Next generation sequencing has identified large numbers of rare variants, creating challenges for association analysis approaches, i.e. limited power, multiple comparisons, and increased false positives. Linkage analysis based on co-segregation of genetic markers with a phenotype through generations is a powerful complement. Data from 1205 Mexican Americans from 90 pedigrees in the Insulin Resistance Atherosclerosis Family Study were analyzed using two-point linkage and association on whole exome sequencing data (452,832 rare variants; MAF<5%). Cardiometabolic phenotypes were targeted (n=53; glucose homeostasis, adiposity, lipids, blood pressure, and biomarkers). Overlapping linkage and association signals were analyzed with family-specific linkage and fine-mapped using whole genome sequencing data. Correlated variants ( $r^2=1$ ) on chr10 were strongly associated and linked with systolic blood pressure (SBP; rs201624882, rs142314590;  $P=1.3 \times 10^{-13}$ , LOD=4.0, MAF=0.25%). rs142314590 is a synonymous variant located in *PRKG1*, a protein kinase family involved in cardiovascular homeostasis. Family-specific linkage identified a single family (LOD<sub>Fam2014</sub>=4.1) with carriers (n=6, 182mmHg) having 1.6 times higher SBP than non-carriers (n=27, 113mmHg). In addition, correlated variants ( $r^2=1$ ) were linked and associated with tri-glyceride levels (TG; rs189547099, chr4:157997598;  $P=6.3 \times 10^{-8}$ , LOD=3.1, MAF=0.50%). Chr4:157997598 is an intronic variant in *GLRB* that modifies a *ZNF263* transcription factor consensus sequence. Family-specific linkage identified a single family (LOD<sub>Fam1045</sub>=3.1) with carriers (n=13, 358mg/dl) having a 2.9 times higher TG than non-carriers (n=12, 124mg/dl). Significant linkage and association was also observed at chr11:35281477 with insulin secretion (AIR; LOD=3.1,  $P=2.50 \times 10^{-7}$ , MAF=0.01%). chr11:35281477 is a 3'UTR variant in *SLC1A2*, a glutamate transporter implicated in insulin secretion. Family-specific linkage identified a single family (LOD<sub>Fam2016</sub>=3.0) with carriers (n=6) having a 3.9 times higher AIR than non-carriers (n=10), conveying a protective effect. Overlapping linkage (LOD>2) and association ( $P<1 \times 10^{-4}$ ) signals were identified for 270 loci with 38 showing family-specific linkage of LOD>3. These results highlight the strength of family-based design for rare variant analysis, i.e. rare variants are enriched and frequent in families. The combination of association and linkage has the potential for large effect rare variant screening.

**Meta-analysis in continental Africans and African Americans identifies PLCB3 as a novel locus of serum uric acid.** *G. Chen, A. Doumatey, J. Zhou, A. Bentley, D. Shriner, A. Adeyemo, C. Rotimi, The AADM study investigators.* NHGRI/NIH, National Institutes of Health, Bethesda, MD.

Objects: Gout and hyperuricemia are disorders caused by impaired urate metabolism with an estimated 8.3 million people affected in the United States. The prevalence of hyperuricemia is highest among African ancestry individuals in the US and similar high prevalence have been observed among sub-Saharan Africans. Compared to European Americans, hyperuricemia has been associated with higher prevalence of cardiovascular and metabolic diseases including hypertension. In 2011, we identified novel GWAS loci for uric acid in African Americans. Here we describe our findings of the first large-scale GWAS in continental Africans. We meta-analyzed our findings with GWAS results from our African American cohort enrolled from Washington, DC as part of the Howard University Family Study (HUFs). Methods: A total of 4,126 individuals enrolled from Nigeria, Ghana and Kenya as part of the African American Diabetes Mellitus (AADM) study were genotyped on the MEGA high density GWAS array and imputed into the African Genome Resources Haplotype Reference Panel using the Sanger Imputation Service. The generalized linear mixed model association test (GMMAT) was used to perform association score test with cryptic relatedness random effect and covariates (sex, age, age<sup>2</sup>, BMI, diabetes status, and significant principal components). Imputation for the African American dataset used for replication and meta-analysis was also performed using the same Sanger reference panel. Results: A total of 111 SNPs reached genome-wide significance ( $p < 5.0 \times 10^{-8}$ ); these SNPs were distributed across five loci [4p16.1: (SLC2A9, and WDR1), and 11q13.1: (SLC22A12, SF1, MAP4K2, and MEN1)] with the lowest p value of  $4.40 \times 10^{-17}$ ; The meta-analysis identified 235 SNPs that reaching genome-wide significance and distributed across six loci [4p16.1 (SLC2A9, and WDR1), and 11q13.1: (SLC22A12, SF1, MAP4K2, MEN1, and PLCB3)] with the lowest p value of  $1.80 \times 10^{-30}$ . Conclusions: This first GWAS of serum uric acid in continental Africans confirms reported association between variants in SLC2A9, WDR1, SLC22A12, MAP4K2 and MEN1 and uric acid in other ancestral populations. Notably, the meta-analysis with African Americans identified a novel locus (PLCB3) that is associated with serum uric acid in African ancestry individuals thus potentially shedding new insight into the biology of this trait.

**Background:** Large meta-analyses have identified approximately 100 loci associated with adult BMI and 60 with birth weight. However, little is known about the genetic influences on infant and childhood BMI. We performed GWAS on longitudinal measurements of BMI from birth to age 8 years in a population-based child cohort. **Methods:** We examined 9540 children from the Norwegian Mother and Child Cohort Study (MoBa) with 12 measurements of height at birth, at months 1, 3, 6, 8, 12 and 18, and at 2, 3, 5, 7 and 8 years. All children were of Norwegian ancestry with anthropometrics measured at hospitals and primary health care. Samples were genotyped using Illumina HumanCoreExome BeadChip. We tested variants for association with BMI SDSs using linear regression adjusting for sex. LD-score regression was used to estimate the genetic correlation between childhood BMI and other traits at each time point. **Results:** We found that variants in the LEPR/LEPROT locus were strongly associated with BMI as early as 3 months of age, peaking at 6-12 months ( $p=5.98E-15$ ) and waning from age 3 with little effect at 8 years of age and no association with adult BMI. The associated markers were not in LD with markers in LEPR previously implicated in severe childhood obesity. Furthermore, we explored effects of established adult BMI SNPs on childhood growth. We identified increasing correlation from birth to 8 years (Pearson's  $r$  0.24 to 0.68) with marked differences in timing and effect sizes between markers. Similarly, LD score regression showed that the pattern of genetic correlations with other traits change from BMI at early infancy to young childhood. **Discussion:** This is the first GWAS performed on BMI as early as 1 month of age with dense longitudinal BMI measurements from birth to 8 years of age. We identified variants in the LEPR/LEPROT region with strong transient effects on BMI in and around adiposity peak. Although LEPR has previously been associated with monogenic obesity and severe polygenic childhood obesity around 8 years of age, our variants are not in LD with previously implicated SNPs indicating a novel effect on weight gain in infants. The absence of association in large adult BMI meta-analyses illustrates a genetic effect specific to early weight gain providing insight into growth biology. Thus, our results are the first sign of transient genetic effects in BMI that might help decipher the complexity of childhood growth and development of obesity.

**Genome-wide scan using Korea Biobank Array discovered that two rare missense variants on GPT gene were associated with liver enzyme level.** Y.J. Kim, S.M. Moon, M.Y. Hwang, B.J. Kim. Division of Genome Research, Center for Genome Science, Korean National Institute of Health, Heungdeok-gu, Chungcheongbuk-do, South Korea.

Recently, genome-wide association studies (GWASs) with hundreds of thousands of samples have implicated unprecedented amount of loci including less common and rare functional variants associated with complex diseases and traits. Since 2014, with the goal of uncovering hidden genetics of complex diseases, we have been conducting the Korea Biobank Array (KBA) project to produce approximately 180,000 cohort-based genome information. KBA, a customized chip optimized for genome study in Korean population, contains about 830,000 markers including about 200K nonsynonymous variants derived from about 2,500 sequenced Korean samples. The KBA achieved higher imputation performance with imputation based genomic coverages of 95.8% and 73.65% for common (MAF  $\geq$  5%) and low-frequency variants (MAF 1-5%), respectively. In this study, we performed genome-wide association study for lipids and liver enzymes using about 7,000 genotyped samples with KBA and replicated the findings in about 6,000 samples of an independent cohort. In discovery study, all loci with common variants ( $P < 5 \times 10^{-7}$ ) were previously known. Among the known loci, we discovered 13 nonsynonymous variants ( $P < 10^{-4}$ , predicted to be damaging) including rare variants within PCSK9 gene replicating the findings from Tang *et al.* 2015. Also, two novel rare missense variants ( $P < 5 \times 10^{-7}$ ) on GPT gene were discovered. In replication study, 15 variants were genotyped using taqman and tested for associations with lipids and liver enzymes. All functional variants were replicated at the level of  $P < 5 \times 10^{-2}$ . Taken together, our study discovered numerous functional rare variants, possible novel therapeutic target, associated with lipids and liver enzymes.

