indicating complex genetic architecture, and no causal variant for XFS has yet been identified. Six other genetic loci have been implicated in XFS through genomewide association studies (GWAS), but additional causal loci for XFS have not yet been found. To search for additional genetic variation contributing to XFS, we conducted a GWAS and gene-based tests of rare variation on a sample of 1,118 XFS cases and 3,661 controls genotyped for the Illumina OmniExpressExome chip and imputed to the Haplotype Resource Consortium panel. A GWAS on 7,626,807 common (minor allele frequency (MAF)  $\geq 0.01$ ) single-nucleotide polymorphisms (SNPs) was carried out by Firth bias-corrected logistic regression using allele dosage as a predictor, adjusting for sex and six principal components. We found overwhelming evidence for association at *LOXL1* (index SNP rs8027022 in intron 1, OR = 0.25 for the A allele,  $p = 4.6E-134$ ) and strong association at a novel locus on chromosome 17q21 (index SNP rs739499 in intron 2 of *SAMD14*, OR = 1.31 for the G allele,  $p = 7.2E-08$ ) near the type 1 collagen subunit  $\alpha 1$  (*COL1A1*) gene. We found suggestive evidence for association at the known XFS risk locus *CACNA1A* (rs78771862 in intron 2, OR = 2.68,  $p = 2.49E-05$ ). Gene-based tests for association of rare genetic variation (MAF < 0.01), using SKAT-O, revealed highly significant signals for *LOXL1* ( $p = 2.3E-10$  for all rare variants;  $p = 1.5E-09$  for exonic variants only) and *LOXL1-AS1* ( $p = 5.1E-09$  for all variants). The rare alleles of all seven exonic SNPs in *LOXL1* were enriched in XFS controls; two missense polymorphisms, rs201884374 (G120S) and rs138183635 (A160P), are predicted to be deleterious by SIFT and PolyPhen. However, gene-based test results were nonsignificant ( $p > 0.05$ ) when previously described *LOXL1* common SNPs G153D and L141R were included in the SKAT-O model. Overall, these analyses add new SNPs, within and outside *LOXL1*, to the growing list of potential causal variants for XFS, and reveals additional complexity of how *LOXL1* variation contributes to the disease. Grant support: NIH/NEI R01 EY020928.

**2863W**

**Whole exome sequencing reveals candidate variants for elevated intraocular pressure in the Beaver Dam Eye Study.** *W. Li<sup>1</sup>, F. Chen<sup>1</sup>, A.P. Klein<sup>2,3</sup>, B.E.K. Klein<sup>4</sup>, R. Klein<sup>4</sup>, K.E. Lee<sup>4</sup>, P. Duggal<sup>1</sup>.* 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA; 2) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, Maryland, USA; 3) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, Maryland, USA; 4) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, Wisconsin, USA.

Nearly 2% of people in the US > 40 years are affected with glaucoma that can lead to vision loss/blindness. Elevated intraocular pressure (IOP) is a key risk factor for glaucoma. To assess the genetic underpinnings of IOP, we performed whole exome sequencing on 135 participants of the Beaver Dam Eye Study (BDES) with extreme baseline IOP or refraction measurements. Single-nucleotide variants (SNVs) and insertions/deletions (INDELS) were called across all 135 samples by GATK Unified Genotyper. All variants were annotated by ANNOVAR, with gene and functional annotations from RefGene and allele frequencies from the 1000 Genome Project. We excluded variants if (1) they failed quality filters based on the variant quality score lod-odds (VQSLOD) derived from selected quality metrics per GATK's best practice, or (2) they were in segmental duplication regions based on UCSC genomic annotations. A total of 309,066 variants with a mean transition transversion ratio (Ti/Tv) of 2.54 were obtained. Principal component analysis (PCA) confirmed the European descent of all individuals and identity-by-descent analysis (IBD) identified 95 first-degree and 102 second-degree relatives pairs, as expected. We focused our analysis on premature terminate variants (PTV) defined as splicing or nonsense SNVs and frameshift INDELS based on RefGene annotations. A total of 30 unrelated individuals with IOP > 21 mmHg or IOP/glaucoma treatment were defined as cases and 11 unrelated individuals with IOP < 15 mmHg were defined as controls. We filtered for PTV variants: (1) in autosomal chromosomes, (2) with allele frequencies in the CEU population of 1000 Genome Project < 1%, and (3) uniquely seen in cases but not in controls. A splicing variant (12:81671194) of the PTPRF interacting protein alpha 2 (*PPFIA2*, [MIM# 603143]) gene was uniquely seen in 7 out of 30 (23%) unrelated high IOP individuals and in 1 relative with high IOP. A frameshift INDEL (6:30995054) of the mucin 22 (*MUC22*, [MIM# 613917]) gene was uniquely seen in 4 out of 30 (13%) unrelated high IOP individuals and in 2 relatives with high IOP. Previously we also identified the prostaglandin E receptor 1 (*PTGER1*, [MIM# 176802]) gene associated with elevated IOP. To validate our findings, we selected 23 variants from these 3 genes and genotyped them in 936 samples with IOP measurements including 316 high IOP and 254 low IOP individuals. Identification of genes associated with IOP may lead to better and targeted therapeutics.

**2864T**

**Individualized glaucoma risk evaluation using the genomic profile.** *X. Gao, F. Fan.* Dept Ophthalmology & Visual Sci, Univ Illinois at Chicago, Chicago, IL.

Glaucoma is a leading cause of irreversible blindness worldwide and has a substantial impact on the quality of life of millions of Americans. Primary open angle glaucoma (POAG) is the most common form of this disease and has a strong genetic component. POAG is usually asymptomatic early in the disease pathogenesis and can be far advanced before patients notice an extensive visual field loss. Therefore, early detection of this disease is important to prevent vision loss. Genomic profiles in combination with recent advances in statistical learning may provide a solution to identify individuals at increased risk for developing POAG. In recent years, genetic risk scores (GRS) have been used in risk prediction for many diseases, such as age-related macular degeneration, type 2 diabetes and coronary artery disease. Currently, few GRS studies have been reported for glaucoma. Furthermore, Hispanics/Latinos have historically been understudied and genetic studies in these admixed populations remain a challenge. Using genomics data available from the Mexican American Glaucoma Genetic Study (MAGGS), we carry out a precision-medicine study. In this study, we construct GRS for POAG including its endophenotypes and build risk prediction models using advanced statistical learning approaches, such as LASSO regression, artificial neural network and Xgboost. We evaluate their risk-classification performance using cross-validation and receiver operating characteristic analyses in these Hispanic/Latino subjects. Since the sample size of any single genetic study can be limited, we further conducted this investigation using large-scale whole-genome simulations (n=100,000). Our results demonstrate that increasing both the sample size of the training dataset and the number of genetic markers in the risk prediction models can improve the prediction accuracy.

**2865F**

**Family based association tests of myopia reveal a potentially hidden association signal upstream of two GABA receptor genes.** C.D. Mid-*dlebrooks*<sup>1</sup>, C.L. *Simpson*<sup>1,2</sup>, A.M. *Musolf*<sup>1</sup>, L. *Portas*<sup>3</sup>, F. *Murgia*<sup>3</sup>, E. *Ciner*<sup>4</sup>, D. *Stambolian*<sup>5</sup>, J.E. *Bailey-Wilson*<sup>1</sup>. 1) National Human Genome Research Institute, Baltimore, MD; 2) Department of Genetics, Genomics and Informatics, Univ of Tennessee Health Science Center, Memphis, TN; 3) Institute of Population Genetics, CNR, Li Punti, Sassari, Italy; 4) Salus University, Elkins Park, PA; 5) Ophthalmology-Stellar Chance Lab, University of Pennsylvania, Philadelphia, PA.

Myopia is an eye condition in which the light entering the eye does not focus on the retina resulting in distant objects appearing out of focus. Within recent years, the incidence and prevalence of myopia have increased in most populations and has reached epidemic proportions in several Asian countries. We have performed a family based association study using Exome Chip genotyping (Illumina Human Exome v1.1 array plus 24,263 custom SNPs) in five family cohorts for a total of 1,718 subjects in 261 families. These cohorts include Amish, Ashkenazi Jewish, African American, Caucasian and Chinese American families who have multiple individuals affected with myopia. Individuals in the families were defined as myopic if their average refractive error was  $\leq -1$  Diopter (D) and were considered unaffected if their average refractive error was  $> 0.0$  D. Children were considered unaffected as follows:  $MSE \geq +2D$  (ages 6-10) or  $MSE \geq +1.5D$  (ages 11-20). After quality control, there were ~127,000 polymorphic SNPs available for analysis. Both gene-level and single-variant association analyses were performed using Family Based Association Test (FBAT) software. This resulted in a significant signal in a novel region upstream of two gamma-Aminobutyric Acid (GABA) receptor genes (*GABRA6*; *GABRB2*). GABA is a neurotransmitter that has previously been implicated in refractive development. The associated SNP, rs1373602, is not found in the Genotype-Tissue Expression (GTEx) project, but a nearby SNP, rs62381591, has been identified as an expression quantitative trait locus for the *GABRA6* gene. As the significant variant is common (~48% across populations), we wondered why the larger, population-based association studies of Myopia have not found a signal in this region. Upon further analysis, we learned that this variant is not in high Linkage disequilibrium (LD) with any other variants in our dataset (highest  $r^2$  was ~0.002) and is indicated as triallelic in the 1000 genomes dataset (although it was biallelic in our smaller dataset). Hence, this triallelic SNP may be filtered out before GWAS and there may not be another SNP that tags this region. We plan to follow-up this analysis by collaborating with groups that have performed genome-wide genotyping studies of Myopia to determine if this signal was missed due to the aforementioned reasons.

**Examination of a rare risk variant in complement factor H for age-related macular degeneration in the Amish.** A.R. *Waksmunski*<sup>1,2</sup>, K. *Miskimen*<sup>3</sup>, Y.E. *Song*<sup>3</sup>, R. *Laux*<sup>3</sup>, D. *Fuzzell*<sup>3</sup>, S. *Fuzzell*<sup>3</sup>, L.D. *Adams*<sup>4</sup>, L. *Caywood*<sup>4</sup>, M. *Prough*<sup>4</sup>, W.K. *Scott*<sup>4</sup>, D. *Stambolian*<sup>5</sup>, M.A. *Pericak-Vance*<sup>4</sup>, J.L. *Haines*<sup>2,3</sup>. 1) Genetics and Genome Sciences, Case Western Reserve University, Cleveland, OH, U.S.A.; 2) Institute for Computational Biology, Case Western Reserve University, Cleveland, OH, U.S.A.; 3) Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH, U.S.A.; 4) Hussman Institute for Human Genomics, University of Miami, Miami, FL, U.S.A.; 5) Ophthalmology and Genetics, University of Pennsylvania, Philadelphia, PA, U.S.A.

The Amish constitute a genetically isolated and socially segregated population located in North America. The present-day Amish population arose from a few hundred founders, who immigrated to North America 300 years ago, resulting in a population bottleneck that has been sustained since that time. Members of this faith community practice endogamy and adhere to a strict, uniform lifestyle. Consequently, they are substantially more genetically and environmentally homogeneous compared to the general Caucasian population. Previous work identified a rare missense mutation for age-related macular degeneration (AMD) in complement factor H (rs570523689, *CFH* P503A) in the Amish. This variant was initially found in 19 Amish individuals from Ohio and Indiana. We performed custom TaqMan genotyping assays and identified an additional 33 carriers of this variant in these Amish populations. This variant was not identified in a cohort of 495 Amish individuals from Lancaster County, Pennsylvania, which may indicate that this variant segregated in particular Amish sub-isolates in the United States. Nearly all of the newly identified carriers are heterozygous for the variant and are the children, siblings, or close relatives of the original 19 *CFH* P503A carriers. Using data from the Anabaptist Genealogy Database, the carriers are connected through a 10 generation pedigree that dates back to the 1700s. The *CFH* P503A carriers appear to have a younger age of first AMD diagnosis compared to elderly non-carrier Amish individuals with AMD. The average age of first AMD diagnosis in the non-carriers is 85, and the average age of first AMD diagnosis in the carriers is 81. Studies are underway to calculate genetic risk scores for the carriers and closely related non-carriers to determine if the carriers have a higher genetic burden for AMD. Functional studies are ongoing to elucidate the consequences of this variant in individuals with AMD.

**2867T**

**Genetic risk score is associated with vertical cup-disc ratio and improves prediction of primary open angle glaucoma in Latinos.** D.R. Nannini, H. Kim, F. Fan, X. Gao, *Mexican American Glaucoma Genetic Study Group*. Department of Ophthalmology and Visual Sciences, University of Illinois at Chicago, Chicago, IL.

Previous genome-wide association studies have identified multiple genetic variants associated with vertical cup-disc ratio (VCDR). Genetic risk scores (GRS) examine the joint genetic effect of individual variants on a trait by aggregating these separate genetic variants into a single measure. The purpose of this study is to construct a GRS for VCDR using previously published single nucleotide polymorphisms (SNPs) and to evaluate whether the GRS is associated with VCDR and whether the GRS increases the discriminatory ability for primary open angle glaucoma (POAG) in a Latino population. We performed a population based-association study using 4,018 Latino study participants. We constructed unweighted and weighted GRS using 68 previously reported VCDR SNPs. Linear and logistic regression analyses were performed to examine the association between both GRS with VCDR and POAG. To evaluate the discriminatory ability of the GRS for POAG, receiver operating characteristic (ROC) analyses were conducted. The GRS were significantly associated with VCDR ( $P < 0.0001$ ), after adjusting for age, gender, central corneal thickness, intraocular pressure, and education. Compared to traditional risk factors for VCDR, the weighted GRS explained an additional 2.75% of the variation in VCDR. Moreover, compared to the lowest quintile of the GRS, study participants in the highest quintile experienced significantly higher odds of POAG. Addition of the weighted GRS improved the discriminatory ability for POAG during ROC analyses ( $P = 0.03$ ). To our knowledge, we are the first to report the association between GRS and VCDR, and the improvement in discriminatory ability of POAG, in a Latino population.

**Grouped association analysis for very rare variants using Fisher's Exact Test and external controls.** A. Kwong<sup>1</sup>, D. Stambolian<sup>2</sup>, E.Y. Chew<sup>3</sup>, A. Swaroop<sup>4</sup>, G. Abecasis<sup>1</sup>. 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI; 2) Department of Ophthalmology, Perelman School of Medicine, University of Pennsylvania Medical School, Philadelphia, PA, United States; 3) Division of Epidemiology and Clinical Applications, National Eye Institute, National Institutes of Health, Bethesda, MD, United States; 4) Neurobiology-Neurodegeneration and Repair Laboratory, National Eye Institute, National Institutes of Health, Bethesda, MD, United States.

Developments in next-generation sequencing technology have led to an exponential increase in the number of very rare variants available for analysis in genetic association studies. Very rare variants with large effect sizes can provide specific clues about disease mechanisms, but identifying these variants is challenging. One major challenge is the requirement of very large sample sizes to achieve power for rare variant association testing, even for burden tests. We evaluate the potential for rare variant association studies to use large external control sets, such as variant lists and genotype counts from the Exome Aggregation Consortium (ExAC), to increase power. Our approach compares counts of very rare variants (allele frequency  $< 0.1\%$ ) in study cases and study controls to those in an external control sets using gene-level comparisons, incorporating variant list filters that consider a range of annotation information, including allele frequency, predicted function, and CADD score. Each individual comparison is based on Fisher's Exact Test for carrier status for rare variants vs. case-control status of samples. We tested this approach on our Age-Related Macular Degeneration (AMD) whole-genome sequencing case-control study with 2,394 cases and 2,393 controls, containing 46,946,619 variants in all. For this analysis, we focused on genes within known associated loci containing very rare frameshift, essential splice, or stop gain variants, totaling 652 variants in 392 genes. We discovered associations for genes with rare variants known to be associated with AMD (*CFH*, *CFI*), along with results suggesting additional potentially associated genes. In conclusion, our approach provides a way to increase the power of very rare variant association analysis by incorporating external controls.

Down syndrome (trisomy 21; T21) patients are often born with congenital heart defects (CHD), including atrioventricular septal defect (AVSD). The incidence of AVSD is 43% in CHD T21 patients (17% in whole T21 population) and very rare in the general population. The genetic architecture of CHD has been previously studied with SNP arrays; with this approach, our group identified two SNPs and three CNVs regions significantly associated with the risk of CHD (Sailani et al., Genome Research, 2013). Here we use chromosome 21-targeted deep sequencing (>120x) to perform a case-control association study in a T21 population to identify SNPs, structural variants and CNVs associated with the AVSD in T21. The study cohort includes 102 Down syndrome patients with AVSD and 145 Down syndrome patients without detectable cardiac defect as controls. A total of 220671 SNPs and 21756 short indels has been called through our in-house pipeline implementing BWA, GATK and Anovar. The association study has been performed with Fisher's exact test and logistic regression following different genetic models. No variant has reached strict 5% Bonferroni level significance; however, the analysis revealed several prominent loci such as rs57685080 ( $p=1.2 \times 10^{-6}$  on allelic model), a 3 bp deletion 2.9 kb upstream APP, or rs79882024 ( $p=3.5 \times 10^{-6}$  on allelic model,  $p=7.9 \times 10^{-6}$  on additive model,  $p=7.8 \times 10^{-6}$  on dominant model), a SNP located within an intron of *PCP4*. Epistasis analysis using logistic regression showed an interaction between rs2824960 (within an intron of MIR548XHG) and rs9975251 (50.1 kb upstream MRPS6) with  $p=2.1 \times 10^{-6}$ , albeit not reaching 5% Bonferroni level. We have also performed CNVs detection with CNVkit and Nexus and association analysis with CNVRuler. This study identified 4 CNVs, one spanning over both exonic and intronic regions of *FAM207A* (3.9 kb, FDR = 0.029) and others over intronic regions of *PCBP3* (0.87 kb, FDR = 0.029) and *CLDN14* (9.6 kb, FDR = 0.029). This study shows that common variants on chromosome 21 may contribute to the developmental phenotype of AVSD and provide insights into the understanding of the genetic mechanisms underlying the development of congenital heart defects. A larger sample size may better characterize the genetic architecture of the chromosome 21 contribution to the AVSD.

## 2870T

**Tracing the dark matter: Prevalence of copy number variants across Mendelian disorders.** R. Truty, S. Lincoln, M. Kennemer, J. Paul, E. Gafni, S. Fay, R. Nussbaum, S. Aradhya. Invitae, San Francisco, CA.

The prevalence of exonic copy number variants (CNVs) in the human genome is not well understood. We applied a next-generation sequencing method to simultaneously detect sequence variants and intragenic CNVs in a large population undergoing clinical testing for neurological, pediatric, hereditary cancer, or cardiac disorders. From testing more than 76,000 unrelated individuals for subsets of 1002 genes (the equivalent of 2.2 million single-gene tests), we identified 1307 clinically reportable CNVs in 221 genes, including 830 deletions and 477 duplications. While CNVs were observed in only 1.7% of patients, they were pathogenic in 9.3% of patients with a positive finding. Most deletions (93%) were pathogenic while only 46% of duplications were. Only 17% of CNVs included an entire gene and, in several instances, these likely represented larger cytogenetic events encompassing several neighboring genes. The frequency of intragenic CNVs among pathogenic variants ranged from 4.8% in cardiac disorders to 32.2% in neurological disorders. CNVs were highly prevalent in neuropathies, muscular dystrophies, neurofibromatosis, epilepsy, familial hypercholesterolemia, and other conditions with loss-of-function (LOF) mutational mechanisms, but were rare in Noonan syndrome, cardiomyopathies, and others which mostly result from gain-of-function variants. We also evaluated genes unrelated to the presenting clinical phenotype in >76000 individuals to estimate the baseline population prevalence of non-morbid intragenic CNVs. Up to 600 genes were examined per individual, representing a total of 13 million single-gene analyses. We observed 2676 high-quality CNVs, with an average of one CNV for every 4534 genes sequenced. The majority of CNVs (64%) were duplications. Most (82%) CNVs were heterozygous variants in recessive genes and/or in genes in which disease-causing variants do not show a LOF mechanism. We identified commonly polymorphic CNVs (e.g., at *NPHP1* and *NIPA1*) but most were novel, rare events. Our data demonstrate that universal exon-level CNV analysis is valuable in diagnostic testing, particularly in pediatrics and neurology, because these events explain a disproportionately high frequency of pathogenic variants. This study describes one of the large clinical datasets on small intragenic CNVs and provides a deeper view into their prevalence in human genes.

**Iterating from discovery to epidemiological consequence through disease mechanism.** *J. Brown, G. Unlu, E. Gamazon, E. Knapik, N. Cox.* Vanderbilt University, Nashville, TN.

In early studies of PrediXcan in BioVU, we observed an association of *GRIK5* with many different eye phenotypes (glaucoma, cataract, vitreous body abnormalities, retinal detachment, etc.), and subsequent studies of zebrafish knockout of the ortholog confirmed the importance of normal expression of this gene for normal eye development in the zebrafish. More detailed studies have uncovered vascular biology as the primary mechanism underlying these effects. The *GRIK5* ortholog is most highly expressed in 3-day old embryos in the developing eye, ear, and brain, and we observe fewer blood vessels in these tissues as well as leaky blood vessels in both knock-out and knock-down models. Motivated by these observations, we are making a systematic study of the relationship of vascular phenotypes and eye disease in both BioVU, the biobank at Vanderbilt University with more than 240,000 samples with DNA, and the entire Synthetic Derivative, the clinical data warehouse with the deidentified and continuously updated image of the electronic health records (EHR) in more than 2.7 million subjects receiving healthcare at Vanderbilt University Medical Center. If vascular biology is the primary genetic mechanism giving rise to the increased risk of eye disease in individuals with reduced expression of *GRIK5*, we hypothesized that eye diseases would be found at increased frequency in individuals reported to have congenital anomalies of the vascular system. We found that subjects with congenital anomalies of the vascular system have a 2-fold increased risk of glaucoma, cataract, retinal detachment, all types of macular degeneration, hypotony, disorders of the vitreous body, scleritis and episcleritis and visual field defects of the eye, and a 3-fold increased risk of diabetic retinopathy. Subjects with congenital anomalies of the vascular system also have a 3-fold increased risk of congenital anomalies of the eye. Many eye phenotypes show a smaller increased risk, not quite 2-fold, including disorders of globe, retinal disorders, disorders of refraction and accommodation, optic atrophy, pain/swelling/discharge of eye, and cancer or neoplasm of the eye. These studies illustrate the utility of iterating between human and model systems as well as the advantages of being able to consider validation studies at the level of phenome relationships in a large clinical data warehouse.

**2872W**

**Genome-wide association analyses in large-scale multi-ancestry cohorts: Statistical challenges and opportunities.** *C. DeBoever<sup>1,2</sup>, C.R. Gignoux<sup>3</sup>, S. Buyske<sup>4</sup>, C.D. Bustamante<sup>1,2</sup>, M.A. Rivas<sup>1</sup>.* 1) Department of Biomedical Data Science, Stanford University; 2) Department of Genetics, Stanford University; 3) Department of Biostatistics and Center for Personalized Medicine, University of Colorado Anschutz Medical Campus; 4) Department of Statistics and Biostatistics, Rutgers University.

Large-scale sequencing projects and biobanks with phenotype data such as the NIH Genome Sequencing Program, which plans to sequence 200-250k whole genomes from a variety of ancestries, present new opportunities to identify genetic associations using larger samples sizes and more diverse cohorts than previous GWAS. However, the size and design of these initiatives also pose new statistical challenges for GWAS. Here, we investigated the utility of diverse GWAS cohorts by developing a Bayesian mixture model to identify genes that are enriched for rare loss-of-function (LoF) variants in subjects with African (AFR) and admixed American (AMR) ancestry relative to Europeans (NFE) in the gnomAD database. We find that 3,950 genes and 3,553 genes are enriched for LoF variants in AFR and AMR subjects, respectively, of which 564 and 659 are associated with traits through GWAS. For instance, *IL2RA* (type 1 diabetes, Crohn's, rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease) LoF alleles are present at frequency 0.003% in NFE but are ~2.5 fold enriched in AFR and AMR and are observed at frequencies 0.007% and 0.006% respectively. Similarly, *CDKN2A* (type 2 diabetes, myocardial infarction, coronary artery disease, endometriosis, glaucoma) LoF alleles are at frequency 0.016% in NFE but are observed twice as frequently (0.033%) in AMR. The differing frequencies of LoF alleles demonstrates the utility of diverse GWAS cohorts for the purpose of pursuing knockout carriers and identifying gene-disease associations. While including subjects from diverse ancestries in GWAS allows for testing a broader range of genes and variants, it also poses challenges for statistical analyses. To explore this, we simulated hundreds of thousands of genomes from different ancestries using msprime, a coalescent simulator that models human demographic history, and examined how the power to detect associations changes under different study designs. We also examined the effect of using unascertained controls on the power to detect rare variant associations and found that both disease prevalence and the case/control ratio can strongly affect statistical power. In particular, we find that the power to detect rare protective variants is more sensitive to the case/control ratio than the power to detect rare risk variants. This work demonstrates the value of utilizing subjects from diverse ancestries in GWAS and suggests guidelines for effectively analyzing such datasets.

**Genetic factors that modulate the relationship between education and Alzheimer's disease.** R.A. Bhatta<sup>1</sup>, S.-Y. Chou<sup>2,3</sup>, Y. Zhao<sup>1</sup>, L. Qu<sup>1</sup>, A. Kuzma<sup>1</sup>, G. Schellenberg<sup>1</sup>, L.-S. Wang<sup>1</sup>. 1) Penn Neurodegeneration Genomics Center, Dept of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 2) Dept of Economics, Lehigh University, Bethlehem, PA; 3) National Bureau of Economic Research, Cambridge, MA.

Neither genetics nor environmental factors alone fully explains observed phenotypic variation in Alzheimer's disease (AD), suggesting a possible role for gene-environment interactions in the etiology of AD. The purpose of this study is to examine one environmental factor implicated to have a protective effect against AD: education. Specifically, using known genetic risk/protective factors for AD, we consider how gene-education interactions relate to AD risk. Using phenotype data from National Alzheimer's Disease Coordinating Center (NACC) and HRC imputation data from Alzheimer's Disease Genetics Consortium (ADGC), we employ a regression approach utilizing linear probability models. All models control for sex, race/ethnicity, APOE, APOE interacted with sex, age at first visit, genotyping cohort, and study recruitment site. Standard errors are clustered by recruitment site, allowing for within-site error correlation. In the first step of our analysis, we interact the top genome-wide significant AD single nucleotide polymorphisms (SNPs) (see Lambert et al., 2013) with indicator variables for education level. The main outcome variable, the likelihood of AD, is regressed on these interaction terms and all control variables. Any statistically significant SNP-education interactions are used for localized analysis in the second step, in which we incorporate all SNPs located within close proximity of this "top" significant SNP. Results from the first step identify a nominally significant, negative interaction between education and rs2718058 (7:37841534), a SNP located near the *NME8* gene. The negative coefficient estimates indicate that higher educated groups possessing a greater number of minor alleles are less likely to develop AD when compared to the least educated group, i.e. the effect of education is amplified by the minor (in this case, protective) allele. Upon closer examination of neighboring SNPs, located within ~300Kbp of this top SNP, we discover both positive and negative interactions with education. These localized results suggest the possibility of at least three haplotypes conferring interaction effects with education level. Further analyses will exploit advanced econometric techniques as well as Mendelian Randomization for causal inference on the relationship between education and AD.

**2874F**

**Vitamin D deficiency: Analysis shows season and dietary vitamin D intake influence the effect of GC, CYP2R1, DHCR7 and CYP24A1 genes on vitamin D levels.** K.E. Hatchell, C.D. Engelman. Population Health Sciences, University of Wisconsin-Madison, School of Medicine and Public Health, Madison, WI.

**Statement of Purpose:** Vitamin D deficiency is determined both environmentally (i.e. diet and sun exposure) and genetically, and is associated with numerous adverse health effects. Genome-wide meta-analyses have shown that *GC*, *CYP2R1*, *DHCR7/NASYN1* and *CYP24A1* play key roles in the biological mechanism of vitamin D deficiency. We sought to determine the additive effect of the most influential SNP in each of these genes on 25-hydroxyvitamin D (25(OH)D) levels in the blood while stratifying by season and dietary vitamin D intake. **Methods Used:** Participants, ages 30-74, were selected from the Survey of the Health of Wisconsin. We calculated a weighted (by beta-coefficients from a linear regression model) polygenic risk score (PRS) using the most significant SNP in *GC*, *CYP2R1*, *DHCR7/NASYN1* and *CYP24A1*. Data were analyzed using linear regression controlling for sex, age, season of blood draw, sun exposed and inherited (unexposed) skin color measured by spectrophotometry, vitamin D intake from food and supplements, waist circumference, and genetic ancestry. Two additional models tested the interaction between the PRS and season of blood draw or quartile of dietary vitamin D intake. **Summary of Results:** The PRS ranged from 0 to 13.3. Preliminary results (N=200) for subjects of European descent, show effect modification of the association between the PRS and 25(OH)D blood levels by both season of blood draw and quartile of dietary vitamin D intake. When stratified by season, the effect of each one unit increase in the PRS on lowering 25(OH)D blood levels is larger in summer ( $b=-1.1$  ng/ml;  $p<.0001$ ) compared to winter ( $b=-0.44$  ng/ml;  $p=.29$ ; PRS X season interaction  $p=0.25$ ). When stratified by quartile of dietary vitamin D intake, the effect of each one unit increase in the PRS on lowering 25(OH)D blood levels is larger as dietary vitamin D intake increases:  $b=-0.38$  ( $p=.35$ ),  $-0.65$  ( $p=.18$ ),  $-0.82$  ( $p=0.07$ ) and  $-1.27$  ( $p=.006$ ) ng/ml for the 1<sup>st</sup>, 2<sup>nd</sup>, 3<sup>rd</sup> and 4<sup>th</sup> quartiles of intake, respectively (PRS X dietary intake interaction  $p=0.03$ ). These findings replicate and expand the findings of our previous study in an independent cohort and have important implications for both study design and precision medicine.

**Evidence of *ZKSCAN5*, *SULT2A1*, *TRIM4* and *BCL2L11* for serum dehydroepiandrosterone sulfate (DHEAS) levels: Replication from the Long Life Family Study (LLFS).** P. An<sup>1</sup>, B. Thyagarajan<sup>2</sup>, J.H. Lee<sup>3</sup>, M.K. Wojczynski<sup>4</sup>, J. Sanders<sup>5</sup>, P.A. Lenzini<sup>6</sup>, S.J. Lin<sup>7</sup>, A. Yashin<sup>8</sup>, K. Christensen<sup>9</sup>, T. Perls<sup>7</sup>, A.B. Newman<sup>8</sup>, M.A. Province<sup>1</sup>. 1) Department of Genetics Division of Statistical Genomics, Washington University School of Medicine, St Louis, MO; 2) Department of Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN; 3) Sergievsky Center / Taub Institute, Columbia University Medical Center, New York, NY; 4) Massachusetts General Hospital Department of Medicine, Boston, MA; 5) Duke University Population Research Institute, Durham, NC; 6) Danish Aging Research Center, Institute of Public Health, University of Southern Denmark, Odense, Denmark; 7) Division of Geriatrics, Department of Medicine, Boston University Medical Center, Boston, MA; 8) University of Pittsburgh, Graduate School of Public Health, Department of Epidemiology, Center for Aging and Population Health, Pittsburgh, PA.

Dehydroepiandrosterone sulfate (DHEAS) is an adrenal androgen and the major precursor of sex steroids. Levels of DHEAS decline substantially over the life course. DHEAS has a modest but significant genetic component ( $h^2=15\%$  in the Long Life Family Study, LLFS). A recent meta-analysis of seven GWA studies in 14,846 subjects of Caucasian origin revealed eight common loci (*BCL2L11*, *ARPC1A*, *ZKSCAN5*, *TRIM4*, *HHEX*, *CYP2C9*, *BMF*, *SULT2A1*) associated with DHEAS levels. To validate these loci, we assessed eight reported SNPs and conducted association tests among 3,686 participants of Caucasian origin in the LLFS. Further, we assessed their pleiotropic effects on healthy aging index in the LLFS. DHEAS levels were natural log-transformed to approximate normality, and adjusted for age, sex, field centers, and principal components for ancestry. A linear mixed effects model, assuming additive genetic effects, was used for association tests; a kinship model was used to correct for random effects of relatedness among family members. In this analysis,  $p<0.006$  (0.05/8) was considered significant for replication. Four of the eight SNPs were replicated. They included *ZKSCAN5* (rs11761528,  $p=1.649e-5$ , minor allele frequency, MAF=0.08), *SULT2A1* (rs2637125,  $p=6.549e-5$ , MAF=0.17), *TRIM4* (rs17277546,  $p=2.375e-5$ , MAF=0.05), and *BCL2L11* (rs6738028,  $p=1.404e-4$ , MAF=0.43). These SNPs may have regulatory signals and long-range interactions according to our GWAS3D, GSEA, TSEA, CSEA, HaploReg and RegulomeDB queries. Each accounted for less than 1% phenotypic variation in DHEAS levels. Interestingly, *SULT2A1*-rs2637125 ( $p<0.01$ ) was also associated with healthy aging index ( $p=0.003$ ,  $\beta=-0.2$ ) among women in the LLFS. The *SULT2A1* encodes sulfotransferase that converts DHEA to DHEAS, and is expressed in the adrenal cortex and liver. The remaining four SNPs (*ARPC1A*-rs740160, *HHEX*-rs2497306, *CYP2C9*-rs2185570, *BMF*-rs7181230) were not replicated in this cohort. Of the eight known candidate loci associated with DHEAS, we replicated *ZKSCAN5*, *TRIM4*, *BCL2L11* and *SULT2A1* in the LLFS, along with initial evidence supporting roles of *SULT2A1* in aging mechanisms.

**2876T**

**Gene by environment interaction in human longevity as observed in Danish birth cohorts from 1905 to 1915.** Q. Tan. Epidemiology, University of Southern Denmark, Odense, Denmark.

The frequencies of variants of major candidate genes (APOE and FOXO3A) have been shown to vary in long-lived individuals of different Danish birth cohorts, e.g. with significantly decreased frequencies in the recent birth cohorts for the e4e4 genotype and also for the minor allele of rs7762395 of FOXO3A gene. We collected genotype and survival information on two birth cohorts, 1905 (1424 subjects) and 1915 (1105 subjects), aged over 95 years at in-take. Since genotype frequency in a population cannot be expected to change over a very short period of 10 years (1905 to 1915), we assume that the reported change in genotype frequencies could reflect cohort-specific genetic risk on mortality resulted from gene-environment interaction. Based on the same observations and recently updated mortality information in the two birth cohorts, we conduct a survival analysis introducing cohort- and sex-specific population survivals from population statistics and specifying and estimating genotype-specific relative risks in cohort 1905 and change in relative risk from 1905 to 1915, with consideration of unobserved frailty. We estimated a trend of risk reduction for APOE4 allele carriers (-0.119, 95% CI: -0.355 to 0.119) while the risk for APOE2 allele carriers remained constant (-0.007, 95% CI: -0.200 to 0.206), in nonagenarians and centenarians. The risk of death for carrying the rs479744 minor allele of FOXO3A showed a trend of increase (0.106, 95% CI: -0.049 to 0.292) while that for rs7762395 was unchanged (-0.038, 95% CI: -0.204 to 0.156). Our novel analysis provided evidence to the varying risks of major candidate genes on mortality at advanced ages due to interaction with the changing environment.

**Genetics of the human microbiome and implications in obesity associated measures.** C.T. Finnicum<sup>1</sup>, S. Doornweerd<sup>2,3,4</sup>, C.V. Dolan<sup>2,5</sup>, J.M. Luningham<sup>6</sup>, J.J. Beck<sup>1</sup>, C. Davis<sup>1</sup>, G. Willemsen<sup>3,5</sup>, E.A. Ehli<sup>1</sup>, D.I. Boomsma<sup>1,3,5</sup>, R.G. Ijzerman<sup>2,3,4</sup>, G.E. Davies<sup>1,5</sup>, E.J.C. de Geus<sup>3,5</sup>. 1) Avera Institute for Human Genetics, Avera McKennan Hospital and University Health Center, Sioux Falls, SD; 2) Department of Internal Medicine, Vrije Universiteit Medical Center, Amsterdam; 3) Amsterdam Public Health Research Institute, Vrije Universiteit medical center, Amsterdam; 4) Amsterdam Cardiovascular Sciences, Vrije Universiteit Medical Center, Amsterdam; 5) Department of Biological Psychology, Behavioral and Movement Sciences, Vrije Universiteit, Amsterdam; 6) Department of Psychology, University of Notre Dame, Notre Dame, IN.

**Background:** The microbial organisms residing within the gut microbiota of humans have been shown to play a pivotal role in human health and disease development. One area in particular that has garnered a lot of interest is the study of the gut microbiota in relation to the development of obesity. Although it is becoming clear that there is a relationship between these two factors, more work is needed to parse out the intricacies of this relationship. **Methods:** In order to explore the relationship between BMI and gut microbiota composition, two separate genetically informative study designs have been formed from participants of the Netherlands Twin Register (NTR). The first group of individuals (N=50) was selected from a large population (N=11,495) for which BMI and polygenic risk score scores for BMI were available. This allows for the use of a four-corner design where the study participants are selected from the top and bottom 25% of the BMI distribution, and the top and bottom 20% of the distribution of BMI polygenic risk scores. The second design that will be used to study the relationship between BMI and the gut microbiota consists of monozygotic (MZ) twin pairs (N=30, 15 pairs total) discordant for BMI ( $d > 2 \text{ kg/m}^2$ ). Fecal samples were collected for all individuals and subjected to DNA extraction. Microbiota composition was explored through the use of 16s rRNA sequencing. **Results:** Our results highlight a negative association between BMI and alpha diversity of the gut microbiota. The low genetic risk / high BMI group of individuals had a lower gut microbiota alpha diversity when compared to the other three groups. Within the discordant MZ design the gut microbiota of the heavier twins had a lower average inverse Simpson value relative to the mean value of the lean twin counterparts; however, this difference failed to reach significance. There were 7 operational taxonomic units (OTUs) associated with either a leaner or heavier phenotype, with enrichment for OTUs classified to the *Ruminococcaceae* and *Oxalobacteraceae* taxonomic families. **Conclusion:** Our study presents evidence of a negative relationship between both body fat and BMI with the alpha diversity of the gut microbiota. In addition to these findings, a number of OTUs were found to be significantly associated with host BMI. These findings may highlight separate sub-types of obesity, one driven by genetic factors, the other more heavily influenced by environmental factors.

**Leukocyte Telomere Length (LTL) as a marker of biological aging in Iranian healthy adult population: Report on assay establishment and recent finding.** F. Larti<sup>1</sup>, S. Dehdahsi<sup>1</sup>, F. Larti<sup>2</sup>, A. Rad<sup>3</sup>, R. Jazayeri<sup>1,4</sup>, M. Mohammad-Zadeh<sup>3</sup>, K. Kahrizi<sup>1</sup>, H. Najmabadi<sup>1</sup>. 1) Genetics research center, University of social welfare and rehabilitation sciences, Tehran, Iran; 2) Cardiology Department, Imam Khomeini Complex Hospital, Tehran University of Medical Sciences, Tehran, Iran; 3) Cellular and Molecular Research Center, Sabzevar University of Medical Sciences, Sabzevar, Iran; 4) Department of Biochemistry, Genetic and Nutrition, Faculty of Medicine, Alborz University of Medical Sciences, Karaj, Iran.

Leukocyte telomere length (LTL) is a marker of biological aging that can be affected by several factors including ethnicity. In population-based human disease studies, especially age-related diseases, knowing the actual body age is very important in interpretation of the results. To investigate the normal variation of LTL in Iranian population, and establish the assay for LTL measurement, we aimed to study relative LTL in a cohort of 1000 healthy adult individuals (>25 years) including eight different Iranian ethnicities, by qPCR method. At the phase of pilot study, 72 healthy individuals (29-77 years), 46 male and 28 female from Persian ethnicity were selected. All subjects were confirmed healthy by detailed clinical and paraclinical tests. They were not related and all lived at least ten years in their current environment. A number of 173 subjects (19-85 years) were also selected from Genetics Research Center DNA bank with unknown health status to examine the reliability of the method. All samples quantified against a 5 point standard curve using a mixture of 5 genomic DNA with different chronological ages as a reference DNA. K562 genomic DNA was included in each plate as a quality control and to avoid more than 5% coefficient of variation between different plates. Analysis was done based on relative standard curve using standards to determine the relative quantity of telomere for each sample. The ratio of quantity of telomere to single copy gene (36B4) for each sample was calculated and normalized by this ratio for K562 genomic DNA from the same plate. Data analysis showed that telomere length decreased as age increased. By classifying the 72 subject, in 10-year age groups, a reverse correlation was found between age and relative LTL ( $R = -0.886$ ), that is fitted in a linear regression model ( $R^2 = 0.730$ ,  $P\text{-value} = 0.019$ ). Reverse correlation ( $R = -0.882$ ) and linear regression ( $R^2 = 0.734$ , and  $P\text{-value} = 0.009$ ) were also found for all studied subjects (245 samples), in 10-year age groups. Due to small sample size, analysis in 5-year age groups and without making groups, showed a weak reverse correlation ( $R = -0.197$ ) between LTL and age. Data presented here, elucidate that variation in LTL may be significantly different in every decade of life, but not in every age of life. Analysis of raw data related to all subjects including other Iranian ethnicities is ongoing.

**Old before our time: Biological ageing in an ethnically diverse cohort of preschool children.** *K.N. Ly, C.G. Walker, S.D. Berry.* University of Auckland, Auckland, New Zealand.