**Objective** To identify novel gout loci including those that are subtype-specific, we performed a genome-wide association study (GWAS) of gout and its subtypes. **Methods** With 1396 clinically-ascertained gout cases and 1268 controls of Japanese males using a custom chip of 1961 single nucleotide polymorphisms (SNPs), putative causal association signals were replicated from a GWAS of 945 cases and 1213 controls. We also first conducted GWASs of gout subtypes. Replication with Caucasian and New Zealand Polynesian samples was done to further validate the loci identified in this study. **Results & Discussion** In addition to the five loci we reported previously, further susceptibility loci were identified at a genome-wide significance level ( $p < 5.0 \times 10^{-8}$ ): urate transporter genes (*SLC22A12* and *SLC17A1*) and *HIST1H2BF-HIST1H4E* for all gout cases, and *NIPAL1* and *FAM35A* for the renal underexcretion gout subtype. Whereas *NIPAL1* encodes a magnesium transporter, functional analysis did not detect urate transport via *NIPAL1*, suggesting its indirect association with urate handling. Localization analysis in the human kidney revealed expression of *NIPAL1* and *FAM35A* mainly in the distal tubules, which suggests the involvement of the distal nephron in urate handling in humans. Clinically-defined male gout cases and controls of Caucasian and Polynesian ancestries were also genotyped, and *FAM35A* was associated with gout in all cases. A meta-analysis of the three populations revealed *FAM35A* to be associated with gout at a genome-wide level of significance ( $P_{\text{meta}} = 3.58 \times 10^{-8}$ ). Further findings after this GWAS will be presented at the meeting. Together with *ALDH2*, which is revealed by the fine mapping of *CUX2* region detected by the previous gout GWAS, our findings including novel gout risk loci provide further understanding of the molecular pathogenesis of gout and lead to a novel concept for the therapeutic target of gout/hyperuricaemia.

Freathy*<sup>11</sup>, *Early Growth Genetics Consortium*. 1) University of Exeter, Exeter, United Kingdom; 2) University of Bergen, Bergen, Norway; 3) Haukeland University Hospital, Bergen, Norway; 4) University CRC, Skåne University Hospital Malmö, SE-205 02, Malmö, Sweden; 5) The Children's Hospital of Philadelphia, Philadelphia, USA; 6) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 7) University of Oulu, Oulu, Finland; 8) University of Cambridge, Cambridge, UK; 9) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 10) University Hospital (CHUV), Lausanne, Switzerland; 11) University of Bristol, Bristol, UK; 12) The University of Queensland Diamantina Institute, Brisbane, Australia.

**Aims/hypothesis:** Rare genomic anomalies at a number of known imprinted loci are associated with disorders affecting birth weight. We hypothesized that common genetic variants would also show parental origin-specific associations with birth weight. **Methods:** We analysed 28,836 parent-offspring trios or mother-child pairs from 11 studies to determine parental origin of alleles at 6.1M SNPs genome-wide (MAF >0.01; imputation quality >0.4; imputed to 1000 Genomes). We tested the associations between birth weight and [i] maternally-inherited alleles, and [ii] paternally-inherited alleles. In addition, for each SNP, we compared birth weight between A1<sub>m</sub>A2<sub>f</sub> and A1A2<sub>m</sub> heterozygotes (test [iii]), where suffixes "m" and "f" represent, respectively, maternal and paternal inheritance of alleles A1 or A2. To complement this approach, we tested for differences in birth weight variance between heterozygotes and homozygotes at 12.2M variants (MAF >0.01; imputation quality >0.4) in 104,722 unrelated individuals from 13 additional, non-overlapping studies. **Results:** There were no loci showing genome-wide evidence of unequal parental effects ( $P < 5 \times 10^{-8}$  in test [iii] and either test [i] or [ii]). However, focusing on 60 known birth weight loci, SNP rs13266210 at *ANK1-NKX6-3* (associated also with type 2 diabetes), showed some evidence for a paternal parent-of-origin effect (POE): each paternally-inherited risk allele was associated with a 0.04 SD (95%CI: 0.02, 0.06 SD) higher birth weight ( $P = 9.8 \times 10^{-3}$ );  $P = 6.0 \times 10^{-4}$  for difference between A1<sub>m</sub>A2<sub>f</sub> and A1A2<sub>m</sub> heterozygotes (test [iii]); no evidence of association with the maternally-inherited allele ( $P = 0.48$ ). Additionally, among independent, unrelated individuals there was evidence of greater variance in heterozygotes than homozygotes for the same SNP ( $P = 2.4 \times 10^{-3}$ ). **Conclusions/interpretation:** Our analysis provides evidence for a possible POE on birth weight at the *ANK1-NKX6-3* locus already known to influence birth weight, although this requires replication in further samples. The upcoming addition of further data, including GWAS in ~200,000 unrelated individuals, will enhance our power to detect robust associations.

**1836F**

**Meta-analysis in 93,701 East Asians identifies new loci associated with type 2 diabetes.** X. Sim<sup>1</sup>, M. Horikoshi<sup>2</sup>, C.N. Spracklen<sup>3</sup>, Y.J. Kim<sup>4</sup>, AGEN and DIAMANTE consortia. 1) Saw Swee Hock School of Public Health, National University of Singapore, Singapore; 2) RIKEN, Centre for Integrative Medical Sciences, Japan; 3) Department of Genetics, University of North Carolina, Chapel Hill, North Carolina, USA; 4) Division of Structural and Functional Genomics, Center for Genome Science, Korean National Institute of Health, Osong, Chungchungbuk-do, South Korea.

To identify new T2D susceptibility loci in East Asians, we conducted genome-wide meta-analysis in 35,948 T2D cases and 57,753 controls from 21 studies based in China, Japan, Korea, Philippines, Singapore, Taiwan, and United States and imputed to 1000 Genomes reference panels. We performed association analyses with and without adjustment for body mass index (BMI), and combined study-specific association statistics using a fixed-effects, effective sample-size weighted meta-analysis approach assuming an additive genetic model. We analysed 6,957,373 variants, and identified 51 loci at genome-wide significance ( $P < 5 \times 10^{-8}$ ). Of the 51 loci, 42 mapped to known T2D loci. At these loci, only the lead variants at *TMEM154*, *SLC30A8*, *CDKN2A/B*, *TLE1*, *KCNQ1* were identical to previously reported lead variants. Among 9 novel loci, the strongest associated variant maps to an intron of *KSR2* (rs7305424, OR=1.08,  $P=1.2 \times 10^{-9}$ ,  $P_{\text{het}}=0.85$ ). *KSR2* regulates energy intake and expenditure, and rare variants in *KSR2* have been implicated in early-onset obesity and severe insulin resistance. Two of the new signals near *SIX2-SIX3* and *TMEM18* map to loci previously reported to be associated with T2D-related quantitative traits, fasting glucose (FG) and obesity, respectively. At *SIX2-SIX3*, the lead variant rs12712928 (OR=1.07,  $P=1.3 \times 10^{-8}$ ,  $P_{\text{het}}=0.20$ ) was in high linkage disequilibrium ( $r^2=0.91$ ) with the East Asian FG-associated variant rs895636 ( $P=6.9 \times 10^{-8}$ ,  $P_{\text{het}}=0.42$ ), and reciprocal conditional analyses eliminated the signal at this locus. The allele associated with higher FG at rs895636 was associated with increased T2D risk. Associations at *TMEM18* attained genome-wide significance only in analyses without BMI adjustment (rs6719883,  $P_{\text{wobMI}}=1.2 \times 10^{-8}$ ,  $P_{\text{BMI}}=1.8 \times 10^{-8}$ ), suggesting mediation effects of BMI on T2D. Furthermore, conditional analysis on known obesity variant rs13021737 eliminated the association with rs6719883. Allele frequencies at variants for novel loci near *PTPN11* (rs77753011, OR=1.12,  $P=9.9 \times 10^{-9}$ , MAF=0.23) and *ZNF208* (rs142395395, OR=1.22,  $P=5.0 \times 10^{-9}$ , MAF=0.04) were higher in East Asians compared to the other ancestries (MAF < 0.0014 in 1000G non-East Asians). Taken together, we replicated 42 known loci in East Asians and identified 9 new loci that highlight additional genes that may contribute to T2D pathophysiology.

**1837W**

**Using genetics to understand the relationship between inflammation and cardiometabolic traits.** N.R. van Zuydam, A. Goel, C. Grace, TRIIC Consortium. WTCHG, University of Oxford, Oxford, Oxfordshire, United Kingdom.

Chronic inflammation is associated with obesity, type 2 diabetes (T2D), cardiovascular disease (CAD) and their complications. It remains unclear whether chronic inflammation makes a causal contribution to the development of T2D and obesity, or is merely a consequence. If the latter, it is possible that chronic inflammation secondary to T2D and obesity plays a role in their complications. The patterns of genetic predisposition underlying these traits can be used to dissect these causal relationships. Genome-wide association statistics were assembled for 33 traits including (a) autoimmune diseases and inflammatory traits (e.g. psoriasis, rheumatoid arthritis [RA], CRP); (b) T2D, obesity/BMI and related traits; (c) CAD; and (d) diabetic complications including chronic kidney disease (CKD). Polygenic scores (PGS) were generated and two-way Mendelian Randomisation analyses conducted to define causal relationships. A Bonferroni threshold of  $8.1 \times 10^{-4}$  was adopted which took account of the PGS comparisons made. Polygenic scores for autoimmune traits were not associated with T2D, obesity or CAD. The PGS for CRP was associated with increased risk of T2D (OR, 1.19 [1.09-1.30],  $p=8.5 \times 10^{-6}$ ), BMI (Beta, 0.06[0.05-0.08] SD,  $p=3.3 \times 10^{-11}$ ), WHR (Beta, 0.04[0.03-0.05] SD,  $p=1.4 \times 10^{-5}$ ) but with decreased risk of CAD (OR=0.95[0.84-0.93],  $p=2.6 \times 10^{-6}$ ). These associations were entirely attributable to variants near *HNF1A* and *APOC1* that are known to be pleiotropic and it is not clear whether the association is due to the effect of lipid traits rather than by CRP levels. Polygenic scores for metabolic traits showed some overlapping protection from psoriasis: T2D (OR, 0.85[0.79-0.92],  $p=3.5 \times 10^{-6}$ ); BMI (0.47[0.37-0.59],  $p=1.4 \times 10^{-10}$ ), WHR (0.26[0.14-0.48],  $p=2.6 \times 10^{-5}$ ) and CAD (0.65[0.55-0.77],  $p=9.3 \times 10^{-5}$ ). We found little evidence for a causal role for inflammation with respect to complications. The only significant association implicated the PGS for RA with CKD in subjects with T2D (OR, 0.90 [0.85-0.94],  $p=1.4 \times 10^{-5}$ ). Overall, despite isolated signals of overlapping predisposition (some of which are likely to reflect pleiotropic signals), there was no consistent pattern supporting a causal relationship between chronic inflammation and cardiometabolic disease.

**1838T**

**Phenome-wide association study of exome data from childhood obesity cohort reveals pleiotropic loci for 13 obesity-related traits.** S.B. Cho, H.B. Jang, H.J. Lee. Korea National Institute of Health, Cheong-ju, South Korea.

Here, we performed phenome-wide association study using exome data with 13 obesity-related traits (BMI, waist to hip ratio, fat mass, fat percent, fat-free mass, SBP, DBP, fasting glucose, total-cholesterol, HDL-cholesterol, TG, ALT, and AST). We applied next generation sequencing of whole exome of 692 Korean adolescents who were recruited for childhood obesity cohort. We filtered loci having minor allele frequency < 0.01 and missing alleles > 85%, and 119,935 loci were used for analysis. Linear regression of each trait and exome was performed with age and sex covariates. The p values of each traits then were summed using Fisher's method. With the Bonferroni's multiple testing correction, 3,342 loci were significant ( $P < 0.05/119,935$ ). The functional annotation of the loci indicated that the result contained a lot of metabolism-related loci that had been identified in the previous researches. We selected 10 loci and preformed validation study using independent cohort ( $n = 1,000$ ). In the validation study, 7 loci showed significance in the phenome-wide association study with the 13 obesity-related traits. We believe that our results shows the possible genetic loci that are functionally related to the biology of obesity.

**1839F**

**Molecular assessment of variants in inherited lipodystrophy genes: Prevalence and clinical impact in a large clinical care cohort.** C. Gonzaga-Jauregui<sup>1</sup>, J. Altarejos<sup>2</sup>, T.M. Teslovich<sup>1</sup>, N.S. Abul-Husn<sup>1</sup>, J. Gromada<sup>2</sup>, A. Baras<sup>1</sup>, O. Gottesman<sup>1</sup>, F. Dewey<sup>1</sup>, Geisinger-Regeneron DiscovEHR Collaboration. 1) Regeneron Genetics Center, Regeneron Pharmaceuticals Inc., Tarrytown, NY; 2) Regeneron Pharmaceuticals Inc., Tarrytown, NY.

Inherited Lipodystrophies are a group of genetic disorders characterized by loss of adipose tissue accompanied by metabolic dysregulation. They are broadly divided into Congenital Generalized Lipodystrophies (CGLs), which are mostly autosomal recessive disorders and Familial Partial Lipodystrophies (FPLs), which are inherited dominantly. Lipodystrophies are generally considered to be very rare genetic disorders with reported prevalences ranging from 1 in 10 million for CGLs, to 1 in 1 million for FPLs. We interrogated the electronic health record (EHR) information for ~1.6 million individuals in the Geisinger Health System for lipodystrophy/lipoatrophy diagnosis codes. We then performed genetic analyses of individuals with available genetic data through our Geisinger-Regeneron DiscovEHR collaboration in order to identify the likely causative variants of lipodystrophy in these patients. Of the 18 lipodystrophy-diagnosed patients with available genetic data, we identified potentially pathogenic variants in known lipodystrophy associated genes in 8 individuals. Of these, 4 individuals carry a pathogenic variant in *LMNA* (p. R482Q) associated with Dunnigan familial partial lipodystrophy. This variant is present in our clinical population at a frequency of 0.000115, with additional 10 individuals harboring a molecular finding for the condition but no documented diagnosis of lipodystrophy. A review of the EHR of these individuals showed that they have metabolic abnormalities consistent with lipodystrophy including diabetes, dyslipidemia, and pancreatitis. We then broadly surveyed the DiscovEHR cohort for pathogenic and likely pathogenic variants in lipodystrophy associated genes in order to evaluate the clinical and metabolic profiles of these variant carriers. We observed a substantial burden of metabolic dysregulation in these individuals. Overall, our data show that partial lipodystrophy is an underdiagnosed condition and that its prevalence, as defined molecularly, might be higher than previously reported. Additionally carriers of lipodystrophy-associated variants show metabolic abnormalities in the spectrum of lipodystrophy disease, however they are more often diagnosed as having type 2 diabetes and unspecified metabolic syndrome. Molecularly-guided stratification of patients with "common" disorders, such as diabetes and dyslipidemia, is an important step towards precision medicine and has the potential to lead to more effective therapies for patients.

**Genetic association of irisin with obesity and metabolic syndrome.** *H.B. Jang, H.J. Kim, H.J. Lee.* Korea National Institute of Health, Cheongju, South Korea.

Circulating irisin have been suggested to be involved in the pathogenesis of various complications of obesity, including metabolic syndrome (MetS) and Type 2 diabetes mellitus. We have performed exome-wide association studies to identify genetic variants that influence serum irisin levels and confer susceptibility to obesity and MetS in 677 Korean adolescents. After adjustment with age and sex, we identified 17, 9, and 4 single nucleotide polymorphisms (SNPs) as being significantly associated with irisin, obesity, and MetS ( $P < 5.0 \times 10^{-5}$ ), respectively. Of these, irisin-related 10 SNPs in seven genes (VPS25, EZH1, RAMP2, WNK4, CNTD1) contributed to the risk for obesity and MetS ( $p < 0.05$ ) and MetS-related genetic variants of MMP8 and MMP27 were associated with serum irisin levels and risk of the obesity ( $p < 0.05$ ). This study provides insight into the pleiotropic effects of exome-wide association loci of irisin, obesity and MetS. Based on these results, we are in conducting replication study for independent Korean population.

**Genotype determination: Analysis of *PNPLA3*, *GC*, and *LCP1* genes in nonalcoholic fatty liver disease in south of Iran.** *S.S. Tabei<sup>1</sup>, H. Faramarzi<sup>2</sup>, M. Silawi<sup>1</sup>.* 1) Medical Genetics, Shiraz University of Medical Sciences, Shiraz, Fars, Iran; 2) Community Medicine Department, Shiraz University of Medical Sciences, Shiraz, Fars, Iran.

Nonalcoholic fatty liver disease (NAFLD) is the most common liver disease and liver manifestations of metabolic syndrome. NAFLD is a complex trait which is influenced by polygenes, environmental factors, age and interaction between these factors and is specified by daily intake of  $< 20$  g alcohol, dysfunction of  $> 5\%$  hepatocells in lipid filtration, altered levels of hepatic transaminases and changed blood lipid profile. Obtained data by National Health and Nutrition Examination Survey during 1998 to 2008, represent that prevalence of chronic liver disease except NAFLD has remained stable. In the current study with regard to the growing number of NAFLD cases, we aimed to study the frequency and impacts of three different SNPs: rs738409 (*PNPLA3* gene), rs222054 (*GC* gene), and rs7324845 (*LCP1* gene) in NAFLD group in comparison with control group by RFLP-PCR approach (case group was comprised by 119 NAFLD patients and 118 individuals as control group). Additionally, demographic data were compared between two groups. We found significant association between rs738409 and fatty liver disease ( $p < 0.001$ ), but no association was seen between rs222054 and rs7324845 and NAFLD ( $P > 0.05$ ). In the next step raised results revealed that BMI, waist circumference, and cholesterol had the most significant association with NAFLD development ( $p < 0.01$ ,  $p < 0.002$ , and  $p < 0.009$ , respectively). Also, the incidence of NAFLD in females compared with males showed significant difference ( $p < 0.001$ ). rs738409 (C>G) which resides in *PNPLA3* gene and since 2008 is considered as a potential risk factor for development and progression of NAFLD. In the current study a significant relation between this variation and fatty liver disease was seen ( $p < 0.001$ ) and confirmed the previous results. The presence of rs738409 seems to be associated with obesity, insulin resistance and elevated levels of hepatic amino-transaminases, but the the last feature was not seen in the current study and needs further investigations.