**Background:** Substantial and accumulating evidence exists to link the early life environment with long term health outcomes. However, the precise biological mechanisms that explain how such early life events influence adult disease risk are poorly understood. One proposed mechanism for the mediation of exposure events on later disease risk is via accelerated biological ageing, for which telomere length is understood to be a useful and valid biomarker. Telomeres are specialised DNA structures located at the ends of chromosomes that function to maintain genomic stability. Telomeres naturally shorten with age, and accelerated telomere shortening is observed in individuals experiencing stressful or adverse environments. **Methods:** This study utilised data from the *Growing Up in New Zealand* longitudinal study. Participants provided saliva samples for DNA extraction when they were 4½ years of age (n=4587). DNA was extracted and relative telomere length (RTL) was measured using quantitative PCR (n=4388). Child ethnicity was determined by mother report at 4½ years of age. Linear regression was used to compare mean differences in RTL associated with gender and ethnicity. For analysis, child ethnicity was defined based on parent report and included European, Māori, Pacific, Asian, and Other. **Results:** There was a significant effect of both gender and ethnicity for RTL. Females had longer telomeres than males ( $P=5.8 \times 10^{-7}$ ) and Pacific people had longer telomeres than all other ethnic groups ( $4.9 \times 10^{-26}$ ). **Conclusion:** Variation in telomere length is evident in preschool children and differs with gender and ethnicity. Further research is required to determine the basis of these differences, including how exposure to stressors throughout pregnancy and postnatal life impact biological age.

**RATIONALE:** Asthma is a complex disease with striking disparities across racial and ethnic groups, which may be partly attributable to genetic factors. One of the main goals of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to discover genes conferring risk to asthma in populations of African descent. We therefore performed admixture mapping of asthma in 6,686 African American and African Caribbean subjects genotyped on a variety of GWAS platforms plus the African Diaspora Power Chip (ADPC). **METHODS:** RFMix was used to infer local ancestry. The 1000 Genomes Project CEU and YRI populations were specified as reference populations. A total of 273,738 phased SNPs that passed quality control filters and overlapped in both CAAPA and reference population data sets were used as input for inferring local ancestry. A total of 15,824 local ancestry segments were estimated. Linear mixed models were used to test for association between the number of copies of African ancestry at each local ancestry segment (0/1/2) and asthma case-control status. The models incorporated a covariance matrix to account for relatedness between all individuals, as well as population structure to account for global ancestry. The originating CAAPA study data set was included as fixed effect covariate. **RESULTS:** An admixture mapping peak was identified on chromosome 6q23.2, with increased African ancestry associated with increased risk of asthma. One segment of local ancestry within this peak, between hg19 base pair positions 134,149,974-134,300,365, crossed the multiple testing threshold of  $p < 1.9e-4$ . Genes falling in this segment include the *Transcription Factor 21 (TCF21)* and *TATA-Box Binding Protein Like 1 (TBPL1)* genes. A previous study showed the *TCF21* gene as differentially expressed in bronchial biopsies of asthmatics compared to controls. The SNP with the most significant asthma association in CAAPA in this region, rs111966851, has a minor allele frequency of 0.308 and 0.006 in Africans and Europeans, respectively. **CONCLUSIONS:** We identified a novel asthma association signal on chromosome 6q23.2 that warrants further investigation.

**Methods to estimate heritability of complex traits under a variety of complex genetic architectures.** L. Evans<sup>1</sup>, R. Tahmasbi<sup>1</sup>, S. Vrieze<sup>1</sup>, G. Abecasis<sup>2</sup>, S. Das<sup>2</sup>, D. Bjelland<sup>1</sup>, T. deCandia<sup>1</sup>, M. Goddard<sup>3</sup>, B. Neale<sup>4</sup>, J. Yang<sup>5</sup>, P. Visscher<sup>6</sup>, M. Keller<sup>6</sup>, *Haplotype Reference Consortium*. 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO; 2) Center for Statistical Genetics, Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109; 3) Faculty of Veterinary and Agricultural Science, University of Melbourne, Parkville, Victoria, Australia; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 5) Institute for Molecular Bioscience and the Queensland Brain Institute, University of Queensland, Brisbane, 4072, Queensland, Australia; 6) Department of Psychology and Neuroscience, University of Colorado, Boulder, CO.

**Statement of Purpose:** Complex trait genetic architecture has important implications for disease genetics as well as providing fundamental understanding of human evolutionary genetics. Narrow-sense heritability ( $h^2$ ) is a central parameter for this, and a number of methods—GREML, LD score regression, LDAK, treelets, etc.—estimate heritability from SNPs ( $h^2_{\text{SNP}}$ ) using genome-wide markers in unrelated individuals. Recent reports have shown that such estimates can be biased or unbiased depending on the assumed genetic architecture. We compared these methods to understand their performance across different genetic architectures, levels of stratification, and marker type (common SNPs from arrays vs. sequence data) using simulated phenotypes in real whole-genome sequence data. **Methods Used:** We used a subset of ~21K whole genome sequences from the Haplotype Reference Consortium to generate phenotypes ( $h^2=0.5$ ) from 1K causal variants (CVs) chosen randomly from different minor allele frequency (MAF) categories from common to very rare. We simulated phenotypes using a variety assumed allelic effects (betas), including betas coupled to minor allele frequency or not, and betas a function of LD weighting from LDAK. We then used either the whole genome sequence data or positions found on commercial SNP arrays to estimate  $h^2$  and examine genomic architecture in mixed effects models using genetic relationship matrices (GRMs) estimated from different methods across levels of stratification, specifically single component GREML and LDAK, and MAF- or LD- & MAF-stratified GREML. **Summary of Results:** We confirm a recent report that the assumed genetic architecture can lead to biases in different methods when using dense whole genome sequence or imputed variant data. However, we demonstrate that model fit (log-likelihood) can be increased even when the estimate is strongly biased, and can therefore lead to incorrect heritability estimates. We also found that MAF- & LD-stratified GREML (i.e., GREML-LDMS) is robust to most misspecifications of the true relationship between MAF and allelic effect sizes, and is robust to many simulated relationships between LD weights and effect sizes. Thus, careful consideration of the robustness of methods to model misspecification must be taken when apply these methods to real data, and the use of an increase in log-likelihood can lead to biased heritability estimates.

**Robust inference of population structure from next-generation sequencing data with systematic differences in sequencing.** Y.J. Hu<sup>1</sup>, G. Satten<sup>2</sup>, P. Liao<sup>1</sup>. 1) Biostatistics and Bioinformatics, Emory University, Atlanta, GA, 30322, USA; 2) Centers for Disease Control and Prevention, Atlanta, GA, 30333, USA.

Inferring population structure is important for both population genetics and genetic epidemiology. Principal components analysis (PCA) has been effective in ascertaining population structure with array genotype data but can be difficult to use with sequencing data, especially when low depth leads to uncertainty in called genotypes. Because PCA is sensitive to differences in variability, PCA using sequencing data can result in components that correspond to differences in sequencing quality (read depth and error rate), rather than differences in population structure. We demonstrate that even existing methods for PCA specifically designed for sequencing data can still yield biased conclusions when used with data having sequencing properties that are systematically different across different groups of samples (i.e., sequencing groups). This situation can arise in population genetics when combining sequencing data from different studies, or in genetic epidemiology when using historical controls such as samples from the 1000 Genomes Project. To allow inference on population structure using PCA in these situations, we provide an approach that is based on using sequencing reads directly without calling genotypes. Our approach is to adjust the data from different sequencing groups to have the same read depth and error rate so that PCA does not generate spurious components representing sequencing quality. To accomplish this, we have developed a subsampling procedure to match the depth distributions in different sequencing groups, and a read-flipping procedure to match the error rates. We average over subsamples and read flips to minimize loss of information. We demonstrate the utility of our approach using two datasets from 1000 Genomes, and further evaluate it using simulation studies.

**Model-based multiple variants test considering causal status.** *J. Joo*<sup>1</sup>, *F. Hornozdiari*<sup>2</sup>, *E. Eskin*<sup>3</sup>. 1) Department of Computer Science Engineering, Dongguk University-Seoul, South Korea; 2) Epidemiology Dept, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 3) Computer Science Dept, University of California, Los Angeles, Los Angeles, CA, USA.

Over the past decade, GWAS have successfully identified many variants associated with diseases and complex traits. The standard GWAS examine one variant at a time to identify causal variants. However, this univariate approach is often underpowered and usually explains only a small fraction of the genetic variation of complex traits. Several studies have demonstrated that multiple causal variants may exist in a region. For those regions, the standard GWAS may be inappropriate due to its low statistical power. Alternatively, an approach considering multiple causal variants simultaneously may increase statistical power by aggregating the effects of causal variants in a region. Unfortunately, we do not know in advance which variants are causal and there are too many possible causal status. Recently, there are many progresses in fine mapping approaches that try to identify causal variants in a region. Causal variants are the variants that are responsible for the association signal at a locus. However, at each locus, there are often tens to hundreds of variants tightly linked to the reported associated single nucleotide polymorphism, therefore, the linkage disequilibrium hinders the identification of causal variants at risk loci. CAVIAR is one of the recent fine mapping approach that estimates the probability of each variant being causal allowing an arbitrary number of causal variants by jointly modeling the association statistics at all variants in a region accounting for linkage disequilibrium. We propose a new model-based method referred to as MARS (Model-Based Association test Reflecting causal Status) that performs association test between variants in a region and a trait to increase statistical power of the test. We extend the likelihood model of CAVIAR to explicitly incorporate linkage disequilibrium utilizing MVN distribution conditional on causal status of variants. Applied to both simulated and real datasets, MARS shows significant improvement on the statistical power compared to some of the representative previous multiple variants testing methods.

**Caring without sharing: Genome-wide association and mapping on cohorts fragmented across institutional silos.** *A. Pourshafeie*<sup>1</sup>, *C. Bustamante*<sup>2,3</sup>, *S. Prabhur*<sup>2,3</sup>. 1) Physics Department, Stanford University, Stanford, CA; 2) Department of genetics, Stanford University, Stanford, CA; 3) Biomedical Data Sciences, Stanford University, Stanford, CA.

We present robust statistical inference on datasets fragmented across multiple institutions as a powerful paradigm for the future of gene mapping and discovery. Though the recent explosion in genomic and phenotypic data from next-gen biomolecular and biometric technologies, respectively, is leading to breakthroughs in our understanding of human disease - as participant data becomes more multifactorial and private, large cohort datasets can be expensive, unsafe and time consuming to generate or maintain at a single centralized facility. Today, "meta-analysis" techniques offer a work-around by combining summary statistics across multiple studies. However, there are a few limitations: (a) the shared summary statistics might be inadequate for some types of inference (e.g. estimating effects from shared two-tailed p-values), (b) subtle differences in models, assumptions and QC can introduce bias (Greco et al. 2013), and (c) parameter estimates can be unreliable when the sample size (N) is small compared to the number of covariates (k). Here, we explore algorithms for inference that allow participant data to remain fragmented across institutional silos. We show that the most popular genetic mapping model - generalized regressions - can easily be performed in such a setting. We compare the performance of three types of algorithms: four stochastic sub-gradient methods with large batch sizes, one stochastic quasi-Newton method and an Alternating Direction Method of Multipliers (ADMM) (Boyd et al. 2010) approach with the estimates from summary statistics and centralized algorithms on simulated datasets. We characterize these algorithms under a variety of conditions - type of predictor (genotype dosage, continuous, categorical), number of silos, sample sizes per silo, etc. Our results show that (a) the derived estimates are identical to simple regression on a centralized dataset (b) ADMM estimates reach the centralized estimates the fastest out of all explored methods and (c) Reliable odds ratio estimates are usually achieved in <1,000 iterations (network communications between the silos). Through simulations, we show that we can recapitulate the findings of seminal GWAS efforts like the WTCCC. Our proof of concept unequivocally demonstrates that multi-institutional mega-analyses can be performed, at scale, in a decentralized setting. A working draft and relevant experiments can be found [https://github.com/apoursh/Decentralized\\_reg](https://github.com/apoursh/Decentralized_reg).

**Some novel methods of detecting gene-drug interactions.** *M. Rao<sup>1</sup>, L. Zhang<sup>1</sup>, Q. Wang<sup>2</sup>, M. Medvedovic<sup>1</sup>.* 1) Environmental Hlth, Univ Cincinnati, Cincinnati, OH; 2) Millennium Pharmaceuticals, Boston, MA.

The data that led to current research is the RNA-sequence data from 60 drugs and controls put forward by Mount Sinai Medical center. Each drug is administered to a certain number of cell lines and RNA sequences for 23,895 genes are recorded from each cell line. RNA-sequences are also recorded from a certain number of cell lines none of which received any drug (controls). **Goals** Compare each drug with the control. Identify drugs significantly different from the control for each gene. Identify blocks of genes and drugs with the property that in each block the drugs are significantly different from the control under each of the genes in the block. **Methods** Implement an ANOVA procedure a la Dunnett (1991) for comparing drugs with the control for each gene. Following the Dunnett procedure or its variations, the given data will be summarized by a data matrix  $Y$  whose rows are indexed by genes and columns by drugs. The entry in the  $i$ -th row and  $j$ -th column is equal to one if the  $j$ -th drug is significantly different from the control under the  $i$ -th gene. A bi-clustering method (2017) is invoked on the 0-1 matrix  $Y$ . The goal is to find maximal sub-matrices of  $Y$  in each of which every entry is equal to one. This is tantamount to identifying drugs significantly different from the control under each of the genes identified in the sub-matrix. **Results, Interpretation, and Illustration** We discuss extensively what each such sub-matrix (bicluster) is giving us. Identify the pathways of the genes identified by each bicluster discovered. Identify the medical conditions the drugs are meant for. Check with Drug x Medical Conditions and Drug x Gene networks. Several biclusters are identified with sizes 85x3, 14x4, 32x3, 5x5, etc. The bicluster of size 14x4 covers four drugs (Aprepitant; Pazopanib; Sunitinib+Estradiol; Sunitinib+Prednisolone) and fourteen genes (A1BG-AS1; ABCG2; BCHE; C10orf10; C6orf52; CLDN14; COL19A1; FGF3; PBK; PDC; PRG4; UBAP1L; UBE2C; XKR6). Drugbank also provides information about drugs and the genes they target. This information is contrasted with the information emanating from the bicluster analysis. **References** C.W. Dunnett and A.C. Tamhane (1991). Step-down multiple tests for comparing treatments with a control in unbalanced one-way layouts. *Statistics in Medicine*, 10, 939-947. **Use low-depth and high-depth whole genome sequencing data to predict 36 blood groups.** *Y. Sun<sup>1</sup>, J. Huang<sup>2</sup>.* 1) Department of mathematics & statistics, Boston university, Boston, MA; 2) Harvard Medical School, Boston, MA.

**Background:** Knowing one's blood type is important for both scientific and medical purpose. As genotyping becomes more common and cost-effective than phenotyping, there is a desire to derive human blood type from genetic data. Recently, whole genome sequencing data from the 1000 genomes' project has been reported to predict as many as 36 blood types, as a proof of principle. **Methods:** Here, we use high-depth whole genome sequencing data from 4,141 individuals enrolled in the Trans-Omics for Precision Medicine program (TopMed), together with the same 2,504 individuals with low-depth sequencing from the 1000 genomes project (1000GP), to predict each person's 36 blood types. We next compare the performance of these two datasets. The genotype data was pre-phased using EAGLE software on the genome-wide scale. The cDNA reference sequences for all known red blood cells and platelet genes listed in the Blood Group Gene Mutation Database were aligned to the human reference genome. **Results:** For TopMed and 1000GP respectively, we discovered a total of 1,671 and 1,330 missense variants in the coding regions of 36 blood group systems. Among them, 443 and 271 are mapped to known blood group polymorphisms, respectively. For 97 individuals in the TopMed dataset also having serological ABO blood types, the concordance between genetically predicated and phenotypically measured blood type is 99.0%. **Conclusion:** We demonstrated empirically the high accuracy of using genetic data to predict blood types. We further show that high-depth whole genome sequencing yields higher resolution of rare genetic variants and haplotypes that are associated with human blood types. More comprehensive evaluation of the performance of genetically predicated blood types would contribute to transfusion medicine and therefore precision medicine.

**Modeling the interactions between coding and non-coding RNA by kernel machines in binary phenotypes.** S. Yang, F. Shao, W. Duan, Y. Zhao, F. Chen. Nanjing Medical University, Nanjing, China.

The etiology of complex disease is likely associated to the genetic factors, along with the interactions between different level data, e.g. microRNA(miRNA)-genes. The relations between miRNA and traits are mediated by gene expression. Most studies of the complex phenotype are on binary traits. The traditional chi-square test requires a large number of degrees of freedom to test the main effects and all the corresponding interactions under a parametric assumption, and hence suffers from low power. Consequently, we extend a powerful joint test for testing the effect of genes and their interactions on the binary outcomes. Considering the similarity between the variance component test and the kernel machine function, we construct a score test to test the garrote kernel function. The procedure of the parameter estimation involves iterations because of the logistic regression framework. The use of kernel functions is promising, because it integrates the information of the weight of genes by the prediction numbers. By type I error simulations, it is clear that the type I error of our method is controlled, rather than that of the traditional main-effect method disperses in some scenarios. The increase of differences between the null model and the whole model possibly leads to the increase of power of our method. Also, our model is hardly sensitivity to the different model assumption. We apply the method to the breast cancer data from The Cancer Genome Atlas.

**High frequency of the MEFV c.1437C>G, p.F479L allele among Druze FMF patients.** V. Adir, O. Sadeh, A. Peleg. Institute of Human Genetics, Carmel Medical Center, Haifa, Israel and the Ruth and Bruce Rappaport Faculty of Medicine, Technion, Israel Institute of Technology, Haifa, Israel.

**Introduction:** Familial Mediterranean fever (FMF) is a hereditary auto inflammatory disease characterized by brief recurrent episodes of synovitis, usually with accompanying fever. FMF disease is caused by mutations in the MEFV gene and is common among Mediterranean populations. Although FMF is considered to be an autosomal recessive disease, some proportion of heterozygotes also express the clinical symptoms. **Results:** 328 samples of Druze, Muslims Arabs, Christian Arabs and Jewish patients with clinical symptoms suspected for FMF were tested. The mutations frequencies were: V726A (31%), E148Q (23%), M694V (21%), M680I (6%), M694I (6%), F479L (5.4%) P369S (3.2%), K695R (1.6%), A744S (1.6%), I692del (0%) and R761H (0%). It has been shown that some rare MEFV mutations tend to be over represented in particular ethnic groups. The reported general population c.1437C>G, (p.F479L) mutation frequency is lower than 1%. In our cohort, a frequency of 5.4% was found. Further analysis showed c.1437C>G, p.F479L mutation was limited to Arabs and Druze ethnicity samples. From a total 139 FMF mutated alleles among Arabs and Druze, eleven alleles were found to be F479L (7.9%) and eight of them were found in Druze patients from the same village. **Conclusion:** Our results show that the F479L allele is very frequent among Druze patients from one village in northern Israel. We recommend including this allele in the mutation panel for FMF testing of Druze patients.

**Family-based rare variant association study of familial myopia in Caucasian families.** D. Lewis<sup>1</sup>, C.L. Simpson<sup>2</sup>, A.M. Musolf<sup>3</sup>, K. Long<sup>1,3</sup>, L. Portas<sup>1,4</sup>, F. Murgia<sup>1,4</sup>, E. Ciner<sup>5</sup>, D. Stambolian<sup>6</sup>, J.E Bailey-Wilson<sup>1</sup>. 1) Computational and Statistical Genomics Branch, National Human Genome Research Institute, Baltimore, MD; 2) Genetics, Genomics and Informatics, University of Tennessee Health Sciences Center, Memphis, TN; 3) University of Texas at El Paso, El Paso, TX; 4) Institute of Population Genetics, CNR, Li Punti, Sassari, Italy; 5) Salus University, Elkins Park, PA; 6) Ophthalmology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Myopia is a common refractive error (RF) which affects at least a third of most populations. Individuals with high myopia are vulnerable to ocular complications later in life. Consequently, great efforts have been undertaken to identify and understand the mechanisms underlying the development and progression of myopia. Genome-wide association studies and linkage studies have identified loci influencing the risk of developing myopia but, few causal variants have been identified with the majority of them being common (minor allele frequency > 0.05). Therefore, this study aims to identify regions associated with rare variants that increase myopia risk using dense Exome Chip genotyping (Illumina Human Exome v1.1 array plus 24,263 custom SNPs) data from 75 myopic Caucasian families from the Penn Family Myopia Study. Myopia was defined based on mean spherical equivalent in Diopters (D): affected ( $\leq -1$ D), unaffected ( $\geq 0$  D) or unknown ( $< 0$ D,  $> -1$  D). Children were considered unaffected as follows:  $MSE \geq +2D$  (ages 6-10) or  $MSE \geq +1.5D$  (ages 11-20). We used the rare-variant transmission disequilibrium test (RV-TDT) to perform gene-based association tests with rare variants in 25 Caucasian parent-child trios (independent completely-genotyped trios from the families above). After quality control, 27,121 SNPs were analyzed and RV-TDT analysis identified a suggestively associated locus on chromosome 2.q31.1 for a non-synonymous coding SNP rs34564141 in *LRP2* after correcting for multiple testing ( $P$  value =  $2.65 \times 10^{-3}$ ). *LRP2* has been implicated in a study of a rare form of severe myopia in patients who had a mutation encoding a receptor *LRP2* in the retina. Greatly enlarged eyes have been observed in mice lacking this *LRP2* gene. We are extending these analyses to include 350 individuals from additional myopic family cohorts, including Ashkenazi Jewish and African American families, and will present these results.

**Exploring the effect of minor allele frequency on the inflation of type I error rates for GWA studies of family data with non-normally distributed traits.** J.A. Sabourin, H. Sung, A.J.M. Sorant, A.F. Wilson. CSGB/NHGRI/NIH, Baltimore, MD.

When the assumptions of an analysis method, such as the normality of the error distribution, are violated, it is often assumed that the type I error rate will be inflated. We previously investigated how the type I error rate in genetic association studies of unrelated subjects was affected by the minor allele frequency (MAF) of the SNV and the degree of deviation from normality. We observed that the deviation from normality only inflated type I error rates for rare SNVs and that transformation of the trait to reduce the degree of non-normality brought the type I error rate closer to the nominal rate. In this study, we extend this work to family data. Simulations were based on the Genetic Analysis Workshop 19 family data which is comprised of whole genome sequencing (8.4million SNVs) of 975 subjects from 20 extended families. Two types of "null" traits were considered. In the first, there was no genetic contribution; all the variability was explained by independent errors. In the second, the null trait had no detectible single SNV genetic effects, but a polygenic effect, whose structure is defined by the estimated kinship matrix, contributed to the phenotypic variability, with the remaining variability explained by independent errors. Several different proportions of the two components were considered. For each null model the normal distribution assumed by the analysis and a gamma distribution (with shape and scale parameters of 3 and 20, respectively) were considered for the independent errors. In addition, null traits based on the gamma distribution were analyzed after transforming with the  $\log_{10}$  and rank-based inverse normal transformations. Two hundred replicates of each trait were analyzed. Samples were analyzed with EMMAX with structure assumed to follow the kinship matrix estimated by EMMAX on a pruned set of SNVs. For common SNVs,  $MAF \geq 0.05$ , results showed no inflation of type I error rates in any traits investigated. For rare SNVs,  $MAF < 0.05$ , an inflation in type I error for non-normally distributed traits was observed. This inflation increased with both decreasing MAF and increasing degree of non-normality, although this effect was lessened as the proportion of the polygenic component increased. As in the previous study, reducing the non-normality of the trait by appropriate transformation reduces the inflation of type I error rates for rare SNVs.

**To ERV is human: A phenotype-wide scan linking polymorphic human endogenous retrovirus-K insertions to tissue-specific gene expression and complex diseases.** A.D. Wallace<sup>1</sup>, G. Wendt<sup>2</sup>, A.J. De Smith<sup>3</sup>, C. Metayer<sup>1</sup>, J. Wiemels<sup>3</sup>, L.F. Barcellos<sup>1</sup>, S.S. Francis<sup>3,3</sup>. 1) Epidemiology, School of Public Health, University of California, Berkeley, Berkeley, CA; 2) University of Nevada Reno, Reno, NV; 3) University of California San Francisco, San Francisco, CA.

Approximately 8% of the human genome is comprised of ancient endogenous retroviruses (ERVs) that integrated into germ cells and were subsequently preserved. They are established regulators of gene expression and thus serve as excellent candidates for causal variants contributing to the heritability of complex phenotypes. Until recently it was assumed that the locations of ERV insertions in the genome were fixed across individuals, thus their potential contribution to phenotypic variation was largely overlooked. Recent studies have shown that the most recent ERV integration, HERV-K, is polymorphic in some genomic locations and is actively expressed in a range of conditions from cancer to neurologic diseases to HIV infection. Using an in-house computational pipeline and whole genome sequencing data from the 1000 Genomes population (n=2,504), we identified 172 polymorphic HERV-K insertion sites. We sought to identify adjacent SNPs associated with these HERV-K insertions to detect potential relationships between HERV-K and phenotypes via established SNP annotations. For 129 sites with estimated prevalence ranging from 20-80%, no HERV-K insertion associated SNPs (hiSNPs) were detected. The mean distance of these 129 sites from recombination hotspots compared to HERV-K with hiSNPs or randomly selected genomic sites suggest that the majority of polymorphic HERV-K insertions are in recombination cold spots (p<0.005) and cannot be tagged with SNPs. Pooled hiSNPs for the 48 polymorphic HERV-K sites that exhibited strong SNP associations were statistically enriched (p<1.0E-16) for eQTLs identified by the GTEx Project Consortium across 44 human tissues. When we restricted to the hiSNP sets identified from the 30 polymorphic HERV-K insertion sites in Europeans, we observed enrichment (p<0.05) of hiSNPs as eQTLs in at least one tissue type for 21 of the 30 insertion sites by Fisher's exact test. Further, a subset of hiSNPs for 15 of the 30 European HERV-K insertions are annotated in the EMBL-EBI GWAS Catalog and are associated with >100 phenotypes in total. Experimental factor ontology enrichment analyses suggest that polymorphic HERV-K insertions may contribute to neurologic and immunologic disease phenotypes, including traits related to intracranial volume (FDR 2.00E-09) and autoimmune diseases (FDR 1.80E-09). For these and other phenotypes identified via this method, polymorphic HERV-K insertions may play an etiologic role and further study is warranted.

**Robust, accurate, and efficient pedigree reconstruction and pedigree-aware distant relatedness detection in 120 rhesus macaques (*Macaca mulatta*) from the Tulane National Primate Research Center using dense whole genome sequence data.** L.E. Petty<sup>1</sup>, M. Raveendran<sup>2</sup>, R.A. Harris<sup>3</sup>, H.M. Kubisch<sup>2</sup>, D.M. Muzny<sup>2</sup>, R.A. Gibbs<sup>3</sup>, R. Bohm<sup>2</sup>, J. Rogers<sup>2</sup>, J.E. Below<sup>1</sup>. 1) The Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN; 2) Tulane National Primate Research Center, Tulane University, Covington, LA; 3) Human Genome Sequencing Center, Baylor College of Medicine, Houston, TX.

Genetic relatedness is informative for many genetic analyses including phasing, imputation, detecting evidence of natural selection, demographic comparisons, estimating heritability, and maximizing power and minimizing type 1 error in trait analysis. We have developed some of the most popular and powerful tools for pedigree reconstruction and distant relatedness detection in humans. However today, whole genome and whole exome sequencing (WGS, WES) are increasingly being applied in cohorts of nonhuman species, in which the complexity of population genetics is exacerbated by incomplete information and complex mating patterns. To fully characterize genetic relatedness in 120 Indian-origin rhesus macaques (*Macaca mulatta*) from the Tulane National Primate Research Center colony, we performed whole genome sequencing at >35x average coverage using 2x150 reads generated on the Illumina HiSeqX platform. Reads were mapped to the rhesus reference genome (NCBI Mmul\_8.0) using BWA-mem and SNPs called using GATK with standard quality filtering. The applicability and accuracy of tools developed to estimate segmental sharing (GERMLINE, PLINK, IBDseq) and relatedness (ERSA, PLINK, KING), as well as reconstruct pedigrees (PRIMUS) and identify pedigree-aware distant relatedness (PADRE) was evaluated using colony records. Thirty-two sire groups were identified by first- and second-degree relationships, and all possible pedigrees were reconstructed and validated using 43 first-, 14 second-, and 14 third-degree relatives within PRIMUS. Using PADRE, pedigrees were connected via pedigree-aware founder relationships by calculating the composite likelihood across all relationship probabilities between and within each pedigree. Predicted relationships were validated against colony records, demonstrating the robustness of these approaches for accurate assessments of varying degrees of kinship and precise pedigree reconstruction in nonhuman primate research populations, and as a natural extension, to wild populations with unknown pedigree structure. Nonhuman primates are central to many aspects of biology and medicine as crucial models for study of infectious disease, neurobiology, and psychobiology. Detecting cryptic relatedness and validating pedigrees are essential for reliable genetic studies. Determination of kinship among nonhuman primates increases our ability to investigate fundamental aspects of primate population biology and disease associations in research populations.

**Genome-wide scan of pulmonary phenotypes on local ancestry in African Americans reveals novel genes interacting with smoking.** A. Ziyatdinov<sup>1</sup>, M.H. Cho<sup>2,3</sup>, M. Parker<sup>2</sup>, T.H. Beaty<sup>2</sup>, P. Kraft<sup>4</sup>, H. Aschard<sup>1,5</sup>. 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA, USA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA, USA; 4) Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, USA; 5) Centre de Bioinformatique, Biostatistique et Biologie Intégrative (C3BI), Institut Pasteur, Paris, France.

**Abstract:** It is now well established that the proportion of African ancestry is associated with lower pulmonary function for a given age and height [1]. At the same time, smoking is the strongest environmental risk factor for reduced pulmonary function. However, the interplay between the two has been seldom explored due to current methodological challenges in interaction analysis as well as limited sample sizes of current studies. This work aims to identify local ancestry-by-smoking interactions in the largest genetic cohort of pulmonary phenotypes in 3,300 African-American individuals from the (Chronic Obstructive Pulmonary Disease) COPDGene study. We performed a systematic screen for local ancestry-by-smoking interaction leveraging multiple pulmonary phenotypes available in COPDGene: the COPD (chronic obstructive pulmonary disease) status and five pulmonary phenotypes, namely FEV1 (force expiratory volume in one second), FVC (force vital capacity), FEV1/FVC ratio, percent emphysema and TLC (total lung capacity as measured by CT scan). We developed novel methods for ancestry-by-smoking interaction that account for confounding due to linkage disequilibrium differences between African and European populations and dependence among association tests using local ancestries. These methods include univariate and joint analysis of multiple phenotypes using principal component analysis; gene-set analysis; and grouping predictors in a risk score. We identified local ancestry segments showing interaction effects with current smoking status. These segments contained several candidate genes, all of which were associated with multiple phenotypes: (1) the *HS6ST3* gene, the nominal p-values between  $1 \times 10^{-4}$  and  $1 \times 10^{-3}$ ; (1) the *PARVA* gene, p-values between  $3 \times 10^{-5}$  and  $5 \times 10^{-4}$ ; (3) the *HNRNPD* gene, p-values  $5 \times 10^{-5}$  and  $3 \times 10^{-4}$ . Previous studies identified an association between *PARVA* methylation and smoking status [2]. Our findings confirm the validity of the approach in using estimated local ancestry information for detection of interaction effects between genes and exposures. Future results will likely identify novel loci, helping unravel the genetic architecture of COPD.

**Genetic analyses for antiepileptic drug-induced cutaneous adverse reaction in a HK population.** J. Ding<sup>1</sup>, M. Kowk<sup>2</sup>, H. Gui<sup>1</sup>, C. Tang<sup>1</sup>, P. Sham<sup>1</sup>, S. Cherny<sup>1</sup>, P. Kwan<sup>3</sup>. 1) Department of Psychiatry, University of Hong Kong, Hong Kong; 2) Department of Medicine & Therapeutics, the Chinese University of Hong Kong, Hong Kong SAR, China; 3) Department of Neurology, Royal Melbourne Hospital, Melbourne, Australia.

Given the widespread use of anti-epileptic drugs (AEDs) in clinical treatments, the appropriateness and safety of this group of medications have posed a serious issue. Previous findings have revealed AEDs may be associated with life-threatening cutaneous adverse drug reactions (cADRs), with evidence pointing to a possible genetic basis, where HLA-B\*15:02 allele has been consistently reported (Zhang *et al.*, 2011). Our study, adopting the whole-genome sequencing method, focuses on identifying rare variants underlying AEDs-induced cADRs and establishing a multi-faceted genetic predisposition model for predicting the prognosis of AEDs. 80 AEDs patients who had experienced severe cADRs (SJS/TEN) and 72 matched AEDs-tolerant control pairs were recruited. Both groups of patients were assayed on Illumina HiSeq x Ten platform. Additional 316 sequenced population controls from collaborative data were included to increase the statistical power. Our results showed that rare variants in gene *ADAMTS5*, *ADAMTS8*, *URO1* and *SPINK6* were marginally significant signals for cADRs. Although strong signals have not been detected, these genes were previously found playing key roles in the immune system and skin-related conditions.

**2895F****Bayesian hierarchical modeling of genic sub-region intolerance.** *T.J.*

*Hayeck<sup>1</sup>, N. Stong<sup>1</sup>, B. Copeland<sup>1</sup>, D. Goldstein<sup>1</sup>, A. Allen<sup>1,2</sup>.* 1) Institute for Genomic Medicine, Columbia University, New York City, NY; 2) Department of Biostatistics and Bioinformatics, Duke University, Durham, NC, USA.

Understanding the local distribution of intolerance within genes will be key in correctly deciphering relationships between genetic variation and disease. Genic intolerance scores have been developed to identify genes subject to purifying selection in the human lineage. These scores have come to play an important role in the interpretation of clinically identified variants, but given they are computed at the gene-level, they are unable to prioritize variation within genes. Frequently, pathogenic mutations can cluster in particular sub-regions of a disease gene, while other benign mutations may occur in other parts of the same gene. Previous methods have had success describing regional intolerance using marginal measures of departure from the amount of common putatively functional variation given the total genic variation. The earlier approaches however have limited utility because many of the subregions of genes carry too little information to provide reliable intolerance scores. We address this limitation and expand on the basic framework by developing a hierarchical Bayesian model framework for analysis of genomic variation, simultaneously modeling genes and their sub-regions (domain or exon). The Bayesian hierarchical framework allows for direct inference on the joint posterior distribution of gene level and sub-region level effects and allows for identification of genes with high levels of variation in regional intolerance. Using standing human variation from 123,136 exome sequences in Genome Aggregation Database (gnomAD), we demonstrate classification of intolerant sub-regions in key genes such as *MECP2*, *VHL*, and *SCN1A*. We further assess our ability to identify regions of the genome harboring pathogenic disease mutations through comparison of our regional intolerance scores and the presence of disease mutations from ClinVar and HgMD mutation databases. Initial results demonstrate significant association between sub-region intolerance scores and the genic sub-regions where pathogenic variants have been reported in ClinVar and HgMD ( $p=2.39e-15$ ). These results suggest our framework can provide improved classification of intolerant regions and improve diagnostic interpretation of both known and novel variation.

**2896W****Mixed-model adjustments for tests of epistasis reduce confounding by other loci.** *N. Patel<sup>1</sup>, W. Bush<sup>1</sup>, A. Fish<sup>2</sup>, J. Capra<sup>2</sup>.*

1) Department of Population and Quantitative Health Sciences, Institute of Computational Biology, Case Western Reserve University, Cleveland, OH; 2) Department of Biological Sciences, Vanderbilt Genomics Institute, Vanderbilt University, 22525 West End Avenue, Nashville, TN.

Recent studies have identified numerous potential examples of epistasis among cis-regulatory variants influencing gene expression traits. However, these tests are subject to different forms of confounding than single-variant association tests - most notably, that multi-locus genotype combinations can tag the effect of nearby cis-eQTLs. As a result, many statistically significant interaction models for eQTL SNPs are more parsimoniously explained by the presence of another nearby SNP, and post-hoc conditional analyses are necessary to identify and characterize these findings. In this study, we develop and evaluate a mixed linear model approach, to adjust for genetic relatedness, in order to correct for this potential confounding. In a prior study, we identified 1,119 cis-regulatory interactions in a discovery set of 210 individuals with array-based gene expression and dense genotyping from lymphoblastoid cell lines, following rigorous false discovery corrections. Even though many of these interactions replicated in whole blood samples from the Genotype Tissue Expression (GTEx) project, all were found to be likely false positives in post-hoc tests for confounding. We re-analyzed these potential interactions using models including a random effect adjustment for the other SNP within the cis-regulatory region. This adjustment dramatically reduced the amount of confounding; likelihood ratio tests for the effect of the interaction terms were non-significant for all but six models. These results illustrate that mixed-model adjustments are a powerful approach for addressing confounding in SNP-SNP interaction analyses. .

**The usage of local ancestry to Inform eQTL mapping in African Americans.** Y. Zhong<sup>1</sup>, E. Gamazon<sup>2</sup>, M. Perera<sup>1</sup>. 1) Department of Pharmacology, Northwestern University, Chicago, IL; 2) Division of Genetic Medicine, Vanderbilt University, Nashville, TN.

Expression quantitative trait loci (eQTL) are genetic variants significantly associated with gene expression. In order to control for population stratification, principal components (PCs) representing the global population structure are commonly used in eQTL mapping. However, this method may be inadequate for admixed populations such as African Americans in which the proportion of ancestry varies widely within each chromosome. Given the paucity of eQTL information in African Americans, it is critical to develop methods that adequately adjust for admixture and thus correctly identify eQTLs in this population. Thus, we investigated whether adjusting for local ancestry (LA) is more effective in identifying true eQTL associations than adjusting for PCs alone in African Americans. Here we developed a highly efficient algorithm to calculate millions of associations between SNPs and gene expression while adjusting for LA. We evaluated this method in an African American (AA) lymphoblastoid cell line (LCL) dataset. We first performed simulations in which we used actual genotype data and simulated gene expression. In simulations, LA adjustment and PC adjustment controlled for population stratification equally well. However, both methods had lower power to uncover associations with the correct effect size for high *Fst* eQTLs than for low *Fst* eQTLs. We also conducted genome-wide eQTL mapping using both LA and PC adjustment and found 221 eQTLs (FDR < 0.05) shared by both methods. For these shared eQTLs, local ancestry adjustment gave more significant p-values than PC adjustment, indicating that the local ancestry adjustment is more powerful to uncover true eQTLs. PC adjustment and LA adjustment identified 50 and 70 unique eQTLs respectively. Interestingly, several eQTLs unique to PC adjustment had highly significant p-values but were not significant in LA adjustment, and this pattern was not observed in eQTLs unique to LA adjustment. Further validation in an independent LCL dataset showed these discordant eQTLs were false positives due to the confounding of local ancestry to gene expression. Overall our analysis demonstrates that the LA adjustment outperforms PC adjustment in removing spurious associations in eQTL mapping.

**Evidence for a major gene for myopia risk in Han Chinese-American families at 10q26.** J.E. Bailey-Wilson<sup>1</sup>, A.M. Musolf<sup>1</sup>, C.L. Simpson<sup>1,2</sup>, B.A. Moiz<sup>1</sup>, K.A. Long<sup>1</sup>, D.D. Lewis<sup>1</sup>, C.D. Middlebrooks<sup>1</sup>, L. Portas<sup>3</sup>, F. Murgia<sup>3</sup>, E. Ciner<sup>4</sup>, D. Stambolian<sup>5</sup>. 1) Computational and Statistical Genomics Branch, NIH/NHGRI, Baltimore, MD; 2) Dept of Genetics, Genomics and Informatics, University of Tennessee Health Science Center, Memphis, TN; 3) Institute of Population Genetics, CNR, Li Punti, Sassari, Italy; 4) Salus University, Elkins Park, PA; 5) Dept of Ophthalmology, University of Pennsylvania, Philadelphia, PA.

Myopia is caused by an overgrowth of the eye which causes light to focus in front of the retina, leading to blurry vision. We studied 34 Han Chinese-descent families from Pennsylvania who were ascertained with an apparent dominant inheritance of myopia to search for linkage between genomic variants (Illumina Human Exome v1.1 array plus 24,263 custom SNPs) and the disease. Affection status was based on mean spherical equivalent (MSE) in Diopters (D): affected ( $\leq -1D$ ), unaffected ( $\geq 0D$ ) or unknown ( $<0D$ ,  $> -1D$ ). Children were considered unaffected as follows:  $MSE \geq +2D$  (ages 6-10) or  $MSE \geq +1.5D$  (ages 11-20). Three types of parametric linkage analyses were performed: single variant two-point, multipoint, and collapsed haplotype pattern variant linkage (CHP). CHP uses multiple rare variants to create a multi-allelic pseudomarker that corresponds to short haplotypes in a genomic region. The resulting pseudomarkers improve information content for a gene-based linkage test. This increases power to detect situations where multiple families harbor different rare mutations in the same causal gene. Two-point linkage analysis is then performed using CHP markers. CHP linkage analysis identified a genome-wide significant locus at 10q26.13, centered on *TACC2* (HLOD=3.73). This pseudomarker consisted of several rare exonic SNPs from the *TACC2* gene. CHP analysis also found 6 more suggestive linkage signals at other genes in 10q24.2-26.2. Single variant two-point identified 34 suggestive linked SNVs on 10q24-26, while multipoint identified evidence of suggestive linkage in 10q26.11-13. Many of the suggestive linkages in both analyses were located in *HTRA1*, a known age-related macular degeneration gene. Three of the families with strongest linkage to this region had rare intronic variants in *HTRA1* on their strongest linked haplotype. Several other promising candidate genes, such as *BAG3* and *DOCK1*, are also present in the region. Multipoint analysis also identified a highly suggestive linkage at 9q33.1. This region includes *TLR4*, a gene known to interact with alpha-crystallin in the retina. Targeted sequencing for both regions is planned to elucidate the causal variants.

## 2899W

**Platelet-derived growth factor genes, maternal binge drinking and obstructive heart defects.** M.A. Cleves<sup>1</sup>, X. Tang<sup>1</sup>, J.K. Eberhart<sup>2</sup>, M. Li<sup>3</sup>, S. MacLeod<sup>4</sup>, W.N. Nembhard<sup>4</sup>, C.A. Hoobs<sup>4</sup>, *The National Birth Defects Prevention Study*. 1) Section of Biostatistics, Department of Pediatrics, College of Medicine, University of Arkansas for Medical Sciences; 2) Department of Molecular and Cell and Developmental Biology, Institute for Cellular and Molecular Biology and Institute for Neuroscience, University of Texas, Austin, Texas.; 3) Department of Epidemiology and Biostatistics, School of Public Health, Indiana University at Bloomington, Bloomington, Indiana; 4) Section of Birth Defects Research, Department of Pediatrics, College of Medicine, University of Arkansas for Medical Sciences.