**Metabolomics screen in five metabolic tissues from healthy, prediabetic and type 2 diabetic subjects suggests new defects and points of gene environment interaction.** C. Wadelius<sup>1</sup>, K. Diamanti<sup>2</sup>, M. Cavalli<sup>3</sup>, G. Pan<sup>4</sup>, U. Riserus<sup>5</sup>, S. Skrtic<sup>6</sup>, J. Komorowski<sup>2,5</sup>. 1) Science for Life Laboratory, Department of Immunology, Genetics and Pathology, Uppsala University, Uppsala SE-75108, Sweden; 2) Science for Life Laboratory, Department of Cell and Molecular Biology, Uppsala University, Uppsala SE-75124, Sweden; 3) Department of Public Health and Caring Sciences, Clinical Nutrition and Metabolism, Uppsala University, Uppsala SE-75185, Sweden; 4) AstraZeneca R&D, Mölndal, Sweden; 5) Institute of Computer Science, Polish Academy of Sciences, Warsaw 01-248, Poland.

Type 2 diabetes (T2D) is a complex disease associated with a large number of genetic variants and other risk factors identified in cross-sectional and longitudinal studies. The main metabolic organs suggested to contribute to disease are pancreatic islets, liver, muscle and fat with secondary effects in other tissues. However, the pathophysiological processes in the main tissues have not been elucidated. Many of the risk factors for diabetes identified in blood are secondary to events elsewhere. In order to search for possible primary disease events, we studied a unique material of tissues (pancreatic islets, liver, muscle, fat and serum) from healthy (16), prediabetic (12) and T2D (12) donors. A comprehensive metabolomics analysis was done on all samples and association to disease was determined based on fold change of 50% or  $p < 0.05$  between the groups, in ANOVA or two-tailed t-tests. In line with published data certain lysophosphatidylcholines (lysoPCs) were decreased in serum in T2D compared to healthy controls, while some bile acids were increased, thus validating the methodological approach. In addition, we found that several lysoPCs were decreased in liver, muscle and fat, indicating a widespread metabolic defect. LysoPCs are derived from components in cell membranes and other structures and act as signaling molecules. Furthermore, we found that several carnitines were increased in T2D tissues. Carnitines are conjugated to fatty acids and catabolized in mitochondria to create energy. LysoPCs derived from several polyunsaturated fatty acids (PUFAs) were decreased in different tissues. These PUFAs are synthesized by enzymes encoded by the polymorphic *FADS1/2* and *ELOVL2/5*, which are associated with a range of diseases and traits. We have recently shown that *FADS1* is regulated by rs174557 in an enhancer, which has several binding sites for SREBP1c and is activated by insulin. Analysis of the regulatory elements controlling *ELOVL2* is ongoing and suggests that other environmental signals act on this gene. In summary, our data suggests widespread metabolic defects in tissues of T2D patients that have not been identified before. Our analysis indicates possible involvement of key metabolic enzymes, which will be investigated further. It also underscores the value of studying disease processes in the relevant tissues and of combining genetic data with other -omics data sets.

**Introduction:** Nonalcoholic steatohepatitis (NASH) can be seen not only in adults but also in infants. In infants, various genetic disorders are thought to be involved in the development of NASH although it is often difficult to identify the etiology. A high concentration of intracellular glucose activates lipid synthesis through up-regulation of the lipogenic enzymes including acetyl-CoA carboxylase and fatty acid synthase. Activities of the lipogenic enzymes are known to be regulated by several transcription factors including a Max-like factor X (Mlx) in mice. Mlx contains the basic helix-loop-helix leucine zipper and the dimerization and cytoplasmic localization domain (DCD). Mlx plays an important role in a glucose-mediated transcription of the lipogenic enzymes in the liver through forming a heterodimer with carbohydrate response element-binding protein (ChREBP) and Mondo-A. Hyperglycemia causes nuclear localization of Mlx-ChREBP and Mlx-Mondo-A heterodimers. The former binds the carbohydrate response element leading to activate transcription of the lipogenic enzyme genes and the latter activates transcription of the genes coding the glycolytic enzymes. We present, for the first time, a patient with infantile onset of NASH with a homozygous mutation in the *MLX* gene. **Case Report:** A 6-month-old Japanese male, a product of consanguineous parents (half siblings through their mother), was presented with developmental delay, hypotonia, massive hepatomegaly, hypoglycemia, ketosis, and lactic acidosis. Liver biopsy at age 6 months showed macrovesicular steatosis and the pathological diagnosis of NASH was made. Whole exome sequencing study identified 12 homozygous mutations on the autosomes in the detected 27 runs of homozygosity. Among the identified 12 genes, *MLX* is the only one involved in fatty acid metabolism, suggesting involvement of the homozygous p.I287S mutation in the DCD of *MLX* in the development of NASH. Immunohistochemical studies using anti-*MLX* antibody clearly showed nuclear hyperactive signals of *MLX* in our case but not in an age matched control. Nuclear expression of *MLX* was seen in the hepatocytes of adult patients with NASH. **Discussion:** We demonstrated the first case of infantile NASH with a p.I287S homozygous mutation of *MLX* with the increased expression of *MLX* in the hepatocytes suggesting involvement of *MLX* in the development of infantile onset NASH. More cases are needed to confirm this hypothesis.

## 1844T

**Causality links between gut microbiome and glucose/insulin metabolism and type 2 diabetes.** S. Sanna<sup>1</sup>, U. Vösa<sup>1</sup>, A. Vich Vila<sup>1,2</sup>, M.J. Bonder<sup>1</sup>, A. Kuriilshikov<sup>1</sup>, F. Imhann<sup>1,2</sup>, R. Weersma<sup>2</sup>, L. Franke<sup>1</sup>, A. Mahajan<sup>3</sup>, N. Van Zuydam<sup>3</sup>, M. Costa<sup>3</sup>, M. McCarthy<sup>3</sup>, A. Zhernakova<sup>1</sup>, J. Fu<sup>1</sup>, C. Wijmenga<sup>1</sup>. 1) University of Groningen, University Medical Center Groningen, Department of Genetics, Groningen, The Netherlands; 2) University of Groningen, University Medical Center Groningen, Department of Gastroenterology and Hepatology, The Netherlands; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK; 4) University of Groningen, University Medical Center Groningen, Department of Pediatrics, The Netherlands.

Accumulating evidence suggests that the gut microbiome influences the development of obesity and metabolic diseases. Studies in mice have proposed a causal effect of gut microbiome on the development of obesity and type 2 diabetes (T2D). Due to the complex host-microbe interaction, we hypothesized that a bi-directional causal effect exists between gut microbiome, T2D and T2D intermediary phenotypes. We investigated the effects of impairments in glucose/insulin metabolism on gut microbiome in the LifeLinesDeep population cohort (952 normo-glycemic individuals with metagenomics and genomic profiles) using a Mendelian Randomization (MR) approach. We extracted summary statistics from 32 published genome-wide association studies on obesity, fasting insulin and glucose, insulin secretion, proinsulin and T2D, and constructed 52 polygenic risk scores (PRS) using LD-pruned SNPs at two levels of significance ( $5 \times 10^{-8}$  [N=20] and  $1 \times 10^{-5}$  [N=32]). Of the 273 taxonomies and 523 bacterial pathways assessed, 32 and 22, respectively, were significantly correlated with at least one PRS (FDR<0.1), indicating which specific microbiome composition and function is affected by the host's innate ability to maintain a correct insulin/glucose metabolism. For example, several species of *Actinobacteria* and *Archaea*, such as *Methanobrevibacter smithii* which are important for the digestion of polysaccharides, were less abundant in individuals genetically predisposed to secrete high levels of insulin after glucose intake, and more abundant in those volunteers at high genetic risk for T2D. Individuals at high-risk for T2D showed also a reduced abundance of bacteria involved in degradation of carbohydrates. Our results highlight a causal relation of insulin/glucose metabolism in modulating the microbiome composition and function, bringing new insights into host-microbe interaction.

## 1845F

**Zebrafish larvae as a model system for high-throughput, image-based screens in insulin resistance and diabetes.** A. Emmanouilidou<sup>1,2</sup>, P. Ranefall<sup>2,3</sup>, M. Bandaru<sup>1,2</sup>, A. Allalou<sup>2,3</sup>, E. Ingelsson<sup>4</sup>, M. den Hoed<sup>1,2</sup>. 1) Department of Immunology, Genetics and Pathology, Uppsala Universitet, Uppsala, Sweden; 2) Science for Life Laboratory, Uppsala University; 3) Department of Information Technology, Division of Visual Information and Interaction, Uppsala University, Sweden; 4) Department of Medicine, Division of Cardiovascular Medicine, Stanford University School of Medicine, Stanford, USA.

**Background** Genome-wide association studies identified >100 loci that are robustly associated with the risk of insulin resistance and diabetes. The causal genes and mechanisms remain unidentified for most loci. We aim to examine if zebrafish larvae can serve as a model system for image-based genetic screens in insulin resistance and diabetes. **Methods** In a dietary screen, ~500 larvae with transgenically expressed fluorescent labels on  $\beta$ -cells and/or hepatocytes were overfed on a normal or cholesterol-supplemented diet in the presence or absence of 3% glucose in the medium from 5 to 10 days post-fertilization. In a separate effort, ~800 larvae were metabolically challenged with or without concomitant treatment with rosiglitazone or metformin. At 10 dpf, larvae were soaked in a lipid staining dye, followed by optical sectioning of the pancreatic islet, liver and subcutaneous lipid stores using an automated positioning system and fluorescence microscope.  $\beta$ -cell volume and subcutaneous and liver fat accumulation were quantified objectively using custom-written scripts. Quantitative outcomes were inverse normally transformed and data were analyzed using linear ( $\beta \pm \text{SE}$ ) or logistic (OR [95% CI]) regression, adjusting for time of imaging and batch. **Results** Continuous exposure to 3% glucose showed a positive main effect ( $0.38 \pm 0.17$  SD) and a positive interaction with cholesterol supplementation ( $0.47 \pm 0.23$  SD) for  $\beta$ -cell volume. Glucose exposure also increased the odds of subcutaneous ( $2.24$  [1.28-3.90]) and hepatic fat accumulation ( $2.44$  [1.20-4.96]). Dietary cholesterol supplementation increased the odds of hepatic fat accumulation ( $2.15$  [1.10-4.22]) but reduced the odds of subcutaneous fat accumulation ( $0.40$  [0.23-0.71]). Treatment with rosiglitazone reduced hepatic fat accumulation by  $-0.82 \pm 0.10$  SD and increased the odds of subcutaneous fat accumulation ( $2.16$  [1.07-4.37]). Treatment with metformin had the opposite effect ( $0.33 \pm 0.09$  SD;  $0.38$  [0.16-0.92]). Neither rosiglitazone nor metformin affected  $\beta$ -cell volume ( $P > 0.3$ ). **Conclusion** Challenging zebrafish larvae metabolically for five days induces an insulin resistant state that can to some extent be prevented by treatment with rosiglitazone. Hence, zebrafish larvae are a promising model system for genetic screens in insulin resistance and diabetes. Multiplex CRISPR-Cas9 mutant models for proof-of-concept genes are currently being screened to further validate the model system.

**1846W****New insights into the role of genetic variation within *FGF21* in the**

**pathogenesis of obesity.** E. Aerts<sup>1</sup>, E. Geets<sup>1</sup>, A. Verrijken<sup>2</sup>, G. Massa<sup>3</sup>, K. Van Hoorenbeeck<sup>4</sup>, S. Verhulst<sup>4</sup>, L. Van Gaal<sup>1</sup>, W. Van Hul<sup>1</sup>. 1) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Endocrinology, Diabetology and Metabolic Diseases, Antwerp University Hospital, Antwerp, Belgium; 3) Department of Pediatrics, Jessa Hospital, Hasselt, Belgium; 4) Department of Pediatrics, Antwerp University Hospital, Antwerp, Belgium.

**Objective** Brown adipose tissue is a key site of heat production that has the potential to increase energy expenditure. After the discovery of active brown fat and inducible “brown-like” or beige adipocytes in human adults, browning of white adipose tissue has been considered an attractive obesity target. The fibroblast growth factor 21 (*FGF21*) is one of the most essential inducers of beige adipocytes and so dysregulation of this endocrine factor may be implicated in energy regulation. Therefore, we hypothesized that pathogenic mutations within *FGF21* might be involved in the pathogenesis of obesity. **Methods** We screened 406 severely overweight or obese children and adolescents for mutations in the coding region of the *FGF21* gene with high-resolution melting curve analysis. Direct sequencing was performed for samples with melting patterns deviating from wild-type. To determine the effect of the mutations on the cAMP and NFAT signaling activity of *FGF21*, luciferase reporter assays were performed. **Results** Our mutation analysis resulted in the identification of two non-synonymous coding variants in two unrelated obese individuals: p.R47Q and p.L142V. For p.L142V we were able to demonstrate a significant decrease of the cAMP and NFAT signaling activity of *FGF21*. **Conclusion** With this study, we have demonstrated the presence of a rare variant in a severely obese 6-year-old girl (BMI z-score 3.01) and confirmed its pathogenic effect by performing a luciferase reporter assay. In conclusion, these data confirm the importance of genetic variation within the *FGF21* gene in energy regulation.

**Genetic evidence that early carbohydrate-stimulated insulin secretion affects accumulation and distribution of adiposity.** C.M. Astley<sup>1,2,3</sup>, S.W. Kim<sup>3</sup>, J.N. Todd<sup>1,2,3,4</sup>, R. Salem<sup>5</sup>, R. Fine<sup>3,2</sup>, C.B. Ebbeling<sup>1,2</sup>, D.S. Ludwig<sup>1,2</sup>, J.C. Florez<sup>2,3,4</sup>, J.N. Hirschhorn<sup>1,2,3</sup>. 1) Boston Children's Hospital, Boston, MA; 2) Broad Institute, Cambridge, MA; 3) Harvard Medical School, Boston, MA; 4) Massachusetts General Hospital, Boston, MA; 5) University of California, San Diego, CA.

According to the Carbohydrate-Insulin Model of obesity, a large carbohydrate load exaggerates early postprandial insulin secretion, thereby altering substrate partitioning toward fat deposition and promoting weight gain. This hypothesis is supported by mechanistic studies of metabolic fuels, observational studies, and dietary intervention clinical trials, but not all studies show consistent findings. Genetic predictors of insulin level at 30 minutes following an oral glucose load (insulin-30) can be used as instrumental variables in Mendelian randomization to help further test causality for the association between genetically-determined insulin-30 and obesity and weight gain and to estimate the effect of insulin-30 on anthropometric traits. These genetic-based methodologies are less susceptible to confounding bias due to the randomization of insulin-30 increasing alleles at meiosis. We sought to test the Carbohydrate-Insulin Model using genetic risk score and Mendelian randomization methods, applied to large data sets from MAGIC and GIANT Consortia, and UK Biobank. We assessed effects on both measures of obesity (waist-to-hip ratio, WHR and body mass index, BMI) as well as interval change in BMI. Genetic risk scores for insulin-30 and anthropometric traits were validated and tested in data sets that are independent from the discovery genome-wide association studies. The genetic risk score for insulin-30 predicted interval gain in BMI (p-value < 0.05) better than the genetic risk score for BMI (p-value = 0.61). Mendelian randomization using genetic instruments for the exposure of insulin-30 support causal relationships of increased insulin-30 with increased BMI, waist-to-hip ratio (WHR), and interval gain in BMI (p-values < 0.05). One of the insulin-30 genetic instruments (near *GIPR*) may be mechanistically linked to enteral carbohydrate stimulated insulin secretion, and is associated with a more metabolically unhealthy phenotype, as assessed by WHR. In conclusion, these results provide further support of the Carbohydrate-Insulin Model of obesity suggesting that early insulin secretion after a carbohydrate load, likely in combination with a higher glycemic load diet, contributes to increased adiposity, central adiposity, and continued weight gain over time.