**Background:** More than 85% of congenital heart defects (CHDs) are thought to result from a complex interaction between maternal exposures, genetic susceptibilities, and epigenetic phenomena. Right- and left-sided obstructive heart defects (OHDs) are the most lethal subtypes of CHDs. Platelet-derived growth factor receptor alpha gene (*Pdgfra*) has been shown in a zebrafish model to interact with ethanol during development leading to craniofacial structural malformations. Previous studies have reported an association between alcohol exposure during the periconceptional period and the risk of CHDs. **Objective:** The goal of our study was to investigate the interaction between variants in the platelet-derived growth factor (*PDGF*) genes and periconceptional alcohol exposure on the risk of OHDs. **Methods:** A genome-wide association study was carried out using buccal cell samples from 806 case-parental triads and 995 control-mother dyads enrolled in Arkansas, California, Georgia, Iowa and Texas sites of the National Birth Defects Prevention Study (NBDPS) with birth dates between 1997 and 2011. DNA samples were genotyped for more than 4.3 million single nucleotide polymorphisms (SNPs) by use of the Illumina Infinium Omni5Exom-4 chip. Among 4.3 million SNPs, 102 SNPs in the *PDGF* family of genes (*PDGFRA*, *PDGFRB* and *PDGFB*) were selected for the current study. Data on maternal alcohol exposure was self-reported via a maternal telephone interview conducted by NBDPS. The exposure window was defined as one month prior to conception to three months after conception. A family-based hybrid log-linear model was used to estimate the maternal and fetal genetic relative risk of each allelic variant in three *PDGF* genes. **Results:** The maternal CT and TT genotypes of rs869978 variant in the *PDGFRA* gene were associated with a 1.51 (95% confidence interval (CI): 1.06 to 2.15) and 2.28 (95% CI: 1.12 to 4.62) increased risk of OHDs compared to the CC genotype, respectively, among women who binge drink during the periconceptional period. In contrast, fetal genotypes of four SNPs (rs2291591, rs2228230, rs1547904, and rs869978) in the *PDGFRA* gene were associated with a decreased risk of OHDs among women who binge drink. **Conclusion:** Our findings suggest that variants in the maternal *PDGFRA* gene may interact with binge drinking, resulting in an increased risk of obstructive heart defects, whereas variants in the infant *PDGFRA* gene may protect against obstructive heart defects among binge drinkers.

Access to clinical genetic testing has been growing continuously around the globe since the introduction of the next generation sequencing technology to the field of genetics about a decade ago. Widespread access to genetic testing will have a remarkable impact on realizing the vision of precision medicine to improve the prevention, diagnosis and treatment of human disorders, many of which have genetic etiology. However, many ethnic groups are not represented in current human genome variation databases. The benefits of precision medicine may not be realized for these groups if we do not address this gap. With this in mind, we established the Iranome database ([www.iranome.com](http://www.iranome.com)) by performing whole exome sequencing on 800 individuals from eight major ethnic groups that live in Iran. The groups include 100 healthy individuals from each of Arabs, Azeris (Turk), Balochs, Kurds, Lurs, Persians, Persian Gulf Islanders and Turkmen ethnic groups, which represent over 80 million Iranians and to some degree half a billion individuals who live in the Middle East. These ethnic groups are among the most underrepresented populations in currently available human genome variation databases. The mean depth of coverage of the exons of the human genome based on CCDS Release15 was 82x with 95% and 91% coverage at 10x and 20x or more, respectively. Principle component analysis indicates that except the Iranian Baloch and Persian Gulf Islander populations, which form their own clusters, the rest of the populations are genetically very close to each other. We identified 1,368,380 variants, which passed filter based on depth of coverage and several other variant calling quality metrics. Of those, 196,776 are insertions or deletions. Also, 44.4% of the variants are singleton and 21.9% of them have a minor allele frequency (MAF) of higher than 1%. Loss of function (LoF) variants constitute 1.2% (15,892 variants) of the database, of which 14.5% are located at OMIM genes with a reported associated phenotype. We found 422,095 novel variants, which were not reported in the Genome Aggregation or 1000 Genome databases, that represent 30.1% of the entire detected variants. As expected, the majority of these novel variants are singleton (65.1%) and only 7.5% and 3.3% of them have a MAF of higher than 1% and 5% respectively. This shows the importance of representing diverse populations in the human genome variation databases to create a more complete picture of human genetic variations.

**2901F****Genome-to-genome analysis of host-pathogen interactions in human tuberculosis.**

*N. Chaturvedi*<sup>1,4</sup>, *S. Gagneux*<sup>2</sup>, *M. Coscolla*<sup>2</sup>, *D. Brites*<sup>2</sup>, *D. Portevin*<sup>2</sup>, *J. Fellay*<sup>1,4</sup>. 1) School of life sciences, Ecole Polytechnique Fédérale de Lausanne, Switzerland; 2) Tuberculosis Research Unit, Swiss Tropical and Public Health Institute, University of Basel, Switzerland; 3) Clinical Immunology Unit, Swiss Tropical and Public Health Institute, University of Basel, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, Switzerland.

Tuberculosis (TB), resulting from infection with *Mycobacterium tuberculosis* (MTB), remains the leading cause of human death in developing countries. It is an ancient disease and MTB has been associated with its human host for a very long time, likely leading to some degree of host-pathogen co-evolution. However, formal evidence of co-evolution and its contributions towards host-pathogen interactions in human TB is lacking. In this work, we used paired human and MTB genomic information from infected patients to assess the potential influence of host genetic variation on MTB genomic diversity. Paired human genome-wide genotyping and MTB whole-genome sequencing were obtained for 81 HIV-infected patients in the Swiss HIV Cohort Study (SHCS) who also developed active TB disease. Human DNA was obtained from whole blood and bacterial DNA was extracted from mycobacteria isolated from sputum. We generated binary variables for 1,812 non-conserved MTB amino acids in 4,000 MTB coding genes. Out of these 1,812 binary variables, 16 were located in known human T cell epitopes. We ran separate single-marker logistic regressions for each dependent outcome and applied Bonferroni correction ( $p < 1.7 \times 10^{-12}$ ) to control for multiple testing. Our sample set was heterogeneous in terms of patient ethnicity and MTB phylogenetic lineage, which has the potential to result in human and bacterial stratification. To avoid spurious associations due to these systematic differences, we added the first five host principal components and the first two pathogen phylogenetic principal components as covariates in all models. This pilot study is statistically powered to detect very strong associations (e.g. odds ratio of  $>20$  for associations between human and pathogen variants). We did not identify any significant associations between specific binary amino acid variables in the MTB genome and human SNPs, which could be due to the large number (~ 27 billion) of tests performed in parallel and a small sample size. The smallest association p-value was  $8.9 \times 10^{-5}$ , between host SNP rs138060913 (gene TJP2, chromosome 9 position 71850428) and amino acid position 252 in the MTB gene Rv1872c. This is the first evaluation of host genetic restriction on MTB genomic diversity, and larger sample sizes are needed to get a clearer picture of the interactions between the human and MTB genomes.

**2902W****Genotype imputation performance using an African-American population.**

*L. Franco*<sup>1,3</sup>, *C.I. Vergara*<sup>2</sup>, *C. Thio*<sup>2</sup>, *A.V. Valencia-Duarte*<sup>2</sup>, *D. Thomas*<sup>2</sup>, *P. Duggal*<sup>4</sup>. 1) University of Antioquia, National Faculty of Public Health, Medellín, Antioquia, Colombia; 2) Johns Hopkins University, School of Medicine, Baltimore, MD.,USA; 3) Universidad Pontificia Bolivariana, School of Medicine, Medellín, Antioquia, Colombia; 4) Johns Hopkins University, Bloomberg School of Public Health, Baltimore, MD.,USA.

Genotype imputation is used to estimate unobserved genotypes from genotypic data, to increase genome coverage and power for genomewide arrays. Imputation has been successful for European ancestry populations. In comparison, African descent populations have been limited on available reference panels but there are enhanced African populations in 1000 genomes (1000G) and The Consortium On Asthma Among African-Ancestry Populations In The Americas (CAAPA). We aimed to compare the performance of these reference panels to impute variation in 447 African Americans (AA) genotyped for 774,792 SNPs using the Illumina OmniQuad array. EagleV2.3 was used for haplotype phasing and imputation was performed with Minimac3 on the Michigan Imputation Server. The haplotypes of 2,504 individuals (1000G) and 883 (CAAPA) were used as reference.  $R^2$  was used for imputation quality, and accuracy was estimated by a "masked analysis" with 25,000 SNPs (MAF:0.01-0.5). We evaluated 17 individuals with both GWAS and 30x WGS for genotype concordance. 1000G imputed 1.56x more variants than CAAPA irrespective of quality. Using an  $R^2 > 0.5$  threshold, 1000G imputed 1.4x more variants. 35% and 9.1% of them were unique for 1000G and CAAPA, respectively. From the 16,814,797 overlapping variants between the two panels, 99% had concordant genotype calls, but the quality was higher for 1000G ( $R^2:0.7-0.9$  vs  $R^2:0.2-0.6$ ). For masked SNPs the concordance between the actual genotypes and the imputed data was similar for both panels (97% in 1000G, 96% in CAAPA), but more accurate for 1000G. Using a single chromosome (chr22) as an example, the concordance between sequenced and imputed data was similar (98.9% of 213,472 variants in 1000G, 99.1% of 190,005 in CAAPA). Functional annotation using ANNOVAR identified 8.7% and 3.6% of variants for 1000G and CAAPA, respectively. Both panels increased the number of variants from a GWAS array for African American individuals with high quality and accuracy although 1000G was higher. Despite the larger reference size of 1000G, a sensitivity analysis restricting to the African populations (N=661), still showed increased quality and accuracy for 1000G. This likely reflects the greater contribution of African ancestry in 1000G as compared to the admixed individuals in CAAPA. The large number of variants that are uniquely imputed with each panel make them complementary but suggests that even more primary African sample references will improve imputation.

**Data-driven genetic encoding (DAGE) allows flexible identification of novel main effects and SNP-SNP interactions.** M.A. Hall<sup>1</sup>, A.M. Lucas<sup>2</sup>, Y. Bradford<sup>2</sup>, J.H. Moore<sup>1</sup>, M.D. Ritchie<sup>2</sup>. 1) Institute for Biomedical Sciences, University of Pennsylvania, Philadelphia, PA; 2) Biomedical and Translational Informatics Institute, Geisinger Health System, Danville, PA.

Certain assumptions are made about a SNP's biological action when choosing a genetic encoding. For each encoding, risk incurred by one copy of the alternate allele in relation to two copies varies: the heterozygous genotype (HET) is coded to bear 0%, 50%, and 100% the risk of homozygous alternate (HA) for recessive (REC), additive (ADD), and dominant (DOM) encodings, respectively. Yet, HET may yield any portion of the risk of HA. Further, SNPs across the genome are unlikely to demonstrate the same genetic action as one another. Choosing one encoding lacks flexibility, while running every encoding raises the multiple testing burden. We present a novel, flexible alternative: the data-driven genetic encoding (DAGE). Here, a HET value is assigned, based on individual SNP action in the dataset. DAGE outperformed traditional encodings in power tests for main effect and genetic interactions in a comprehensive combination of simulated genetic models. Further, DAGE maintained a low false positive rate, while the additive and dominant encodings demonstrated significant inflation. We applied DAGE to data from the Electronic Medical Records and Genomics (eMERGE) Network using age-related macular degeneration, age-related cataract, glaucoma, type 2 diabetes, hypothyroidism, and resistant hypertension and assessed these traits with ADD, REC, and DOM encodings as well. Across each trait, DAGE categorized SNP action consistent with p-values for ADD/DOM/REC (e.g., SNPs categorized by DAGE as having dominant action were found to have low significance for REC, high significance for DOM, and moderate significance for ADD). Further, DAGE identified numerous Bonferroni significant main effect and interaction signals not identified by traditional encodings. For example, DAGE found an interaction between SNPs rs4695885 and rs7787286 (Bonferroni-adjusted  $p: 0.018$ ) predictive of age-related cataract that no other encoding identified. SNP rs4695885 was categorized as additive and rs7787286 as recessive using DAGE. This is the first time these intronic SNPs have been implicated in age-related cataract, perhaps due to the limitation of traditional encodings. Our results demonstrate the impact of choosing a genetic encoding and the need for an individualized method for assigning SNP action. We offer DAGE as a flexible and robust method to identify novel main effect and SNP-SNP interactions in GWAS data.

Vitamin D is a steroid hormone precursor that has established associations with a range of human traits and diseases. Despite relatively high heritability estimates from family studies, GWAS of serum 25-hydroxyvitamin D concentrations from the SUNLIGHT Consortium have identified only four loci (*GC*, *NADSYN1/DHCR7*, *CYP2R1*, *CYP24A1*) harboring genome-wide significant variants. To better understand the genetic architecture underlying serum 25-hydroxyvitamin D, as well as to test for interactions between dietary vitamin D intake and genetic factors, we conducted the largest GWAS meta-analysis to date on this important vitamin. We expanded our previous GWAS dramatically, and undertook a large, multicenter, genome-wide association study. This single stage discovery meta-analysis consisted of 79,366 samples of European descent drawn from 31 studies, five times larger than our previously published GWAS. We also performed a genome-wide screen leveraging the possibility that genetic effects may depend on dietary vitamin D intake. We performed linkage disequilibrium score regression analysis to estimate the SNP-heritability of serum 25-hydroxyvitamin D concentrations. We additionally assembled summary statistics from GWAS of 39 traits performed in individuals of European descent, and calculated the pairwise genetic correlations between 25-hydroxyvitamin D and each trait. We also conducted cell-type-specific analysis to identify the enrichment of tissues in vitamin D. Our larger GWAS yielded only two additional loci harboring genome-wide significant variants ( $P=4.7 \times 10^{-9}$  at rs8018720 in *SEC23A*, and  $P=1.9 \times 10^{-11}$  at rs10745742 in *AMDHD1*). The overall heritability of 25-hydroxyvitamin D serum concentrations attributable to GWAS SNPs was 7.54%. Statistically significant loci accounted for 38% of this total (2.84% out of 7.54%). Further investigation identified signal enrichment in immune hematopoietic tissues, and clustering with autoimmune diseases in cell-type-specific analysis. Genome-wide genotype-by-dietary vitamin D interaction analyses identified no significant interactions. These results suggest circulating 25-hydroxyvitamin D has an oligogenic genetic architecture and is largely influenced by a small number of loci. Efforts to ensure adequate vitamin D concentrations and to understand the known variability in responses to vitamin D supplementation may be able to focus on the limited number of genetic determinants that we have identified.

Strug<sup>1,2,4</sup>. 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada; 3) Program in Physiology and Experimental Medicine, The Hospital for Sick Children, Toronto, ON, Canada; 4) Department of Statistics, University of Toronto, Toronto, ON, Canada; 5) Biostatistics Division, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada; 6) Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 7) Pediatric Pulmonary Department, Hospital Trousseau, Assistance Publique-Hôpitaux de Paris (AP-HP), Institut National de la Santé et la Recherche Médicale (INSERM), U938, Paris, France; 8) Pierre et Marie Curie University-Paris 6, Paris, France; 9) Department of Pediatrics, Case Western Reserve University, Cleveland, Ohio, USA; 10) Department of Genetics, Case Western Reserve University, Cleveland, Ohio, USA; 11) Cystic Fibrosis Pulmonary Research and Treatment Center, University of North Carolina, Chapel Hill, North Carolina, USA; 12) McKusick-Nathans Institute of Genetic Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland, USA; 13) Department of Molecular Genetics, University of Toronto, Toronto, ON, Canada; 14) These authors contributed equally to this work.

Genotype imputation improves fine mapping and enables meta-analysis of cohorts genotyped on different platforms. Traditional imputation uses whole genome sequence (WGS) reference panels e.g. 1000 Genomes Project (1KGP, n=2,504). However, imputation with the 1KGP failed to impute variants in the cystic fibrosis (CF) transmembrane conductance regulator (*CFTR*) for the International CF Gene Modifier Consortium, genotyped on the Illumina Human660W-Quad BeadChip (n=1,995). *CFTR* displays significant allelic heterogeneity and is associated with CF co-morbidities of complex inheritance such as intestinal obstruction. Using larger reference panels such as the Haplotype Reference Consortium (HRC; n=32,470), or alternatives that incorporate in-sample WGS may be preferable. We compare imputation in *CFTR* using the HRC to a composite reference combining the 1KGP with WGS from 101 CF patients; the latter enriching the reference with study-specific haplotypes. The 1KGP, HRC and composite reference provide, respectively, 1,438, 2,164 and 2,439 biallelic variants for imputation in *CFTR*. The composite reference results in more variants imputed; greater concordance between imputed and known CF-causing mutations, e.g. W1282X with 98.3% vs. 96.6% in HRC; and imputation of the most common CF mutation (p.Phe508del) missed by HRC which does not support indels, a consequence of low coverage sequencing. Notably, the composite reference displayed greater ability to detect association between *CFTR* and intestinal obstruction over 1KGP or HRC panels. Results suggest that traditional imputation can omit the most disease-relevant genotypes when there is allelic heterogeneity at causal loci, but incorporating WGS on a subset of the study population can improve imputation and causal variant identification.

## 2906T

**Assessing pleiotropy and mediation in loci associated with chronic obstructive pulmonary disease.** M.M. Parker<sup>1</sup>, S.M. Lutz<sup>2</sup>, B.D. Hobbs<sup>1,3</sup>, R. Cho<sup>1,3</sup>. 1) Channing Laboratory, Brigham and Women's Hospital/HMS, Boston, MA; 2) Department of Biostatistics and Informatics, University of Colorado, Anschutz Medical Campus, Denver, CO, USA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, Massachusetts, USA; 4) Division of Pulmonary, Allergy, and Critical Care Medicine, University of Alabama, School of Medicine, Birmingham AL, USA; 5) Division of General Internal Medicine and Primary Care, Brigham and Women's Hospital, Boston, Massachusetts, USA.

**Rationale:** COPD is a complex, heterogeneous disease. Large GWAS studies have identified several variants associated with case/control status. Many of these loci also show significant associations with other COPD-related phenotypes (e.g. emphysema). We aimed to distinguish if these loci act directly on a set of COPD-related traits or if the association is predominately due to a mediator (e.g. cigarette smoking). **Methods:** We tested the association of 22 COPD loci identified from a recent case-control GWAS with 12 COPD-related phenotypes in 5,873 non-Hispanic whites from the COPDGene study. SNPs associated with >1 phenotype at  $p < 10^{-4}$  were tested for pleiotropy via the pleiotropy R package. In cases of significant pleiotropy, we performed mediation analysis (using the R package mediation) to test if SNPs had a direct or mediated effect on the outcome of interest. Causal models assumed FEV<sub>1</sub>/FVC or cigarette smoking as the mediator. **Results:** Of the known COPD loci, 5 were associated with > 1 outcome at  $p < 10^{-2}$  (nearest genes: *RARB*, *RIN3*, *CHRNA5*, *AGER*, *HHIP*). Tests for pleiotropy between genotype and associated outcomes were significant for all loci ( $p < 0.05$ ). The *RARB* and *RIN3* SNPs had a significant mediated effect on emphysema through FEV<sub>1</sub>/FVC; however there was not a significant direct effect. In contrast, we found evidence for both direct and mediated effects for *AGER*, *CHRNA5*, and *HHIP*. At the *CHRNA5* locus, we confirmed an effect on lung function partially mediated through cigarette smoking ( $p$  direct effect = 0.01), though the effects of SNP on emphysema and emphysema distribution were entirely mediated through FEV<sub>1</sub>/FVC ( $p$  direct effect = 0.19, 0.07, respectively). The SNP in *AGER* was associated with FEV<sub>1</sub>/FVC, emphysema, and total lung capacity. The association with emphysema and total lung capacity was partially mediated through FEV<sub>1</sub>/FVC, but there was also a direct effect of genotype on both phenotypes ( $p$  direct effect = < 0.001,  $p=0.01$ , respectively). Lastly, the *HHIP* locus was associated with FEV<sub>1</sub>/FVC, emphysema, and emphysema distribution. Effects were partially mediated by FEV<sub>1</sub>/FVC but there was also a direct effect of SNP on both emphysema phenotypes ( $p$  direct effect = 0.02, <0.001). **Conclusions:** We used causal modeling to identify 3 SNPs with direct associations to multiple outcomes (*AGER*, *CHRNA5*, *HHIP*), suggesting these SNPs may act directly on these COPD-related phenotypes and that this pleiotropic relationship is not solely due to mediators.

**2907F****Genetic determinants of urinary biomarkers in the UK Biobank. D.**

Zanetti<sup>1</sup>, S. Gustafsson<sup>2</sup>, E. Ingelsson<sup>1</sup>: 1) Department of Medicine, Division of Cardiovascular Medicine, Stanford University, School of Medicine, CA; 2) Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Sweden.

**Background:** Urine biomarkers, such as sodium, potassium, creatinine and microalbumin, are strongly associated with several common diseases including diabetes mellitus, cardiovascular disease and chronic kidney disease. Knowledge about genetic determinants of these biomarkers can shed light on pathophysiological mechanisms underlying disease development.

**Methods:** We performed four genome-wide association studies (GWAS) of urinary sodium, potassium, creatinine and microalbumin in up to 116,860 individuals of European ancestry from the UK Biobank, a large population-based cohort study of ~500,000 individuals aged 40-69 years recruited at 21 centers across UK in 2006-2010. Further, we explored tissue and pathway enrichment using DEPICT in an expanded set of independent variants ( $P < 10^{-5}$ ). **Results:** In these preliminary analyses of the first release of data from the UK Biobank, we found 7 genome-wide significant ( $P < 5 \times 10^{-8}$ ) independent loci for sodium (4), potassium (1), creatinine (1) and microalbumin (1). We confirmed the well-known association with microalbuminuria near *CUBN* ( $P = 4.41 \times 10^{-12}$ ), and one of the associations with sodium was near *GCKR*, a well-known diabetes locus that also has been associated with chronic kidney disease in prior studies ( $P = 6.43 \times 10^{-10}$ ). The other associations were novel in terms of urinary biomarkers and kidney function, but signals for urinary sodium and creatinine mapped in loci previously associated with breast cancer (*MLLT10/DNAJC1*) and coffee intake (*CYP1A1/CYP1A2*), respectively. Tissue enrichment analyses in DEPICT highlighted parietal brain lobe as significantly enriched among associations with urinary sodium ( $FDR < 0.05$ ). We detected some degree of overlap across associations between the four urinary biomarkers. Specifically, two genome-wide significant loci for urinary sodium and one for potassium showed a strong association also with urinary creatinine ( $P < 10^{-5}$ ). **Conclusion:** We report seven genome-wide significant associations with urinary sodium, potassium, creatinine and microalbumin in 116,860 individuals from the UK Biobank, confirming several known associations and providing new insights into the genetic basis of these traits, and their connection to chronic diseases.

**2908W****Whole genome sequencing association analysis of red blood cell traits in a multi-ethnic population from the Trans-Omics for Precision Medicine (TOPMed) Project. X. Zheng<sup>1</sup>, Y. Hu<sup>2</sup>, D. Jain<sup>1</sup>, C.A. Laurie<sup>1</sup>, S.M. Gogarten<sup>1</sup>, M. Chen<sup>3,4</sup>, J.R. O'Connell<sup>5</sup>, J.P. Lewis<sup>4</sup>, L.M. Raffield<sup>5</sup>, A. Correa<sup>6</sup>, L.A. Cupples<sup>3,7</sup>, K.M. Rice<sup>1</sup>, A.D. Johnson<sup>3,8</sup>, C.C. Laurie<sup>1</sup>, A.P. 1) Department of Biostatistics, University of Washington at Seattle, Seattle, WA; 2) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 3) NHLBI's the Framingham Heart Study, Framingham, MA; 4) School of Medicine, University of Maryland, Baltimore, MD; 5) Department of Genetics, University of North Carolina, Chapel Hill, NC; 6) Department of Medicine, University of Mississippi Medical Center, Jackson, MS; 7) Department of Biostatistics, Boston University, Boston, MA; 8) NHLBI, Population Sciences Branch, Bethesda, MD; 9) Department of Epidemiology, University of Washington, Seattle, WA.

Red blood cell (RBC) measurements are polygenic traits, and genome-wide association studies (GWAS), exome chip and sequencing analyses have identified hundreds of associated genetic variants in European-, Asian-, African- and Hispanic-ancestry populations. However, additional loci remain undiscovered and causal variant(s) at each locus have not been well characterized. We performed whole genome sequencing (WGS) analyses for hemoglobin (HGB), hematocrit (HCT), mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), mean corpuscular volume (MCV), RBC count and red cell distribution width (RDW) in a multi-ethnic population from phase 1 of the NHLBI TOPMed Project. 7,490 Amish-, European- and African-ancestry individuals from the Old Order Amish Study, the Framingham Heart Study and the Jackson Heart Study, respectively, were pooled for single variant tests using inverse-normal transformed residuals as outcomes, with adjustment for age, sex, study, relatedness, population structure, and residual heteroscedasticity. We identified nine putatively novel loci reaching genome-wide significance ( $P < 5 \times 10^{-8}$ ), including two each for HGB (*4q22-rs10030052* and *ADAMTS20-rs563075310*,  $MAF = 0.001$ ), HCT (*4q22-rs10030052* and *chrX: 53479481*,  $MAF = 0.001$ ), MCH (*1p11-rs114421285* and *2q14.1-rs150467776*,  $MAF = 0.013$  and  $0.005$ , respectively) and MCHC (*ELOVL6-rs111995643* and *PHACTR-rs141007575*,  $MAF = 0.014$  and  $0.001$ , respectively), and one each for RBC count (*ITPR3-rs555173304*,  $MAF = 0.004$ ) and RDW (*chr22: 51068271*,  $MAF = 0.001$ ). The novel variants showed disparate allele frequencies across European and African ancestral populations, and will require validation in additional independent samples. We also confirmed seven previously reported loci for associations with multiple RBC traits. The lead variant for six (*HFE*, *BYSL*, *MYB*, *TMPRSS6*, *CD36* and *G6PD*) was the same as the reported index SNP or in strong LD ( $r^2 > 0.8$ ). The lead variants at *ITFG3/LUC7L* for MCH, MCHC, MCV and RBC were in strong LD with the reported index SNP while lead variants for HGB and RDW were not. At the *HBB* locus, the strongest association signal was *rs34598529*, with novel evidence of associations with MCH, MCV, RBC and RDW ( $P \leq 9 \times 10^{-9}$ ). This variant lies in a putative erythroid regulatory element and has been identified in African American beta thalassemia patients. In summary, our initial results suggest identification of novel rare RBC variants from WGS analyses of a multi-ethnic population.

**2909T**

**Large-scale inference in population cohorts.** *M.A. Rivas.* Biomedical Data Science, Stanford University, Stanford, CA.

Whole genome sequencing studies applied to large population cohorts, biobanks, and case-control studies with extensive phenotyping raise novel analytic challenges. The need to consider many variants at a locus or group of genes simultaneously and the potential to study many correlated phenotypes with shared genetic architecture provide opportunities for discovery and inference that are not addressed by the traditional one variant-one phenotype association study. Here we introduce an online resource, Global Biobank Engine (GBE, [biobankengine.stanford.edu](http://biobankengine.stanford.edu)), along with novel methodology for estimating correlation, scale, and location of genetic effects across a group of genetic variants, phenotypes, and studies implemented in GBE using the probabilistic programming language, STAN. We consider two components: 1) Bayesian model comparison, and 2) an Empirical Bayes mixture model, which can scale to millions of samples. After a signal is detected by model comparison, the mixture model estimates the underlying mixture of neutral and functional variants and thereby improves estimation of the effect size profile of any particular variant across a broad range of traits. Notably, this helps to assess whether protective alleles exist (location) without severe side-effects (correlation) and whether differences in strength of effects (scale) exist among various annotation classes of genetic variants such as mildly deleterious missense variants and highly disruptive protein-truncating variants. Taken together, the inference generated by the application of MRP to large-scale human genetic data should improve the generation of effective therapeutic hypotheses. Here, we present the Global Biobank Engine and its application to the first genetic data release by UK Biobank from 150,000 participants, pinpointing protective alleles in: IL33 conferring protection to asthma (posterior odds ratio=.59, [.49-.72]), IFIH1 to hypothyroidism (number of cases=7539, posterior odds ratio=.75 [.64-.88]), and TYK2 to psoriasis, rheumatoid arthritis, hypothyroidism, and sarcoidosis (posterior odds ratio range .5-.8); and estimation of genetic parameters including genetic correlation among various measurable phenotypes and diseases including Parkinson's disease and severe depression ( $\rho_{g} = .63$  [0.53-0.74]).

**2910F**

**Population pharmacokinetics of sulindac and genetic polymorphisms of *FMO3* and *AOX1* in women with preterm labor.** *J. Yee<sup>1</sup>, K. Lee<sup>2</sup>, J. Chung<sup>3</sup>, J. Sung<sup>4</sup>, S. Park<sup>1</sup>, Y. Kim<sup>1</sup>, H. Gwak<sup>1</sup>.* 1) College of Pharmacy & Division of Life and Pharmaceutical Sciences, Ewha Womans University, Seoul, South Korea; 2) College of Pharmacy, Chungbuk National University, Cheongju, South Korea; 3) College of Pharmacy, Sungkyunkwan University, Suwon, South Korea; 4) School of Medicine, Ewha Womans University, Seoul, South Korea.

This prospective study was aimed to establish a population pharmacokinetic model of sulindac and its active metabolite and to evaluate the effects of genetic polymorphisms in sulindac-related metabolizing enzyme genes including *FMO3* and *AOX1* on the population pharmacokinetics of sulindac in pregnant women with preterm labor. Sixty-eight patients diagnosed with preterm labor between 16 and 37 weeks' gestation were enrolled and data of 58 patients were analyzed. Plasma samples were collected at 1.5, 4, and 10 hr after the first oral administration of sulindac. Plasma concentration of sulindac and its active metabolite (sulindac sulfide) were determined using HPLC. To evaluate the effects of metabolizing gene polymorphisms on the pharmacokinetics of sulindac, 10 single nucleotide polymorphisms (SNPs) were analyzed by Snapshot and TaqMan genotyping assays. Pharmacokinetic analysis was performed with NONMEM 7.3. The mean maternal age and gestational age at dosing were  $32.5 \pm 4.4$  (range, 20-41) years old and  $27.4 \pm 4.4$  (range, 16.4-33.4) weeks, respectively. Of the patients, 38 (65.5%) were over 26 weeks of gestational age at dosing and the mean body weight was  $60.2 \pm 9.7$  (range, 45.0-92.0). In population pharmacokinetic analysis, one depot compartment model of sulindac with absorption lag time best described the data. The metabolism of sulindac and sulindac sulfide was described using Michaelis-Menten kinetics. In stepwise modeling, gestational age (divided into groups of  $\geq 26$  weeks and  $<26$  weeks) impacted volume of distribution and *FMO3* rs2266782 was shown by the Michaelis constant to affect conversion of sulindac sulfide to sulindac in the final model. The present study details the pharmacokinetic characteristics of sulindac and its metabolites in pregnant woman and verifies that genetic polymorphisms of *FMO3* and *AOX1* affect the pharmacokinetics of sulindac in women who undergo preterm labor. It is expected that the results could help clinicians predict the efficacies of sulindac in the development of individualized treatment plans for patients who undergo preterm labor.

H. Chan School of Public Health, Boston, MA.

**Background:** Prior studies suggest dental caries traits in childhood are heritable, but there has been no large-scale consortium genome-wide association study (GWAS) to date. **Participants and methods:** We performed GWAS for dental caries status on a case:control basis. The participants were children (aged 2.5-18.0 years) of European ancestry. Phenotype definitions were created for the presence or absence of treated or untreated dental caries, stratified by primary and permanent dentition. All studies tested genotype dosage (imputed to Haplotype Reference Consortium or 1000 Genomes phase 1 version 3 panels) whilst accounting for population stratification. Fixed-effects meta-analysis was performed weighted by standard error. Analysis included 17,037 individuals / 6,922 cases for primary teeth; 13,353 individuals / 5,875 cases for permanent teeth. Heritability was estimated using univariate linkage disequilibrium score regression. **Results:** There was modest evidence for association with caries status at single variants including rs1594318-C for primary teeth (intronic *ALLC*, OR 0.85, EAF 0.60,  $p$  4.13e-8, effects consistent in all but 2 of the 22 sex-stratified results files) and rs7738851-A (intronic, *NEDD4*, OR 1.28, EAF 0.85,  $p$  1.63e-8, effects consistent in all but 2 of the 14 files) for permanent teeth. Consortium-wide estimated heritability of caries was low ( $h^2$  of 1% [95% CI: 0%:7%] and 6% [95% CI 0%:13%] for primary and permanent dentitions, respectively). **Discussion:** This study was designed to identify common genetic variants with modest effects which are consistent across different populations. We did not identify convincing evidence for single variant association in the primary dentition under these assumptions. Phenotypic heterogeneity between cohorts may have contributed; these findings could also reflect complexity not captured by our study design, such as genetic effects which are conditional on environmental exposure. Prior studies have nominated fluoride exposure and tooth age as potential modifiers of genetic effects. In contrast to previous estimates from single cohorts, we observed low consortium-wide heritability estimates, highlighting the importance of non-genetic factors for the development of dental caries in children. The nomination of *NEDD4* as a novel candidate is notable given that neural crest cells participate in enamel and dentine formation. *NEDD4* transcripts are reported to regulate cranial neural crest signalling pathways.

## 2912T

**Leveraging whole genome sequence data to improve imputation and increase power in GWAS of diverse populations.** C. Quick<sup>1</sup>, C. Fuchsberger<sup>1,2</sup>, M. Boehnke<sup>1</sup>. 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI; 2) Center for Biomedicine, European Academy of Bolzano/Bozen (EURAC), affiliated with the University of Lübeck, Bolzano, Italy.

Imputation reference panels are instrumental in genome-wide association studies (GWAS), providing increased genomic coverage and statistical power from genotyping arrays. Current reference panels, e.g. from the Haplotype Reference Consortium (HRC), include tens of thousands of largely European (EU) individuals. These panels provide high imputation quality in many EU populations, but lower quality in non-EU, admixed, and isolate populations, particularly for rare variants. Capturing genetic variation across diverse populations is crucial to detect population differences in genetic risk and pharmacogenetic factors, maximize gene discovery, and identify causal variants through trans-ethnic fine-mapping. In diverse populations, multi-ethnic or population-matched reference panels can increase imputation quality. Here, we consider an approach in which a subset of participants is sequenced and the rest are array-genotyped and imputed using an augmented reference panel comprised of the sequenced participants and individuals from an external panel. We identify cost-effective approaches to increase imputation quality and maximize statistical power for GWAS in African American (AA), Latin American (LA), Sardinian, and Finnish populations. We used sequence data from 3412 AA and 2068 LA individuals in the TOPMed WGS project and from 2995 Finns and 3445 Sardinians in the HRC to compare imputation quality across multiple reference panels and genotyping arrays. For each population, we selected 2K individuals to use in reference panels and imputed the rest using Illumina Core, OmniExpress, Omni2.5, and Omni5 array SNPs. We assessed imputation quality by comparing true and imputed genotypes for each array using reference panels comprised of 0, 100, ..., 2K individuals from the target population and ~29K individuals from the HRC, and used Monte Carlo methods to estimate power as a function of sequenced and imputed sample size and genotyping array. Augmented reference panels substantially increased imputation quality for populations with high genetic distance from the HRC EU panel. For example, adding 2K population-matched individuals to the HRC panel increased coverage for MAF 0.05-1% variants 3.7-fold for AA vs. 1.1-fold for Finns. Our results suggest that sequencing a fraction of participants typically maximizes power given fixed resources in a single study. More broadly, constructing diverse reference panels will be critical to facilitate GWAS in diverse populations.

**GWAS data analysis with non-local prior based Bayesian iterative variable selection-regression.** *N. Sanyal, C.-H. Chen.* Radiology, University of California, San Diego, San Diego, CA.

We focus on multiple SNP analysis of genome wide association study (GWAS) data. Because of the ultra high dimension of GWAS data, most multiple SNP analysis approaches, both in the frequentist and in the Bayesian domain, effectively perform some sort of SNP selection by means of shrinkage of the effect sizes. Most commonly used frequentist shrinkage methods such as LASSO and elastic net often produce large number of false positive SNPs. On the other hand, though taking the Bayesian approach helps to reduce the number of false positives, high dimensional GWAS data analysis using existing Bayesian methods such as for example piMASS is computationally quite prohibitive. We present a novel Bayesian GWAS data analysis method that purports to ameliorate the above issues by harmoniously combining two features - dimension reduction as yielded by the use of stepwise selection approach and parsimonious selection as yielded by the use of recently proposed non-local priors. Our proposed method performs SNP selection in an iterative manner, followed by prediction based on the selected SNPs. Iterations proceed guided by a few tuning parameters that specify our method algorithmically, and within each iteration, SNPs are selected by using non-local prior based variable selection. Our method can be applied to both GWAS genotype level data and GWAS summary statistics. In order to illustrate the usefulness and flexibility of our method, we have performed several simulated data analyses using both independent and real genotyped SNPs and both binary and continuous phenotypes. Compared to several existing frequentist and Bayesian methods, our method has shown overall superior performance in terms of number of false positives, estimation error in the effect sizes, and mean squared error. Finally, several real GWAS data analyses demonstrate the accuracy of our method by comparing the results with existing established knowledge.

**Genome-wide association study of HIV-1 subtype C in Botswana population.** *A.K. Shevchenko<sup>1</sup>, S.V. Malov<sup>1</sup>, D.V. Zhernakova<sup>1,2</sup>, N. Cherkasov<sup>1</sup>, A. Svitin<sup>1</sup>, W. Xie<sup>3,4</sup>, V. Novitsky<sup>3,4</sup>, M. Essex<sup>3,4</sup>, S.J. O'Brien<sup>1</sup>.* 1) Theodosius Dobzhansky Center for Genome Bioinformatics, St. Petersburg State University, St. Petersburg, Russian Federation; 2) University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, the Netherlands; 3) Harvard T.H. Chan School of Public Health AIDS Initiative, Department of Immunology and Infectious Diseases, Harvard T.H. Chan School of Public Health, Boston, Massachusetts, USA; 4) Botswana Harvard AIDS Institute, Gaborone, Botswana.

HIV-infection is a deadly chronic disease spreading across all continents. More than 36 000 000 people currently live with HIV and more than 1 000 000 die due to AIDS (UNAIDS, 2015). Despite efforts and resources directed to the fight against the HIV epidemics for more than three decades, still currently there exists no effective vaccine or cure. According to UNAIDS, Botswana falls into top 3 countries with the highest HIV prevalence in the world with adult aged 15 to 49 HIV prevalence rate of 22.2% (UNAIDS, 2015). Moreover, HIV-1 subtype C (widespread in Botswana), which accounts for over half of HIV-1 infections worldwide, is understudied, because most studies focus on other subtypes. Genome-wide association studies (GWAS) allow to identify common variants associated with the trait in question. In order to efficiently search for the genetic associations we have previously developed GWATCH web platform (Svitin et al, 2014). The broad goal of the Botswana GWAS project is to identify genetic determinants of susceptibility and resistance to infection by HIV-1 subtype C among people severely affected by HIV/AIDS in Botswana. By conducting GWAS analysis on HIV-1C case/control dataset consisting of 955 Tswana people (combined from two partly overlapping datasets of 809 microarray and 362 WGS samples), we found several gene regions slightly below significance level. One of these loci was successfully replicated in the longitudinal study on CD4 and viral load (VL) trajectories in a total of 556 treatment-naive HIV-1C infected individuals in Botswana, which was the first GWAS for HIV-1C acquisition and control of viral replication and the first GWAS in this population (Xie et al, 2016). Despite different types of clinical data in the compared cohorts (HIV infection & AIDS progression), this is an interesting and noteworthy replication. Currently we are working on the replication of our findings in other available datasets. 1. Svitin A. et al. (2014). GWATCH: a web platform for automated gene association discovery analysis. *GigaScience*. 2. Xie W. et al. 2016. Genome-Wide Analyses Reveal Gene Influence on HIV Disease progression and HIV-1C Acquisition in Southern Africa. *AIDS Research and Human Retroviruses*.

**2915T****Genome-wide association study identifies novel susceptibility loci for tanning ability in Japanese population: From ToMMo cohort study.**

K. Shido<sup>1</sup>, K. Kojima<sup>2</sup>, A. Hozawa<sup>2,3</sup>, S. Ogishima<sup>3</sup>, N. Minegishi<sup>2,3</sup>, Y. Kawai<sup>3</sup>, G. Tamiya<sup>3</sup>, K. Tanno<sup>4,5</sup>, K. Yamasaki<sup>1</sup>, S. Aiba<sup>1</sup>, Y. Suzuki<sup>2,3</sup>, M. Nagasaki<sup>3</sup>. 1) Department of Dermatology, Tohoku University Graduate School, Sendai, Miyagi prefecture, Japan; 2) Graduate School of Medicine, Tohoku University, Sendai, Japan; 3) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 4) Iwate Tohoku Medical Megabank Organization, Disaster Reconstruction Center, Iwate Medical University, Yahaba, Iwate, Japan; 5) School of Medicine, Iwate Medical University, Morioka, Japan.

Genome-wide association studies (GWAS) in European populations identified genes such as MC1R, MATP, OCA2, HER2, SLC24A4, and IRF4 as candidate genes involved in melanogenesis and associated with hair, eye, and skin color. In this study, we tried to identify genes relating to skin types in a Japanese population. We employed GWAS using data from the Tohoku Medical Megabank Organization (ToMMo) cohort study. Japanese skin type I-III were classified based on an individual's susceptibility to sunburn and ability to tan: type I, always burns, never tans; type II, moderately burns, moderately tans; type III, never burns, always tans. Single nucleotide polymorphisms (SNPs) were tested for association with three types of Japanese skin type among 9,966 Japanese who participated in ToMMo cohort study in Miyagi and Iwate prefectures. As a result, we identified two candidate genes at genome-wide significance of less than  $5 \times 10^{-8}$ : chr15:28228553 C>T (rs74653330) at 15q12-13 (Oculocutaneous albinism II (OCA2) gene) and chr9:16808172 C>G (rs10122901) at 9p22.3-22.2 (Basonuclin 2 (BNC2) gene) in the population of Miyagi. The association between the nonsynonymous SNP in the OCA2 gene and normal skin pigmentation of East Asian and Japanese has already been reported in the previous studies. We confirmed that the SNP of OCA2 gene had a strong relation to Japanese skin type, and the SNP located in a non-coding region of BNC2 gene was also closely linked with Japanese skin type in the population of Miyagi as well as Iwate prefecture. Furthermore, we additionally found the following three loci in the combined analysis of Miyagi and Iwate prefecture: KITLG rs11104947 on chromosome 12, RAB32 rs11104947 on chromosome 6, and DBNDD1 rs138160245 on chromosome 16. The recent functional analysis showed these genes are involved in the process of melanogenesis. Thus our data from ToMMo cohort study confirmed the involvement of OCA2, BNC2, and KITLG and added two new gene loci RAB32 and DBNDD1 in human skin types in real life.

**2916F****Comparison of power of summary based methods for identifying expression-trait associations.** Y. Veturi, M.D. Ritchie. Biomedical and Translational Informatics, Geisinger Health System, State College, PA.

Transcriptome-wide association studies (TWAS) have recently been employed as one way to draw upon the advantages of both GWAS and gene expression studies to identify genes associated with complex traits. Unlike standard GWAS, TWAS only require summary level data and offer improved statistical power. Two popular TWAS methods include either (a) imputing the *cis* genetic component of gene expression from smaller sized studies into much larger effective sample sizes afforded by GWAS or (b) using summary-based Mendelian randomization (SMR). Although these methods have been effective at detecting functional variants, it remains unclear how extensive variability in the genetic architecture of complex traits and diseases impacts TWAS results. Our goal was to investigate the different scenarios under which these methods yielded enough power to detect significant expression-trait associations. In this study, we conducted extensive simulations on 6000 randomly chosen, unrelated Caucasian males from Geisinger's MyCode population to compare the power to detect *cis* expression-trait associations (within 500 KB of a gene) using the above-described approaches. To test TWAS across varying genetic backgrounds we simulated gene expression and phenotypes with different numbers of quantitative trait loci per gene and gene expression/genomic heritability using genetic models that differentiate the effect of direct causality from that of pleiotropy. For each gene, on a training set of 1000 individuals, we either (a) imputed gene expression and estimated corresponding weights using five different methods: LASSO, elastic net, Bayesian LASSO, Bayesian spike-slab, and best linear unbiased predictor or (b) obtained the top performing *cis*-eQTL. We then sampled with replacement 50,000, 150,000, and 300,000 individuals respectively from the testing set of the remaining 5000 individuals and conducted GWAS on each set. Subsequently, we integrated the GWAS summary statistics derived from the testing set with the weights (or eQTLs) derived from the training set to identify expression-trait associations using (a) imputed gene expression and (b) SMR. Finally, we examined the power to detect functionally relevant genes using the different approaches under the considered simulation scenarios. We observed substantial differences in power between the methods under varying genetic architectures. All the reported results are based on simulated data from the MyCode population.

**Improving imputation by maximizing power.** Y. Wu<sup>1</sup>, E. Eskin<sup>1,2</sup>, S. San-kararaman<sup>1</sup>. 1) Computer Science Department, UCLA, Los Angeles, CA; 2) Department of Human Genetics, UCLA, Los Angeles, CA.

GWAS estimates the correlations between disease status and collected genetic variants. After estimating the correlations, we perform a statistical test to indicate if each of the estimated correlation is statistically significant. If the absolute value of the association statistics is smaller than the threshold we set, we reject the null hypothesis. In GWAS, imputation is used to aid the interpretation of a GWAS by predicting the association statistics at untyped variants. People perform imputation in two sets of ways. One way is that to impute the genotypes directly at the untyped variants, and then perform a statistical test. The other sets of ways is to utilize summary statistics and impute the association statistics directly. Having the predicted statistics of the untyped variants, people indicate significance in two ways. One way is to adjust the rejection threshold for the untyped SNPs, basing on the correlation between the untyped and typed variants, to control the family-wise error rate. The other way is to set the same reject threshold for all association statistics of the typed and untyped SNPs. In this paper, we closely examine the different methods of imputation and the significant indicating methods. We found that while imputation increasing power, previous methods to indicate significance lose power. Thus we propose our method, where we impute untagged SNPs using a causal model, which assumes a subset of SNPs in the locus being causal, and then we find a set of thresholds to maximize the power of tagged SNPs. In an association test, by rejecting null hypothesis for SNPs at different threshold, we can control the false positive rate while maximizing the power.

Age-related macular degeneration (AMD) is a heritable eye disease and the leading cause of blindness in elderly population in the United States. Family-based and population-based genetic studies have successfully identified multiple disease-susceptibility genes for AMD. However, most studies to date have focused on AMD status (disease or normal) while the genetic influences on AMD progression are largely unexplored. In this study, we performed a genome-wide bivariate time-to-event analysis to test for association of time-to-advanced-AMD (either choroidal neovascularization [CNV] or geographic atrophy [GA]) with ~9 million variants (either from exome chip or imputed) on 2,721 Caucasians from a large multi-center randomized clinical trial, the Age-Related Eye Disease Study. We used a robust Cox proportional hazards model to appropriately account for between-eye correlation when analyzing the progression time in the two eyes of each participant. We identified four susceptibility loci associated with AMD progression with  $P < 5 \times 10^{-8}$ . All of them were previously reported to be associated with AMD risk, near *ARMS2-HTRA1* ( $P = 8.1 \times 10^{-43}$ ), *CFH* ( $P = 3.5 \times 10^{-37}$ ), *C2-CFB-SKIV2L* ( $P = 8.1 \times 10^{-10}$ ), and *C3* ( $P = 1.2 \times 10^{-9}$ ). In a secondary analysis, limited to the 34 known AMD risk variants, *LIPC* and *CTRB2-CTRB1* were also found to be associated with AMD progression ( $P < 0.0015$ ). Finally, our analysis replicated the finding that rs142450006 near *MMP9* was specifically associated with progression to choroidal neovascularization ( $P = 0.0006$ ) but not with geographic atrophy. In this study, we performed the first genome-wide association study for AMD progression. Our findings expand our understanding of AMD genetics in a clinically-relevant manner by assaying genetic effects on AMD progression.

**2919F****Logolas: A tool for visualizing enrichment of genetic signature profiles.**

*K. Dey, M. Stephens.* University of Chicago, Chicago, IL.

Logo plots are popular in genomics for identifying transcription factor (TF) binding motifs. Popular logo plotting tools, such as seqLogo and motifStack, use a library of 4 symbols - A, C, G and T corresponding to 4 bases - to represent the TF binding motifs. While it is adequate for viewing TF binding signature profile, the limited size of the library of symbols makes it hard to extend the applicability of logo plots to other areas of genetics and beyond. We propose a new R package called Logolas, which has a much wider library of logos comprising of all alphabets from A to Z, numbers from 0 to 9 and other symbols like dashes, arrows etc. Most importantly, Logolas allows the user to easily combine the logo representations of these alphanumeric characters to create string logos. This enables the user to represent almost anything that can be written using alphanumerics, say methylation profile, histone names, protein amino acids, names of metagenomic/ecological taxa and also mutations (symbols like C->T, T->A etc). Additionally, Logolas provides a simple user interface where an user can build from scratch a logo for a symbol of her own choice and add it to the library. Besides the entropy based representation of enrichment of symbols commonly used in TF binding motifs, Logolas also presents an alternative representation aimed at highlighting both the enrichment and depletion of symbols, compared to the background, in each position of the signature pattern of a motif. We show a number of applications of Logolas to demonstrate how it can be used for visualization for representing TF binding motifs, protein amino acid motifs, mutational profiles, with additional applications in phylogenetics and histone modifications. The package can be installed from Bioconductor (<https://bioconductor.org/packages/release/bioc/html/Logolas.html>). .

**2920W****A semi-supervised method for predicting functional consequences of genome-wide coding and noncoding variants.** *Z. He, I. Ionita-Laza.* Biostatistics, Columbia University, 722 W 168th Street.

The tremendous progress in massively parallel sequencing technologies enables investigators to efficiently obtain genetic information down to single base resolution on a genome-wide scale. However understanding the functional effect of genetic variants is much more challenging especially for variants in noncoding regions. Projects such as Encyclopedia of DNA Elements (ENCODE) and Roadmap Epigenomics provide a rich set of functional genomics annotations that can be used to predict functional effects of variants. Most of the methods integrating different functional annotations are unsupervised, particularly due to a lack of experimentally validated functional variants. However as more experimental data across different tissues and cell types becomes available it becomes feasible to employ semi-supervised methods for functional prediction. We propose here such an approach based on manifold regularization to utilize both experimentally confirmed regulatory variants and billions of unlabeled variants, with the goal to improve the accuracy of functional predictions. Through extensive simulations, we show that the proposed method significantly improve prediction compared to existing unsupervised methods. We apply the proposed method to several experimental datasets to predict functional consequences of genetic variants in different cell types, tissues and disease phenotypes and show substantially improved power relative to existing unsupervised approaches.

## 2921T

**Genome-to-genome analysis: Correcting for population stratification in joint association analysis of host and pathogen genomes (G2G) reduces false positive and negative results.** O. Naret, N. Chaturvedi, C. Hammer, J. Fellay. School of Life Sciences, EPFL, Lausanne, Switzerland.

**Background:** Genome-wide association studies of host and pathogen genomic variation, which we here call genome-to-genome (G2G) analysis, can identify sites of genomic conflicts between host and pathogens. Due to stratification of host and pathogen populations, G2G analysis can suffer from inflated type I (false positive) and type II (false negative) error rates. We demonstrated through simulation studies that correcting for host and pathogen stratifications reduces spurious signals and increases power. We confirmed the simulation by showing comparable results in a G2G analysis of paired human and HIV genomes. **Method:** To generate human SNPs and pathogen variants, we used the Balding-Nichols model. Additionally, to simulate the causal association between a SNP and a pathogen variant, we used a logistic model. To test associations, we used logistic regression with pathogen variants as dependent variables and host SNPs as independent variables. To correct for host stratification, we included the top five principal components of the SNPs data as covariates. To correct for pathogen stratification, we included phylogenetic principal components as covariates. We then compared the association p-values trend without correction, with correction on host side, with correction on pathogen side and with correction on both sides. **Results and discussion:** In the simulation, we observed a better control of false positive signals after adjustment for host and pathogen covariates. The median association p-values were  $p_{\text{no correction}} = 5.7 \times 10^{-3}$ ,  $p_{\text{host}} = 1.9 \times 10^{-1}$ ,  $p_{\text{pathogen}} = 3.4 \times 10^{-1}$  and  $p_{\text{both}} = 4.9 \times 10^{-1}$ . For true associations, we observed an overall improvement in the strength of the signal after adjustment for host and pathogen covariates. The median association p-values were  $p_{\text{no correction}} = 1.1 \times 10^{-1}$ ,  $p_{\text{host}} = 3.6 \times 10^{-4}$ ,  $p_{\text{pathogen}} = 4.1 \times 10^{-5}$  and  $p_{\text{both}} = 8.3 \times 10^{-7}$ . We then confirmed what we observed in the simulation on the HIV data. For the likely false positive association between *rs4913471* on chromosome 12 and amino acid 67 of the protease, the p-values were  $p_{\text{no correction}} = 1.5 \times 10^{-16}$ ,  $p_{\text{host}} = 3.2 \times 10^{-7}$ ,  $p_{\text{pathogen}} = 4.5 \times 10^{-5}$  and  $p_{\text{both}} = 3 \times 10^{-4}$ . For the known association between *rs9266628* in the HLA region and amino acid 135 of the reverse transcriptase, the p-values were  $p_{\text{no correction}} = 5.2 \times 10^{-18}$ ,  $p_{\text{host}} = 1.12 \times 10^{-18}$ ,  $p_{\text{pathogen}} = 5.9 \times 10^{-19}$  and  $p_{\text{both}} = 3.7 \times 10^{-20}$ . Our results demonstrated that correcting for stratification on human and pathogen sides offers a better control of type I and II errors.

## 2922F

**Mapping genetic organization and disease liabilities of human cortical surface with summary statistics of vertexwise genome-wide association studies.** C. Fan<sup>1,2</sup>, N. Schork<sup>3</sup>. 1) Cognitive Science, University of California, San Diego, La Jolla, CA; 2) Center for Multimodal Imaging and Genetics, University of California, San Diego, CA; 3) J. Craig Venter Institute, La Jolla, CA.

Defining genetic distances from one trait to another has been a critical tool for understanding human diseases and complex traits. This is particularly important for imaging genetics, where the phenotypes in interest are inherently high dimension, composing thousands of measures simultaneously extracted from the same individual. Although genetic correlations were oftentimes used for this context, the logistic hurdles of imaging phenotypes make either moment based summary statistic methods or mixed effects model based methods difficult to apply. Here we proposed two summary statistic based methods to map the genetic topologies of human cortical surface. The first genetic distance metric we defined is weighted Euclidean distance on summary statistics from vertexwise genome-wide association study (vGWAS). This enables us to identify homogeneous clusters from measurements based on the same group of individuals. The second metric is weighted summary statistic based Mendelian randomization (weighted SMR) that gauges the magnitude of associations from brain regions to complex traits. Our simulations indicate our methods identify the genetic topologies well even when signal to noise ratio is low. We applied our methods empirically to imaging genetic cohorts ( $n=2039$ ) and demonstrated that our methods can provide biological insight on the formation of human brain. In addition to homogeneous modules of cortical surface regions, we reveal the topological maps varying according to the complex traits in interest, including schizophrenia, education attainment, and Alzheimer's disease.

**2923W**

**Gene-based pleiotropic analysis of multiple survival traits via functional regressions with applications to eye diseases.** *R. Fan<sup>1</sup>, C. Chiu<sup>2</sup>, T. Sang<sup>1</sup>, R.J. Cook<sup>3</sup>, Y. Ding<sup>4</sup>, W. Chen<sup>4,5,6</sup>, D.E. Weeks<sup>4,5</sup>, M.L.T. Lee<sup>7</sup>, E.Y. Chew<sup>8</sup>, M.M. Xiong<sup>9</sup>. 1) Department of Biostatistics, Bioinformatics, and Biomathematics, GEORGETOWN UNIVERSITY MEDICAL CENTER, Washington, DC; 2) Biostatistics and Bioinformatics Branch, Division of Intramural Population Health Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health (NIH), Bethesda, MD 20892; 3) Department of Statistics and Actuarial Science, 200 University Avenue West, Waterloo, ON, Canada N2L 3G1; 4) Division of Pulmonary Medicine, Allergy and Immunology, Children's Hospital, of Pittsburgh at The University of Pittsburgh, Pittsburgh, PA 15224; 5) Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Crabtree Hall, Room A303 130 DeSoto Street, Pittsburgh, PA 15261; 6) Department of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Crabtree Hall, Room A303 130 DeSoto Street, Pittsburgh, PA 15261; 7) Departments of Epidemiology and Biostatistics, University of Maryland, College Park, MD 20740; 8) Division of Epidemiology and Clinical Applications, National Eye Institute, NIH, Bethesda, MD 20892; 9) Human Genetics Center, University of Texas – Houston, P.O. Box 20334, TX 77225.*

One way to analyze a set of phenotypic traits caused by pleiotropy is to analyze the traits one by one. This approach may lead to low power since it ignores the extra information obtained by combining multiple traits in one unified analysis. In the literature, there are no gene-based statistical methods for a joint analysis of multiple survival traits. We build on our previous work involving functional Cox regression for censored univariate time to event data. Specifically we develop methods for a combined association analysis between a pleiotropic gene (rather than a single SNP) and multiple survival traits through use of multivariate mixed effect Cox proportional hazard model using functional regressions. The methods are evaluated and refined by extensive simulation studies. An application to a motivating study of AMD progression is provided for illustration where we analyze jointly the times to vision loss in left and right eyes.

**2924T**

**Exploring genetic associations using self-reported phenotypes in genes for good.** *A. Pandit<sup>1</sup>, E.M. Schmidt<sup>1</sup>, G.J.M. Zajac<sup>1</sup>, W. Li<sup>1</sup>, K.K. Brieger<sup>1</sup>, G. Datta<sup>2</sup>, S.I. Vrieze<sup>2</sup>, G.R. Abecasis<sup>1</sup>.* 1) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI., USA; 2) Institute for Behavioral Genetics, University of Colorado, Boulder, CO, USA.

Genes for Good is a genetics study that engages 10,000s of individuals through social media to help better understand the genetic basis of human health and disease. As an incentive to contribute, participants receive ancestry results and the option to download their raw, uninterpreted genetic data, including imputed genotypes. All phenotypes are self-reported through online surveys in the Genes for Good Facebook app. To ensure a sufficient amount of phenotypic data per participant, participants must complete a minimum number of surveys in order to receive a spit kit in the mail and provide a sample for genotyping. As of June 2017, >45,000 individuals from all 50 U.S. states have enrolled. While collecting phenotypes via social media is convenient for both parties, the reliability of self-reported measures is hotly debated. To assess the accuracy of our data, we evaluate our ability to replicate known associations. When analyzing an initial freeze of 4,286 European individuals, we were able to reproduce several known genetic association signals, for example associations between body mass index and *FTO* ( $p=2.9 \times 10^{-8}$ ) and between high LDL cholesterol (binary) and *APOE* ( $p=5.2 \times 10^{-10}$ ). Population-level associations between health traits, such as diabetes and obesity, were also replicated. The convenience of collecting phenotypes online allows us room to explore interesting behavioral outcomes, for instance the number of meals or snacks that one eats per day and whether someone prefers to eat alone. When analyzing the number of meals per day in our relatively small sample size, we noted multiple hits approaching genome-wide significance on *CASP1*, a protein-coding gene that plays an integral role in cell apoptosis and has been linked to appetite regulation and body weight ( $p=4.7 \times 10^{-7}$ ). As we continue to explore these relationships in our growing population, we improve our ability to uncover novel genetic associations in diverse behavioral and health-related traits.

**The 1M Africa genotype array: A powerful tool for medical genetic research globally.** *T. Carstensen*<sup>1,3</sup>, *A. Mitta*<sup>2,3</sup>, *M.H. Woehrmann*<sup>2,3</sup>, *J. Gollub*<sup>2,3</sup>. 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, United Kingdom; 2) Thermo Fisher Scientific, Santa Clara, CA, USA; 3) AGR investigators.

Large-scale genome-wide association studies in Africa are essential to better understand genetic determinants of complex traits in this region. The high levels of genetic diversity across Africa, and the high proportion of population specific variation are unlikely to be captured well by existing arrays that are based primarily on European populations, or a small subset of relatively homogenous populations across western Africa. Development of representative and cost-effective genotype arrays is key to facilitating medical genetics research across the continent. Here, we present the development and design of an Africa specific array, a cost-effective array, with high accuracy across African populations and globally. African 1M genotype array has been developed based on the African Genome Resource, a resource of low coverage sequence data (4x, 6x and 8x) encompassing 5000 individuals and 10 African populations, including populations from the 1000 Genomes Project Phase 3. Markers were selected using the Axiom™ genotyping array technology. We used a hybrid imputation and tagging approach to identify the most efficient set of 1 million tag SNPs across populations, to maximise accuracy of capture of common variation across all populations studied. We calculated coverage in each population as the proportion of common variants imputed with >0.80 accuracy ( $r^2$ ) imputed with the AGR reference panel using 5-fold cross validation, also excluding each target population from the reference panel in turn. We additionally included pre-selected markers important in the context of disease research and pharmacogenomics in global populations. The Africa 1M genotype array provided >90% coverage of common variants (MAF≥5%) across all African, European and Asian populations, including the most diverse indigenous population groups from Africa (the Nama), providing strong evidence of the utility of the array across the region, and in multi-ethnic populations globally. The African 1M array developed using the African Genome Resource has the potential to provide a cost-effective and powerful tool for large-scale GWAS in African and multi-ethnic populations worldwide.

**Clonal hematopoiesis: Genetic and phenotypic associations.** *C. Tian*, *P. Fontanillas*, *J. Tung*, *D. Hinds*. Research, 23andme, Mountain View, CA.

Age-related clonal hematopoiesis is a common condition that is associated with an increase in hematologic cancer and in all-cause mortality. Studies have shown that 10% of individuals over the age of 65 years have recurrent somatic mutations and large-scale somatic events. We analyzed SNP array data with custom probes for 13 previously characterized single-nucleotide somatic mutations (*DNMT3A* r882c/r882h, *IDH1* r132h/r132l, *IDH2* r140q, *JAK2* v617f, *KRAS* g12d/g13d, *NRAS* g13r, *NRAS* q61r, *SF3B1* k700e, *TP53* r248q and *U2AF1* s34p) in ~800k 23andMe consented research participants and we further used the data to detect large mosaic structure alterations. The presence of the 13 somatic single-nucleotide mutations was detectable in 1.15% of the study population, and it increased from 0.7% in young individuals (<= 45 years old) to 2.0% in older individuals (> 65 years old). Large mosaic structural alterations were detected in 1.5% of the study population. To understand risk factors that contributed to having a detectable somatic mutation, we performed a genome-wide association scan for each of the 13 single-nucleotide somatic mutations. As previously described, *JAK2* (rs12349785,  $P=4.0e-95$ , OR=0.436), *TERT* (rs2736100,  $P=1.4e-42$ , OR=1.722), *TET2* (rs199741557,  $P=6.0e-14$ , OR=0.497), *SH2B3* (rs653178,  $P=5.4e-9$ , OR=0.795) and *ATM* (rs11212666,  $P=1.3e-9$ , OR=1.27) were significantly associated with *JAK2* v617f carrier status. We identified novel associations with *IFT80* (rs201009932,  $P=1.2e-15$ , OR=3.14), and with two regions that were both in DNase hotspots (rs7803075, DNase hotspot in leukemia tissue,  $P=1.7e-13$ , OR=0.735; and rs621940, 9q34.13, GF11B-[]-GTF3C5,  $P=1.7e-10$ , OR=1.376). *TERT* is also significantly associated with having *DNMT3A* r882c/r882h mutations. Variants in 15q26.3 region (rs76685039,  $P=6.3e-16$ , OR=1.3) are found to be significantly associated with having *KRAS* g13d somatic mutations. A region in 6q21 indexed by rs1832777 ( $P=2.7e-11$ , OR=1.5), previously reported to be associated with red blood traits, is significantly associated with having the *SF3B1* k700e mutations. These data indicate that the germline variants predispose individuals to clonal hematopoiesis, which may later cause an overt neoplasm. The presence of somatic mutations was also analyzed for association with self-reported phenotypes. Somatic mutation carriers reported higher instances of having ever taken chemotherapy meds ( $P=6.1e-15$ , OR=1.81) and being current tobacco users ( $P=2e-4$ , OR=1.2).

**Summary statistic GWAS joint analyses across 50+ traits.** *H. Aschard*<sup>1,2</sup>, *C. Lasry*<sup>1</sup>, *P. Lechat*<sup>1</sup>, *H. Menager*<sup>1</sup>, *B.J. Vilhjalmsson*<sup>2,3</sup>, *V. Guillemot*<sup>1</sup>. 1) C3BI, Institut Pasteur, Paris, France; 2) Department of Epidemiology, Harvard TH Chan School of Public Health, Boston, MA, USA; 3) Bioinformatics Research Centre, Aarhus University, Aarhus, Denmark.

Genome-wide association studies (GWAS) have been performed on hundreds of traits and diseases, identifying thousands of significant genetic associations. Besides genome-wide associated variants these studies carry large amount of information that can be used to further deciphering the genetic architecture of human phenotypes. In particular, the joint analysis of multiple diseases and traits has received limited attention, even though multivariate analyses have the potential to improve the detection of new genetic variants. Here we propose JASS (Joint Analysis of Summary Statistics), a computationally efficient framework for the joint analysis of multiple phenotypes based on GWAS summary statistics. JASS allows for the application of several multi-trait statistical tests, including standard omnibus approach and hypothesis driven weighted sum of individual phenotypes statistics. Our framework also solves several practical and methodological issues which have been overlooked in previous studies. We demonstrate how these issues can result in bias when testing association between single nucleotide polymorphisms (SNPs) and multiple phenotypes, illustrate the resulting increased false positives rate in real data, and developed solutions to avoid such pitfalls. We applied JASS for the joint analysis of publicly available GWAS summary statistics of more than 50 phenotypes altogether, or using sub-groups of phenotypes based on shared genetics or shared environmental variances. We detected dozens of genome-wide significant variants missed by univariate phenotype screenings. The newly identified variants include strong candidate genes. For example the joint analysis of 5 psychiatric diseases identified *PCDHA1*, a gene with a potential role on cell-cell connections in the brain, while the joint analysis of 5 auto-immune diseases, identified *PLCL1*, a gene known to play a role in allergy (while our auto-immune phenotype set did not include allergy-related phenotypes). Comparison between joint tests highlighted higher power of the omnibus approach on average, while weighted sum of individual phenotype statistics show better performances only in a few specific scenarios. Finally, we present a publicly available implementation of our framework ([jass.pasteur.fr/static/](http://jass.pasteur.fr/static/)), which includes all 50 publicly available GWAS curated by our group, thus allowing investigators to assess association with any subset of phenotypes of interest for a specific disease.

**2928F**

**Polymorphisms in the *HSF2*, *LRR6*, *MEIG1* and *PTIP* genes correlate with sperm motility.** *S. Rajender*<sup>1</sup>, *N. Gupta*<sup>1</sup>, *S.N. Sankhwar*<sup>1</sup>. 1) Endocrinology Division, Central Drug Research Institute, Lucknow, UP, India; 2) Dept. of Urology, King George's Medical University, Lucknow, India.

Abnormality in the genes involved in the process of sperm production or maturation may cause morphological and functional changes in spermatozoa, which would be reflected in the form of poor semen parameters or loss of fertility. Implication of sex chromosomal genes (X or Y) in male infertility has been well studied, particularly the association of Y-deletions with loss of fertility. However, alterations in the autosomal genes could also be a contributing factor in the etiology of male infertility. We have genotyped 24 functionally important SNPs from 24 infertility strong autosomal candidate genes in 500 infertile men. The genotype data for these polymorphisms were segregated into two groups according to the dominant model of genetic analysis (11 and 12 plus 22). Sperm count and motility were compared between the alternate genotypes at each test locus. We observed a significant change in sperm motility between the alternate genotypes for *LRR6* rs200321595 C>G polymorphism (P = 0.012; CC: 35.98 ± 18.06, CG+GG: 45.47 ± 17.01), *MEIG1* rs150031795 G>A polymorphism (P = 0.040; GG: 36.18 ± 18.04, AA: 47.57 ± 20.04), *HSF2* rs143986686 T>C polymorphism (P = 0.0021; TT: 36.18 ± 18.06, CC: 47.95 ± 18.32) and *PTIP* rs61752013 polymorphism (P = 0.013; CC: 35.97 ± 17.79, CT: 46.70 ± 19.21). Sperm count between the above comparisons did not differ significantly. Multi-dimensionality reduction analysis revealed that rs61752013 (*PTIP*) and rs200321595 (*LRR6*) were the best interacting SNPs for sperm motility analysis. We conclude that polymorphisms in *HSF2* (rs143986686), *LRR6* (rs200321595), *MEIG1* (rs150031795) and *PTIP* (rs61752013) correlate with sperm motility and hence infertility risk. .

**Transformation of summary statistics from linear mixed model association on all-or-none traits to odds ratio.** *L.R. Lloyd-Jones<sup>1</sup>, J. Yang<sup>1,2</sup>, P.M. Visscher<sup>2</sup>.* 1) Institute for Molecular Bioscience, University of Queensland, Brisbane, Queensland, Australia; 2) Queensland Brain Institute, University of Queensland, Brisbane, Queensland, Australia.

Genome-wide association studies (GWAS) have identified thousands of loci that are robustly associated with complex diseases. GWAS are often hindered by population stratification and cryptic relatedness, which can induce spurious associations if not properly accounted for. Principal component correction in combination with logistic regression is a popular method for GWAS of disease traits when population structure is of concern. The use of linear mixed model (LMM) methodology for GWAS is becoming more prevalent due to its ability to control for population structure and cryptic relatedness. The odds ratio (OR) is a common measure of the association of a disease with an exposure (e.g. a genetic variant) and is readily available from logistic regression. However, when the LMM is applied to all-or-none traits it provides estimates of genetic effects on the observed 0-1 scale, a different scale to that in logistic regression. This limits the comparability of results across studies, for example in a meta-analysis, and makes the interpretation of the magnitude of an effect from an LMM GWAS difficult. In this study, we derive transformations from the effects generated under the LMM to the OR that only rely on summary statistics. To test the proposed transformations, we used real genotypes from two large (60,000 and 150,000 individuals) publicly available data sets to simulate 50 all-or-none phenotypes for each of five scenarios that differed in underlying model, disease prevalence and heritability. We measured the performance of each transformation by estimating the slope and adjusted  $R^2$  from regression of the OR estimates from the LMM (from 10,000 loci for each scenario) on the simulated truth. For each scenario, the slope and adjusted  $R^2$  were close to unity indicating a very high concordance between the transformed OR and the truth. Furthermore, we applied these transformations to GWAS results for type 2 diabetes generated from 108,042 individuals in the UK Biobank. We observed very high concordance between the transformed OR from the LMM and those estimated from logistic regression, reinforcing the reliability of the derived transformations. These transformations improve the comparability of results from prospective and already performed LMM GWAS by providing a common comparative scale for the genetic effects. We have developed an R Shiny application implementing the methodology, which is available at <http://cnsgenomics.com/shiny/LMOR/>.

**Assessing the causal impact of smoking and drinking on human health outcomes: Using 239 novel genetic associations for smoking and drinking addictions and a robust ensemble method for causal inference.** *F. Chen, Y. Jiang, D.J. Liu.* Penn State College of Medicine, Hershey, PA.

Cigarette smoking and alcohol consumption are modifiable risk factors for human health outcomes. While generally believed to be harmful, their causal impacts on many human health outcomes remain elusive. Conventional correlation analyses of smoking/drinking traits with diseases are subject to the influence of confounders and reverse causation, so cannot be used to assess causal impact. Mendelian Randomization (MR) is a powerful approach to identify the causal relations between risk factors and diseases. But the success of MR relies critically on the availability of smoking/drinking associated genetic variants that can be used as instrument variables. Despite the known heritability of smoking/drinking addictions, very few loci were consistently implicated in previous studies, which limits the applicability of MR. Recently, the GWAS & Sequencing Consortium of Alcohol and Nicotine use (GSCAN) project identified 239 novel independent loci associated with five traits of smoking/drinking: cigarettes per day, smoking initiation, smoking cessation, drinking per week and drinker vs. nondrinker, which enabled unprecedentedly powerful MR study. Taking advantage of these newly identified loci for smoking/drinking and publically available summary association statistics, we performed MR analysis on a myriad of human health outcomes, ranging from metabolic traits, cardiovascular diseases to cancer. We synthesized the results from multiple approaches using a novel ensemble method, including traditional multiple instrument MR, egger regression and two-stage regression. We identified several robust pairs of causal relations for smoking/drinking. For example, we noted that tobacco consumptions causes an increased risk for coronary artery disease (CAD). An increased consumption of 5 cigarettes per day will cause a 1.4 fold increase in the odds of developing CAD (95% CI: 1.16-1.72,  $p < 0.01$ ). However, smoking showed an interesting protective effect on gout, for which smoking reduces the OR by 10% (95% CI for OR: 0.08- 0.16,  $p < 0.01$ ). The protective effect is supported by the biological connections between nicotine in-take and urate crystals. Together, these results provide robust novel insights on the causal relations between smoking/drinking and human health outcomes. It also provides support for previous inconclusive causal inference. The method and results will be very useful for predicting disease risk and guiding clinical intervention.

**Simulating autosomal genotypes with realistic linkage disequilibrium and a spiked in genetic effect.** M. Shi, D.M. Umbach, A.S. Wise, C.R. Weinberg. Biostatistics and Computational Biology Branch, NIEHS, Res Triangle Park, NC.

To evaluate statistical methods one needs to be able to simulate realistic genome-wide genotypes. We here describe a method that can simulate autosome-wide single-nucleotide polymorphism (SNP) data with realistic linkage disequilibrium (LD) and with spiked in, user-specified, multi-SNP causal effects. Our construction uses existing genome-wide association (GWAS) data from unrelated case-parent triads, augmented by including a hypothetical complement triad for each triad (same parents but with a hypothetical offspring who carries the non-transmitted parental alleles). We assign offspring qualitative or quantitative traits probabilistically through a specified risk model and show that our approach destroys the risk signals from the original data. Our method can simulate genetically homogeneous or stratified populations and can simulate cross-sectional studies, case-parent studies, studies of quantitative traits, or studies based on outcome-dependent sampling. We show that allele frequencies and LD structure in the original GWAS sample are preserved in the simulated data. We have implemented our method in a R package "TriadSim".

**X wide association analysis identifies a novel *FRMPD4* locus associated with the differential sex risk for multiple sclerosis.** Y. Zhou, J. Charlesworth, I. van der Mei, B. Taylor, ANZgene Consortium. Menzies Institute for Medical Research, Hobart, Tasmania, Australia.

Multiple sclerosis is characterised by a significant sex imbalance with an increasing female to male ratio of 2.3-3.5:1 for relapse onset MS. Characterising the role of the X chromosome in MS will enable a unique biological perspective on MS aetiology. However, the vast majority of GWAS studies have either not assessed or under assessed the X chromosome, as most of the analysis pipelines are designed for autosomal loci. The availability of a recently developed software (XWAS) that is specially designed for X chromosome analysis has allowed us to assess the role genetic variation of the X chromosome in MS onset. We therefore conducted an X-wide association analysis using the ANZgene MS GWAS data (2482 MS cases and 4304 controls) as a discovery sample involving 6,518 SNPs and replicated using Australian MS exome array data (583 MS cases and 410 controls). We identified a significant association in *FRMPD4* (rs6641026) that showed different effects by sex. In the discovery stage, the MS risk OR for males was 2.06 ( $P=1.84 \times 10^{-6}$ ), while the OR for females was 0.94 ( $P=0.35$ ). In the validation stage, the OR for males was 5.09 ( $P=0.03$ ) while the OR for females was 0.83 ( $P=0.38$ ). The combined test for differentiated effect size between sexes was significant after multiple testing ( $P=3.9 \times 10^{-6}$ ). This gene *FRMPD4* functions as a positive regulator of dendritic spine morphogenesis and density, and is required for the maintenance of excitatory synaptic transmission. The finding of an association with MS risk only in males may suggest a significant parent of origin effect or suggest a gene dosage effect is important and may be protective in females. This gene thus has high biological plausibility for involvement in MS risk. The differential effect by sexes requires more research to elucidate the mechanisms.

## 2933T

**Genome-wide association study identifies novel genetic loci in the Major Histocompatibility Complex (MHC) associated with reduction in *Clostridium difficile* Infection (CDI) recurrence in patients treated with bezlotoxumab.** J. Shen<sup>1</sup>, D.V. Mehrotra<sup>1</sup>, M.B. Dorr<sup>1</sup>, Z. Zeng<sup>1</sup>, J. Li<sup>2</sup>, M.H. Wilcox<sup>3</sup>, R. Mogg<sup>1</sup>, R.L. Blanchard<sup>1</sup>, P.M. Shaw<sup>1</sup>. 1) Merck & Co., Inc., Kenilworth, NJ; 2) BGI-Shenzhen, Shenzhen, China; 3) University of Leeds, Leeds, UK.

Bezlotoxumab (BEZ) and actoxumab (ACT) are monoclonal antibodies against *C. difficile* toxins B and A, respectively. Patients receiving a single infusion of BEZ alone or with ACT in the MODIFY I/II trials showed a reduction in the rate of CDI recurrence (rCDI) over a 12-week period compared with a placebo (PBO) infusion. To identify genetic variants that associate with the treatment effect on rCDI, we performed a pharmacogenetics genome-wide association study (GWAS) of pooled data from the MODIFY I/II trials (191 with rCDI and 513 without rCDI). Genetic data were generated on a commercial Affymetrix Axiom array platform. Genotype imputation was performed using the 1000 Genomes Phase 3 reference data and Impute2 software after genetic quality control. Classic human leukocyte antigen (HLA) alleles at *HLA-A*, *-B*, *-C*, *-DPB1*, *-DQA1*, *-DQB1* and *-DRB1* were imputed using HIBAG, and HLA association analyses were conducted. We identified a common intergenic SNP associated with treatment effect on rCDI in the MHC of chromosome 6 located between the HCP5 and MICB genes (rs2516513, MAF = 0.24,  $P = 3.04E-08$ , per allele odds ratio [OR] in treated patients = 0.31 and 95% CI: 0.18 to 0.48). Imputation of classic HLA alleles identified two class II HLA alleles in high linkage disequilibrium (LD  $r=0.98$ ) associated with the treatment effect on rCDI (*HLA-DRB1\*07:01*,  $P = 1.93E-05$ , per allele OR in treatment arms = 0.19 and 95% CI: 0.06 to 0.44 and *HLA-DQA1\*02:01*,  $P = 5.18E-05$ , per allele OR in treatment arms = 0.21 and 95% CI: 0.08 to 0.46). Carriers of the T allele of rs2516513 and *HLA-DRB1\*07:01* allele were associated with statistically significant reduction in rCDI in BEZ and Bez+ACT-treated patients compared with PBO-treated patients (rCDI reduction = 21.5% and 32.3%; one-sided Fisher's exact test  $P = 1.10E-05$  and  $7.18E-06$ , respectively). Conditional regression analyses showed that the signals from rs2516513 and *HLA-DRB1\*07:01* were relatively independent although the majority of the association was explained by the SNP. The identified genetic associations within the MHC support a potential role of immune mechanisms in the rCDI response to BEZ and may provide new opportunities for predicting patients more likely to respond to treatment. Further work is required to validate these associations in an independent validation study.

**A *CREBRF* missense mutation substantially affects height in Samoans.**

S.L. Rosenthal<sup>1</sup>, R.L. Minster<sup>1</sup>, N.L. Hawley<sup>2</sup>, G. Sun<sup>3</sup>, O.D. Buhule<sup>4</sup>, H. Cheng<sup>5</sup>, T. Naseri<sup>6</sup>, M.S. Reupena<sup>6</sup>, R. Deka<sup>3</sup>, D.E. Weeks<sup>1,4</sup>, S.T. McGarvey<sup>7,8</sup>. 1) Department of Human Genetics, University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, USA; 2) Department of Epidemiology (Chronic Disease), Yale University School of Public Health, New Haven, Connecticut, USA; 3) Department of Environmental Health, University of Cincinnati College of Medicine, Cincinnati, Ohio, USA; 4) Department of Statistical Methods and Actuarial Science, Makerere University, Kampala, Uganda; 5) Bureau of Statistics, Government of Samoa, Apia, Samoa; 6) Ministry of Health, Government of Samoa, Apia, Samoa; 7) International Health Institute, Department of Epidemiology, Brown University School of Public Health, Providence, Rhode Island, USA; 8) Department of Anthropology, Brown University, Providence, Rhode Island, USA.

The Samoan population is a genetically isolated population ideal for genetic studies as evidenced by the recent identification of a missense mutation (Arg457Gln) in *CREBRF* that significantly affects body mass index (BMI). This SNP, rs373863828 (G>A), is virtually absent in non-Pacific Islander populations (minor allele frequency, MAF < 0.0001), despite being common in Samoans (MAF=0.259). In prior research, we observed that *CREBRF*, and rs373863828 specifically, is also associated with other body size phenotypes—waist circumference, hip circumference, and percent body fat, although not waist-hip ratio. We were concerned that perhaps the increase in BMI might, in part, be due to a decrease in height, which is in the denominator of the equation for BMI. We tested the hypothesis that the minor A allele of rs373863828, which is associated with increased BMI, was associated with decreased height using a cross-sectional sample of Samoan individuals ( $n=3,068$ ) recruited from 33 villages across both islands of the Independent State of Samoa. We used linear regression to calculate the residuals with age and sex as fixed effects and tested the association of this missense mutation with height residuals adjusting for relatedness using an empirical kinship matrix. Our results show the A allele was associated with an increase, not a decrease, in height ( $p=1.94 \times 10^{-5}$ , effect size=0.65 cm per copy of the A allele). We repeated our analysis in a replication sample of 2,191 Samoan individuals collected in 1990–91 and 2002–03 from Independent Samoa and American Samoa. When calculating residuals for the heights in the replication sample, we included the additional fixed effects of polity and study cohort in our regression model. Results from the replication study supported the findings in our discovery group ( $p=4.42 \times 10^{-5}$ , 0.85 cm per copy of the A allele). These results suggest that rs373863828 strongly affects height as well as BMI, and alters height at an effect size among the largest seen in common variants affecting height.

**2935W**

**Investigation of post-colonial demographic structure and the implications for association analyses.** *K.A. Rand<sup>1</sup>, J.M. Granka<sup>1</sup>, D. Garrigan<sup>1</sup>, J. Byrnes<sup>1</sup>, E.L. Hong<sup>1</sup>, C.A. Ball<sup>1</sup>, K.G. Chahine<sup>2</sup>.* 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

Recent work has highlighted the need to evaluate the impact of fine-scale population structure on association analyses. Despite thousands of high-powered genome-wide association studies (GWAS), only about one-fifth of all studies include individuals of non-European descent. It is understood that GWAS conducted in European populations are not always generalizable to non-European populations, and that continental population structure is an important factor to consider. However, it remains unclear whether fine-scale population structure, particularly more recent within-continental structure, contributes to bias in the interpretation of GWAS results. From our database of over four-million AncestryDNA customers, we visualize regional fine-scale structure, within continental ethnicity groups, in a subset of over one million AncestryDNA customers who have consented to research. In most cases, such regional United States population structure, identified to relate to post-colonial demography during the last several hundred years, is undetectable in a principal component analysis (PCA). However, we still observe regional allele frequency variation at the single-variant level. To explore whether these regional allele frequency differences play a role in association analyses, we examine the frequency distribution of previously-identified variants in the GWAS and ClinVar catalogs. To account for the effects of continental population structure, we examine regional sub-population frequencies of variant subsets that have been identified in each specific continental population (i.e., SNPs identified in a GWAS of European ancestry for European-descent US subpopulations). While observed frequency differences occur across only some regional groups, in some cases these differences suggest residual confounding due to within-continental population structure. It is unclear whether the observed differences can be attributed to true differences in disease risk, or whether they are solely an artifact of generalizing GWAS results to other, unstudied populations. Our results show that, even when considering very recent time scales, small frequency differences can impact GWAS conclusions and interpretations. This work highlights the fundamental need to understand the generalizability of GWAS results through the lens of both continental, and within-continental, population structure, particularly in large-scale analyses.