**1848F**

**Exome sequencing in African American children with early-onset obesity reveals new insights.** A. Ches<sup>1</sup>, S.E. McCormack<sup>2,3</sup>, V.V. Thaker<sup>4,5</sup>, H. Hakonarson<sup>3,6</sup>, J.N. Hirschhorn<sup>4</sup>, S.F.A. Grant<sup>1,2,3,6,7,8</sup>. 1) Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Diabetes and Endocrinology, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Division of Endocrinology, Boston Children's Hospital and Harvard Medical School, Boston, MA; 5) Division of Molecular Genetics, Columbia University Medical Center, New York, NY; 6) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 7) Institute of Diabetes, Obesity and Metabolism, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 8) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

African American (AA) youth have an excess burden of obesity compared to children of European ancestry (19.5% vs 14.7%). Given that genetics of obesity have been relatively understudied in populations of African descent, this ethnicity offers an opportunity to uncover of additional causal variants over what has been previously reported. We prioritized for whole exome sequencing AA children (n=181) with both early-onset obesity (<6 yrs) and the most rapid rise in BMI to allow for exploration of rare coding variants typically undetected by GWAS. 'Super Imposition by Translation And Rotation' (SITAR) was leveraged to select cases by fitting BMI curves using a shape-invariant model with a regression B-spline mean curve and subject-specific random effects on both measurement and age scales. Children with known genetic etiologies and/or underlying predisposing conditions were excluded. To reduce the analytical search space and to identify variants more likely to contribute to the trait, we employed two approaches: 1) leveraging a panel of 32 genes with known association to monogenic forms of obesity, 2) examining all genes (n=166) harbored within corresponding topologically-associating domains (TADs) to established BMI/obesity GWAS signals. We focused our analysis on variants predicted to confer a severe (stop-gain, splice-site donor/acceptor, frameshift indel) or moderate (missense, non-frameshift indel) effect on their transcripts, and a MAF<1% in the African population available in ExAC. In known monogenic obesity genes, we identified 8 severe heterozygous variants (4 novel, plus notably a stop-gain R143X in *UCP3* annotated as pathogenic in ClinVar for severe obesity and T2D and a frameshift in *BBS10* annotated as likely pathogenic for recessive Bardet Biedl syndrome) and 63 moderate variants (20 novel, plus the following known: *POMC* R236G associated with early-onset obesity, *MC4R* F202L annotated as of uncertain significance for obesity susceptibility and *VPS13B* V3941VD annotated as probably pathogenic for recessive Cohen syndrome). Going TAD-wise, we identified an additional 34 severe variants (9 novel, including a R734X stop-gain in *RPGRIP1L*, a neighboring gene of *FTO*) and 173 moderate variants (34 novel). As such we uncovered rare genetic variants in AA children with early-onset and persistent obesity, a phenotype more likely to have a genetic etiology. These findings warrant further investigation in larger cohorts and assessment in functional studies.

**Identifying subject-specific regulatory networks of diet-induced weight loss.** D.C. Croteau-Chonka<sup>1</sup>, K. Glass<sup>1</sup>, S.R. Smith<sup>2</sup>, B.J. Stubbs<sup>1</sup>, N.M. Laranjo<sup>1</sup>, F.M. Sacks<sup>1,3</sup>, G.A. Bray<sup>4</sup>, L. Qi<sup>1,5</sup>, V.J. Carey<sup>1</sup>, B.A. Raby<sup>1</sup>. 1) Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 2) Translational Institute, Florida Hospital, Orlando, FL; 3) Department of Nutrition, Harvard School of Public Health, Boston, MA; 4) Pennington Biomedical Research Center, Louisiana State University, Baton Rouge, LA; 5) Obesity Research Center, Tulane University, New Orleans, LA.

Our aim was to characterize the effects of weight loss on adipose tissue biology. We hypothesized that weight loss induces specific structural changes to the transcriptional regulatory network and that the extent of change is correlated with the amount of weight loss. Preventing Overweight Using Novel Dietary Strategies (POUNDS Lost) was a randomized clinical trial testing the effect of dietary interventions on weight loss. We studied 101 POUNDS Lost subjects (mean age = 52.4 years, standard deviation (SD) = 7.9) who lost an average of 8.3 kg (SD = 4.6) over six months. Paired subcutaneous adipose tissue (SAT) samples collected at baseline and six months later for each subject were assayed for 48,803 gene expression probes. We used LIONESS, or Linear Interpolation to Obtain Network Estimates for Single Samples, an extension of the Passing Attributes between Networks for Data Assimilation (PANDA) method, to construct subject-specific regulatory networks before and after weight loss. Overall, there was a trend towards more within-subject network remodeling in SAT of subjects who lost more weight ( $r = 0.18$ ,  $P = 0.072$ ). Subjects who lost less weight tended to have pre- and post-dieting networks that were more similar to one another, while those individuals who lost more weight tended to have more network alterations. Among 462,340 transcription factor (TF)-gene pairs in the aggregate network, sets of 89 and 119 genes demonstrated significantly increased and decreased targeting, respectively, by specific TFs in relation to amount of weight loss ( $P < 0.05$ ). The 89 increasingly targeted genes were enriched for targets of three TFs (adjusted  $P < 0.05$ ): LKLF, SLUG, and PPARA. PPARA, or peroxisome proliferator activated receptor alpha, plays a role in the management of energy stores during fasting. LKLF, or Krüppel-like factor 2, is highly expressed in fat and is a negative regulator of adipocyte differentiation, acting to inhibit PPAR gamma (PPARG). SLUG, or snail family transcriptional repressor 2, also mediates adipogenesis via PPARG. Diet-induced weight loss alters gene expression in adipose tissue, reflecting perturbations of regulatory networks representing coherent and specific biological pathways. Network analyses will help further characterize specific regulatory relationships among genes responding to weight loss at aggregate and individual scales.

**1850T**

**Copy number variation and mutation analysis indicate a possible interesting role of *POU3F2* in the Prader Willi like phenotype.** E. Geets<sup>1</sup>, E. Aerts<sup>1</sup>, A. Verrijken<sup>2,3</sup>, G. Massa<sup>4</sup>, K. Van Hoorenbeeck<sup>2</sup>, S. Verhulst<sup>5</sup>, L. Van Gaal<sup>3</sup>, W. Van Hul<sup>1</sup>. 1) Department of Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Endocrinology, Diabetology and Metabolic Diseases, Antwerp University Hospital, Antwerp, Belgium; 3) Laboratory of Experimental Medicine and Paediatrics, Faculty of Medicine and Health Sciences, University of Antwerp, Antwerp, Belgium; 4) Department of Paediatrics, Jessa Hospital, Hasselt, Belgium; 5) Department of Paediatrics, Antwerp University Hospital, Antwerp, Belgium.

**Background:** Prader-Willi syndrome (PWS), caused by a paternal defect on 15q11.2 – q13, is the most common form of syndromic obesity. Once a clinical diagnosis of PWS cannot be confirmed molecularly with the use of MS-MLPA or additional techniques, patients are classified as Prader Willi like (PWL). Deletions at 6q14.1 – q16.3 encompassing *SIM1* were reported in some individuals with a PWL phenotype. More recently, Kasher and colleagues also identified small deletions encompassing *POU3F2*, and not *SIM1*, in ten individuals from six families with developmental delay, intellectual disability, neonatal hypotonia, susceptibility to obesity and hyperphagia, characteristics resembling the PWL phenotype. In addition, with the use of morpholino and mutant zebrafish models, they showed that the gene lies downstream of *SIM1* in the leptin-melanocortin signaling pathway which indicates that *POU3F2* also has a potentially interesting role in the obesity phenotype of PWL patients. Consequently, we decided to perform copy number variation (CNV) analysis of the *POU3F2* region in a PWL cohort followed by mutation analysis of the gene in both a PWL cohort and obese children and adolescents. **Methods:** A genome-wide microarray analysis was performed in a group of 109 PWL patients. Next, we screened 95 PWL patients and 459 obese children and adolescents for mutations in *POU3F2* using high-resolution melting curve analysis and Sanger sequencing. **Results:** CNV analysis of 109 PWL patients did not show any structural variation encompassing the *POU3F2* gene. The mutation screening resulted in the identification of three interesting nonsynonymous variants: a previously unreported variant p.H255R (c.764A>G) in one PWL patient and two variants, p.G85R (c.253G>A) and p.G352V (c.1055G>T), in two obese adolescents. The latter was also not previously described in public sequencing databases. Additionally, *in silico* analysis showed a probably damaging effect of all three variants on the protein structure of *POU3F2*.

**Conclusions:** In contrast to Kasher and colleagues, no gene harboring deletions were identified in the *POU3F2* region in our PWL cohort. Secondly, taking into account their absence or very low minor allele frequencies in public sequencing databases and the results of *in silico* prediction programs, further functional analysis of p.G85R, p.H255R and p.G352V is useful. This would provide further support for a possible role of *POU3F2* in the pathogenesis of the PWL phenotype.

**A dinucleotide deletion in a putative miRNA target site in long-chain fatty acid elongase *Elovl6* associates with higher thermogenesis and lower body mass index in Pima Indians.** P. Kumar, P. Piaggi, M. Traurig, L.J. Baier. Phoenix Epidemiology and Clinical Research Branch, National Institute of Diabetes and Digestive and Kidney Diseases, Phoenix, AZ.

To determine whether miRNAs have a role in influencing obesity among Pima Indians, variation in miRNAs and predicted miRNA binding sites was identified in whole-genome sequence data from 335 Pima Indians. A dinucleotide deletion (CT; rs200193952) in the 3'-UTR of the *ELOVL6* gene was identified that may disrupt a predicted binding site for miR-204/211. *Elovl6* encodes the long-chain fatty acid elongase that catalyzes the conversion of C16 saturated and monounsaturated fatty acids to C18 fatty acids. *Elovl6* also has an important role in thermogenic action of brown adipose tissue (BAT). Loss-of-function of *Elovl6* causes reduced expression of mitochondrial electron transport chain components that lower the BAT thermogenic capacity. *Elovl6* deficient mice gain weight with increased subcutaneous white adipose tissue and impaired carbohydrate metabolism when beige fat was disabled by thermoneutrality or aging. The CT deletion has a frequency of 5.1% in Pima Indians, while among the populations reported in the 1000 Genomes database, this variant has a frequency of less than or equal to 4.1%. Association analysis of rs200193952 in Pima Indians who had been longitudinally studied identified a modest association with maximum BMI in adulthood ( $p=0.009$ ,  $\beta=-0.0287$  BMI log<sub>e</sub> units,  $N=6714$ ), and maximum BMI Z-score in childhood ( $p=0.005$ ,  $\beta=-0.1611$ ,  $N=5256$ ), where the deletion predicted leanness. We hypothesize that the dinucleotide deletion within the miR-204/211 target site would lead to higher *Elovl6* protein levels, which would increase the thermogenic capacity resulting in a lean phenotype. Therefore, we analyzed energy expenditure (EE) data as continuously measured over 24 hours inside a whole-room indirect calorimeter during energy balance and weight stability. The 24-hour EE trajectory of deletion carriers showed a higher post-prandial thermogenesis despite similar sleeping EE. As a result, carriers had higher "awake and fed" thermogenesis (AFT), calculated as energy expenditure of the non-active fed condition above the minimum metabolic requirement during sleep ( $p=0.008$ ,  $\beta=94.2$  kcal/day,  $N=382$ ). In summary, we have identified variation in a regulatory miRNA target site in *ELOVL6* that associates with lower BMI in Pima Indians and may regulate *Elovl6* levels ultimately increasing daily thermogenesis.

**Low serum insulin-like growth factor-II levels correlate with high body mass index in older American Indian adults.** Y. Muller, D. Mahkee, P. Piaggi, W. Knowler, C. Bogardus, R. Hanson, L. Baier. Phoenix Epidemiology and Clinical Research Branch, National Institutes of Health, Phoenix, AZ.

The hormone insulin-like growth factor-II (IGF-II) regulates metabolism and growth. Data from experimental and gene-association studies have shown that IGF-II may influence body weight or Body Mass Index (BMI). In mouse models, there is an inverse relationship between IGF-II levels and body weight, where overexpression of IGF-II leads to a significant reduction in fat mass and lipid content. In humans, however, both positive and inverse relationships have been reported between circulating IGF-II levels and weight gain or obesity. Therefore, in the current study we assessed the relationship between serum IGF-II levels and BMI in a population based sample of American Indians. Serum samples for measurement of IGF-II levels were available on 713 subjects who were part of a longitudinal study of the etiology of type 2 diabetes among the Gila River Indian Community in Arizona. Blood samples were drawn during an exam when BMI was measured by a medical professional and the subject was determined to be non-diabetic. Serum IGF-II was measured using the method of Enzyme-linked Immunosorbent Assay (ELISA). Cross-sectional analysis showed that serum IGF-II levels did not differ by gender (mean IGF-II=444.3 ng/ml in 285 males; mean IGF-II=449.0 ng/ml in 428 females;  $P=0.77$ ); however, serum IGF-II levels had a strong inverse correlation with age ( $r=-0.39$ ,  $P=2.6 \times 10^{-29}$ ). Among all subjects, lower IGF-II levels correlated with higher BMI ( $r=-0.17$ ,  $P=8.2 \times 10^{-6}$ , adjusted for age, sex and serum storage time). When stratified by age, the strongest correlation was observed in subjects  $\geq 30$  years ( $r=-0.29$ ,  $P=5.2 \times 10^{-7}$ ,  $N=283$ ), a modest correlation was observed in subjects 20-29 years ( $r=-0.15$ ,  $P=0.016$ ,  $N=267$ ) and no correlation was observed in subjects 15-20 years ( $r=0.08$ ,  $P=0.21$ ,  $N=192$ ). Among the 713 subjects, 231 subsequently developed type 2 diabetes. In a Cox proportional hazards model, IGF-II levels did not significantly predict subsequent development of diabetes (HRR=0.98,  $P=0.80$ , adjusted for age, sex, serum storage time and BMI). In summary, our data from a population based sample of American Indians indicate an inverse relationship between serum IGF-II levels and BMI, where the correlation is stronger at older ages.

**Contrasting the genetic architecture of human thinness and severe obesity.** F. Riveros Mckay Aguilera<sup>1</sup>, V. Mistry<sup>2</sup>, R. Bounds<sup>2</sup>, A.E. Hendricks<sup>1,3</sup>, J.M Keogh<sup>2</sup>, H. Thomas<sup>2</sup>, E. Henning<sup>2</sup>, S. O'Rahilly<sup>2</sup>, E. Zeggini<sup>1</sup>, E. Wheeler<sup>1</sup>, I. Barroso<sup>1,2</sup>, I.S. Farooq<sup>2</sup>, *Understanding Society Scientific Group.* 1) Wellcome Trust Sanger Institute, Cambridge, United Kingdom; 2) University of Cambridge Metabolic Research Laboratories and NIHR Cambridge Biomedical Research Centre, Wellcome Trust-MRC Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, United Kingdom; 3) Department of Mathematical and Statistical Sciences, University of Colorado-Denver, Denver, CO 80204, USA.

Obesity is a highly heritable trait and one of the leading causes of preventable death worldwide. In recent years, the prevalence of the condition has been steadily increasing making it a major global public health priority. In Western countries this rise in prevalence has been linked to environments facilitating poor-quality food choices and sedentary behaviour. Genetic association studies so far have been mainly focused on identifying genes and pathways associated with either body mass index or obesity. From a drug development perspective though, identifying biological pathways associated with lifelong healthy thinness within an "obesogenic" environment can lead to novel plausible therapeutic targets. To this end, we characterised the heritability of persistent human healthy thinness in 1471 individuals, and contrasted it with that of early onset severe childhood obesity ( $N=1456$ ). Our analysis revealed that persistent leanness is a heritable trait ( $h^2=28.07\%$ ) comparable to childhood obesity ( $h^2=32.33\%$ ). Persistent thinness has a negative genetic correlation with adult BMI ( $r^2=-0.63$ , 95% CI [-0.44,-0.82],  $p=3.54 \times 10^{-11}$ ) while childhood obesity has a positive and stronger genetic correlation ( $r^2=0.86$ , 95% CI [0.74, 0.98],  $p=1.86 \times 10^{-43}$ ). We also found that the loci influencing these traits at the tails of the BMI distribution are not complete mirror images of each other. Instead some loci, like *CADM2*, have a stronger effect on the lower end of the BMI distribution, supporting the hypothesis of different mechanisms, or gene-environment interactions in the two extremes of the distribution. Finally, using a genome-wide association approach with imputation to UK10K + 1000 genomes (genome-wide significance threshold  $P=5 \times 10^{-8}$ ), we highlight a novel variant associated with persistent thinness near *PI15* (rs12362703,  $p=1.52 \times 10^{-9}$ ) and a new locus associated with obesity (*FAM150B*,  $OR=1.72$ ,  $p=5.68 \times 10^{-9}$ ). Altogether, our results show that studying persistent thinness can be a powerful approach to further understand the genetic architecture of body weight regulation.

**The role of genetic and self-identified ancestry in determining obesity among African and Hispanic Americans.** A. Vishnu<sup>1,2</sup>, G. Belbin<sup>1</sup>, E. Kenny<sup>1</sup>, E. Bottinger<sup>1</sup>, R.J.F. Loos<sup>1,2</sup>. 1) The Charles Bronfman Institute for Personalized Me, Icahn School of Medicine at Mount Sinai, New York, NY; 2) The Genetics of Obesity and Metabolic Traits Program, Icahn School of Medicine at Mount Sinai, New York, NY.

Individuals of African and Hispanic ancestry are at higher risk of obesity than individuals of European ancestry in the United States (US). This may be due to differences in environmental factors, such as cultural and social practices, but may also in part be genetically driven. Here, we examined to what extent African ancestry is associated with body-mass index (BMI) among 6,368 African-American (AA) and 7,569 Hispanic American (HA) participants in the New York City based BioMe™ biobank. We quantified global genetic ancestry using ADMIXTURE, specifying two putative ancestral populations (k=2) to distinguish African from non-African ancestry. We excluded participants with significant Native American ancestry i.e. ≥30% (determined with k=3). We used linear regression to examine association between percentage African ancestry and BMI among AAs and HAs. Covariates examined were age, sex, self-reported ancestry (HA vs. AA), US vs. non-US born status, and their interactions. Stepwise regression procedures were used to select variables which significantly ( $P < 0.05$ ) contributed. Participants exhibited varying levels of admixture, resulting in a wide spectrum of African ancestry present in both self-reported AAs (25<sup>th</sup>, 50<sup>th</sup>, 75<sup>th</sup>, 90<sup>th</sup> pcts: 79%, 86%, 92%, 96%, respectively) and HAs (15%, 26%, 41%, 60%, respectively). Among AAs and HAs, 18% and 60% of participants are non-US born, respectively. As analysis showed a strong interaction between ancestry and sex, we report results for men and women separately. Among women, genetic and self-reported ancestry, age and country of birth were significantly associated with BMI. However, the association differed between US-born and non-US-born women ( $P$ -interaction=0.004). For every 10% higher genetic African ancestry, BMI increases by 0.40 kg/m<sup>2</sup> ( $P=1.7E-07$ ; ~1.09kg for a 1.65m tall woman) and 0.19 kg/m<sup>2</sup> ( $P=3.1E-04$ ; ~0.51kg) among US-born and non-US born women, respectively. Independent of genetic ancestry, BMI in women who self-report as AA was 0.79 kg/m<sup>2</sup> ( $P=1.2E-02$ ) lower than self-reported HAs. In contrast, among men self-reported HA status (+0.96 kg/m<sup>2</sup>, ~2.94 kg for a 1.75m tall man) and being US-born (+1.37 kg/m<sup>2</sup>, ~4.21kg) influenced BMI, while no significant association was detected for genetic ancestry ( $P=0.2$ ). Besides the contribution of environmental factors, genetic ancestry contributes to variation in BMI among HA and AA women. However, among men, only country of origin and self-reported ancestry play a role.