**2936T**

**Comparison of PC-based and LME-based population structure adjustment using GWAS and WES markers.** *Y. Chen<sup>1</sup>, GM. Peloso<sup>1</sup>, AL. DeStefano<sup>1,2</sup>, S. Seshadri<sup>2</sup>, J. Dupuis<sup>1</sup>.* 1) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 2) Department of Neurology, Boston University School of Medicine, Boston, MA.

Whole exome sequencing (WES) captures only ~1% of the genome that is in the coding regions of genes. This provides a lower coverage of the entire genome compared with genotyping array-based data. Population structure can cause inflated type-I error and spurious association in genome-wide association studies (GWAS), a problem that is also inherent with WES data. Two established approaches to adjust for population structure are principal components (PCs) and linear mixed effect (LME) models. Due to the lower number of variants available in WES, the performance of these two approaches in WES data may be inadequate. We compare the PCs and model performance of the two approaches using GWAS and WES variants by simulation using 1000 Genome data. We consider the scenarios where both European and African Ancestry individuals are included, and a more subtle population structure scenario with only European Ancestry samples. We find that the differences in GWAS-computed PCs and WES-computed PCs are due to the number of markers included in the calculation, with GWAS-computed PCs having a smaller variance. Association results are similar when adjusting for GWAS-computed PCs or WES-computed PCs, which extends to LME using a genetic relationship matrix computed from GWAS or WES markers. While the approach based on PCs performs better for variants not confounded by population structure, the LME-based approach can achieve higher power for variants confounded by population structure. Finally we explored the above models in a real data set from the Framingham Heart Study (FHS).

**2937F****Pharmacological insights from genetic mapping of the plasma proteome.**

Genetic perturbations of biological processes can be used to inform the development of drugs with similar mechanisms of action. To identify genetic variants that influence circulating protein levels, we mapped protein quantitative trait loci (pQTL) for 2,994 plasma proteins using 3,301 healthy donors from the INTERVAL study. We found pQTL for 1,478 proteins, including 244 known drug targets. These proteins were targeted by drugs at all stages of development, including; 119 in preclinical studies, 76 in clinical trials, and 49 approved compounds. We overlapped pQTL with publically available GWAS data to provide insight into the potential phenotypic consequences of perturbing drug targets. In some cases genetics appears to support proposed indications. For example, we found that indications match associated traits for 7 of the 15 proteins with cis-acting pQTL that overlap GWAS signals. For other drugs targets, pQTL-GWAS overlaps do not support indications and/or point to safety concerns. We also identified novel disease-protein connections that could guide future drug development. For example, we found 77 novel candidate drug targets that are not currently targeted by any reported drug but which have pQTL that overlap disease GWAS signals. These analyses highlight the potential to use pQTL to inform drug development efforts.

**2938W****Measuring the rate and heritability of aging using machine learning methods.**

*J. Ding<sup>1</sup>, E.D. Sun<sup>1</sup>, J.Y. Zhao<sup>1</sup>, G.R. Abecasis<sup>2</sup>, F. Cucca<sup>3</sup>, I.G. Goldberg<sup>1</sup>, D. Schlessinger<sup>1</sup>.* 1) Laboratory of Genetics and Genomics, National Institute on Aging, Baltimore, MD; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan Ann Arbor, MI; 3) Institute of Genetic and Biomedical Research, National Research Council, Monserrato, Cagliari, Italy.

It is widely thought that individuals age at different rates. A method that measures physiological age independently of chronological age could therefore be a first step to understand relevant mechanisms; but searches for individual biochemical markers of physiological age have had limited success. In this study, we assessed the extent to which an individual's physiological age could be determined as a composite score inferred from a broad range of biochemical and physiological data. Data were collected in population studies in Sardinia ("SardiNIA") and Tuscany ("InCHIANTI"). We used machine learning strategies on data for ~6,000 Sardinian participants, who ranged in age from 12 to 81. The best predictive models were determined from multiple combinations of dimensionality reduction, classification, and regression algorithms. They reached very strong correlations ( $R > 0.9$ ) between predicted and actual ages, and showed relative stability in successive visits of the same individuals ( $R > 0.5$ ). Similar results were also seen for participants in the InCHIANTI study. We then defined an Effective Rate of Aging (ERA) for each participant, a continuous trait measured as the ratio of an individual's predicted age to his/her chronological age. The inference that individuals have a characteristic rate of aging is supported by findings that in the SardiNIA cohort, the inferred values of ERA showed genetic heritability of 40%. This has been sufficient to initiate genome-wide association studies that identify genetic variants influencing the rate of aging in genes that affect telomere length and metabolic activity.

Many genetic studies have contributed to the long list of genes recognized as influencing risk to non-syndromic oral clefts (NSOC). Majority of the identified common risk loci are not directly causal and collectively can only account for a small portion of heritability. A few sequencing studies have identified some potentially causal rare variants for NSOC. Our main goal is to identify single nucleotide variants (SNVs) as potentially causal for NSOC using whole genome sequence data. We sequenced 170 distantly related members of 58 multiplex cleft families with four different ethnic backgrounds: European-American, Central-American, Middle Eastern and Asian. We restricted our analysis to coding non-synonymous SNVs in autosomes with minor allele frequency reported as less than 1% in the 1000 Genomes project, ExAC and ESP samples. We performed further filtering using CADD, SIFT and PolyPhen to target potentially causal variants. After quality control and variant filtering steps, we included 151 distantly related subjects with NSOC from 53 families in the final analysis. We calculated the exact probability of all affected individuals in a family sharing an SNV, provided one of the affected family members carried it. We also calculated the sharing probability across families irrespective of ethnic groups and corrected for multiple testing. In our analysis of 151 affected family members, ten potentially causal variants achieved statistical significance after adjusting for multiple testing. The most significant SNV in *PERM1* ( $p=2.4e-9$ ) was shared by 6 Filipino families followed by an SNV in *LOC100129697* ( $p=6.9e-8$ ), which was shared by 7 families (4 Asian and 3 Syrian). All individuals (totaling 13) in 3 Filipino families shared 2 SNVs in *RNF39* and 2 in *TRIM31*. One SNV in *COL11A2* was shared by 4 Filipino families. One SNV in *SES2* and one SNV in *ZFYVE26* were shared by 3 and 4 Filipino families, respectively. One SNV in *ZNF574* was shared by 2 Filipino and 1 Chinese families. We identified 10 novel SNVs in 8 protein coding genes using an exact probability method for families from four ethnic groups. Some of these families show enrichment of potentially causal deleterious variants. However, these sharing probabilities (and p-values) may be underestimated if the variants are more frequent in these populations than in the reference databases used. We plan to further assess the role of each of these variants and perform functional analyses where feasible.

In recent years, fixed effect functional and additive regression models have been developed for unrelated samples to test for gene-based association between a quantitative/dichotomous/survival trait and multiple genetic variants in a gene region. The functional regression models reduce high dimensionality of next-generation sequencing data to draw useful information. In major gene association analysis, these models have similar or higher power than sequence kernel association tests (SKAT), its optimal unified tests (SKAT-O), and a combined sum test of rare and common variant effect (SKAT-C). Here we extend this approach to accommodate family-based data using additive generalized linear mixed models (GLMM) and generalized functional linear mixed models (GFLMM) to test for association between a dichotomous trait and genetic variants in a defined chromosome region. The GLMM and GFLMM model the effect of a major gene as a fixed mean, the polygenic contributions as a random variation, and the correlation of pedigree members by kinship coefficients. Then likelihood ratio test (LRT) statistics are used to test if the fixed mean is zero to perform gene-based association tests. Simulation results indicate that the LRT statistics accurately control the type I error rates for a pedigree dataset of moderate sample size (i.e., 456 individuals in 50 pedigrees). We illustrate the behavior of these statistics by applying them to an age-related macular degeneration (AMD) family data set.

**TRUFFLE: Tests of undetermined relationships between founders - fast, light and efficient.** A. Dimitromanolakis<sup>1,3</sup>, L. Sun<sup>1,2</sup>, A.D. Paterson<sup>4,2</sup>. 1) Department of Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Division of Biostatistics and Epidemiology, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada; 3) Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Ontario, Canada; 4) The Hospital for Sick Children Research Institute, Toronto, Ontario, Canada.

As studies generate GWAS data on large (>0.5M) numbers of subjects, estimating relatedness and co-ancestry among pairs of individuals is important for family-based analyses, but a computationally intensive challenge. Maximum likelihood methods, such as PLINK and PREST are not very accurate in estimating distant relatedness and have bias in mixed ethnicities. More recently, GERMLINE, ERSAs and fastIBD estimate recent shared ancestry between pairs of individuals by identifying small shared chromosomal segments using dense genetic data. However, they typically require phasing which is computationally intensive, and can introduce errors. We develop a new method and software (TRUFFLE) that enables the simple and accurate identification of IBD1 and 2 segments, calculation of total IBD1/2 probabilities and provide graphical reporting of distribution of shared segments across pairs of individuals of mixed ethnicities. By skipping the haplotype phasing step and, instead, relying on a simpler region based model, we avoid the influence of haplotype phasing errors and simplify the analysis pipeline. In addition this makes our method much more computationally efficient. TRUFFLE has high power to distinguish 5th to 6th degree relatives from unrelated pairs and the IBD1/2 estimates are as accurate as MLE for close relatives. In addition the method is robust to population structure. We illustrate our approach using phase 3 1000 Genomes data from 2504 individuals. Despite the large number of pairs to be examined, the running time of TRUFFLE was only 30 minutes, using 16 cores of a 2Ghz Xeon processor and memory usage was very low at < 1 GB. There is little influence of TRUFFLE to the effects of the extreme population stratification in this dataset, especially when compared to estimates from PLINK and KING. When examining 2nd-cousin relationships, PLINK reported 687,084 pairs with kinship coefficient > 0.0156, many of which are likely false. While KING was more robust to population structure, it still reported 57,839 such pairs. In contrast, TRUFFLE estimated only 142 such pairs. The TRUFFLE estimated kinship is in high agreement with BEAGLE IBD procedure, but without the very significant computational burden of BEAGLE and the necessity of haplotype phasing.

## 2942T

**A fast algorithm for Bayesian multi-locus model in genome-wide association studies.** W. Duan<sup>1,2,3</sup>, Y. Zhao<sup>1,2,3</sup>, Y. Wei<sup>1,2,3</sup>, F. Chen<sup>1,2,3</sup>. 1) Department of Biostatistics, Nanjing Medical University, Nanjing, Jiangsu, China; 2) The Key Laboratory of Modern Toxicology of Ministry of Education, Nanjing Medical University, Nanjing, Jiangsu, China; 3) Key Laboratory of Biomedical Big Data, Nanjing Medical University, Nanjing, Jiangsu, China.

**Purpose:** Many multi-locus shrinkage models have been proposed to identify single nucleotide polymorphisms (SNPs) associated with complex traits under a Bayesian framework. However, most use Markov Chain Monte Carlo (MCMC) algorithm, which are time consuming and challenging to apply to data from genome-wide association studies (GWAS). Therefore, an accelerating strategy is needed. **Methods:** Here we propose a variational inference of Bayesian lasso with adaptive prior (BAL-VI) for detecting underlying susceptible variants by fitting all SNPs in GWAS simultaneously. BAL-VI approximates the intractable joint posterior distribution of model with a factorized form including a tractable distribution and minimizes the Kullback-Liebler (KL) distance between this factorized form and full posterior distribution. We use extensive simulations and real data analysis to appreciate the accuracy, time using, and other properties of this model. MCMC version of Bayesian lasso (BL) and BAL are compared with BAL-VI. **Results:** BAL-MCMC and BAL-VI give nearly equal effect estimators for causal variants and much more accurate results than BL. BAL-VI obtains the highest power (TPR) with a well-controlled FPR among all methods by 95% credible interval (Table 1). Compared with BAL-MCMC, the narrow credible interval of BAL-VI makes it easy to falsely include neutral variants. In real data analysis, a data from GWAS of lung cancer susceptibility in China is used. BAL-VI presents similar association signal with BAL-MCMC, but requires less time (Table 2). Sensitive analysis of hyper-parameters on shrinkage factors indicate that BAL-VI under given hyper-parameters performs well in variable selection and effect estimation. Table 1. Simulation: False positive rate (FPR) and true positive rate (TPR) in variable selection with 50 replications ( $h^2=0.2$ ;  $n=1,000$ ;  $p=7,349$ )

Method	FPR	TPR
BL	9.62E-4	0.3
BAL-MCMC	4.90E-5	0.528
BAL-VI	1.07E-3	0.913

Table 2. Computation time for application in simulation trials and GWAS\*Time for GWAS.

Data dimensionality	Computation time, hours (SD)		
	BL	BAL-MCMC	BAL-VI
n=500; p=1,000	0.21(0.02)	0.21(0.02)	0.005(0.001)
n=1,000; p=7,349	2.92(0.33)	2.83(0.32)	0.020(0.006)
n=3,435; p=569,615 <sup>a</sup>	-- <sup>b</sup>	~120	~13

<sup>a</sup>BL model was not applied to GWAS data. **Conclusions:** BAL-VI is a fast and accurate model and can be applied to analyze all SNPs simultaneously in GWAS.

## 2943F

**The SUPERBABY PROJECT: Genetic determinants of the favorable NICU course in premature newborns.** *K.M. Gnana<sup>1,2,4</sup>, WCL. Stewart<sup>2,5,6</sup>, P. White<sup>3,5</sup>, M. Klebanoff<sup>1,5</sup>, LD. Nelin<sup>1,5</sup>, IA. Buhimschi<sup>1,5</sup>.* 1) Center for Perinatal Research; 2) Battelle Center for Mathematical Medicine; 3) Institute of Genomics Medicine, The Research Institute at Nationwide Children's Hospital, Columbus, Ohio; 4) Department of Biophysics; 5) Department of Pediatrics; 6) Department of Statistics, The Ohio State University, Columbus, OH.

**OBJECTIVE:** Premature infants are at increased risk for complications [e.g. bronchopulmonary dysplasia (BPD), necrotizing enterocolitis (NEC), intraventricular hemorrhage (IVH), and retinopathy of prematurity (ROP)], and many of these conditions can lead to long-term disability. However, among premature infants there is remarkable variation in the presence and severity of complications. We hypothesize that the accumulation of rare variants influences the risk for neonatal complications, which may also explain the clinically noted gender-ancestry effect. **METHODS:** We sequenced the exomes of 209 extensively phenotyped premature newborns (born between 26-31 completed weeks of gestation) who were cared for in the same time period and NICU setting. Ninety infants did not develop severe complications (termed "superbabies", SB), whereas 119 newborns developed at least one severe complication (IVH  $gr \geq 3$   $n=9$ , NEC  $gr \geq 2$   $n=6$ , ROP  $gr \geq 2$   $n=27$ , BPD  $n=106$ ) (termed "controls", CRL). For each gene, we performed a rank-sum test on the total count of rare variants, and we used a false discovery rate (FDR) approach to identify genes (and pathways) of interest. **RESULTS:** Across 24,121 genes, the distribution of p-values ( $p < 7 \times 10^{-5}$ ) was not uniform, implying that SB and CRL are genetically different. To confirm control of type 1 error, we used real data to compute the distribution of p-values in the absence of association, and found that we could not reject the null hypothesis of "no association" ( $p=0.87$ ). Furthermore, we used an FDR of 20% to identify genes with excess accumulation of rare variants in either SB or CRL infants. Among these, we highlight *HSP90AA1* ( $q$ -value  $\approx 0.08$ ), which is in the *HSP90* protein-folding pathway and has known anti-oxidant and anti-prototoxic function. Lastly, in contrasting the exomes of CRL Caucasian males ( $n=52$ ) with the exomes of SB African-American females ( $n=14$ ) we confirmed the non-uniform distribution of p-values ( $p=1.8 \times 10^{-14}$ ) suggesting that the gender-ancestry interaction effect could in fact be strong. **CONCLUSIONS:** With respect to rare variants, the genomic architecture of SB infants is different from CRLs, and this difference appears to influence risk for neonatal complications. We propose that exposure of the premature newborn lung to increased oxygen concentrations carries heightened risk for complications for carriers of *HSP90* and/or DNA repair pathway mutations.

Cystic Fibrosis (CF) is caused by dysfunction of the CF transmembrane conductance regulator (CFTR). *CFTR* does not fully explain the variation in disease severity across multiple affected organs such as the lungs, pancreas, and intestine. The international CF gene modifier consortium conducted a genome-wide association study (GWAS) of intestinal obstruction at birth (MI) in 6,770 individuals with CF. Development of a novel statistic that integrates gene expression enabled insights into the mechanism by which gene modifiers influence the presence of MI in CF. Three loci with genome-wide significant variants just 5' of *SLC26A9*, *SLC6A14* and *ATP12A*, and suggestive *PRSS1* variants (that were independently replicated), were identified. The 5' location of the associated variants combined with the identification of *PRSS1*, a pancreas-specific enzyme, suggested that the loci may impact MI through gene regulation in the pancreas. To test this hypothesis, expression quantitative trait loci (eQTLs) p-values were downloaded from the genotype tissue expression project (GTEx), and a test statistic was defined to assess the evidence for significant GWAS and gene-expression variants colocalizing. The statistic is a standardized difference in summed GWAS Wald association statistics between variants that overlap GTEx eQTLs versus variants that are not eQTLs at a given locus. The corresponding p-value is obtained by permutation, accounting for correlation between variants. To assess the most probable contributing gene and tissue, a similar statistic contrasted standardized average GWAS test statistics for tissue- and gene-specific eQTLs, with a companion R script displaying gene-by-tissue colocalization heatmaps. Generalizations using a unifying regression framework are underway, providing scalable analytic solutions for more complex data. Applying this method to the CF MI loci demonstrated that the associated variants colocalized with eQTLs for *SLC26A9*, *SLC6A14* and *ATP12A* in the pancreas, and showed significant tissue-specific enrichment in the pancreas over all other tissues investigated, eg. small intestine, transverse colon, stomach and esophagus. Results suggest that *SLC26A9*, *SLC6A14* and *ATP12A* are the most likely contributing genes, and may impact MI by varying gene expression in the CF pancreas. The proposed methodology is applicable to any trait where summary association statistics are available to integrate with functional data to test mechanistic hypotheses.

**2945T**

**Bayesian methods for genetic associations and causal inference yield potential biological insight for genetics of gene regulation.** *B. Jo<sup>1</sup>, C. Brown<sup>2</sup>, B. Engelhardt<sup>3</sup>.* 1) Department of Quantitative and Computational Biology, Princeton University, Princeton, NJ, USA; 2) Department of Genetics, University of Pennsylvania, Philadelphia, PA, USA; 3) Department of Computer Science and Center for Statistics and Machine Learning, Princeton University, Princeton, NJ, USA.

Expression quantitative trait loci, or eQTLs, are enriched for polymorphisms that have been found to be associated with disease risk. Meanwhile, Mendelian randomization (MR) uses the naturally randomized genotype as instrumental variables to conduct statistical tests of causality, such as among gene expression levels. With the recent advances in genomic sequencing technologies, large-scale projects such as the Genotype Tissue Expression (GTEx) project version v6p, including of 449 individuals with RNA-sequencing data across 44 tissue types, allow us to identify both local and distal eQTLs with sufficient power, and to use MR to test for causal, potentially mechanistic associations among gene expression levels. In this study, we develop a Bayesian method for MR, and we compare different methods for causal inference to study the mechanisms of distal expression QTLs and genome-wide association studies. A number of methods that have similar goals exist, including Mendelian randomization, mediation analysis (e.g., PrediXcan), and co-localization analysis (e.g., RTC or coloc). In this work, we combine the association Bayes Factor with the co-localization analysis to yield a novel set of tissue-specific Bayesian causal genetic networks, as well as a biological interpretation of the expected frequency of local and distal eQTLs encoded in terms of priors. We then compare the frequentist causal inference Wald statistic to the Bayesian causal analysis. Therefore, this work extends the current Bayesian causal inference methods, and then provides a novel, rigorous comparison of frequentist and Bayesian methods in genetic association and causal inference studies in a large-scale, multi-tissue expression dataset. Finally, we also provide a potential biological insight for genetics of gene regulation derived from this application.

**2946F**

**Human knockouts in the Ashkenazi Jewish population.** *A. Kleinman, O. Sazonova, S. Pitts, V. Vacic, R. Gentleman.* 23andMe, Inc., Mountain View, CA.

The Ashkenazi Jews are a founder population that went through a population bottleneck event approximately 700 years ago. As a result, the population features both pervasive IBD sharing and a number of deleterious variants fixed at relatively high frequency. This means that by only sequencing a relatively modest number of Ashkenazim, we expect to be able to build a imputation panel that captures a relatively large amount of the haplotypic diversity within the population, and that we should be able to impute a number of deleterious variants well. We started with a set of 40,000 genotyped consented research participants whose genomes we classified as > 85% Ashkenazi. To aid imputation, we selected samples for sequencing according to a computationally efficient greedy algorithm that seeks to maximize the total amount of population genome that is in IBD with one or more of the sequenced individuals. This resulted in a set of 481 individuals who covered an average of ~3040 cM (89%) of the autosome of each non-sequenced individual. By comparison, we computed that a random selection algorithm would have to choose more than 510 individuals to achieve the same coverage. We sequenced the chosen individuals at a median ~30x coverage and annotated the variants using VEP/LOFTEE, which showed a total of 5,291 autosomal loss-of-function SNPs and indels in 3,714 genes. We removed variants which we observed only once, leaving us with 16.3M SNPs and 4.7M indels, and then imputed these variants into 48,916 additional genotyped and prephased Ashkenazim. The imputed variants included 4,151 loss-of-function variants. There are 1,768 genes in which we observed at least one loss-of-function variant, and 394 in which we observed more than one. The genes HLA-A, HLA-B, HLA-DQA1, HLA-DRB1 and HLA-DRB5 each had more than 5 loss-of-function variants, and together accounted for 59 of the total. There are 2178 imputed individuals (4.4%) who are homozygous loss-of-function in at least one of 664 genes. We restricted to variants with accurate imputation and calculated transmission probabilities for these LOFs in 1736 trios. In comparison to the expectation under Mendelian inheritance, we observed a deficit of 46 double transmissions of the minor allele per 1,000 transmissions from a pair of heterozygous parents ( $p=0.062$ ), with 61 of 300 possible double transmissions corresponding to a double-transmission probability of 20.3%, suggesting that homozygous loss-of-functions are counter-selected.

**A genetic variants simulation program to simulate high order epistatic interactions for family-based studies.** Q. Li, J. Bailey-Wilson. Computational and Statistical Genomics Branch, NIH/NHGRI, Baltimore, MD.

In recent years, with the increased popularity of sequence data, the research community has paid more attention to family-based studies of complex traits. Therefore, an efficient simulation program is in demand to accommodate the current variety of genetic variant data and complex disease mechanisms. Most of the existing simulation software rely on gene-dropping methods and can be inefficient to generate high order gene-gene interaction effects for extended pedigrees. Previously, we developed an R package, trio, which incorporated a haplotype-based simulation of case-parent trios when the disease risk depends on higher-order epistatic interactions or gene-environment interactions. In this work, we extend that algorithm to simulate genetic variants, including rare variants, in extended pedigrees. By conditioning on the haplotypes of the set of initially ascertained, affected children, we can calculate the haplotype frequencies as well as the probability of affection status of the parents and other relatives. We allow various pedigree configurations and gene-based epistatic interactions which may involve different causal rare variants in the same genes within, or across pedigrees. We compared the validity and the efficiency of our simulation program with other existing simulation software, SIMLA, SIMLINK and SIMULATE.

**Modeling functional enrichment improves polygenic prediction accuracy in UK Biobank and 23andMe data sets.** C. Marquez-Luna<sup>1</sup>, S. Gaza<sup>2,3</sup>, P. Loh<sup>2,3</sup>, N. Furlotte<sup>4</sup>, A. Auton<sup>4</sup>, A. Price<sup>1,2,3</sup>, 23andMe Research Team. 1) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 4) 23andMe Inc., Mountain View, CA.

Recent methods for polygenic prediction place priors on unobserved causal effect sizes and shrink observed effect sizes to obtain posterior means, accounting for statistical noise as well as linkage disequilibrium (LD) between variants (e.g. LDpred-inf; Vilhjalmsón et al. 2015 AJHG). Here, we extend LDpred-inf to incorporate functionally informed priors using the baseline-LD model trained on a set of 31 independent diseases and complex traits (average N=84,686; Gazal et al. bioRxiv). This model jointly infers enrichment of functional elements (coding, conserved, histone marks, enhancers, etc.) as well as LD-dependent causal effect size architectures using stratified LD score regression (Finucane et al. 2015 Nat Genet). Our polygenic prediction method specifies a prior distribution of causal effect sizes based on the expected per-SNP heritability under the baseline-LD model and computes posterior means accordingly, again accounting for statistical noise as well as LD between variants. We applied the method to predict height in the UK Biobank. We used association statistics from N=113,660 UK-ancestry samples as training data (correcting for 10 PCs) and N=8,441 samples of other European ancestries as validation data, to minimize confounding due to uncorrected population stratification or cryptic relatedness. We analyzed 2.1 million genotyped and imputed SNPs with minor allele frequencies greater than 1% that passed quality control filters. As expected, LDpred-inf obtained higher prediction accuracy ( $r^2=0.239$ ) compared to standard pruning/thresholding methods ( $r^2=0.229$ ). Incorporating priors from the baseline-LD model produced an additional 10% increase in prediction accuracy ( $r^2=0.263$ ;  $P<10^{-16}$  for improvement). We repeated the analysis using European training data from 23andMe customers who consented to participate in research (N=429,528), and observed moderately higher prediction accuracies ( $r^2=0.280-0.301$ ). The moderate improvement despite the much larger sample size is consistent with the observed 30% higher heritability in UK Biobank, which is similar to previous work (Ge et al. 2017 PLoS Genet). Overall, our results show that modeling functional enrichment substantially improves polygenic prediction accuracy, bringing polygenic prediction of complex traits closer to clinical utility.

**Total serum IgE whole genome sequence association analysis in families from Barbados.** A. Shetty<sup>1</sup>, M. Daya<sup>1</sup>, N. Rafaels<sup>1</sup>, MP. Boorgula<sup>1</sup>, S. Chavan<sup>1</sup>, C. Foster<sup>2</sup>, P. Maul<sup>3</sup>, T. Maul<sup>3</sup>, H. Watson<sup>4</sup>, I. Ruczinski<sup>5</sup>, TH. Beaty<sup>6</sup>, RA. Mathias<sup>2</sup>, KC. Barnes<sup>1</sup>. 1) Center for Personalized Medicine and Biomedical Informatics, School of Medicine, University of Colorado, Anschutz Medical Campus, Denver, CO; 2) Johns Hopkins Asthma & Allergy Center, Johns Hopkins University School of Medicine, Baltimore, MD; 3) Genetics and Epidemiology of Asthma in Barbados, The University of the West Indies, Barbados; 4) School of Clinical Medicine and Research, Queen Elizabeth Hospital, The University of the West Indies, Barbados; 5) Department of Biostatistics, School of Public Health, Johns Hopkins University, Baltimore, MD; 6) Department of Epidemiology, School of Public Health, Johns Hopkins University, Baltimore, MD.

**RATIONALE:** Asthma is a complex disease with striking disparities between ethnic and racial groups, Asthmatics of African descent have more severe asthma, poorer response to therapy, and higher total serum IgE (tIgE) levels compared to asthmatics of European ancestry. tIgE has been shown to play an important role as both a marker and mediator in allergic disease. Genetics of asthma research has been conducted in the Barbados Asthma Genetics Study (BAGS) for more than two decades focused on a population of African descent. As part of the NHLBI's Trans-Omics for Precision Medicine (TOPMed) Program, high coverage whole genome sequencing (WGS; 39.4 average depth) was performed on samples collected from 189 families (mean pedigree size of 5.3 individuals, ranging from 1 to 48 individuals). This dataset provides us with the opportunity to investigate genetic variants that underpin tIgE levels in the BAGS population. **METHODS:** We used TOPMed freeze 3a data of 967 BAGS samples that passed quality control filters to test for association of tIgE levels. The dependent variable, tIgE, was logarithmically (natural log) transformed to normalize its distribution and diminish the effect of outliers. tIgE association analysis was then performed using linear mixed models implemented in the GENESIS R-package. Age, sex, asthma case-control status, tIgE batch and principal components associated with tIgE were included as fixed effect covariates. A kinship matrix was included as random effect to account for relatedness between subjects. **RESULTS:** Previously, the NHLBI-supported EVE Consortium performed a genome-wide meta-analysis of tIgE in 4292 ethnically/racially diverse (i.e. African American, Latino, and European American) asthma cases and controls. We investigated the 10 most significant associations from EVE, and found that SNPs rs10944017 (6:85300836), rs9469220 (6:32658310), rs7751374 (6:107981856), rs10124954 (9:82836415) and rs16977747 (17:71699790) were similarly associated in BAGS, with effect directions consistent with EVE. However, the p-values from BAGS (p=0.01-0.04) were marginal, which may be explained by environmental differences and/or the much smaller sample size of BAGS. In future, we will be performing burden tests, fine-mapping and pathway analysis.

## 2950W

**Sum ranking, simple but powerful method for detecting pleiotropic loci.** G.V. Roshchupkin<sup>1,2,3</sup>, H.H.H. Adams<sup>2,3</sup>, R.A. Poot<sup>4</sup>, M.A. Ikram<sup>2,3,5</sup>, W.J. Niessen<sup>1,3,6</sup>, H. Tiemeier<sup>2,7,8</sup>. 1) Department of Medical Informatics, Erasmus MC, Rotterdam, Netherlands; 2) Department of Epidemiology, Erasmus MC, Netherlands; 3) Department of Radiology and Nuclear Medicine, Erasmus MC, Rotterdam, Netherlands; 4) Department of Cell Biology, Erasmus MC, Rotterdam, The Netherlands; 5) Department of Neurology, Erasmus MC, Rotterdam, Netherlands; 6) Faculty of Applied Sciences, Delft University of Technology, Delft, Netherlands; 7) Department of Child and Adolescent Psychiatry, Erasmus MC, Rotterdam, the Netherlands; 8) Department of Psychiatry, Erasmus MC, Rotterdam, the Netherlands.

Genetic pleiotropy is when a single gene influences more than one trait. Genome-wide associations studies (GWAS) have identified many variants that each affects multiple traits, suggesting that pleiotropy may be common phenomena for many human complex phenotypes. However, systematic detection of such variants based on meta-analysis summary data is challenging and current methods do not satisfy pleiotropy requirements for the null hypothesis test. Here we propose a simple and feasible statistical test for single loci pleiotropy detection. This test is based just on GWAS summary p-values, which convert to individual rank per every variant, and has elegant combinatorics interpretation. Compare to classical methods for combining summary statistics, our approach is robust to extreme values. The higher rank "overwrites" the effect of small one. Therefore, the null hypothesis holds true if some SNP has very significant association with only one trait, but not with another. The null hypothesis will be rejected only if the rank of association is below some threshold for all traits. This property is an exact requirement for pleiotropy. Using this method, we confirmed the known pleiotropic loci (from *TOMM40*, *TMEM161B*, *AKAP6*, *TNRC6B* genes) as well as identified new variants (from *PEF1*, *ITIH1*, *CADM2*, *C3orf38*, *POU3F2*, *KNOP1*, *CDH7* genes) between body mass index and cognition, with pleiotropy p-values < 5x10<sup>-8</sup>. Moreover, because the method is aimed to detect a single variant we were able to identify 28 independent pleiotropic loci between seven subcortical brain structures (putamen, hippocampus, amygdala, thalamus, caudate, accumbens, pallidum) and schizophrenia, while absent of significant LD score genetic correlation. They are located in such genes as *MEI1* for hippocampus, *DCC* for putamen, *CACNA1I* for thalamus.

Price<sup>2</sup>, The Brainstorm Consortium.* 1) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA; 2) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 3) Department of Computer Science, Harvard University, Cambridge, MA; 4) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 5) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA; 6) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 7) Bioinformatics and Integrative Genomics, Harvard University, Cambridge, MA; 8) Department of Genetics, Harvard Medical School, Boston, MA; 9) Medical Research Council Epidemiology Unit, Cambridge Biomedical Campus, Cambridge, UK; 10) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

There are many diseases whose causal tissues or cell types are unknown. Identifying these tissues and cell types is critical for exploring gene regulatory mechanisms that may contribute to disease. Different types of data characterizing tissue- and cell-type-specific activity have been analyzed together with GWAS data to identify disease-relevant tissues and cell types: histone marks, DHS, eQTLs, and gene expression. Of these, gene expression data—without genotypes or eQTLs—has the advantage of being available in the widest range of tissues and cell types. We analyze gene expression data from several sources, together with genome-wide association study (GWAS) summary statistics for 48 diseases and traits with an average sample size of 86,850, to identify disease-relevant tissues and cell types. We develop and apply a new method, LDSC-Specifically Expressed Genes (LDSC-SEG), that uses stratified LD score regression to test whether disease heritability is enriched in regions surrounding genes with the highest specific expression in a given tissue. We show via simulations that LDSC-SEG is well-powered to identify true enrichments for polygenic traits while avoiding genomic confounding, in contrast to other methods that use information about tissue-specific expression. We then analyze two gene expression data sets containing a wide range of tissues to infer system-level enrichments. We identify immune enrichments for immunology diseases, brain enrichments for psychiatric diseases, liver enrichments for lipid traits, and other enrichments consistent with known biology. We also analyze chromatin data from the Roadmap Epigenomics project across the same set of diseases and traits, and conclude that gene expression and chromatin provide complementary information. We then analyze system-specific gene expression data sets that allow us to achieve higher resolution. We detect an enrichment of neurons over other brain cell types for several brain-related traits, enrichment of inhibitory neurons over excitatory neurons for bipolar disorder, and enrichments in the striatum for migraine and in the cortex for schizophrenia, depressive symptoms, bipolar disorder, and BMI. We identify enrichments of alpha beta T cells for asthma and eczema, B cells for primary biliary cirrhosis, and myeloid cells for lupus and Alzheimer's disease. Our results demonstrate that our polygenic approach is a powerful way to leverage gene expression data for interpreting GWAS signal.

**2952F****Multivariate generalized linear model for genetic pleiotropy.**

*D.J. Schaid<sup>1</sup>, X. Tong<sup>2</sup>, A. Batzler<sup>1</sup>, J.P. Sinnwell<sup>1</sup>, J. Qing<sup>2</sup>, J.M. Biernacka<sup>1</sup>.* 1) Health Sciences Research, Mayo Clinic, Rochester, MN; 2) School of Statistics, Beijing Normal University, Beijing, China.

When a single gene influences more than one trait, known as pleiotropy, it is important to detect pleiotropy to improve the biological understanding of a gene. Yet, most current multivariate methods to evaluate pleiotropy test the null hypothesis that none of the traits are associated with a variant; departures from the null could be driven by just one associated trait. A formal test of pleiotropy should assume a null hypothesis that one or fewer traits are associated with a genetic variant. We have developed statistical methods to analyze pleiotropy for analysis of binary, ordinal, or quantitative traits, or a mixture of these types of traits, based on generalized linear models and estimating equations. Our framework provides a sequential approach to test the null hypothesis that  $k+1$  traits are associated, given that the null of  $k$  traits are associated was rejected. This provides a method to determine the number of traits associated with a genetic variant, as well as which traits, while accounting for correlations among the traits. By simulations, we illustrate the Type-I error rate and power of our new methods, describe how they are influenced by sample size, the number of traits, and the trait correlations, and apply the new methods to a genome-wide association study of multivariate traits. Our new approach provides a quantitative assessment of pleiotropy, enhancing current analytic practice.

**Quantification of MAF-dependent architectures in 14 UK Biobank traits reveals strength of genome-wide negative selection.**

A. Schoech<sup>1,2</sup>, P. Loh<sup>1,2</sup>, D. Jordan<sup>3</sup>, S. Gazal<sup>1,2</sup>, L. O'Connor<sup>1,2</sup>, D. Balick<sup>2,4</sup>, P. Palamara<sup>1,2</sup>, H. Finucane<sup>1,2,5</sup>, S. Sunyaev<sup>2,4</sup>, A. Price<sup>1,2</sup>. 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Broad Institute of MIT and Harvard, Cambridge, MA; 3) Icahn School of Medicine at Mount Sinai, New York City, NY; 4) Division of Genetics, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 5) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA.

Understanding the role of rare variants is important in elucidating the genetic basis of human diseases and complex traits. It has been hypothesized that negative selection may cause rare variants to have larger per-allele effect sizes than common variants. Here, we develop a method to estimate the minor allele frequency (MAF) dependence of SNP effect sizes. We employ a model in which per-allele effect sizes have variance proportional to  $[p(1-p)]^{\alpha}$ ; where  $p$  is the MAF and negative values of  $\alpha$  imply larger effect sizes for rare variants. We estimate  $\alpha$  by maximizing its profile likelihood in a linear mixed model framework. Simulations based on imputed genotypes from the UK Biobank show that our method obtains unbiased estimates of  $\alpha$  under a wide range of genetic architectures, including LD-dependent SNP effects (Gazal et al. bioRxiv). We estimated  $\alpha$  for each of 14 UK Biobank diseases and complex traits, including height, BMI, hypertension and asthma, using imputed genotypes from British ancestry individuals ( $N=114K$ ). All 14 traits produced negative  $\alpha$  estimates with 9 significantly negative, implying larger rare variant effect sizes. The inferred best-fit distribution of true  $\alpha$  values across traits has mean  $-0.38$  and standard deviation  $0.06$ , with statistically significant heterogeneity across traits. Despite the larger rare variant effect sizes, we show that for most traits analyzed, rare variants (MAF < 1%) explain <10% of total SNP-heritability. We interpret our results using the Eyre-Walker model (2010 PNAS), which quantifies how frequency-dependent architectures depend on the joint distribution of SNP effects on trait and fitness. By performing forward simulations using SLiM 2 (Haller and Messer 2017 MBE) under a realistic European demographic model, we find that an average genome-wide selection coefficient of  $-10^{-4}$  or stronger is necessary to explain the  $\alpha$  values that we inferred, under plausible levels of coupling between trait and fitness effects. In conclusion, our results show that rare variants have increased effect sizes on human diseases and complex traits due to significant genome-wide negative selection, but this increase is not large enough for rare variants to explain a substantial proportion of total SNP-heritability.

## 2954T

**Local genetic correlation gives insights into the shared genetic architecture of complex traits.**

H. Shi<sup>1</sup>, N. Mancuso<sup>2</sup>, S. Spendlove<sup>4</sup>, B. Pasaniuc<sup>2,3</sup>. 1) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, CA; 2) Department of Pathology and Laboratory Medicine, UCLA, Los Angeles, CA; 3) Department of Human Genetics, UCLA, Los Angeles, CA; 4) Department of Biology, Brigham Young University, Provo, UT.

Although genetic correlations between complex traits provide valuable insights into epidemiological and etiological studies, a precise quantification of which genomic regions contribute to the genome-wide genetic correlation is currently lacking. Here, we introduce  $\rho$ -HESS, a technique to quantify the correlation between pairs of traits due to genetic variation at a small region in the genome. Like cross-trait LD Score regression (Bulik-Sullivan et al., Nat Genet 2015), our approach only requires GWAS summary-level data, however, it makes no distributional assumption on the causal variant effects sizes while accounting for linkage disequilibrium (LD) and overlapping GWAS samples. We evaluated our method through extensive simulations, and showed that  $\rho$ -HESS is approximately unbiased and more consistent than cross-trait LD Score regression. We then analyzed summary association data from 11 large-scale GWAS consortia across 36 complex traits (630 pairs) spanning 1703 LD-independent loci, and identified 25 genomic regions that contribute significantly to the genetic correlation among these traits. As an example, our analysis indicated the region chr2:21-23M, showing significant local genetic correlation for HDL and TG,  $r_{g,local} = -0.94$  (95% CI [-1.00, -0.65]). We note that this region harbors the APOA gene, known to associate with lipid phenotypes (e.g. HDL, LDL, TG; GLGC, Nat Genet 2013). Notably, we also find 6 genomic regions that contribute to the genetic correlation of 10 pairs of traits that show negligible genome-wide correlation, including the HBS1L region (chr6:134-136M), showing significant local genetic correlation for PLT (number of platelets) and MCH (mean cell hemoglobin),  $r_{g,local} = 1.00$  (95% CI [0.72, 1.00]). Interestingly, this region has been previously identified to associate with blood phenotypes (e.g. PLT, RBC, MCH; van der Harst et al, Nature 2012). These results further showcase the power of local genetic correlation analyses. Finally, we report the distribution of local genetic correlations across the genome for 55 pairs of traits that show putative causal relationships. As an example, our bi-directional analyses showed that causal regions for BMI consistently increase triglycerides (TG),  $r_{g,local,BMI} = 0.47$  (95% CI [0.37, 0.57]), but not vice versa  $r_{g,local,TG} = 0.02$  (95% CI [-0.14, 0.10]), providing further evidence that BMI causally increases triglycerides (Mancuso et al., AJHG 2017; Pickrell et al., Nat Genet 2016).

**2955F****MEGA analysis of alcohol consumption in diverse populations: The Population Architecture using Genomics and Epidemiology (PAGE) Study.**

*K.L. Young<sup>1</sup>, L. Park<sup>2</sup>, I. Cheng<sup>3</sup>, Y. Li<sup>3</sup>, S. Bien<sup>4</sup>, M. Graff<sup>5</sup>, H. Highland<sup>1</sup>, R. Tao<sup>6</sup>, L. LeMarchand<sup>6</sup>, C. Schurmann<sup>7</sup>, D. Stram<sup>8</sup>, S.P. David<sup>8</sup>, U. Peters<sup>4</sup>, K.E. North<sup>1</sup>, T. Matise<sup>9</sup>, S. Buyske<sup>9</sup> on behalf of the PAGE Study.* 1) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 2) University of Southern California, Los Angeles, CA; 3) Cancer Prevention Institute of California, Fremont, CA; 4) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 5) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN; 6) University of Hawaii Cancer Center, Honolulu, HI; 7) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 8) Division of Primary Care and Population Health Stanford University School of Medicine, Palo Alto, CA; 9) Rutgers University, New Brunswick, NJ.

Harmful use of alcohol results in 3.3 million deaths annually and 139 million disability-adjusted life years worldwide, and is a risk factor for obesity, hypertension, and stroke. According to the NIAAA, while some minority groups (African Americans and Hispanics) are more likely to abstain from alcohol, those who do drink have higher rates of alcohol consumption and binge drinking. In addition, most genetic studies of alcohol have focused on dependence phenotypes. In populations of European and East Asian ancestry, genes related to alcohol metabolism, including *ADH* and *ALDH*, have been identified, and *AUTS2* and *SLC6A1* have been associated with alcohol consumption. Studies of diverse populations are necessary to provide insight into population-specific genetic variability to guide precision screening and intervention efforts for those at greatest risk of alcohol misuse. We performed the first discovery study for alcohol traits using the Multi-Ethnic Genotyping Array (MEGA), a custom array designed to capture genetic variants in diverse populations to allow for imputation to low minor allele frequencies across ancestries, as well as identification of clinically relevant variants and deep genotyping of previously identified GWAS regions associated with complex diseases. MEGA genotype data imputed to 1KGP3 in African American, Hispanic, Asian, Native Hawaiian, and Native American PAGE participants were used to identify genetic variants influencing alcohol consumption. We compared moderate vs. more than moderate drinkers over the age of 21 (N=30,264) in study-specific pooled single variant additive regression models controlling for sex, age, ancestry, top 10 global ancestry principal components, and study center. Five known variants reached genome-wide significance ( $p < 5 \times 10^{-8}$ ), one near *ADH1B* and four near *ALDH2*. An additional 12 novel variants reached suggestive significance ( $p < 1 \times 10^{-6}$ ), most of which were low frequency (effect allele frequency [EAF]  $< 5\%$  in the 1000 Genomes EUR reference population), but common (EAF  $\geq 5\%$  in PAGE). Three risk variants were common in African descent groups (OR [95%CI]=1.65[1.37-1.99] near *MIR548AB/MIR548A3*, 1.80[1.44-2.25] near *PIGZ/MF12*, and 1.40[1.23-1.60] near *PER2/NDUFA4*). One risk variant near *MIR548AU* (OR [95% CI]=1.43[1.25-1.64]) was common in all PAGE populations except Africans. Future work will focus on analyses of other alcohol consumption phenotypes, as well as fine-mapping known alcohol-related loci typed on the MEGA chip.

**2956W****Association detection between ordinal trait and rare variants based on adaptive combination of p-values.** *Y. Zhou, M. Wang.* Heilongjiang University, Harbin, China.

Next generation sequencing technology not only presents a new method for the detection of human genomic structural variation, but also provides a large number of genetic data of rare variants for us. Currently, how to detect association between human complex diseases and rare variants using genetical data has attracted extensive attention. In the field of medicine, many of people's health and disease conditions are measured by ordinal response variables, namely, the trait value reflects the development stage or severity of a certain condition. However, most existing methods to test for association between rare variants and complex diseases are designed to deal with dichotomous or quantitative traits. Association analysis methods of ordinal traits are relatively fewer, and considering ordinal traits as dichotomous and quantitative traits will inevitably lose some valuable information in the original data. Therefore, in this paper, we extend an existing method of adaptive combination of P-values (ADA) and propose a new method of association analysis for ordinal trait based on it (called OR-ADA) to test for possible association between ordinal trait and rare variants. In our method, we establish a cumulative logistic regression model, in which the regression coefficients are estimated by the NR algorithm and the likelihood ratio test is used to test the association. Through a large number of simulation studies and an example, we demonstrate the performance of the new method and compare it with several methods. The analysis results show that the OR-ADA strategy is robust to the signs of effects of causal variants and more powerful under many scenarios.

**2957T**

**A large-scale genome-wide enrichment analysis identifies new trait-associated genes, pathways and tissues across 31 human phenotypes.** X. Zhu<sup>1</sup>, M. Stephens<sup>1,2</sup>. 1) Department of Statistics, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

Genome-wide association studies (GWAS) aim to identify genetic factors that are associated with complex traits. However, individual genetic variants have small effects, making them hard to identify. In addition, lists of individual variant associations give limited biological insights. “Enrichment analyses” can address these problems by focussing on a *set of related genes* (e.g. genes in a biological pathway), instead of individual genetic variants. Here we develop an efficient enrichment analysis method that jointly models GWAS summary statistics at millions of common variants, and use it to analyse 3,913 biological pathways and 113 tissue-based gene sets in 31 human phenotypes. Our results highlight several relevant pathways and tissues for complex traits that were not identified in previous analyses of the same data. For example, the *endochondral ossification pathway* is enriched for associations with adult height, and *liver-related* genes are enriched for Alzheimer’s disease. A key feature of our method is that inferred gene set enrichment automatically informs new trait-associated genes. For example, enrichment in *lipid transport* genes suggests strong evidence for association between *MTTP* and low-density lipoprotein cholesterol levels, whereas conventional analyses of the same data found no significant variant near this gene.

**2958F**

**VikNGS: A C++ Variant Integration Kit for Next Generation Sequencing across research studies for robust rare and common variant association analysis.** Z. Baskurt<sup>1</sup>, S. Mastromatteo<sup>2</sup>, J. Gong<sup>3</sup>, L.J. Strug<sup>3,4</sup>. 1) Genetics and Genome Biology, The Hospital for Sick Children, Toronto, ON, Canada; 2) Department of Computer Science, University of Toronto, ON, Canada; 3) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, ON, Canada; 4) The Centre for Applied Genomics, The Hospital for Sick Children, Toronto, ON, Canada.

The use of next generation sequencing (NGS) in association studies of complex traits is on the rise. Large sample sizes and consortium efforts will be necessary to increase power. However, integration of NGS from different research groups is a challenge because uncertainty in genotype calls differs across experimental designs. For example, different sequencing platforms, parameters (eg. read depth), and variant calling algorithms, which can all impact genotype uncertainty differentially, can result in spurious association findings. Previously we developed a robust score statistic (RVS) and a workflow (Derkach, 2014) and an R package (Gong, 2016, ASHG) for case-control association analysis of common and rare variants when cases and controls were not sequenced as part of the same experimental design, but the aligned reads in BAM format were available for both groups. The RVS for case control studies has been useful for several research groups (eg. Luo et al. Nat Gen 2017). However, analysis of large sample sizes is not sufficiently enabled by the R package, and more functionality is needed. Here we introduce *Variant Integration Kit for NGS* (vikNGS). *VikNGS* provides a fast and computationally efficient C++ implementation of the RVS workflow for rare and common variant analysis in case-control studies, as well as generalizations for quantitative trait analysis and the integration of NGS from an arbitrary number of cohorts (k). The *VikNGS* provides functionality for covariate adjustment, user-defined specification for rare variant collapsing, and power estimation for study planning. *VikNGS* requires a multi-sample VCF file and a tab-separated file containing individual-level information as input. We derive RVS generalizations for integrating sequence from k-cohorts, and for quantitative trait analysis. Simulation studies demonstrate that the generalizations enable integration of sequence across cohorts with different error models and sequencing depth, retaining the expected Type I error and comparable power to analyses with the true genotypes. We provide a benchmark for computing time between the C++ and R implementations, with the C++ implementation demonstrating significant speed advantages while enabling computation with larger data sets. Large samples sizes will be required to identify rare variation contributing to disease, and *vikNGS* will enable mega-analysis from large consortia despite differences in sequencing design.

**2959W**

**GLMM-seq: Gene-based detection of allele-specific expression by RNA sequencing.** J. Fan<sup>1</sup>, J. Hu<sup>1</sup>, M. Reilly<sup>2</sup>, R. Xiao<sup>1</sup>, M. Li<sup>1</sup>. 1) Department of Biostatistics, Epidemiology and Informatics, University of Pennsylvania, Philadelphia, PA; 2) Cardiology Division, Department of Medicine, Columbia University Medical Center, New York, NY.

Allele-specific gene expression (ASE) analysis, an alternative and complementary approach to eQTL analysis, is a powerful tool for identifying variation in gene expression. ASE quantifies the relative expression of two alleles in a diploid individual, and the imbalance of expression of the two alleles may explain phenotypic variation and disease pathophysiology. To understand the role of ASE in complex diseases, we can exploit this imbalance by RNA sequencing (RNA-seq), which provides allele-specific read counts distinguished by heterozygous sites. Existing ASE detection methods using RNA-seq data, e.g. MBASED and GeneiASE, report evidence of ASE in single samples, and for each sample, the ASE is quantified for each SNP and a gene-level measure of ASE is obtained by integrating the ASE effects across SNPs in the same gene. However, evidence of ASE is often shared across individuals. It is desirable to have an ASE detection method that can simultaneously model both multi-SNP and multi-individual information. To this end, we developed GLMM-seq, a generalized linear mixed-effects model, which allows the modeling of the RNA-seq read counts across multiple individuals and multiple SNPs in the same gene and the adjustment of covariates. This method is able to detect gene-level ASE for RNA-seq samples under one condition, and can also be modified to detect differential ASE between two conditions (e.g., diseased vs. healthy controls). To evaluate the performance of GLMM-seq when haplotype phase information is known or unknown, we conducted extensive simulations and found that GLMM-seq performs consistently well and outperforms MBASED and GeneiASE, especially when sample size is small, read depth is low, and the degree of expression imbalance is low to moderate. We will further apply GLMM-seq to RNA-seq data generated in the Genetics of Evoked Response to Niacin and Endotoxemia Study. Results from this analysis will provide novel candidates for modulation of innate immune responses in humans.

**2960T**

**Reverse regression enables disease only case-control association studies for burden tests.** J. Tom<sup>1</sup>, A. Wuster<sup>1,2</sup>, D. Chang<sup>1,2</sup>, K. Mukhyala<sup>1</sup>, J. Vogel<sup>1</sup>, J. Reeder<sup>1</sup>, J. Hunkapiller<sup>2</sup>, M. Brauer<sup>1</sup>, T. Behrens<sup>2</sup>, W. Forrest<sup>1</sup>, T. Bhangale<sup>1,2</sup>. 1) Bioinformatics and Computational Biology, Genentech, South San Francisco, CA; 2) Human Genetics, Genentech, South San Francisco, CA.

Acquiring an adequate number of sequenced controls is non-trivial due to high cost and the difficulty in locating ancestry-matched disease free samples. Using samples with known diseases as controls is possible but problematic, as associations cannot definitively be attributed to the cases or disease of interest. Reverse regression in the context of pleiotropy uses genotype as the dependent variable and disease indicators as the independent variables. For case-control analysis we first performed a genome-wide association study with our disease of interest compared against all other diseases (acting as controls). Then, in order to ensure that associations were due to the disease of interest, we implemented reverse regression (with genotype for common variants or burden score for rare variants as the dependent variable), covariates (such as age, sex, and eigenvectors), and disease indicators relative to the disease of interest followed by model selection. For a given variant, the subset of disease indicators selected determined which disease the variant was associated with. For common variants, we tested reverse binomial regression followed by model selection on a 30x whole genome sequenced dataset jointly genotyped using GATK best practices (n=6,585). In this dataset, Asthma (n=3,225) was the disease of interest, and Rheumatoid Arthritis (RA, n=2,185) and Age-Related Macular Degeneration (AMD, n=1,175) samples acted as controls. We found that an indicator for AMD best explained the known AMD loci CFH and ARMS2-HTRA1 and that the known Asthma locus TSLP was attributed to Asthma. For rare variants, associations were screened using reverse logistic regression with burden score as the dependent variable. This was tested in a 30x whole exome sequenced jointly genotyped dataset (n=15,885) where RA (n=2,299) was the disease of interest and samples from eight diseases were used as controls. Of the 17,957 genes tested with rare variants, we found evidence 926 of these were associated with disease(s) other than RA. As examples, the genes C3, ARMS2, and CFH were attributed to AMD and the gene MUC5AC was attributed to IPF. Simulations were used to assess power.

**Estimating cell-type-specific DNA methylation effects in the presence of cellular heterogeneity.** Y. Feng<sup>1</sup>, L. Liang<sup>1,2</sup>. 1) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA.

DNA methylation is an epigenetic modification that controls cell lineage and regulates gene expression. Signatures of DNA methylation differ across tissues and cell types, and cell composition can largely confound the association between phenotype and methylation when samples consist a mixture of cell populations (e.g. whole blood). Many statistical methods have been developed to adjust for this potential bias. More importantly, examining cell-type-specific DNA methylation effects can help identify the causal cell type(s) to follow up and gain insight into the underlying biology. However, purified cell types are usually not available in large scale studies due to impediment cost. In this work, we proposed a method to estimate cell-specific methylation-phenotype associations from unsorted whole tissue data where cell type proportions are also available. We used a framework that combines Monte Carlo EM algorithm and Metropolis-Hastings sampler to recreate the unobserved cell-specific methylation and to estimate its effect on phenotypes. Through simulations, we demonstrated that the method can successfully identify the true effects under various parameter settings, even when the causal cell type is relatively rare. Application to an Illumina HumanMethylation27 dataset showed that cell-specific methylation pattern decomposed from whole blood using the algorithm matches the directly measured methylation status in purified cell types. The method can be readily applied to existing EWAS datasets and is free of bias due to cell type distribution.

**Generalizing genetic risk scores from Europeans to Hispanics/Latinos.**

T. Sofer<sup>1</sup>, K. Grinde<sup>1</sup>, Q. Qi<sup>2</sup>, T. Thornton<sup>1</sup>, S. Liu<sup>3,4</sup>, A. Shadyab<sup>5</sup>, K.H. Chan<sup>6</sup>, A. Reiner<sup>7</sup>. 1) Biostatistics, University of Washington, Seattle, WA; 2) Epidemiology and Population Health, Albert Einstein College of Medicine, New York; 3) Epidemiology, Brown University School of Public Health, Rhode Island; 4) Medicine, Alpert School of Medicine, Brown University, Rhode Island; 5) Division of Epidemiology, Department of Family Medicine and Public Health, University of California, San Diego School of Medicine, California; 6) Laboratory of Molecular Epidemiology and Nutrition, Department of Epidemiology, Brown University, Rhode Island; 7) Department of Epidemiology, University of Washington, Washington.

**Introduction:** Genetic risk scores (GRSs) are constructed by taking the simple or the weighted sum of all trait-increasing alleles, the latter with weights equal to the estimated effect sizes of the variants. GRSs are widely used in studies involving trait or risk prediction and Mendelian randomization. Single nucleotide polymorphisms (SNPs) used in the GRSs and their weights are often based on results from genome-wide association studies (GWASs), most of which were conducted in populations of European ancestry (EA). However, optimal GRSs may differ between Hispanic/Latino and EA populations due to differences in linkage disequilibrium (LD) structure, gene-environmental interactions, and allelic heterogeneity. **Methods:** We investigated methods for constructing GRSs in samples of Hispanics/Latinos by combining information from results of GWAS in large EA populations with results from GWAS in a medium-sized study of Hispanics/Latinos. We studied approaches for selection of both SNPs and weights in constructing the GRSs. We built GRSs for a few anthropometric, blood cell count, and blood pressure (BP) traits using publicly available summary statistics from GWAS in EA studies and the Hispanic Community Health Study/Study of Latinos HCHS/SOL, (n=12,784). We evaluated the performance of these GRSs in an independent study of 3,582 Hispanic women from the Women's Health Initiative. **Results:** For anthropometric traits (height, BMI, waist circumference, waist-to-hip ratio, and hip circumference), selecting SNPs based on the EA GWAS results or on the meta-analysis of the EA GWAS and the HCHS/SOL GWAS (dubbed Meta) performed equally well. Using SNP weights calculated in META was slightly better. For BP traits (Systolic-, Diastolic-, mean arterial-, and pulse-pressure), selection of SNPs using EA GWAS performed poorly, unless SNP weights were derived from the effect sizes estimated in the HCHS/SOL. When selecting SNPs based on Meta, GRSs were more robust to weight selection. For blood count traits (platelet, white blood cells, and hemoglobin counts) GRSs, using the effect sizes from the HCHS/SOL as weights was beneficial for all approaches of SNP selection. **Conclusion:** Variant selection for a GRS based on the EA GWAS performed well, as long as the SNP weights were derived from the Hispanics/Latinos study (i.e., for blood pressure and blood count traits), or in the meta-analysis of the EA study and the Hispanics/Latinos study (i.e., for anthropometric traits).

**Imputation of exome array variants to the Haplotype Reference Consortium (HRC).** S. Bormotti<sup>1</sup>, A.P. Klein<sup>1,2,3</sup>, C. Vergara<sup>4</sup>, C. Valencia<sup>1</sup>, B.E.K. Klein<sup>5</sup>, K.E. Lee<sup>5</sup>, R. Klein<sup>5</sup>, P. Duggal<sup>1</sup>. 1) Department of Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Oncology, Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, MD; 3) Department of Pathology, Johns Hopkins School of Medicine, Baltimore, MD; 4) Division of Infectious Diseases, Johns Hopkins University School of Medicine, Baltimore, MD; 5) Department of Ophthalmology and Visual Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI.

Exome arrays are a cost-effective alternative to exome sequencing for interrogating less frequent variants. To assess imputation quality and to determine if genome-wide coverage of the exome array can be improved, we imputed 1,871 European-Americans from the Beaver Dam Eye Study who had been genotyped on the Illumina exome array (95,376 variants) to the Haplotype Reference Consortium reference panel using SHAPEIT2 and Minimac3 on the Michigan Imputation Server. Two common metrics were used to assess imputation quality: empirical  $R^2$  (Emp $R^2$ ) and imputation  $R^2$  (Imp $R^2$ ). Emp $R^2$  is the masked squared correlation between imputed dosages and actual discrete allelic dosages obtained from the exome array. Imp $R^2$  is the squared correlation between imputed genotypes and true, unobserved genotypes. Using an Imp $R^2$  of 0.6, the imputed dataset included 1,024,985 variants. Imputation quality increased with increasing minor allele frequency (MAF). Common variants (MAF > 0.05) and rare variants (MAF < 0.01) had a mean Imp $R^2$  of 0.99 and 0.92, respectively. Mean Emp $R^2$  was lower for common variants (mean Emp $R^2$  = 0.66) compared to rare variants (mean Emp $R^2$  = 0.79). The imputed geographic coverage was 1.8 variants per 5 kb. While coverage was dense in regions originally targeted by the exome array, regions like the short arm of chromosome 22 with no exome array variants were not imputed. Overall, the total number of high quality variants increased 10-fold. These metrics consistently suggest the exome array performed well in spite of its low marker density when imputed to the HRC, but they show opposing trends with MAF. The increasing Imp $R^2$  with increasing MAF is expected. The high Imp $R^2$  among rare variants in particular may reflect the strong number of less frequent and rare variants on the exome array. The decreasing Emp $R^2$  with increasing MAF suggests that reference alleles of rare variants are easier to correctly impute by chance alone, which may indicate a weakness of this metric. Moreover, this metric treats exome array genotypes as a gold standard, which may not be true. While both metrics are informative, the Imp $R^2$  appears more useful. These results indicate imputation of exome array variants could enhance our ability to detect associations with a larger number of variants, including common variants, in the exome. However, these imputed variants do not provide complete genome-wide coverage and should not be considered as a comprehensive representation of the genome.

**Fast permutation tests and related methods for association between rare variants and binary outcomes.** A. Sondhi, K.M. Rice. Department of Biostatistics, University of Washington, Seattle, WA.

In large scale genetic association studies, a primary aim is to test for association between genetic variants and a disease outcome. The variants of interest are often rare, and appear with low frequency among subjects. In this situation, statistical tests based on standard asymptotic results do not adequately control the Type I error rate, especially if the case:control ratio is unbalanced. In this paper, we propose the use of permutation and approximate unconditional tests for testing association with rare variants. We use novel analytical calculations to efficiently approximate the true Type I error rate under common study designs, and in numerical studies show that the proposed classes of tests significantly improve upon standard testing methods. We also illustrate our methods in data from a recent case-control study, for genetic causes of a severe side-effect of a common drug treatment.

**Epistasis detection for human complex diseases in structured populations.** K. Van Steen<sup>1,2,3</sup>, K. Chaichoompu<sup>1</sup>, F. Abegaz<sup>1</sup>. 1) GIGA-R Medical Genomics - BIO3, University of Liege, Liege, Liege, Belgium; 2) WELBIO, University of Liège, Liège, Belgium; 3) Department of Human Genetics, University of Leuven, Leuven, Belgium.

Epistasis, or interaction between genes, has been identified as a component of complex phenotypes in a number of studies. When explaining multifactorial trait variation in humans, gene-gene interactions should not be ignored and potentially complex population-dependent modes of inheritance need to be assumed. Even simple genetic diseases may be complex. For example, Mendelian disorders such as Hirschsprung's disease and cystic fibrosis are documented examples of epistasis where modifier genes have been identified to affect phenotypic differences. In general, epistasis studies help to identify novel drug targets and biomarkers relevant to the underlying mechanisms of disease that are not captured by single locus analysis. Moreover, there have been various studies to find pharmacogenetic evidence of epistatic interactions underlying drug resistance, for example, in malaria<sup>1</sup>, epilepsy<sup>2</sup> and influenza<sup>3</sup>. Despite the fact that more and more researchers explore epistasis or genome-wide association interaction (GWA) studies in an attempt to discover more of the hidden or missing heritability of complex traits, there are still several important challenges and considerations to bear in mind. This study aims to investigate the effect of population substructures and admixture on epistasis detection and to develop and apply remedial measures to confounding by shared genetic ancestry in epistasis analyses. Both real-life data and synthetic data will be used for illustration. Starting point is the versatile epistasis analysis tool Model-Based Multifactor Dimensionality Reduction (MB-MDR)<sup>4</sup>. It is non-parametric in that it does not make any assumptions about the epistasis inheritance model and has several advantages over classic regression-based detection tools. **References** 1. **Leveraging polygenic functional enrichment to improve GWAS power.** G. Kichaev<sup>1</sup>, G. Bhatia<sup>2</sup>, S. Gazal<sup>2</sup>, P.R. Loh<sup>2</sup>, K. Burch<sup>1</sup>, M. Kumar<sup>2</sup>, A. Scoech<sup>2</sup>, B. Pasaniuc<sup>1,3</sup>, A.L. Price<sup>2,4</sup>. 1) Inter-departmental Program in Bioinformatics, University of California, Los Angeles, Los Angeles CA, 90024 USA; 2) Department of Biostatistics, Harvard T.H. Chan School of Public Health. Boston MA, 02115 USA; 3) Department of Human Genetics, University of California, Los Angeles, Los Angeles CA, 90024 USA; 4) Department of Epidemiology, Harvard T.H. Chan School of Public Health. Boston MA, 02115 USA.

Functional genomics data has the potential to increase GWAS power by identifying SNPs that have a higher prior probability of association. In this work, we introduce a powerful association method that discretizes SNPs based on the extent to which they tag functional annotations that are enriched for heritability. Roughly, we stratify SNPs into bins of expected chi-squared statistic from stratified LD score regression (Finucane et al. 2015 Nat Genet) and then apply p-value weights that correspond to the expected fraction of rejections within a bin. Our method operates directly on summary statistics and outputs well-calibrated p-values -- in contrast to Bayesian approaches (Pickrell 2014 AJHG). We assessed false-positive rate and power using simulations with UK Biobank genotypes (N=113K). We used functional enrichment from the baselineLD model (Gazal et al. biorxiv) to inform the genetic architecture of the simulated traits. We compared our methodology to three FDR-controlling procedures that incorporate prior information: stratified FDR (Sun et al. 2006 Genetic Epi), Grouped Benjamini-Hochberg (Hu et al. 2010 JASA) and Independent Hypothesis Weighting (Ignatiadis et al. Nat Methods 2016). We find that our method correctly controls false positives, whereas the other three methods had false-positive rates at null loci 3-6 times greater than expected. At causal loci, our method attains a 10-30% increase in the number of independent loci, depending on the polygenicity of the simulated trait. We applied our method to 49 diseases and complex traits for which summary statistics were available in large sample size (N=26K-330K). We identified 218 new GWAS risk loci at genome-wide significance ( $P=5 \times 10^{-8}$ ). For five of these traits, we were able to obtain independent GWAS summary statistics for replication; the index variants at 55 novel risk loci had a highly significant replication slope (0.58,  $P = 2 \times 10^{-16}$ ), with 49 of 55 loci replicating at  $P < 0.05$ . In conclusion, we have shown that leveraging polygenic functional enrichment using our method robustly increases GWAS power. .

**Background** Successful clinical reporting of genetic sequencing results relies on the accuracy and consistency of variant interpretation. Standards and guidelines for the interpretation of sequence variants have been published by the American College of Medical Genetics and Genomics (ACMG) and the Association for Molecular Pathology (AMP). Our goal was to improve our variant interpretation process for inherited disorders by applying the published practice guidelines, enriching with gene specific rules and defined laboratory policies to develop an evidence-based semi-quantitative scoring tool. **Results** The scoring tool, developed for clinical use, guides the variant curator to enter applicable evidence for specific variants using a quantitative score for each criterion predefined in the tool. As a result, appropriate contextualized evidence is captured in a more robust and semi-automated fashion to enable the establishment of formalized algorithmic reasoning. Once all the evidence is entered into the tool, a pathogenicity score for the variant is generated. Final review and variant score approval is required. A subset of our variant list database ~1000 variants in 229 genes was classified using this tool. Variant curation was conducted by multiple curators to measure inter-user differences. Variants were curated in parallel with and without the scoring system based on ACMG evidence levels. For the vast majority of variants (~94%), the classification obtained using ACMG guidelines matched the scoring tool results. Approximately 3% of the discordant results were due to applying gene specific rules noted in our laboratory policy. The remaining discordance is within acceptable limits specified in guidelines. **Conclusions** Published guidelines provide a consensus and outline for interpreting sequence variation for clinical sequencing. Our laboratory developed tool creates more consistency between curators by robust implementation of guidelines. It also allows for gene-specific and laboratory specific standard policies to be put in place. Furthermore, this tool facilitates recuration of variants as new evidence accumulates in the literature due to the additive nature of the scoring system.

**2968W****POLARIS: Polygenic LD-Adjusted Risk Score approach for analysis of GWAS data.**

*E. Baker*<sup>1</sup>, *K.M. Schmidt*<sup>2</sup>, *R. Sims*<sup>1</sup>, *P. Holmans*<sup>1</sup>, *M.C. O'Donovan*<sup>1</sup>, *J. Williams*<sup>1</sup>, *V. Escott-Price*<sup>1</sup>. 1) Institute of Neuropsychiatric Genetics and Genomics, Cardiff University, Cardiff, UK; 2) School of Mathematics, Cardiff University, Cardiff, UK.

Polygenic risk scores (PRS) provide a method for combining information from individual SNPs into a single measure of risk allele burden. In its most widely used form, PRS have been applied to genome wide SNP data where they can capture a useful fraction of genetic liability to polygenic traits. PRS assume independence between SNPs, and thus linkage disequilibrium (LD) pruning is required to use this approach. We propose the adaptation of PRS with an additional component of adjustment for LD; this informs the analysis with previously reported effect sizes of a SNP's association to disease, and accounts for LD between SNPs. We call this method POLARIS: POLygenic Linkage disequilibrium-Adjusted Risk Score. POLARIS identifies the LD structure of SNPs in the individual genotype data using spectral decomposition of the SNP correlation matrix and adjusts the effect sizes from the summary statistic data used in the risk score. POLARIS scores are calculated per subject and the overall association to disease is determined using logistic regression on the adjusted polygenic risk score and additional population covariates. LDpred is an alternative method which also adjusts effect sizes for LD structure. LDpred uses a Bayesian approach to estimate the posterior mean effect sizes from the summary statistic data and the LD information of the SNPs. We used simulations to compare the Type I Error of POLARIS and of standard PRS to assess the LD adjustment. The power between POLARIS and PRS is also compared in real data. Since the general concept of  $\beta$  adjustment in LDpred is similar to POLARIS, the  $\beta$  adjustments of POLARIS and LDpred are compared in both simulated and real data. We observed that POLARIS successfully adjusts for LD between SNPs since the inflated Type I Error observed using standard PRS in the presence of LD is reduced. POLARIS also has higher power than standard PRS, particularly when higher ( $p > 0.1$ ) inclusion thresholds are used in marker selection. LDpred, like POLARIS, does not adjust the  $\beta$  values for independent SNPs. In our simulations, LDpred had some sensitivity to the sample size of the data used to estimate LD; larger sample sizes result in far less pronounced  $\beta$  adjustments. In comparison, the  $\beta$  adjustment in POLARIS is largely unaffected by the sample size of the data used to estimate LD.

Recently, genetics research has seen a surge of statistical approaches for fine-mapping of causal variants that work on summary statistics from Genome-Wide Association Studies (GWAS). All these approaches require information about the Linkage Disequilibrium (LD) between the variants. Unfortunately, for fine-mapping from summary statistics of large GWAS meta-analyses, publicly available reference panels are too inaccurate to provide the LD. GWAS consortia are therefore conducting fine-mapping 1) by meta-analyzing conditional analysis results from participating studies requiring multiple rounds of time-consuming coordination and repeated analysis efforts, 2) by using meta-analyzed summary statistics under the assumption of a single causal variant in the genomic region even when multiple causal variants may be present, or 3) by using genotype data from one study to obtain LD, which may be inaccurate. We introduce a new idea of sequential fine-mapping that we have implemented in the FINEMAP software. Sequential fine-mapping is a message-passing procedure where the fine-mapping output from the preceding study serves as an input for the subsequent study. This way sequential fine-mapping 1) circumvents the need of sharing LD, 2) requires only minimal communication between studies and no repeated analysis efforts while it still 3) enables fine-mapping down to any allele frequency by using summary statistics locally together with LD from the original GWAS data. We demonstrate with simulations over 10 GWAS regions and a meta-analysis of body mass index combining the UK biobank with six cohorts from Finland and The Netherlands that 4) sequential fine-mapping is as accurate as fine-mapping from meta-analyzed summary statistics and pooled LD. As an important practical result for ongoing GWAS meta-analyses we show that sequential fine-mapping can be more accurate than fine-mapping from meta-analyzed summary statistics assuming a single causal variant or using one study to obtain LD. In a meta-analysis of the association between the *APOE* locus and LDL-C, sequential fine-mapping identified two well-known missense variants (rs7412 and rs429358), a hepatic control region polymorphism and two novel SNPs. The same 5-SNP configuration was verified by meta-analyzing conditional analysis results whereas fine-mapping the whole locus jointly using LD from the largest study missed rs429358 and the approach of assuming a single causal variant highlighted only rs7412.

## 2970F

**A meta-analysis strategy based on the SPA test to combine multiple PheWAS studies.** R. Dey<sup>1,2</sup>, S. Lee<sup>1,2</sup>. 1) Biostatistics, University of Michigan, Ann Arbor, MI; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

With phenome-wide association studies (PheWASs) gaining increasing attention in the genomics literature for unraveling novel genetic variants associated with clinical phenotypes, methods to combine multiple PheWAS results for improved power is of great interest. Because PheWAS can test 1000s of binary phenotypes, and most of them have unbalanced (case:control = 1:10) or often extremely unbalanced (case:control = 1:600) case-control ratios, very few methods can provide well-calibrated tests for associations. For example, traditional p value-based meta-analysis often results in very conservative or anti-conservative type I error rates in such unbalanced scenarios. We propose a meta-analysis strategy to combine multiple PheWAS results using the saddlepoint approximation-based score test method (SPA). Our method involves sharing an approximation of the distribution of the score test statistic from each study using cubic Hermite splines. It can adjust for covariates and control type I error rates even when the case-control ratios in the individual studies are extremely unbalanced. We compare our proposed method with traditional p value-based meta-analysis strategies, and demonstrate the superior performance of our proposed method using numerical simulations and real data applications.

**Admixture mapping: Controlling for multiple testing and spurious associations in the presence of population structure.** K. Grinde, S.R. Browning. Department of Biostatistics, University of Washington, Seattle, WA.

Admixture mapping in populations with mixed ancestry is a powerful approach for identifying genetic variants associated with complex traits. Genome-wide admixture mapping scans are being employed more and more frequently in recent years, due in part to technological advances and growing international effort to increase the diversity of genetic studies. However, many open questions remain about appropriate implementation of admixture mapping studies, including how best to control for multiple testing and/or spurious associations in the presence of heterogeneous global ancestry proportions (i.e., population structure). In this study, we extend an existing theoretical framework to characterize the pattern of admixture linkage disequilibrium in admixed populations with arbitrary population structure. This theoretical framework motivates our derivation of admixture mapping significance thresholds that control family-wise error rate in the presence of population structure, as well as our proposal of approaches to control for spurious associations induced by population structure. We validate our proposed significance thresholds and population-structure-adjustment approaches via simulation studies and application to genotype data from 8,421 unrelated African American women from the Women's Health Initiative SNP Health Association Resource (WHI SHARe) study. Our theoretical work and data analyses demonstrate that population structure in admixed populations induces long-range correlation in local ancestry, which can in turn cause spurious associations if admixture mapping models do not appropriately account for population structure. We highlight the critical importance of adjusting for global ancestry in admixture mapping studies to control for spurious associations caused by this long-range admixture linkage disequilibrium. Furthermore, we show that particularly careful consideration is needed in data analyses to appropriately adjust for heterogeneous global ancestry and avoid spurious associations. Our findings hold many practical implications for researchers regarding best practices in admixture mapping studies in admixed populations with population structure. 1. Siegmund, David, and Benjamin Yakir. *The Statistics of Gene Mapping*. Springer, 2007.

**Incorporating multiple functional annotations to infer trait-relevant tissues in genome-wide association studies.** X. Hao<sup>1,2</sup>, P. Zeng<sup>1,2</sup>, X. Zhou<sup>1,2</sup>. 1) Department of Biostatistics, University of Michigan, Ann Arbor, MI 48109, USA; 2) Center for Statistical Genetics, University of Michigan, Ann Arbor, MI 48109, USA.

Genome-wide association studies (GWASs) have identified many disease associated loci, the majority of which have unknown biological functions. Understanding the biological mechanism underlying trait associations requires the identification of trait-relevant tissues, as the effects of genetic variants often act through a tissue-specific fashion. Recent computational and experimental studies have produced a rich category of SNP annotations, with which trait-relevant tissues can be inferred. However, existing methods for trait-relevant tissue inference can only make use of one annotation, and examining one annotation at a time is suboptimal as this approach fails to account for other annotations that can contain complementary information. Here, we develop a simple extension of the commonly used linear mixed model to jointly model multiple annotations with GWAS traits to facilitate the identification of trait-relevant tissues. We also develop an accompanying algorithm based on the widely used generalized estimating equation (GEE) framework for parameter inference. GEE allows us to perform inference using summary statistics and naturally accounts for genetic correlation due to linkage disequilibrium. With simulations, we show that, compared with using a single annotation alone, using multiple annotations jointly can improve power for identifying the correct trait-relevant tissues. Because of a close link between our method and the commonly used SNP set test SKAT, we are also able to exploit parameter estimates from the inferred trait-relevant tissues to construct more powerful SNP set tests in new association studies. We apply our method for an in-depth analysis of 43 traits from 26 GWASs using tissue-specific annotations in 105 tissue types derived from ENCODE and Roadmap. Our results reveal new patterns of relationship among traits in terms of their tissue relevance footprint, pinpoint important annotations that are particularly informative of trait-tissue relationship, and illustrate how parameter estimates from the inferred trait-relevant tissues can lead to more powerful gene set tests in the Wellcome trust case control consortium study.

**2973F****Increasing the power of meta-analysis of genome-wide association**

**studies to detect heterogeneous effects.** C.H. Lee<sup>1</sup>, E. Eskin<sup>2,3</sup>, B. Han<sup>1</sup>. 1) Department of Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center, Songpa-gu, Seoul 138-736, Korea; 2) Department of Computer Science, University of California, Los Angeles, CA 90095, USA; 3) Department of Human Genetics, University of California, Los Angeles, CA 90095, USA.

**Motivation:** Meta-analysis is essential to combine the results of genome-wide association studies (GWASs). Recent large-scale meta-analyses have combined studies of different ethnicities, environments, and even studies of different related phenotypes. These differences between studies can manifest as effect size heterogeneity. We previously developed a modified random effects model (RE2) that can achieve higher power to detect heterogeneous effects than the commonly used fixed effects model (FE). However, RE2 has some limitations. First, RE2 cannot perform meta-analysis of correlated statistics, which are found in recent research designs. For example, in cross-disease meta-analyses, it is common that some controls are used in more than one studies, which can cause correlations of statistics. The second limitation of RE2 is that the identified variants often overlap with those found by FE.

**Results:** Here, we propose RE2C, which increases the power of RE2 in two ways. First, we generalized the likelihood model to account for correlations of statistics to achieve optimal power, using an optimization technique based on spectral decomposition for efficient parameter estimation. Our optimization technique utilizes the properties of restricted maximum likelihood function (Patterson and Thompson, 1971) to reduce the number of unknown parameters of the likelihood function into one, which resulted in a dramatic reduction in computation time. Second, we designed a novel statistic to focus on the heterogeneous effects that FE cannot detect, thereby, increasing the power to identify new associations. We developed an efficient and accurate p-value approximation procedure using analytical decomposition of the statistic. In simulations, RE2C achieved a dramatic increase in power compared with the decoupling approach (71% vs. 21%) when the statistics were correlated. Even when the statistics are uncorrelated, RE2C achieves a modest increase in power. When we applied RE2C to the cross-disease study data of Parkinson's disease (PD) and Alzheimer's disease (AD) by Moskvina et al. (2013), we observed considerable improvements in association p-values relative to the competing approaches at the pleiotropic loci with heterogeneous effects. RE2C is highly efficient and can meta-analyze one hundred GWASs in an hour. **Availability:** The software is freely available at <http://software.buhaman.com/RE2C>.

**2974W****Integrative analysis of GWAS summary statistics and imputed gene expression in 44 tissues deciphers genetic architecture for many complex traits.** M. Li, Q. Lu, Y. Hu, H. Zhao. Yale University, New Haven, CT.

Genome-wide association studies (GWAS) have been successful in identifying DNA variants associated with complex traits. Enrichment of these variants in regulatory regions in the genome suggests the importance of genetically predisposed RNA transcription in disease etiology. In order to understand the architecture of gene expression's mediation effects in complex traits, we proposed **Gene-based LD Score Regression (GLDSR)** to estimate gene-mediated heritability using GWAS summary statistics and imputed gene expression. The method relies on the idea that linkage disequilibrium (LD) between eQTL and other SNPs contribute to the significance of test statistics in GWAS. Jointly modeling SNP-level test statistics and LD provides an estimate of gene-mediated heritability, while distinguishing it from effects of other biological mechanisms. We first evaluated the performance of GLDSR through simulation, which showed that the method provided unbiased estimation of gene-mediated heritability in a range of settings. We then applied our method to summary statistics of 68 GWAS traits (N = 5.1 million) with gene expression imputed in 44 tissues using GTEx data. Our results demonstrate that GLDSR provides robust estimation even when the sample size of GWAS was relatively small. We found that the overall mean proportion of heritability mediated by gene expression across tissues and traits was 0.075 (sd = 0.006), with 0.178 (sd = 0.013) in the most relevant tissue across traits. By comparing the estimation across 44 tissues, we found evidence suggesting that the expression-mediated SNP effect was cross-tissue in most of the psychiatric traits, but tissue-specific in most of the immune and metabolic traits. We further explored the method on multiple immune diseases including Crohn's disease, eczema, rheumatoid arthritis, systemic lupus erythematosus and ulcerative colitis. Blood tissue has the highest gene-mediated heritability estimation for all the diseases, suggesting our method is capable of identifying the most relevant tissue to disease.

**A hierarchical clustering method for joint analysis of multiple phenotypes.** *X. Liang, Q. Sha, Y. Rho, S. Zhang.* Mathematical Sciences, Michigan Technological University, Houghton, MI.

Genome-wide association study (GWAS) has become a very effective research tool to identify genetic variants underlying various complex diseases. In spite of the success of GWAS in identifying thousands of reproducible associations between genetic variants and complex disease, in general, the association between genetic variants and each phenotype is usually weak. It is increasingly recognized that joint analysis of multiple phenotypes can be potentially more powerful than the univariate analysis, and shed new light on underlying biological mechanisms of complex diseases. In this paper, we develop a hierarchical clustering method (HCM) for joint analysis of multiple phenotypes in association studies. The proposed method applies a dimension reduction technique by selecting a representative phenotype for each cluster of phenotypes. Then, we can use existing methods to test the association between genetic variants and the representative phenotypes rather than the individual phenotypes. We perform extensive simulation studies to compare the powers of Multivariate Analysis of Variance (MANOVA), joint model of Multiple Phenotypes (MultiPhen), and Trait-based Association Test that uses Extended Simes procedure (TATES) using HCM with those of without using HCM. Our simulation studies show that using HCM is more powerful than without using HCM in most scenarios.

**Testing for goodness rather than lack of fit of a X-Chromosomal SNP to the Hardy-Weinberg Model.** *S. Wellek<sup>1</sup>, A. Ziegler<sup>2</sup>.* 1) Dep. of Biostatistics, CIMH Mannheim/Univ. of Heidelberg, Mannheim, Germany; 2) Prof. Dr. Andreas Ziegler, Moenring 2, D-23560 Luebeck.

The problem of checking the genotype distribution obtained for some diallelic marker for compatibility with the Hardy-Weinberg equilibrium (HWE) condition arises also at loci on the X chromosome. In that case the genotypes which can be discriminated in terms of the marker depend on the sex of the individual under study: for females, the data generated through determining the genotype are trinomial as in the case of an autosomal locus, whereas for males a binomial proportion is observed. Like in genetic association studies with autosomal SNPs, interest is typically in establishing approximate compatibility of the observed genotype frequencies with HWE which requires to replace traditional methods tailored for detecting lack of fit to the model with an equivalence testing procedure to be derived by treating approximate compatibility with the model as the alternative hypothesis. The test constructed here is based on an upper confidence bound to an easy to interpret combined measure of distance between true and HWE conforming genotype distributions in female and male subjects. A particular focus is on the asymptotic distribution of the test statistic under null alternatives which is not of the usual Gaussian form. A closed sample size formula is provided and shown to behave very satisfactorily in terms of the approximation error.

**Robust genetic prediction of complex traits with latent Dirichlet process regression models.** X. Zhou, P. Zeng. Department of Biostatistics, University of Michigan, ANN ARBOR, MI.

There has been a growing interest in using genotype data to perform genetic prediction of complex traits. Accurate genetic prediction can facilitate genomic selection in animal and plant breeding programs, and can aid in the development of personalized medicine in humans. Because most complex traits have a polygenic architecture and are each influenced by many genetic variants with small effects, accurate genetic prediction requires the development of polygenic methods that can model all genetic variants jointly. Many recently developed polygenic methods make parametric modeling assumptions on the effect size distribution and different polygenic methods differ in such effect size assumption. However, depending on how well the effect size distribution assumption matches the unknown truth, existing polygenic methods can perform well for some traits but poorly for others. To enable robust phenotype prediction performance across a range of phenotypes, we develop a novel polygenic model with a flexible assumption on the effect size distribution. We refer to our model as the latent Dirichlet Process Regression (DPR). DPR relies on the Dirichlet process to assign a prior on the effect size distribution itself, is non-parametric in nature, and is capable of inferring the effect size distribution from the data at hand. Because of the flexible modeling assumption, DPR is able to adapt to a broad spectrum of genetic architectures and achieves robust predictive performance for a variety of complex traits. We compare the predictive performance of DPR with several commonly used polygenic methods in simulations. We further illustrate the benefits of DPR by applying it to predict gene expressions using cis-SNPs, to conduct PrediXcan based gene set test, to perform genomic selection of four traits in two species, and to predict eight complex traits in a human cohort.

**Estimating higher-order heritability components in GWAS data from 133,515 individuals.** S.R. McCurdy<sup>1</sup>, L.F. Barcellos<sup>1,2</sup>, O. Zuk<sup>3</sup>. 1) California Institute for Quantitative Biosciences, UC Berkeley, Berkeley, CA; 2) Genetic Epidemiology and Genomics Laboratory, Division of Epidemiology, School of Public Health, UC Berkeley, Berkeley, CA; 3) Department of Statistics, Hebrew University of Jerusalem, Jerusalem, Israel.

Most genome-wide association studies (GWAS) to date have focused on estimating the additive contributions of genetic variation to the phenotype of interest. Recent work on estimating the dominance contribution to the heritability of multiple phenotypic traits suggests that dominance frequently contributes little to the genetic variation (Zhu et al., 2015). However, higher-order dominant and epistatic contributions to the total genetic variation remain largely unexamined, in part because estimating them reliably is statistically challenging and requires very large sample sizes. Characterization of higher-order dominant and epistatic effects is important for at least two reasons: first, the characterization is a necessary step towards understanding the total genetic variation of a phenotypic trait, the broad-sense heritability; second, understanding the relative importance of the different orders of complex genetic interactions contributing to a specific trait could guide further study on specific interactions. We test and apply new methods for estimating the heritability of complex traits and diseases for general genetic architectures that include higher-order dominant and epistatic effects. We explore these methods through simulation studies of phenotypes with both dense and sparse genetic architectures, and study the sample sizes and other population parameters required to estimate the higher-order contributions reliably. We also estimate higher-order dominant and epistatic effects for dozens of human complex traits, analyzing separately phenotypes collected by the electronic Medical Records and Genomics (eMERGE) Network and the Resource for Genetic Epidemiology Research on Aging (GERA) Cohort. The eMERGE Network collected data on 41 phenotypes, including case-control disease status and continuous phenotypes such as body mass index (BMI), and single nucleotide polymorphism (SNP) genotypes imputed from the 1000 Genomes Project, for 55,029 participants. The GERA Cohort collected data on 22 case-control phenotypes and continuous phenotypes such as BMI, and collected SNP genotypes on high-density Affymetrix Axiom arrays, for 78,486 participants. These cohorts are ideal for estimating these effects due to their size and diversity.

Study of heritability of disease is essential to precision medicine efforts, allowing to determine the fraction of phenotypic variance attributable to genetic factors. However, estimation of disease heritability traditionally requires prospective family studies, with laborious patient recruitment and phenotype ascertainment, limiting sample sizes and therefore, power. Electronic Health Records (EHR) are now broadly implemented, capturing health information of thousands of patients daily, representing a novel resource for studying heritability of traits that are not usually explored. Using emergency contact data provided by millions of patients at three large academic medical centers, Columbia, Cornell and Mount Sinai, we used Relationship Inference From the EHR (RIFTEHR) to infer 7.4 million familial relationships. We validated these relationships using both clinical and genetic data sources. The relationships are consistent with clinical data and genetically-derived relatedness. We then computed disease heritability using only EHR data for 500 distinct clinical traits. To compute heritability using observational data, we need to account for ascertainment biases that vary from family to family and therefore can produce unstable heritability estimates. We developed a procedure called SOLARStrap, using repeated subsampling to produce heritability estimates that are robust to this bias. To validate the accuracy and robustness of this method, we used simulations of quantitative and qualitative traits. We found that both SOLAR and SOLARStrap produce accurate heritability estimates in the presence of random missingness; however, SOLARStrap produces accurate estimates in the presence of ascertainment bias. Overall, heritability estimates are correlated across sites (Columbia  $r=0.35$ ,  $p=1.32e-05$ , Cornell  $r=0.48$ ,  $p=8.20e-10$  and Mount Sinai  $r=0.36$ ,  $p=5.48e-03$  with other sites) and consistent with the published literature ( $r=0.45$ ,  $p=9.11e-03$ ). Using EHR for heritability studies can increase the sample size of traits previously studied, such as height ( $h^2=0.80$ ,  $CI=0.74-0.86$ ) but it can also clarify traits that are poorly studied. We computed heritability estimates for 500 traits, only 33 of which had been previously studied as part of the latest meta-analysis or identified by our literature review. We present the first systematic study of disease heritability using EHR data. These analyses provide a novel validation of the use of EHRs for genetics and disease research.

Testing for an association between a set of genetic markers and a phenotype is a fundamental question in genetic studies. Set-tests attempt to increase power in association studies by aggregating weak individual effects of the tested set of markers. When the entire genome is considered, linear mixed model (LMM) set-tests are equivalent to testing for the heritability of a phenotype, defined as the proportion of phenotypic variance explained by genetics. When evaluating the heritability of a phenotype, it is important to accurately measure the statistical significance of obtaining the estimate under the hypothesis of no true phenotypic heritability. The standard approaches for this task, as implemented in commonly used software such as GCTA, strongly rely on the LMM parametric model, and are not robust to deviations from it: studying the p-values for heritability estimates of methylation profiles of 431,366 CpG sites from a cohort of 1,799 individuals, we show that due to model mis-specification, p-values may be extremely inflated, frequently by many (e.g., 15) orders of magnitude, resulting in more than 45% possible false positives. In contrast, permutation testing is a popular nonparametric alternative, which does not require the assumption of a parametric form of the distribution of the statistic, and that it does not rely on asymptotic assumptions. Indeed, we show that permutation p-values are significantly larger than their parametric counterparts for the studied sites. Thus, we conclude that many non-heritable sites are falsely significantly heritable according to the parametric test. Permutation testing, however, is often computationally prohibitive. Here, we propose an efficient method to perform permutation testing for heritability. Our approach can rapidly identify heritable sites out of millions of sites acquired via high-throughput technologies, does not suffer from model mis-specification and is highly efficient, obtaining speedups of up to seven orders of magnitude.

**Estimating effect-size distributions using summary level statistics from genomewide association studies and projecting trajectories of future discoveries for 32 complex traits.** *Y. Zhang<sup>1</sup>, G. Qi<sup>1</sup>, N. Chatterjee<sup>1,2</sup>.* 1) Department of Biostatistics, Johns Hopkins University, Baltimore, MD; 2) Department of Oncology, Johns Hopkins University, Baltimore, MD.

**Background** Estimation of heritability based on SNP-arrays has been much focus of research in modern GWAS. While such estimates of heritability provides an understanding of the limit of GWAS to explain trait variation, further understanding of effect-size distribution, i.e. how the heritability is distributed across many GWAS markers, is critical for understanding how fast one can approach the limit as a function of sample size and also for developing more efficient approach for analysis of existing GWAS. **Method** We describe a novel likelihood based approach for analyzing summary-level data to estimate effect-size distribution of underlying susceptibility SNPs. We show that under a mixture-normal model for the effects of the genetic variants in a multivariate model, the distribution of summary-statistics can be approximated by an alternative mixture normal distributions with variance parameters depending on the sample size, LD-score and the unknown numbers of causal variants with different types of effects the individual GWAS SNPs tag, mixed according to a multinomial probability distribution of the last. The representation allows estimating parameters of the underlying effect-size distribution based on an expectation maximization (EM) algorithm. **Results** We apply the proposed methods on publicly available summary level results across 19 continuous traits and 13 diseases. Our analyses show that fairly parsimonious models for effect-size distribution, involving four or less parameters, can adequately describe distribution of p-values observed in some of the largest GWAS across almost all traits. The estimated values of the model parameters provide insights into heritability, degree of polygenicity and presence of distinct clusters of effects. Among continuous traits, we predict that, even in optimistic scenario, the sample size needed to identify SNPs that will explain 80% of GWAS heritability could be as large as 300K-500K for some of the early growth traits, between 1-2 millions for some anthropometric and cholesterol traits and into multiple millions for the remaining traits. Among disease traits, the corresponding sample size requirement could be 200K-400K for inflammatory bowel diseases, close to one million for most common adult onset chronic diseases, and between 1-2 millions for the psychiatric diseases. **Conclusion** We provide most comprehensive analysis of effect-size distribution in GWAS and accordingly provide projections for future discoveries.

**Combining sequence data from multiple studies: Impact of analysis strategies on rare variant association results.** *Z. Chen, M. Boehnke, C. Fuchsberger.* Biostatistics, University of Michigan, Ann Arbor, MI.

Although technological advances in high-throughput DNA sequencing have dramatically increased the abundance of genome and exome sequence data, individual studies often have limited power to detect association with rare and low-frequency variants. A common strategy to increase power for association is to aggregate data or results from multiple studies using joint or meta-analysis. For studying rare variants in sequence data, jointly calling and analyzing all samples together is the ideal "gold standard" strategy but is often difficult to implement due to privacy restrictions and computational burden. Here, we explore alternative strategies by comparing the gold standard against single-cohort variant calling and subsequent meta-analysis of single-cohort callsets in terms of: (1) variant detection sensitivity, (2) genotype accuracy, and (3) association power. We address these issues as a function of sequencing coverage and different software pipelines. To do so, we analyzed deep-coverage (~82X) whole exome (WES) and low-coverage (~5X) whole genome (WGS) sequence data on 2,250 European individuals from the Genetics of Type 2 Diabetes (GoT2D) study applying the broadly used GATK and GotCloud pipelines at default settings. We analyzed all 2,250 individuals jointly and then separately within 5 non-overlapping cohorts of 193 to 890 individuals determined by geographic region. We then carried out gene-based and single-variant association tests of type 2 diabetes (T2D) status for the joint and single-cohort callsets and combined the single-cohort results using fixed-effects meta-analysis. We show for deep-coverage sequencing data: (1) 93% of the detected rare single-nucleotide variants (SNVs) are found in both the joint callset and the union of single-cohort callsets; (2) non-reference concordance with a set of highly accurate genotypes is  $\geq 99\%$  for rare SNVs found in both joint and union callsets; (3) meta-analysis have similar power to joint analysis for gene-based tests (Least-square regression (LSR) slope: 0.938-1.03) but are noticeably less powerful than joint analysis for rare SNVs in single-variant tests (LSR slope: 0.837). We propose single-cohort analysis strategies as a viable alternative to joint analysis strategy for deep-coverage sequencing data with some limitations for gene-based testing: there is no information on whether rare SNVs detected in only one cohort are missing, reference, or filtered out in other cohorts.

**Pervasive pleiotropy in the human genome revealed by a novel quantitative analysis of summary association statistics.** *D.M. Jordan, M. Verbanck, R. Do. Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mt. Sinai, New York, NY.*

It is well known that a single genetic variant may have effects on multiple traits, a phenomenon known as pleiotropy. The extent and strength of pleiotropy in the human genome has far-reaching implications for the design of future genetic studies, and for our understanding of the genetic architecture of human traits. Attempts have been made to catalog multi-trait causation for all available human traits and variants, but these efforts fall short of being true systematic measurements of pleiotropy. This is largely due to the use of arbitrary and highly correlated lists of traits which overrepresent well-studied diseases and biological processes. To address this problem, we developed a novel statistical method to transform an arbitrary list of traits into a decorrelated list of independent traits, representing the true set of biological traits underlying the measured traits. Using this method, we developed statistics to quantify both the number of independent traits each variant affects and the total magnitude of effect each variant has. We used summary statistics from published genome-wide association studies of human quantitative traits, diseases, and metabolites, spanning a total of >700 traits in >5,000,000 individuals, to assign a two-dimensional pleiotropy score and an associated P-value to each of >1,000,000 genetic variants. As validation, these scores were shown to be correlated with existing, less widely applicable measures of pleiotropy and functional effect derived from gene expression. Overall, we find that approximately 27% of variants are significantly pleiotropic and 26% have significant overall functional impact, with an overlap of 19% of variants both affecting multiple traits and having a high functional impact. This represents a highly significant excess of pleiotropy, meaning that the average genetic variant affects many more traits than expected by chance. In addition, we identify hundreds of individual loci that exhibit extreme levels of pleiotropy or biological function, passing the threshold for genome-wide significance ( $P < 5 \times 10^{-8}$ ). These effectively represent genetic associations for pleiotropy and/or overall biological function. A subset of these loci have not been reported for any individual trait, and may represent previously unknown biology. In summary, our results suggest that pleiotropy is pervasive in the human genome, and evaluation of this phenomenon is crucial to understanding the biology of human traits and diseases.

**2984T**

**GWAS genes whose expression is implicated by Mendelian randomization are highly connected in tissue-specific regulatory circuits.** *E. Porcu<sup>1,2</sup>, D. Marbach<sup>2,3</sup>, A. Reymond<sup>4</sup>, Z. Kutalik<sup>2,4</sup>, eQTLGen Consortium.* 1) Center of Integrative Genomics, University of Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne Switzerland; 3) Department of Computational Biology, University of Lausanne, Lausanne, Switzerland; 4) Institute of Social and Preventive Medicine, CHUV and University of Lausanne, Switzerland.

Genome-Wide association studies (GWAS) have identified thousands of variants associated with complex traits but both the causative genes and pathways often remain unknown. Most of these variants fall into regulatory regions and overlap with expression Quantitative Trait Loci (eQTLs), indicating their potential involvement in regulation of expression. We propose an advanced summary statistics-based Mendelian Randomization (MR) approach that uses simultaneously multiple SNPs and gene expression traits as instruments and exposures, respectively. Having access to eQTLs from multiple tissues, i.e. a large-scale unpublished peripheral blood study ( $n=14,117$ ) and the GTEx consortium, enabled us to compare the resulting causal genes for a dozen of complex traits across tissues. We highlight the ambiguity on how different tissues point to different genes; for example our approach, in line with literature evidence, identifies *SORT1* expression to be causal for LDL levels specifically in liver. Furthermore, we found several examples of causally associated genes in regions with no genome-wide significant GWAS SNPs. To translate our findings into deeper understanding of biological processes, we evaluated the over-representation of our causally associated genes in biological pathways. Our findings go far beyond state-of-the-art pathway analyses in several aspects: (i) We find enrichment in trait-relevant pathways that were missed by previous studies (e.g., phospholipid metabolic process (GO:0006644) and lipid biosynthetic process (GO:0008610) for HDL); (ii) Some traits, not enriched for classical pathways, exhibit significant connectivity enrichment for tissue-specific regulatory circuits (e.g., systolic and pulse pressure-associated genes disturb regulatory modules in endothelial cells); (iii) We find stronger connectivity enrichment when using our causally associated gene-set rather than the genes scored by physical proximity to GWAS hits (e.g., genes that are causally associated with BMI show increased connectivity in regulatory circuits of hormonal glands). Our results demonstrate the importance of integrating expression data from various tissues when trying to interpret GWAS results. With the increasing number of samples and tissues, our MR approach should become a standard tool in the interpretation of GWAS results. It will yield a far deeper insight into biological mechanisms underlying complex trait, as well as new avenues of therapeutic intervention.

**2985F**

**Widespread pleiotropy confounds causal relationships between complex traits and diseases inferred from Mendelian randomization.** *M. Verbanck<sup>1</sup>, C.Y. Chen<sup>2,3,4</sup>, B. Neale<sup>2,3,4</sup>, R. Do<sup>1</sup>.* 1) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, MA; 4) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Boston, MA.

Mendelian randomization (MR) is a commonly-used method to infer causality between exposures and complex diseases. A fundamental assumption of MR is that the single nucleotide variant (SNV) used as the instrumental variable must not have pleiotropy. Pleiotropy occurs when the SNV has a direct or indirect effect on the outcome that is not mediated through the exposure. Specifically, pleiotropy can confound MR tests, leading to biased estimates and false positive causal relationships. However, the extent to which pleiotropy alters MR results between complex traits and diseases is currently unknown. We developed a method called the Mendelian Randomization Pleiotropy RESidual Sum and Outlier (MR-PRESSO) to both detect and correct for pleiotropy in multi-instrument summary-level MR testing. MR-PRESSO is a unified framework comprised of three components: 1) global detection of pleiotropy, 2) correction of pleiotropy via outlier removal and 3) testing of the distortion of the causal estimate before and after correction for pleiotropy. Through extensive simulations, we showed that our method can reliably detect and correct for pleiotropy, and thoroughly outperforms existing approaches including MR-Egger which was underpowered and the Q test which showed a severely inflated type-I error. An extensive evaluation of pleiotropy was conducted in 4,250 MR analyses from pairwise comparisons of >80 complex traits and diseases from summary level genome-wide association data. First, using a stringent Bonferroni cut-off ( $P < 1.17 \times 10^{-5}$ ), MR-PRESSO detected pleiotropy in 22 % (N = 922) of the 4,250 tests whereas MR-Egger was severely underpowered having detected none. Moreover, when restricting to significant causal relationships, MR-PRESSO detected pleiotropy at a higher rate of 41% (N = 78) of the total number of tests (N = 191). However, using the outlier detection test, MR-PRESSO was able to correct pleiotropy in approximately 47% (N = 437) of the pleiotropic relationships. Finally, at a nominal however commonly-used significance threshold of 5%, pleiotropy is responsible for up to 10% of false positive causal relationships in MR tests and significantly distorts the causal estimate by a 2.8-fold on average. In conclusion, our results demonstrate that pleiotropy is widespread and pervasive, and must be properly corrected for in order to maintain validity of MR.

**Allele specific information in Mendelian randomization.** *X. Wang<sup>1</sup>, M. Li<sup>2</sup>, N. Zhang<sup>3</sup>, D. Small<sup>1</sup>.* 1) Applied Mathematics and Computational Science, School of Art and Science, University of Pennsylvania, Philadelphia, PA; 2) Department of Biostatistics and Epidemiology, School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Statistics, The Wharton School, University of Pennsylvania, Philadelphia, PA.

Mendelian randomization (MR) is a statistical framework for quantifying the causal effect of genetic-modifiable exposure to phenotypes, in which genetic variants are used as instrumental variables (IV). The "modifiable exposure" examined by MR studies have traditionally encompassed blood pressure, obesity, smoking, alcohol intake etc. With the rapid accumulation of high throughput sequencing technologies, the exposure of interest can now encompass gene expression through the use of expression quantitative trait loci (eQTLs) as the IV. As exemplified by recent transcriptome-wide association studies (TWAS), MR offers a powerful framework for identifying and quantifying the downstream causal effects of gene expression. Sequencing technologies allow quantification of allele-specific gene expression, where the expression level of both alleles at heterozygous loci are measured for each subject. Current methods for Mendelian randomization do not take advantage of allele-specific measurements. For example, two-stage least squares (TSLS), the classical MR method, uses only total expression. We present a new framework that makes use of allele specific expression to estimate the causal effect of gene expression on quantitative phenotypes. We call this new framework allele specific Mendelian randomization (ASMR). Simulations show that ASMR gives unbiased estimate of causal effect size, and, in many cases, improves estimation precision over TSLS. By utilizing allele-specific information, ASMR reduces estimation variance and improves detection sensitivity in cases where the eQTL strength varies across subjects. We illustrate the new framework on the problem of quantifying downstream effects of lncRNA expression on mRNA expression of protein coding genes on data from the GEUVADIS consortium.

**A highly adaptive microbiome-based survival analysis method.** *H. Koh<sup>1</sup>, A.E. Livanos<sup>2</sup>, M.J. Blaser<sup>2</sup>, H. Li<sup>1</sup>.* 1) Department of Population Health, New York University School of Medicine, New York, NY; 2) Department of Medicine, Columbia University Medical Center, New York, NY; 3) Department of Medicine, New York University School of Medicine, New York, NY.

There has been increasing interest in discovering microbial taxa that are associated with human health and disease, gathering momentum through the advances in next-generation sequencing technologies. Investigators have also increasingly employed prospective study designs to survey survival (i.e., time-to-event) outcomes, but current item-by-item statistical methods have limitations due to the unknown true nature of the state. Thus, here, we propose a new adaptive microbiome-based association test for survival outcomes, namely, optimal microbiome-based survival analysis (OMiSA). OMiSA approximates to the most powerful association test in two domains: 1) microbiome-based survival analysis using linear and non-linear bases of OTUs (MiSALN) which weighs rare, mid-abundant, and abundant OTUs, respectively, and 2) microbiome-based kernel association test for survival traits (MiRKAT-S) which incorporates different distance metrics (e.g., unique fraction (UniFrac) distance and Bray-Curtis dissimilarity), respectively. We illustrate that OMiSA powerfully discovers microbial taxa whether their underlying associated lineages are rare or abundant and phylogenetically related or not. OMiSA is a semi-parametric method based on a variance-component score test and a re-sampling method; hence, it is free from any distributional assumption on the effect of microbial composition and advantageous to robustly control type I error rates. Our extensive simulations demonstrate the highly robust performance of OMiSA. We also present the use of OMiSA with real data applications.

**Lower frequency of genetic mosaicism observed on the X chromosomes of males relative to the X chromosomes of females.** *M.J. Machiela<sup>1</sup>, W. Zhou<sup>1,2</sup>, N.D. Freedman<sup>1</sup>, D. Albanes<sup>1</sup>, S.I. Berndt<sup>1</sup>, S.M. Gapstur<sup>2</sup>, M. Dean<sup>1</sup>, M. Yeager<sup>1,2</sup>, S.J. Chanock<sup>1</sup> on behalf of the Genetic Mosaicism Consortium.*

1) Division of Cancer Epidemiology and Genetics, National Cancer Institute, Bethesda, MD; 2) Cancer Genomics Research Laboratory, Leidos Biomedical Research Inc., Bethesda, MD; 3) Epidemiology Research Program, American Cancer Society, Atlanta, GA.

Genetic mosaicism is the presence of clonal populations of cells harboring post-zygotic mutations that are not present in germline DNA. Mosaic mutations range in size from single point mutations to large structural events that involve an entire chromosome. Population-based studies have detected age-related genetic mosaicism in blood and buccal derived DNA in apparently healthy individuals. Recent evidence suggests select mosaic mutations may predispose to some forms of cancer and chronic disease. Large structural (> 2 Mb in size) mosaicism of the autosomes affects approximately (1%) of adults. Mosaicism of the sex chromosomes appears more frequently, with mosaic Y loss affecting over 15% of elderly men and mosaicism of the female X chromosome observed at 4 times the base pair adjusted rate of events observed in autosomes. Interestingly, in comparison to the autosomes, mosaicism of the female X chromosome more frequently includes the entire chromosome, with a high proportion of mosaic events involving the inactivated X chromosome. To our knowledge, the frequency of mosaicism on the male X chromosome has yet to be estimated. Herein, we investigate the frequency of genetic mosaicism of the male X chromosome in a population of 42,127 males with high genotyping completion rates ( $\geq 0.98\%$ ). We systematically scanned for deviations in log R ratio (LRR) data extracted from commercially available genotyping arrays of blood or buccal derived DNA. We detected 4 (0.01%) men with evidence for large structural (> 2 Mb) chromosome X mosaicism. Furthermore, 4 (0.01%) additional men were detected with constitutional Klinefelter syndrome (XXY). Of the detected instances of male X mosaicism, all 4 events were mosaic gains and not mosaic losses. We observed 3 of the 4 mosaic gains encompassing the entire X chromosome and 1 mosaic gain affecting only the q arm of chromosome X. The lower frequency of X mosaicism in males (0.01%) relative to females (0.25%) plausibly reflects the importance of some or all of the approximately 800 genes residing on the X chromosome; the majority of which are not directly related to sex determination. Whereas in females the loss or gain of an inactivated copy of the X chromosome may be well tolerated, we hypothesize that the loss or gain of the X chromosome in males is substantially less common because such events are not well tolerated, particularly if the mosaic event involves loss of a substantial proportion of the male X chromosome.

**Identifying the clinical impact of loss-of-function intolerant genes using SKAT-O PheWAS.** R. Sivley<sup>1</sup>, W. Bush<sup>2</sup>, A. Capra<sup>3,1</sup>. 1) Biomedical Informatics, Vanderbilt University, Nashville, TN; 2) Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 3) Biological Sciences, Vanderbilt University, Nashville, TN.

Many large-scale whole-exome and whole-genome sequencing projects have recently been compiled by the Exome Aggregation Consortium (ExAC) to produce a large reference database of coding variation in human populations. Analysis of loss-function (LoF) variants in this database revealed 3,230 genes with a significant depletion of LoF variants. Despite this evidence of biological importance and many missense variants in these genes, 72% of them have no associated human disease phenotype in ClinVar or OMIM. We hypothesize that low-frequency missense variants that cause less severe perturbations of gene function may be of clinical relevance. Phenome-wide association studies (PheWAS) leverage the wealth of phenotypic information contained in electronic medical records (EMR) to evaluate the clinical impact of genetic variants. While most PheWAS have been conducted using common variants, aggregate association statistics, like the burden test and the sequence-kernel association test (SKAT), can extend this approach to evaluate the collective impact of multiple variants within a genomic region. Using gene-based SKAT-O association tests and exome chip genotyping of 21,957 individuals of European ancestry from Vanderbilt's EMR-linked biobank (BioVU), we apply PheWAS as a tool for discovering the clinical impact of low-frequency missense variation in LoF-intolerant genes.

**PheCLC: A novel statistical method for phenome-wide association studies.** H. Zhu, S. Zhang, Q. Sha. Michigan Technological University, Houghton, MI.

Over the last decade, genome-wide association studies (GWAS) have been widely performed to identify genetic associations for many complex diseases. Typically, GWAS use a phenotype-to-genotype strategy, starting with a particular phenotype that is associated with genetic variants across the genome, and over 1,000 GWAS have been published linking thousands of statistically significant genetic variants to hundreds of human diseases and traits. A common limitation of GWAS is that they focus on only a single phenotype or a small set of phenotypes at a time. As a complement to GWAS, phenome-wide association studies (PheWAS) use a genotype-to-phenotype approach, beginning with a genotype to test for associations over a broad range of phenotypes. PheWAS were first demonstrated with electronic health record (EHR) data in 2010 and have already demonstrated their capacity to discover genetic association related to a wide range of diseases. In this article, we derived a novel and powerful multivariate method, which we referred as PheCLC, to test the association between a genetic variant with large numbers of phenotypes. Suppose that there is a certain number of phenotypic categories containing different phenotypes. PheCLC first calculates the p-values for testing the variant of interest and the phenotypes within each phenotypic category using a clustering linear combination method recently proposed by our group. Then, it combines the p-values obtained from the first step using the method similar to adaptive Fisher's combination method [Liang *et al.*, 2016, Scientific Reports 6]. We perform extensive simulation studies to compare the PheCLC method with other existing methods. The results show that our proposed PheCLC method controls the type I error rates very well and has outstanding performance over other methods.

**Simulation study on different sample sizes for rare-variant association analysis.** X. Zhang<sup>1</sup>, A.O. Basile<sup>2</sup>, S.A. Pendergrass<sup>3</sup>, M.D. Ritchie<sup>3</sup>. 1) The Huck Institute of the Life Sciences, The Pennsylvania State University, University Park, PA; 2) Department of Biochemistry, Microbiology and Molecular Biology, The Pennsylvania State University, University Park, PA; 3) Biomedical and Translational Informatics Institute, Geisinger Health System, Danville, PA.

The development of new sequencing techniques and statistical methods for rare variant analyses provide opportunities for identifying the impact of rare variation on traits and outcomes. However, it is important to characterize the impact of sample size, case numbers, and the balance of the numbers of case vs controls for burden and dispersion based low frequency variant association methods. For example, Phenome-Wide Association Studies (PheWAS) may have a wide range of case and control numbers and sample sizes across hundreds of diagnoses and traits, and with the application of these methods to rare variants it is important to understand the strengths and limitations of the analysis. We investigated the effect of these study design scenarios (sample size, case number, and ratio of cases to controls) on type I error and power for regression and SKAT based approaches. We conducted a large scale simulation of randomly selected low-frequency protein-coding regions through eleven different balanced sample size and twenty-one unbalanced sample size scenarios. We also explored the statistical performance of different minor allele frequency thresholds and effect sizes. All simulated datasets were evaluated using BioBin, a software that performs rare variant analysis burden and dispersion tests. Our simulation results demonstrate that using an unbalanced sample size has an overall higher type I error rate for both burden and dispersion tests compared with balanced samples. Interestingly, the burden (regression) test has overall higher type I error for balanced samples while SKAT has higher type I error for unbalanced samples. For scenarios that include various unbalanced sample sizes with a constant control sample size, when increasing the number of case samples, the type I error decreases and power increases. We also observed that case numbers larger than 200 yield higher power with relatively controlled type I error for both tests. Our results provide the landscape of type I error and statistical power for a wide range of sample sizes, which provide important insights for rare variant association study designs. These results can serve as a benchmark for making decisions about future PheWAS study design for rare variant studies.

**DESCEND: Expression distribution deconvolution in scRNA-seq and characterization of transcriptional bursting and expression dispersion.** J. Wang<sup>1</sup>, N. Zhang<sup>1</sup>, M. Li<sup>2</sup>, A. Raj<sup>3</sup>, J. Murray<sup>4</sup>. 1) the Wharton School, University of Pennsylvania, Philadelphia, PA, USA; 2) Biostatistics and Epidemiology, University of Pennsylvania, Philadelphia, PA, USA; 3) Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, USA; 4) Department of Genetics, University of Pennsylvania, Philadelphia, PA, USA.

Individual cells vary greatly in their gene expression levels, reflecting the dynamism of transcription across cells in a cell population. Single-cell RNA-seq (scRNA-seq) enables the quantification and comparison of much richer properties of gene expression beyond the mean, such as dispersion, burstiness, and other features of the gene expression distribution across cells. However, scRNA-seq data is very noisy, and the observed distribution is usually a poor representation of the true distribution. Here we describe DESCEND (DEconvolution of Single Cell Expression Distribution), a method that deconvolves the true cross-cell gene expression distribution from observed scRNA-seq read counts. DESCEND adopts the "G-modelling" nonparametric empirical Bayes distribution deconvolution framework (Efron 2016). Given cell-specific technical noise model, DESCEND recovers the distribution of the unobserved true expression levels and allows adjustment for covariates such as cell size or cell cycle. The accuracy of DESCEND is evaluated through RNA FISH data generated from the same cell population. It shows that DESCEND can reliably deconvolve the true gene expression distribution, leading to the improved characterization of features such as transcriptional bursting and expression dispersion. Reliable deconvolution of the gene expression distribution allows improved downstream analyses. As a first example, we show through the analysis of the Klein et al. (2015) embryonic stem cell differentiation data that dispersion measurements, such as the GINI coefficient, calculated from the recovered gene expression distribution, can be used to identify early differentiation marker genes that are otherwise missed in differential expression analysis based on the mean expression. We then apply DESCEND to characterize transcriptional bursting among cells of a fixed cell-type in data from Zeisel et al. (2015). Bursting is quantified by two parameters: active fraction (fraction of cells where the gene is expressed) and active intensity (mean expression level when the gene is expressed). We show that transcriptome-wide, in all cell types analyzed, cell size is positively correlated with both active fraction and active intensity, which is confirmed by reanalysis of the RNA FISH data. Finally, DESCEND characterizes in detail changes in active fraction and active intensity between cell types in mouse brain, after controlling for differences in cell size.

**A novel approach for parsing distribution of polygenic risk.** *L. Almasy*<sup>1,2</sup>.

1) DBHi, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Genetic risk scoring (GRS) relies on utilizing GWAS results to estimate aggregate genetic burden rather than pointing to any particular variant or gene. GRS has been widely applied and studying these aggregate genetic effects has provided insight into the architecture of multiple human phenotypes. However, GRS accounts for only a portion of the known genetic component to various complex disorders. It has been speculated that non-additive genetic components and interactions account for some of this 'missing heritability'. We propose a novel approach for assessing the impact of GRS distribution, independent of burden. We hypothesize that similar burdens of risk alleles may differentially impact liability depending on how they are distributed, with individuals whose burden of 'hits' are concentrated in fewer pathways having higher risk than those of similar GRS whose risk alleles are spread evenly across all pathways. To quantify this clustering within GRS, we construct a score, VARD, that summarizes in a single number the extent to which risk alleles distribute non-randomly across biological pathways. For each pathway,  $x$ , we count the number of possible GRS risk alleles in that pathway,  $POS_x$ . Risk alleles are defined as alleles with GWAS OR > 1 or by sign of effect for quantitative phenotypes. For each individual, we tally the observed number of risk alleles they carry in pathway  $x$ ,  $OBS_x$ . VARD for each individual is the variance across pathways in the ratio of  $OBS_x$  to  $POS_x$ . Alternatively,  $OBS_x$  and  $POS_x$  may be weighted by each SNP's GWAS effect size to reflect differing contributions of each variant to risk. To the extent that the risk alleles carried by an individual are spread evenly across pathways in proportion to the number of GRS SNPs in that pathway, we expect VARD to be small, with little variation in  $OBS_x/POS_x$  across pathways. When an individual carries more hits in some pathways than would be expected by chance, VARD is larger. Similar to the way the GRS summarizes aggregate burden of risk, VARD summarizes aggregate distribution of risk, without singling out specific pathways.

**Statistical framework for integrating biological knowledge to accelerate discovery from GWAS data.** *S. Bhattacharjee, S. Biswas, S. Pal*. National Institute of Biomedical Genomics, Kalyani, West Bengal, India.

Genome-wide Association Studies (GWAS) have successfully identified thousands of genetic polymorphisms (SNPs) to be associated with various complex diseases. For most traits, the discovered variants tend to map near genes that are clustered in few biological pathways. It therefore appears naïve to perform an unbiased GWA scan without taking pathway/network information into account. Post-hoc enrichment analysis helps in the biological interpretation of already discovered variants; it does not improve the power for novel discovery. It is well-recognized that typical GWAS are under-powered to detect all associated variants due to a huge multiple-testing burden. This is particularly true for variants that are relatively less common and/or those with weaker effects that could have been missed in GWA studies conducted thus far. Pathway/network information, if properly harnessed, has the potential to improve the power of GWAS drastically. We have developed a flexible statistical framework for incorporation of prior knowledge in various forms such as pathways and SNP annotations into GWAS. It enables 'pathway-guided SNP prioritization' thus allowing a genome-wide search to gain substantial power when the associated SNPs cluster in a few biological pathways. The method is data adaptive in the sense that in the worst case, i.e., when the pathway or other prior knowledge is non-informative, the method would behave similar to unbiased search without incurring power loss. Our framework is computationally efficient and allows incorporation of large amount of prior knowledge from various sources. Using a novel whole-genome simulation technique we simulated a large number of causal SNPs with varying degrees of connectivity in pathways. We demonstrate using simulations and real GWAS datasets that the method correctly controls type-1 error at the genome-wide scale, at the same time improving power considerably. We have developed an user-friendly R package named 'GKnowMTest' (Genomic Knowledge-guided Multiple Testing) to be freely available, where p-values of SNPs from a GWAS can be re-weighted using pathways and other annotation databases.

**Improved methods to estimate functional enrichment from genome-wide summary association data.** *K. Burch<sup>1</sup>, G. Kichaev<sup>1</sup>, B. Pasaniuc<sup>1,2,3</sup>*. 1) Bioinformatics Interdepartmental Program, University of California Los Angeles, Los Angeles, CA; 2) Department of Human Genetics, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA; 3) Department of Pathology and Laboratory Medicine, David Geffen School of Medicine, University of California Los Angeles, Los Angeles, CA.

The majority of risk variants identified through GWAS of complex diseases lie in noncoding regions of the genome, rendering biological interpretation of these loci difficult. This has motivated several large-scale efforts to extensively annotate regulatory features in a range of tissue and cell types. Methods that jointly model functional genomic data and GWAS can reveal novel biological insights about the genetic architecture of complex traits; for example, recent work has shown that the heritability of complex diseases is enriched in regulatory features of relevant tissue and cell types. However, existing methods that jointly analyze GWAS and functional annotations either use only genome-wide significant regions, assume one causal SNP per region, do not account for LD, or make prior assumptions about the distribution of SNP effect sizes. In addition, because there are thousands of highly correlated annotations publicly available, it is still unclear how to effectively leverage these data for a particular analysis. Here, we propose a method for estimating functional enrichments from genome-wide GWAS summary data that explicitly models LD and accounts for collinearity in annotations. The novelty of our method lies in the use of the truncated eigendecomposition of the LD matrix to transform the GWAS z-scores such that their underlying LD structure is removed, after which a penalized regression method is used to estimate the effects of the annotations on the de-correlated effect sizes. The resulting functional enrichments can be used to identify the most informative tissues and regulatory features for a given trait, predict the true effect sizes of causal SNPs, increase association power, and improve fine-mapping accuracy.

**HiREPRO: Evaluating Hi-C data REproducibility via Regression.** *C. Crowley<sup>1</sup>, P. Giusti-Rodríguez<sup>2</sup>, P. Sullivan<sup>2,4</sup>, M. Hu<sup>3</sup>, Y. Li<sup>1,2</sup>*. 1) Department of Biostatistics, University of North Carolina Chapel Hill, Chapel Hill, NC; 2) Department of Genetics, University of North Carolina Chapel Hill, Chapel Hill, NC; 3) Department of Quantitative Health Sciences, Lerner Research Institute, Cleveland Clinic Foundation, Cleveland, OH; 4) Department of Medical Epidemiology and Biostatistics, Karolinska Institutet, Stockholm, Sweden.

Hi-C technology is a powerful tool to measure genome-wide chromatin interactions, providing an unbiased view of chromatin spatial originations. Similar to other types of next generation sequencing technologies, such as RNA-Seq and ChIP-Seq, it is critical to rigorously evaluate the reproducibility of Hi-C data among multiple biological replicates. One unique feature of Hi-C data is that the chromatin interaction frequency between two genomic loci shows a dramatic decrease pattern with the increase of the 1D genomic distance between them. Therefore, it is necessary to control 1D genomic distance when evaluating data reproducibility. To achieve this goal, we propose HiREPRO, a zero-inflated negative binomial semi-parametric regression model to quantify Hi-C data reproducibility, while simultaneously adjusting for 1D genomic distance and multiple other confounding factors. HiREPRO provides both point and variance estimates of Hi-C data reproducibility, enabling straightforward practical interpretation. We compared HiREPRO with two other existing methods, HiCRep and HiC-Spector, using multiple deeply sequenced real Hi-C datasets in both human cell lines and primary tissues. We found that HiREPRO not only makes valid assumptions in real Hi-C data, but also provides rigorous statistical inference on Hi-C data reproducibility. More interestingly, the reproducibility estimated by HiREPRO can be used as the discrepancy metric between any two Hi-C datasets, and facilitates the downstream clustering and differential interaction analysis among multiple Hi-C datasets.

**2997F****Powerful and robust cross-phenotype association test for case-parent trios.**

*T. Fischer<sup>1</sup>, Y. Jiang<sup>2</sup>, K.A. Broadaway<sup>1,3</sup>, K.N. Conneely<sup>1,3</sup>, M.P. Epstein<sup>1,3</sup>.* 1) Dept of Human Genetics, Emory University, Atlanta, GA; 2) Dept of Biostatistics and Bioinformatics, Emory University, Atlanta, GA; 3) Center for Computational and Quantitative Genetics, Emory University, Atlanta, GA.

There has been increasing interest in identifying pleiotropic genes within the human genome that influence multiple diverse phenotypes. In the presence of pleiotropy, joint testing of these phenotypes is not only biologically meaningful but also statistically more powerful than univariate analysis of each separate phenotype accounting for multiple testing. While many cross-phenotype association tests exist, the majority of such methods assume samples comprised of unrelated subjects and therefore are not applicable to family-based designs, including the valuable case-parent trio design. In this study, we describe a robust gene-based association test of multiple phenotypes collected in a case-parent trio study. Our method is based on the kernel distance covariance (KDC) method, where we first construct a similarity matrix for multiple phenotypes and a similarity matrix for genetic variants in a gene; we then test the dependency between the two similarity matrices. The method is applicable to either common variants or rare variants in a gene and resulting tests from the method are by design robust to confounding due to population stratification. We evaluated our method through simulation studies and observed that the method is substantially more powerful than standard univariate testing of each separate phenotype. We also applied our method to phenotypic and genotypic data collected in case-parent trios as part of The Genetics of Kidneys in Diabetes (GoKinD) study and identified a genome-wide significant gene demonstrating cross-phenotype effects that was not identified using standard univariate approaches.

**2998W****Learning causal networks of molecular phenotypes with Mendelian randomization.**

*A.Q. Fu<sup>1,2,3</sup>, M.B. Badsha<sup>1,2,3</sup>.* 1) Department of Statistical Science, University of Idaho, Moscow, ID; 2) Institute for Bioinformatics and Evolutionary Studies, University of Idaho, Moscow, ID; 3) Center for Modeling Complex Interactions, University of Idaho, Moscow, ID.

It has been challenging both experimentally and computationally to elucidate the regulatory (or causal) relationships among genes, to identify the genuine target of an eQTL from multiple associated genes, or to establish causality between different biological processes (such as transcription versus DNA methylation). Correlation (or association) is often used to represent a potential causal relationship, but similar levels of correlation can arise from different causal mechanisms. Is it possible to go beyond correlation and learn causality directly from genomic data collected *in vivo*? Is it possible to establish causality for many molecular phenotypes simultaneously? Here we present MRPC, a novel algorithm based on Mendelian Randomization (MR), which uses both genotypes (SNPs, indels, and copy number variation) and molecular phenotypes (e.g. gene expression and DNA methylation), and efficiently learns a causal regulatory network (or a causal graph, which has directed edges); MR views genetic variants in a natural population as perturbations randomly performed by Nature. Our algorithm is a variation of the classical PC algorithm for learning causal graphs, and conducts a series of statistical tests for marginal and conditional independence. However, unlike other PC algorithms, our algorithm incorporates MR and fixes several issues with existing implementations, such as R packages *bnlearn* and *pcalg*, both of which have been widely used. Our method further controls the false discovery rate and reduces the impact of outliers. We performed extensive simulations and demonstrated superior performance of MRPC to *pcalg* and *bnlearn*. For example, on 1000 data sets simulated for a complex graph of 22 nodes and 23 edges with moderate signal strength and sample size, the mean distance (with standard deviation) between the inferred graph and the truth is only 2.21 (0.65) for MRPC, but 6.80 (2.08) for *bnlearn* and 8.71 (2.07) for *pcalg*. We applied MRPC to the SNP and gene expression data in yeast to replicate some of the published gene regulatory networks, to the copy number variation, gene expression and DNA methylation data of the breast cancer patients in TCGA to study the regulatory relationships among cancer genes and between transcription and methylation, as well as to the SNP and gene expression data in GEUVADIS to identify the true target of eQTLs from multiple associated genes. MRPC is implemented in an R package and freely available on GitHub.

**A test for Hardy-Weinberg equilibrium in structured populations.** *W. Hao, J.D. Storey.* Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ.

Hardy-Weinberg Equilibrium (HWE) is a general and far-reaching principle in population genetics which often serves as an assumption in statistical applications. In studies with genome-wide genotyping data such as genome-wide association studies (GWAS), it is a common procedure to test markers for HWE as a quality control step with the goal of identifying genotyping errors. A significant test provides evidence that HWE may not hold but does not determine the reason for the violation, which could be the result of effects other than genotyping error such as population structure or selection, so practitioners often employ *ad hoc* procedures to try to ensure that only genotyping errors are removed. We propose a procedure for testing for Hardy-Weinberg Equilibrium that is conditional on population structure called the "structural HWE" (sHWE) test. The sHWE test utilizes a formulation of population structure that provides a flexible approach to parameterizing allele frequencies, which can be fit using many models of structure. sHWE can be applied on a marker-to-marker basis to determine which markers violate HWE while accounting for the confounding effects of population structure. Further, the genome-wide joint distribution of sHWE p-values can be used to assess a global goodness-of-fit of the model of population structure. This allows one to choose optimal values of tuning parameters such as the latent dimensionality of a model. We demonstrate our method on several publicly available global human datasets. We first analyze these datasets independently, showing how the sHWE procedure allows one to choose the dimensionality of the population structure model. Then, we compared SNPs that are misspecified with respect to the population structure model between datasets and technologies, showing that the sHWE procedure identifies SNPs affected by genotyping errors and that results are replicable between datasets.

**PolyGEE: A generalized estimating equation approach to the efficient and robust estimation of polygenic effects in large-scale association studies.** *J. Hecker<sup>1</sup>, D. Prokopenko<sup>2</sup>, C. Lange<sup>1,2</sup>, H. Loeblein Fier<sup>1,3</sup>.* 1) Department of Biostatistics, Harvard T.H. Chan School of Public Health, Boston, USA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, USA; 3) Working Group of Genomic Mathematics, Bonn, Germany.

In order to quantify the polygenic effects, i.e. undetected genetic effects, in large-scale association studies, we propose a novel generalized estimating equation (GEE) based estimation framework. We develop a marginal model for single-variant association test statistics of complex diseases that generalizes existing approaches as LD Score regression and is applicable to population-based designs, to family-based designs or to combinations of both. We utilize and extend the standard GEE approach so that the parameters of the proposed marginal model can be estimated based on working-correlation/linkage-disequilibrium (LD) matrices from external reference panels. Our method achieves substantial efficiency gains over standard approaches while being robust to misspecification of the LD structure, i.e. the LD structure of the reference panel can differ substantially from the LD structure in the study population. In simulation studies and in applications to population-based and family-based studies, we evaluate and illustrate the features of the proposed GEE-framework. Our results suggest that the approach can be up to 100% more efficient than existing methodology. .

**Estimating genetic correlations in functionally annotated regions using genome-wide summary association statistics.** D.L. Kassler<sup>1</sup>, A.L. Price<sup>1,2</sup>, H. Finucane<sup>1,2</sup>. 1) Epidemiology Dept, Harvard T. H. Chan School of Public Health, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA.

Identifying functional annotations of the genome for which genetic correlation between traits is higher may provide more specific etiological insights. We present a new method, stratified cross-trait LD score regression, that combines features of both stratified LD score regression (Finucane et al. 2015 Nat Genet) and cross-trait LD score regression (Bulik-Sullivan et al. 2015 Nat Genet) to estimate genetic correlation for annotated regions using only GWAS summary association statistics. We regress the product of z-scores for two traits on annotation-level LD-scores, interpreting the regression coefficients as an annotation-level contribution to genetic covariance. Normalizing the weighted sum of regression coefficients by the root product of the weighted sums of per-annotation heritabilities (which can be computed using stratified LD-score regression), where weights are given by the amount of overlap between annotations, yields estimates of genetic correlation for individual annotations. Standard errors are calculated using a weighted jackknife. Early results from simulated data are promising, demonstrating the efficacy of LD score regression in recovering genetic covariance and of using the resulting regression coefficients to estimate genetic correlation for functional annotations with high heritability. We simulated traits with heritability enrichment in three overlapping annotations of different sizes, with and without enrichment of genetic correlation in two of the annotations. Our method was able to estimate genetic correlation with roughly 90% confidence interval coverage of the true value (for 95% confidence intervals), and an average bias of less than 0.01 in estimates of enriched correlation. Type 1 error was controlled. We present the results of further simulation studies, along with results from applying stratified cross-trait LD score regression to studies of various traits and annotations.

**Estimating the contribution of gene-environment interactions to phenotypic variance.** V. Laville<sup>1</sup>, Y.J. Sung<sup>2</sup>, M. Province<sup>3</sup>, J. Gauderman<sup>4</sup>, D. Chasman<sup>5</sup>, D.C. Rao<sup>2</sup>, H. Aschard<sup>1</sup> on behalf of the CHARGE Gene-Lifestyle Interactions Working Group. 1) Institut Pasteur, Paris, France; 2) Division of Biostatistics, Washington University School of Medicine, St. Louis, MO, USA; 3) Division of Statistical Genomics, Washington University School of Medicine, St. Louis, MO, USA; 4) Department of Preventive Medicine, University of Southern California, Los Angeles, CA, USA; 5) Division of Preventive Medicine, Brigham and Women's Hospital, Boston, MA, USA.

Several genome-wide Gene-by-Environment (GxE) interaction analyses have been published with the aim of identifying single genetic variants interacting with environmental exposure in human traits and diseases. Conversely, little has been done to estimate the overall contribution of GxE interactions to heritability. Indeed, GxE are often overlooked because of their limited impact on prediction models although previous work showed it may lead to more effective strategies for prevention and treatment. Following the Occam's razor principle, contribution of interaction effects to phenotypic variance is commonly estimated using an orthogonalized model where GxE contribution corresponds to the phenotypic variance explained on top of marginal genetic effects. In this model the genetic additive variance (whose standardized value is the narrow sense heritability) is measured at the mean of E, while GxE contribution to phenotypic variance ( $h^2_x$ ) captures changes in heritability that would occur with changes in the exposure variance. We propose an alternative strategy which consists of estimating the contribution of GxE to heritability ( $h^2_{NT}$ ) as the difference between the in-sample genetic additive variance and the expected genetic variance at a baseline value of the exposure. For simplicity, we first focused on quantitative outcome assuming independence between genes and the environment and independence between genetic and interaction effects. We first demonstrate analytically that  $h^2_x \leq h^2_{NT}$ . Performing series of simulations, we observed that  $h^2_x$  is very small in most scenarios even when GxE explain the majority of the phenotypic variance. On the other hand,  $h^2_{NT}$  correctly infers the contribution of GxE terms to the outcome variance. To allow the application of our method in large-scale data, we first developed an approach to approximate both parameters ( $h^2_x$  and  $h^2_{NT}$ ) using only genome-wide GxE analysis summary statistics. We also considered the special case of binary exposure where genetic additive variance can be compared between strata. We applied these strategies on real summary data from gene-smoking interactions in blood pressure in ~70,000 individuals from the CHARGE Gene-Lifestyle Interactions Working Group. Preliminary results highlighted differences up to 5.5% in genetic heritability between exposed and unexposed individuals although not significant ( $P = 0.19$ ).

**A generalized permutation testing method for binary trait association in structured samples.** *J. Mbatchou<sup>1</sup>, M.S. McPeck<sup>1,2</sup>*. 1) Department of Statistics, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL.

In testing for association between a phenotype and a predictor based on genetic or genomic data, permutation testing can be useful when a null distribution for the test statistic is not readily available. For example, such situations arise in the analysis of rare variants using adaptive tests, or in the context of correcting for multiple comparisons in genome-wide association studies. The naïve permutation approach on the phenotype vector relies on the exchangeability of the entries under the null hypothesis, an assumption that is generally not valid in the presence of population structure or related individuals. In the context of quantitative traits, a permutation-based method has been developed that incorporates the presence of important covariates and correlation in the data (Abney et al, 2002). We extend this approach to binary traits, where we account for the binary nature of the trait and the correlation structure present in the data through a quasi-likelihood framework, and generate phenotypic replicates using a transformation of the residuals that results in uncorrelated entries (hence second-order exchangeability). This approach can be used to generate phenotypic replicates in a wide range of applications involving humans or other model organisms. Simulation analyses are performed to evaluate the type 1 error rate and power performance of the proposed approach. We illustrate the application of this method in the assessment of genome-wide significance for association mapping in dogs.

**Integrative analysis of eQTL and GWAS summary statistics to identify functional relationships.** *J. Morrison, J. Marcus, N. Knoblauch, X. He, M. Stephens*. Human Genetics, University of Chicago, Chicago, IL.

Genome-wide association studies (GWAS) have successfully identified thousands of associations between genetic variants and complex traits. However, the functional mechanisms underlying most of these associations remain unclear. One way to help elucidate functional mechanisms is to combine GWAS results with gene expression data. For example, if a disease-associated variant is also associated with expression of a particular gene, then this gene might play a role in disease etiology. However, this pattern could also be caused by a pleiotropic SNP that influences disease risk through another mechanism. Methods have been proposed by Barbeira et al. (2016) and Gusev et al. (2016) that use cis (close to gene) expression quantitative trait loci (eQTLs) to impute the heritable component of gene expression in GWAS studies and estimate the correlation between imputed expression and phenotype. Imputing expression eliminates some environmental sources of noise in measured expression levels, but there are still many non-causal mechanisms that produce the shared genetic effects detected by these methods. For example, disease risk and gene expression might both depend on a third factor but not be causally related. We propose a new statistical approach based on explicit modeling of the bivariate distribution of GWAS and eQTL effects (both cis and trans) with the goal of disentangling causal and non-causal mechanisms. The intuition behind this method is that, if expression of a gene causally affects a phenotype, then every eQTL for that gene should also be associated with phenotype. Further, the eQTL and phenotype effect sizes should be correlated. Non-causal mechanisms leading to correlation result in only a small portion of eQTLs being associated with the phenotype. In simulations, our method correctly controls type 1 error and has dramatically better power than the Sherlock method of He et al. (2013) which uses the same intuition. Importantly, Sherlock and the imputation-based correlation methods can be misled by the presence of one or two pleiotropic SNPs with strong effects in both the GWAS and the eQTL study, making them prone to false positives. By analyzing patterns across all SNPs, we avoid this undesirable feature. In real GWAS and eQTL data, our method detects known relationships between traits without using the SNPs with the strongest effects, indicating that our method can be valuable even the absence of genome-wide significant associations.

**3005T****Modeling ancestry-dependent phenotypic variance increases power in multi-ethnic association studies and enables detection of variance effects.**

*S. Musharoff<sup>1</sup>, D. Park<sup>1</sup>, J. Galanter<sup>2</sup>, S. Huntsman<sup>1</sup>, C. Eng<sup>1</sup>, E.G. Burchard<sup>1,3</sup>, N. Zaitlen<sup>1</sup>.* 1) Lung Biology, University of California, San Francisco, San Francisco, CA; 2) Genentech, South San Francisco, CA; 3) Bioengineering and Therapeutic Sciences, University of California, San Francisco, San Francisco, CA.

Multi-ethnic genetic analyses are challenging due to differential genetic and phenotypic structures, but also provide unique opportunities for unravelling the architecture of complex disease. Here we consider the possibility that populations with differences in phenotypic mean also have differences in phenotypic variance. We first demonstrate that, in addition to GxG and GxE interactions, variable selective pressures directly induce changes of phenotypic variance, which can produce large differences in disease burden. We next develop an analysis method based on the double generalized linear model (ADGLM), which accounts for relationships between ancestry and phenotypic variance in genetic association studies. In realistic simulations with ancestry-variance relationships we show that linear regression and linear mixed models can give inflated or deflated association p-values. For example, simulated population-differentiated SNPs produce test statistics with a  $\lambda_{oc}$  value of 1.56 when analyzed with linear regression, while ADGLM analyses produce a  $\lambda_{oc}$  value of 1.00. Furthermore, ADGLM has better power than both tests, with increases as large as 66%, and gives unbiased parameter estimates. We applied ADGLM the Study of African Americans, Asthma, Genes and Environments (SAGE). We observed a significant association of European ancestry proportion and baseline lung function (FEV<sub>1</sub>) variance (p-value < 1.5e-2), implying differential selective pressure for this phenotype between ancestral European and African populations. Furthermore, ADGLM finds significant associations of FEV<sub>1</sub> with global ancestry, while linear regression fails to detect this known association. We next examined a methylation QTL analysis of Puerto Ricans from the Genetics of Asthma in Latino Americans (GALA) study. We detected associations of ancestry with methylation variance at 44 CpG sites (p-values < 1.6e-7), which may be due to ancestry-associated gene-environment interactions. Consistent with simulations, ADGLM identifies significant associations with methylation at 8 of ~320K sites while linear regression finds only one. In summary, we show in simulated and real data that ancestry proportion can affect phenotypic variance, linear regression and linear mixed models are miscalibrated when ancestry is correlated with variance, and ADGLM is more powerful and correctly calibrated in these situations. We conclude that ADGLM is an essential tool for genetic analyses of admixed populations.

**3006F****Y chromosome variants associate with height but not disease risk factors: The Ygen consortium.**

*N. Pirastu<sup>1</sup>, I. Gandini<sup>2</sup>, Y. Okada<sup>3,4,5</sup>, P.K. Joshi<sup>1</sup>, P. Gasparini<sup>6</sup>, M. Kubo<sup>5</sup>, T. Esko<sup>7,8</sup>, J.F. Wilson<sup>9</sup>, Y-Gen.* 1) Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, Midlothian, United Kingdom; 2) Medical Genetics, Institute for Maternal and Child Health - IRCCS Burlo Garofolo, Trieste, Italy; 3) Laboratory for Auto-immune Diseases, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 4) Department of Statistical Genetics, Osaka University Graduate School of Medicine, Osaka, Japan; 5) Laboratory of Statistical Immunology, Immunology Frontier Research Center (WPI-IFReC), Osaka University, Suita, Japan; 6) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 7) Estonian Genome Center, University of Tartu, Tartu, Estonia; 8) Broad Institute of Harvard and MIT, Cambridge, MA, USA; 9) Medical Genetics, Institute for Maternal and Child Health - IRCCS "Burlo Garofolo", Trieste, Italy; Medical Sciences, Chirurgical and Health Department, University of Trieste, Trieste, Italy.

The Y chromosome is perhaps the least studied part of the genome and displays challenging levels of population genetic structure. Despite its involvement in several rare disorders, the impact of Y chromosome variation on common disease is still mostly unknown. We have conducted the largest association study of Y chromosome genetic variation, analysing 41 quantitative traits in 159 cohorts including 5 ethnicities and comprising up to 412,856 men. 68 markers available across all populations have been used to infer haplogroup identity for each studied individual and thus population frequency. In order to detect association between Y chromosome variation and the traits of biomedical or evolutionary interest, we used three different methods: 1) single point association, 2) summary statistic-derived ANOVA, 3) Y-Wide association. Analyses were performed in each population separately and combined by meta-analysis. Results for the three different approaches agreed across traits. We detected strong association across multiple samples only with height and a weaker one with weight as a consequence. The associations were with a haplogroup which is only common in our data in Japan and which is defined by >200 phylogenetically equivalent markers (in perfect LD), making determination of the causal variant challenging. No other significant effects were detected across traits assessing lung, liver, kidney, heart and cognitive function, glycaemic, fertility, inflammatory, anthropometric and ocular traits. Several putative associations of a specific haplogroup to a specific trait were observed in single populations, but these were not replicated. To further empower analysis of the rarer haplogroups, we conducted similar analyses in UK Biobank, but this confirmed our finding that no associations were present. Our results suggest that common variation on the Y chromosome plays only a very minor role, if any, in complex disease risk. Further more detailed study will be required to understand if the population-specific associations are due to private downstream variants or are false positives. .

**Heritability informed power optimization (HIPO) leads to improved methods of discovering genetic association across multiple traits.** G. Qi<sup>1</sup>, N. Chatterjee<sup>1,2</sup>. 1) Department of Biostatistics, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; 2) Department of Oncology, Johns Hopkins School of Medicine, Baltimore, MD.

**Background** Genomewide association studies have shown that pleiotropy is a common phenomenon and can be potentially exploited for enhanced detection of susceptibility loci that are implicated across multiple traits. Existing statistical methods typically carry out pleiotropic analysis at the level of individual loci failing to take into account the degree of genetic correlation that could be informed using genomewide analysis. **Methods** We propose heritability informed power optimization (HIPO) for conducting powerful pleiotropic analysis using summary-level association statistics across traits. We utilize LD score regression to estimate genotypic and phenotypic variance-covariance matrices associated with the traits and then utilize them to find optimal linear combinations of association coefficients that are expected to yield the highest non-centrality parameter for the underlying test statistics. These optimal weights can take into account difference in sample sizes across traits and can be computed by eigen decomposition of suitable matrices. **Results** Simulation studies show HIPO can maintain right type-I error and can have genomewide average  $\chi^2$  statistics much higher than those for individual traits. We applied HIPO to conduct cross-trait association analysis across LDL, HDL, triglycerides and total cholesterol using publicly available data from the Global Lipids Genetics Consortium (N=188,577) and identified 25 novel loci which were not identified by any of the individual trait analysis ( $p < 5 \times 10^{-8}$ , LD-pruning performed with  $r^2$  threshold 0.1 and new region defined to be at 500 Kb apart from known SNPs). A second application of HIPO for cross-disorder (autism spectrum disorder, ADHD, bipolar disorder, major depressive disorder and schizophrenia) using data from Psychiatric Genomics Consortium (33,332 cases and 27,888 controls in total) identified 5 loci at high-level of significance ( $p < 5 \times 10^{-7}$ ) that were not detectable at the same level of significance by either single trait analysis or cross-disorder meta-analysis. Three of the 5 loci showed evidence of replication in the most recent large study of SCZ. **Conclusions** HIPO is a powerful method for association signals across genetically correlated traits. It can be potentially extended to high-dimensional phenotypes as a way of dimension reduction to maximize power for subsequent genetic association testing.

**We didn't see this in GWAS: Understanding and fixing unfamiliar problems in association analyses, when pooling whole genome sequence data from multiple studies.** K. Rice<sup>1</sup>, X. Zheng<sup>1</sup>, S. Gogarten<sup>1</sup>, T. Sofer<sup>1</sup>, C.A. Laurie<sup>1</sup>, C.C. Laurie<sup>1</sup>, B. Weir<sup>1</sup>, T. Thornton<sup>1</sup>, A. Szpiro<sup>1</sup>, J. Bis<sup>2</sup>, J. Brody<sup>2</sup>. 1) Biostatistics, University of Washington, Seattle, WA; 2) Cardiovascular Health Research Unit, University of Washington, Seattle, WA.

Large-scale association analyses are now underway, using whole genome sequence (WGS) data on thousands of participants. Unlike earlier GWAS work, where data were combined using meta-analyses of summary statistics, in WGS participant-level data from multiple studies is typically pooled, and results are obtained from a single analysis. While there are good reasons for this approach to WGS, not least computational tractability, we describe how it can lead to false-positive results when the equivalent GWAS-style approach would not. Specifically, we consider the impact of differential phenotype variances by study (due to e.g. different measurement protocols) and its interplay with adjustment for relatedness across studies (e.g. allowing random variability proportional to a kinship matrix, or other genetic relatedness matrix). As well as explaining why these issues lead to difficulties in WGS where they did not for GWAS, we describe methods suitable for WGS work – available in straightforward and freely-available software – that used pooled data and provide appropriate control of false-positive results. For both single-SNP and region-based analyses, the problems and their solutions are illustrated with several examples from the NHLBI Trans-Omics for Precision Medicine Whole Genome Sequencing Program, TOPMed.

**Investigating shrinkage methods to improve accuracy of GWAS and PRS effect size estimates.** *Y. Ruan, S. Choi, P. O'Reilly.* SGDP, IoPPN, King's College London, London, United Kingdom.

As the scale and power of GWAS have increased to detect the small genetic effect sizes involved in complex polygenic traits, the results of GWAS, especially SNP effect size estimates, are increasingly utilised for prediction. A popular approach is the application of polygenic risk scores (PRS). However, the effect size estimates are inherently prone to overfit the specific samples on which the GWAS were performed (e.g. "the Winner's Curse"). The inflation of effect size estimation reduces the out-of-sample accuracy of prediction based on GWAS results. Many shrinkage methods have been developed to correct for such inflation. As GWAS results and large individual genotype data sets and become widely available, there is greater opportunity to accurately evaluate effect size inflation and compare the performance of different shrinkage methods. Using large-scale real genotype data, we show that SNP effect sizes were overfitted even in relatively large samples. We develop a novel permutation-based shrinkage method and compare its performance with previously developed methods based on local false discovery rates and the LASSO. We evaluate performance across a wide range of phenotypes and investigate different factors (e.g. phenotype heritability) that influence their impact on the predictive power of polygenic risk scores.

**3010W**

**A simple, consistent estimator of heritability from GWAS summary statistics.** *A. Schork<sup>1</sup>, W. Thompson<sup>1,2</sup>, A. Schwartzman<sup>2</sup>.* 1) Institute of Biological Psychiatry, Roskilde, Denmark; 2) UC San Diego, La Jolla, CA, USA.

Estimating the total contribution of common genetic variants to various quantitative and disease traits has become a common and insightful investigation into the genetic architecture of complex phenotypes. The current "gold standard" approach for these analyses, GREML analysis using the GCTA software developed by Yang et al., requires access to actual subject genotypes which is not always feasible. Further, recent reports have suggested this "gold standard" model, which assumes a particular form for the distribution of per allele effects, may perform poorly when this assumed distribution is far from the truth. The LD-score regression has been proposed as an alternative that relaxes the dependence on actual genotypes. It estimates heritability from GWAS summary statistics using a similar, but not equivalent set of assumptions, and is also sensitive to deviant effect distributions. We propose a novel estimator for heritability explained by common SNPs that is derived analytically from first principles of fixed effects multiple linear models. As such, our estimator makes no assumptions about the underlying distribution of per allele effects allowing it to remain unbiased across a broad range of scenarios. Further, our estimator requires only GWAS summary statistics and three simple scalar summaries of the SNP LD matrix. In this paper we introduce this estimator and compare its performance to GREML by GCTA and LDSC regression on a wide range of simulated and real phenotypic data.

**3011T**

**GWAS meta-analysis allowing for sample overlap estimated using summary statistics.** S. Sengupta, G. Abecasis. Department of Biostatistics, Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Meta-analysis leads to an increase in sample size and power in genome-wide association studies, enabling discovery of novel signals and refinement of previously discovered loci. To facilitate successive rounds of meta-analysis, many studies and consortia now make GWAS summary statistics publicly available. However, when published studies or meta-analysis include overlapping subjects, meta-analysis that do not account for this overlap can lead to inflated Type I error. Here, we propose a method to identify overlap among GWAS using summary statistics, estimate the degree of overlap and finally correctly meta-analyze potentially overlapping studies. Our method builds upon and extends previous methods that allow meta-analysis of GWAS studies with known overlap proportions. We first used actual genotypes from 5,000 GWAS samples to create a series of overlapping studies with simulated phenotypes. We then attempted to estimate sample overlap using GWAS summary statistics and to conduct a meta-analysis that accounted for this estimated overlap. Simulation results show that our method provides an accurate estimate of sample overlap (for example, when GWAS studies overlapped by 18% of samples, we estimate overlapping proportions as 17.9%  $\pm$  0.3%). We then meta-analyzed GWAS summary statistics accounting for estimated overlap and observed that the mean genomic control was 1.0 (mean genomic control 1.2 when meta-analyzed without considering overlap). We next created another series of overlapping GWAS studies using actual lipids and type II diabetes (t2d) GWAS data. We were able to estimate the overlap proportions (0.14 estimated as 0.15 for lipids, 0.08 estimated as 0.09 for t2d) and meta-analyze the data, obtaining well calibrated statistics (correlations between Z-scores from analysis of datasets with no overlap and Z-scores from analysis of datasets with duplicated samples analyzed using our method were 95.6-97.5%). Finally, we estimated the overlap in GWAS data for schizophrenia (SCZ) from the Psychiatric Genomics Consortium (PGC). Two phases of SCZ European summary statistics (SCZ1 + Swedish cohort, N=33,100; SCZ2 - SCZ1 + Swedish cohort, N=34,158) are available with a Swedish cohort of known sample size (N=11,244) overlapping and the overlap was estimated as 11,566. In conclusion, we have developed a method that allows us to meta-analyze data using summary statistics where different studies may overlap.

**3012F**

**Statistical and population genetics of extreme phenotypes.** O. Soylemez<sup>1,2,3</sup>, S. Sunyaev<sup>1,2,3</sup>. 1) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Boston, MA; 2) Medical and Population Genetics Program, Broad Institute, Cambridge, MA; 3) Harvard Medical School, Boston, MA.

Extreme values of quantitative traits or rare severe phenotypic presentations can be caused by individual mutations of very large effects segregating in Mendelian fashion. Alternatively, such phenotypes may reflect extremes of polygenic or oligogenic genetic inheritance. Beyond importance for basic genetics, this distinction is practically important for the design of genetic studies that can follow either Mendelian or complex trait paradigm. Currently, sequencing studies of rare phenotypes attribute only a fraction of cases to an obvious monogenic cause. Frequently, individuals with extreme phenotype have family members with milder presentation. Thus, it is expected that family history is informative about genetic architecture of extreme phenotypes. To inform our thinking about this problem, we developed a statistical and population genetics modeling framework to analyze the genetic architecture of extreme phenotypes. We performed forward simulations using SLiM2.0 under various demographic history scenarios to generate large-scale DNA sequence variation with a range of distributions of selective effects. Then, we used a liability threshold disease model to simulate pedigrees of individuals with extreme liability. The simulations explored the impact of various parameters - coupling between selective and phenotypic effect, incomplete penetrance, level of polygenicity, prevalence for rare and extreme phenotypes, and familial clustering of the phenotype - on the genetic architecture of extreme phenotypes. We estimated the relative likelihood that an individual with an extreme phenotype carries a mappable Mendelian mutation of large effect as opposed to the likelihood that the individual's presentation represents the high extreme of the phenotypic distribution characterized by polygenic inheritance. Next, we evaluated whether presence of mildly affected family members carries a substantial amount of information about the genetic model underlying the extreme phenotype. We apply the results of this analysis in the studies of extreme, rare and unique phenotypes. Our results inform large-scale sequencing studies of rare genetic conditions, and help characterize the genetic landscape of apparently Mendelian phenotypes.

**Bayesian model averaging for the X-chromosome inactivation dilemma in genetic association study.** *L. Sun<sup>1,2</sup>, B. Chen<sup>1</sup>, R.V. Craiu<sup>1</sup>.* 1) Department of Statistical Sciences, University of Toronto, Toronto, ON, Canada; 2) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, ON, Canada.

Due to analytical challenges, the so-called 'whole-genome' association scans routinely omit the X-chromosome, because it differs intrinsically between males and females. Almost a decade ago, Clayton (2008) in his seminal review paper has outlined many related analytical challenges and corresponding remedies, including the assumptions of Hardy-Weinberg equilibrium and equal allele frequencies or sample sizes between female and males. Yet, Wise et al. (2013) noted recently that more than two thirds of published studies do not include X-chromosome, and they made a plea to the research community "toward integrating the X chromosome in genome-wide association analyses". The bottleneck is the lack of sound statistical approaches to address the inherent model ambiguity associated the X-inactivation phenomenon, where one of the two alleles in a female may or may not be silenced. In the absence of biological evidence in favor of one specific model, we consider a Bayesian model averaging (BMA) framework that offers a principled way to account for the inherent model uncertainty. We obtain the posterior distributions generated from Bayesian regression models for analyzing X-chromosome SNPs under the X-inactivation and no X-inactivation assumptions. We combine the estimates from the two models following the BMA principle. We calculate the BMA-based highest posterior density (HPD) region for the parameter of interest. The BMA posterior distribution is directly interpretable as a weighted average for the genetic effect, averaged over the two models, with more weight given to the one with stronger support from the data. To rank multiple SNPs, we calculate Bayes factors comparing the averaged model with the null model of no association for each SNP. We evaluate the performance of the proposed Bayesian approach via extensive simulations and application studies. We show that the proposed Bayesian method provides more feature-rich quantities than frequentist's approaches. We also highlight a few interesting findings, including the importance of using g-priors in this settings and the choice of reference allele when analyzing X-chromosome SNPs.

**3014T**

**Estimating the proportions of additive, dominant and recessive genetic effects.** *H. Wu, E. Baker, P.F. O'Reilly.* MRC Centre for SGDP, King's College London, London, United Kingdom.

GWAS have been applied to a huge range of complex traits, but the analyses performed almost always assume additive genetic effects. While these additive models are well-powered for the detection of both additive and dominant effects, they are typically underpowered to detect recessive effects. Therefore, if recessive effects are reasonably common then the power of GWAS may be substantially reduced by testing for additive effects only. This could also lead to reduced power for downstream analyses, such as the application of polygenic risk scores. Here we investigate the statistical power of different inheritance models in GWAS, including the additive, dominant, and recessive models. We analyse the performance of these models via simulation of large-scale genetic data. We also perform the same analysis on real large-scale genetic data across a range of complex traits. Our results suggest that there are a substantial proportion of recessive effects in the genome for the tested complex traits. We conclude that statistical power can be optimised by taking a more nuanced approach to the inheritance model assumed. We estimate the potential increase in susceptibility loci and in the predictive power of polygenic risk score analyses by taking such an approach.

**3015F**

**Scalable Bayesian functional genome-wide association study method with summary statistics.** *J. Yang, X. Zhou, G. Abecasis.* Center for Statistical Genetics, Department of Biostatistics, University of Michigan School of Public Health, Ann Arbor, MI.

Combining standard genome-wide association study (GWAS) association results by single variant tests with the functional annotations of variants can help interpret association results and understand underlying biology. Our previously proposed Bayesian functional GWAS method (bfGWAS) that integrates functional information into GWAS simultaneously evaluate association evidence for genome-wide variants, select likely causal variants to help fine-mapping, and assess the importance of each functional category. Even with parallel computation enabled by bfGWAS, the Markov chain Monte Carlo (MCMC) methods that carry out these computations using individual-level data can require thousands of computer hours for a single GWAS. To speed up computation, we propose an implementation based on summary statistics for bfGWAS. Since bfGWAS evaluates association evidence based on a joint variable selection linear regression model of genome-wide variants, by using the correlation or linkage disequilibrium (LD) between variants that are jointly evaluated in the model. Thus, we use either an LD matrix estimated from study samples or from a reference sample, such as an appropriate subset of the 1000 Genomes samples. Additionally required summary statistics include the effect sizes by single variant tests, phenotype variance, and sample size. Different from the previously proposed Bayesian Regression with Summary Statistics (RSS) method for GWAS that models the true joint likelihood conditioning on effect sizes and effect-size variances by single variant tests, we derive analytical formulas for conducting the MCMC computations by summary statistics. We applied bfGWAS with summary statistics to the real GWAS data of Age-related Macular Degeneration (~33K samples, ~10M variants). We found that implementing bfGWAS with summary statistics saved up to 90% CPU time while producing the same results as using individual-level data. In addition, we found that using the LD matrix estimated from a reference panel of the same ethnic group as the study samples produced approximately the same results as using the actual LD matrix of the study samples. In conclusion, we successfully implement bfGWAS with summary statistics, which has the same efficiency as using individual-level data, greatly saves computational cost, and makes the meta-analysis of bfGWAS possible by using only summary statistics from individual studies.

**3016W**

**Using imputation for haplotype association.** *G.J.M. Zajac, S. Das, E.M. Schmidt, S. Zöllner, G.R. Abecasis.* Department of Biostatistics and Center for Statistical Genetics, University of Michigan, Ann Arbor, MI.

Haplotype association testing offers many advantages over single-marker tests, especially when there is allelic heterogeneity or epistatic interaction. Powerful and scalable haplotype association tests may reveal new biological insights into complex traits. Here we propose a new GWAS-scale haplotype association test that evaluates whether phenotype similarity is correlated with haplotype similarity as measured by Li and Stephens-based haplotype copying models. We modified our imputation software to calculate a site-specific score for each individual that summarizes affinity between individual haplotypes and all case haplotypes. To search for haplotype association, we search for loci where case haplotypes have systematically higher scores than control haplotypes. To search for marker association, we evaluate the effect of individual genotypes after accounting for this local haplotype similarity score, allowing us to test for the effect of a marker, conditioned on the background haplotype. In both models, we control for population stratification and cryptic relatedness. We tested the method on 97 electronic health record defined cases of primary hypercoagulable state and 583 controls from the Michigan Genomics Initiative, matched on ancestry and age. The samples were genotyped using the HumanCoreExome chip at 600,000 markers. Testing for haplotype association reproduced the GWAS hit in the F5 locus (p-value  $1 \times 10^{-3}$  compared to GWAS p-value  $4 \times 10^{-7}$ ). Jointly regressing case-control status on genotype and haplotype score resulted in a stronger signal overall and reduced the signal from many SNPs in high LD with the locus. Our method allows testing for association between a trait and haplotypes in a region rather than the genotype at a specific SNP at large scale. Thus, we expect the method to be useful to find new associations not previously discoverable by GWAS.

## 3017T

**Robustly doubling the sample size: A unifying regression framework for allele-based association test.** L. Zhang<sup>1</sup>, L. Sun<sup>1,2</sup>. 1) Department of Statistical Sciences, University of Toronto, Toronto, Ontario, Canada; 2) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Ontario, Canada.

Allele-based association test, comparing difference in allele frequency between cases and controls, is locally most powerful. However, the seminal work of Sasieni (1997) highlighted the importance of the Hardy-Weinberg equilibrium (HWE) assumption, thus cemented the current use of genotype-based association test that is robust to HWE. Here, we revisit the problem and aim to develop an alternative allele-based association test that is not only robust to HWE, but also handles quantitative traits as well as various data complications such as genotype uncertainty, correlated individuals from pedigrees, and presence of additional covariates. To this end, we propose a unifying regression framework with *individual allele as the response variable*. We show that the score test statistic derived from this novel regression model contains a correction factor that explicitly adjusts for the departure from HWE. In the simple case of a population-based case-control association study with no genotype uncertainty, we prove that the proposed robust allele-based score test statistic (derived from model regressing individual allele on phenotype) and the standard genotype-based score test statistic (derived from model regressing phenotype on genotype) have *identical form*, despite their apparent differences in the choice of response variable and corresponding sample size. This analytical result has several important implications. It provides theoretical insights on why genotype-based test is robust to HWE, explains why earlier attempts to correcting for the biased allele-based test (e.g. Schaid and Jacobsen 1999) do not lead to improved power, allows decomposition of the individual association and Hardy-Weinberg disequilibrium components in one single regression framework, and leads to the possibility of joint analysis of multiple (continuous and/or binary) phenotypes using allele-based approach, all in the presence of missing data, familial correlation and population heterogeneity. To support our analytical findings, we provide empirical evidence from extensive simulation and application studies.

## 3018F

**On simulation design for evaluating type 1 error: What is the 'correct' null model?** T. Zhang<sup>1</sup>, L. Sun<sup>1,2</sup>. 1) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto; 2) Department of Statistical Sciences, Faculty of Arts and Science, University of Toronto.

When developing any new statistical test for association between an outcome  $Y$  and genotype  $G$  of a SNP, the first step is to check its accuracy or type 1 error (T1E) control using simulations. This is often achieved by the following standard simulation design, denoted as  $S0$ .  $S0$  simulates phenotype values  $Y0$  under the 'conceptual' null model of no association, e.g.  $Y0 \sim 1 + e$ , then independently generates genotype data  $G$  and estimate the empirical T1E from  $Y0 \sim G + e$ ; for notation simplicity and w.l.g. additional covariates are omitted from the regression model. Robustness to assumptions such as normality is also typically evaluated using  $S0$  where  $e$  would be generated from other distributions. In practice, whole-genome scans study association between an empirical  $Y$  that comes from an (unknown) alternative and a large number of  $G$ s, of which the majority are not associated with  $Y$ , i.e. under the 'empirical' null. This reality can be mimicked by design  $S1.1$  where one simulates  $Y$  from an alternative, e.g.  $Y1 \sim G + E + G \times E + e$ , then it independently generates  $G^{new}$  and evaluates T1E from  $Y1 \sim G^{new} + e$ ;  $E$  was used in data simulation but assumed not being collected in practice. Finally, design  $S1.2$  can be used where one permutes simulated  $Y1$  and evaluates T1E from  $Y1^{permute} \sim G$ , again under the 'empirical' null. It is important to note, however, that even if the error term  $e$  is normal, marginally  $Y1$  is not in contrast to  $Y0$ . This distinction can be consequential particularly for more advanced association tests. For example, the recent scale-tests, developed to inform presence of interaction effects (e.g. Cao et al. 2014 and Soave et al. 2015), are generally more sensitive to the assumption of normality than the traditional location-tests focusing on genetic mean effects. Importantly, even if the departure from normality is generally minor in practice and appears to pass standard diagnostic tools for non-normality, it can noticeably affect T1E evaluation. For example, when using the likelihood ratio test for variance heterogeneity, while simulation design  $S0$  shows the method being accurate,  $S1.1$  and  $S1.2$  suggest otherwise with empirical T1E values as high as 0.07 for the 0.05 nominal level, and 0.002 for 0.001. This is an important observation that could impact many emerging association tests that are designed to improve power by going beyond the first moment.

Decreases in genotyping cost allow for large biobanks to genotype all participants, enabling phenome-wide association studies (PheWAS) on electronic health record-based phenotypes. Both widely used linear mixed models and the recently proposed logistic mixed model (GMMAT) approaches perform poorly -- producing large type 1 error rates -- in the analysis of the resulting case-control studies, where there are typically many controls for each case. Linear mixed model approaches are not designed to handle binary traits and extremely unbalanced case-control ratios invalidate asymptotic assumptions of logistic regression. In addition, since GMMAT requires inverting the kinship matrix, it cannot be used for large cohorts. Here, we describe a novel method to allow for analysis of very large samples (>50,000 individuals), for binary traits with unbalanced case-control ratios, and account for sample relatedness. Our method, called SPA-GMMAT, uses the saddlepoint approximation (SPA) to calibrate the distribution of score test statistics from logistic mixed models. Similar to BOLT-LMM, a linear mixed-model method that handles very large samples, our method utilizes state-of-art optimization strategies for large cohorts. Our method can analyze 67,619 samples and 20.5 million variants in ~1 day using 16 threads and computing time scales linearly with increases in both the numbers of samples and markers. Through simulation studies, we show SPA-GMMAT can control for the type 1 error rates even when the case-control ratios are extremely unbalanced (1:100). In contrast, BOLT-LMM and GMMAT tend to produce inflated test statistics especially for less frequent and rare variants. To illustrate the practical advantages of our approach, we apply SPA-GMMAT and BOLT-LMM to binary traits in the Nord-Trøndelag Health (HUNT) Study with substantial sample relatedness. As an example, we conducted genome-wide analyses of 20.5 million variants (MAF > 0.0001) for venous thromboembolism (case:control=2,325:65,294). Four previously reported GWAS loci passed the genome-wide significant threshold by SPA-GMMAT, while 135 loci were significant by BOLT-LMM. The genomic inflation factor ( $\lambda_{GC}$ ) at the 0.1 percentile drops from 1.32 ( $\lambda_{GC}$  of BOLT-LMM) to 1.03 ( $\lambda_{GC}$  of SPA-GMMAT). In summary, we propose a novel method that control for unbalanced case-control ratios and sample relatedness for binary traits. It efficiently handles large sample sizes and can be applied to PheWAS by large biobanks.

Recently proposed transcriptome-wide association studies (TWAS) methods have been shown to be promising for revealing genes associated with complex traits. TWAS methods utilize a three step process. Specifically, one first trains a predictive model of gene expression based on an eQTL dataset, and then applies this model to large-scale GWAS dataset(s) for which expression measurements are typically unavailable. Finally these predicted expression values are used to conduct association analysis with phenotypic trait(s) of interest. Basic current TWAS methods use point estimates from the predictive model without considering multiple sources of uncertainty, including variable selection uncertainty, gene expression prediction uncertainty, and genotype measurement uncertainty (for example, due to using imputed genotypes in either the training eQTL or testing GWAS dataset, or both). We propose a novel unified Bayesian framework that addresses all of the above challenges. We adopt a Bayesian variable selection and multiple imputation framework that also takes into consideration genotype measurement uncertainty in both training eQTL and testing GWAS datasets. Our simulation studies demonstrate the advantages of our proposed method over existing ones in terms of both power and validity. More interestingly, our preliminary analysis revealed multiple genes associated with blood cell related traits.