**Genetic diversity and functional genomic mapping in an Emirati population with type 2 diabetes.** K.S. Elliott<sup>1</sup>, H. Daggag<sup>2</sup>, G.B. Busby<sup>1</sup>, L.J. Petherbridge<sup>1</sup>, E. Lau<sup>1</sup>, M. Butler<sup>3</sup>, A. Yavari<sup>3</sup>, M.T. Barakat<sup>2</sup>, H. Ashrafian<sup>3</sup>, J.C. Knight<sup>1</sup>. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, UK; 2) Imperial College of London Diabetes Centre, Abu Dhabi, UAE; 3) Experimental Therapeutics, Radcliffe Department of Medicine, University of Oxford, UK.

Type 2 diabetes (T2D) is a leading global health problem, particularly acute in the Middle East where prevalence in Arab countries is 25.5% compared to 9.3% in the US. Unique genetic architecture due to marriage culture can provide a powerful resource to uncover novel genetic factors previously unidentified in large Caucasian cohorts. To explore this, over 700 individuals of Emirati descent (comprising confirmed and undiagnosed T2D) have been recruited through the ICLDC in Abu Dhabi. Genotyping used Illumina's Multi Global Ethnic SNP array was followed by principle components analysis (PCA) with 1000 Genomes phase 3 data. Overlap with West Asian and African populations is consistent with geography and human population history. Further PCA centred on the Abu Dhabi Emirati cohort has shown that many individuals with the same family name cluster together indicating a shared ancestry. More detailed analysis using Finestructure revealed distinct groups which share more ancestry with each other than other individuals within the cohort which also correlates with family name. T2D and obesity related clinical records have allowed GWAS to search for disease risk alleles. Preliminary analysis has revealed an excess of  $p < 10^{-4}$  signals in known BMI genes ( $p=2.3 \times 10^{-4}$ ) and one of the top signals in T2D is a SNP in the *CDKAL1* gene ( $p=4.6 \times 10^{-6}$ , OR=1.2) independent of the previously reported GWAS hit in Europeans. The presence of this variant in one of the largest effect size T2D genes increases confidence in positive replication. Such an association in a relatively small sample size infers that the genetic component of metabolic disease in the Emirati population may be greater compared to Caucasian populations, where very large sample sizes have been required to detect equivalent signals. This gives optimism for discovery of further novel T2D and obesity variants as analysis continues. Verification of these results is being sought in appropriate related populations. Using publicly available data we will extend the analysis to include other geographically neighbouring populations from the Middle East, North Africa, Caucasus and Western Asia also providing further insights into the genetic architecture and evolution of the Emirati population. This novel population makes a powerful and innovative dataset for identifying T2D and obesity variants specific to the Emirati population which could be used in the future to direct appropriate healthcare and treatment.

**1856T****Effects of long noncoding RNA regulation of gene expression on type 2 diabetes.**

A.J. Payne<sup>1</sup>, M. van de Bunt<sup>1,2</sup>, C.M. Lindgren<sup>1,3,4</sup>, M.I. McCarthy<sup>1,2,5</sup>, *The GTEx Consortium*. 1) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 2) Oxford Centre for Diabetes, Endocrinology & Metabolism, University of Oxford, Oxford, United Kingdom; 3) The Big Data Institute, University of Oxford, Oxford, United Kingdom; 4) Broad Institute of Harvard and MIT, Cambridge, MA, United States; 5) NIHR Oxford Biomedical Research Centre, Churchill Hospital, Oxford, United Kingdom.

Long noncoding RNAs (lncRNAs) account for a large proportion of human transcripts and have been implicated in cellular function which when disrupted can contribute to disease. We assessed lncRNA associations with type 2 diabetes (T2D) and relevant processes using data from the GTEx Project. Using 48 tissues from up to 565 individuals in GTEx v7 (22% with T2D), analysis identified 355 genes with significant (FDR of 0.01) differential expression (DE) between T2D cases and controls, 344 of them coding genes, and 11 lncRNAs. To assess the potential of lncRNAs as regulators in T2D-associated processes, co-expression modules were constructed using all expressed genes in each tissue. Enrichment for T2D-associated lncRNAs was assessed in each module by comparing the Fisher score of DE p-values of its lncRNAs to a distribution of Fisher scores from random lncRNAs. Of the 5580 total modules, 131 were enriched (FDR of 0.01). Two-sample Mendelian Randomisation (MR) using genetic instruments associated with each module eigengene found no causal effects of the 131 T2D-lncRNA-enriched module eigengenes on any of 8 diabetes-related GWAS phenotypes, including T2D, fasting insulin, and fasting glucose. One module of 54 co-expressed genes (from pancreas) was enriched for the GO terms 'insulin secretion' and 'regulation of insulin secretion': no other modules over-represented terms containing 'insulin' or 'glucose'. This module's eigengene was significantly associated with T2D risk (logistic regression  $p=6.75 \times 10^{-5}$ ). The module contained 5 coding genes with significant T2D DE (*PPP1R1A*, *IAPP*, *G6PC2*, *HADH*, *HHATL*), and a lncRNA with nominal DE (*CTB-12O2.1*;  $p_{\text{adjusted}}=0.012$ ). T2D-risk was associated with lower expression of each. *CTB-12O2.1*, a long intergenic noncoding RNA, has no known links to T2D or glycaemic traits. Two-stage least squares regression MR using elastic-net-derived genetic instruments found that *CTB-12O2.1* expression affected the module's eigengene ( $p=0.0013$ ), suggesting a regulatory function of *CTB-12O2.1* amongst the module's genes. This study identified a cluster of genes co-expressed in whole human pancreas that is enriched for lncRNA T2D DE, is over-representative of genes involved in insulin secretion, and has aggregate expression associated with T2D risk. lncRNA *CTB-12O2.1* has a potential regulatory effect on expression of this module, making it a candidate regulator of a T2D-associated process in humans.

**1857F****Identification of eQTLs affecting expression levels in both adipose and skeletal muscle tissues.** W.-C. Hsueh, S. Kobes, R.L. Hanson. NIDDK, NIH, Phoenix, AZ.

Transcriptomic studies in tissues related to glucose metabolism may yield insights into genetic causes of diabetes. By analyses of empirical identity by descent (IBD) sharing between individuals in a founder population, we previously showed significant heritability in many of 16,820 transcripts measured in both skeletal muscle ( $n=220$ ) and subcutaneous abdominal adipose tissues ( $n=209$ ). We now extend this to examine the role of expression quantitative trait loci (eQTL) across tissues. Transcript levels were measured on the Affymetrix Human Exon 1.0 ST Array and genotypes on the Illumina HumanCore-Exome-24 BeadChip. Extent of both genome-wide and gene-specific (200kb up- and down-stream of its coding region) IBD between all pairs of subjects was estimated based on genotypes for ~217,000 SNPs with Beagle. We estimated narrow-sense heritability ( $h^2$ ) of each transcript affecting levels in both tissues, and partitioned out the contributions of *cis*- ( $h^2_{\text{cis}}$ ) and *trans*-elements ( $h^2_{\text{trans}}$ ), adjusting for age, sex and an ancestry estimate. With correction for multiple comparisons by the false discovery rate (FDR), we identified 470 significant ( $p_{\text{FDR}} < 0.05$ ) *cis*-eQTL for muscle tissue and 196 *cis*-eQTL for adipose. *Cis*-eQTL identified in one tissue were significantly more likely to also be *cis*-eQTL in the other (Yule's  $Q=0.89$ ,  $p=3.9 \times 10^{-119}$ ). Transcript level measures in both muscle and adipose tissues were available from 103 individuals. Levels of 1,028 transcripts (6%) were nominally ( $p < 0.05$ ) correlated across tissues. Adipose *cis*-eQTL were 6.4 times more likely to correlate across tissues than the usual transcript, while muscle *cis*-eQTL were 4.6 times more likely ( $p < 0.0001$  for both). For 53 transcripts that were significantly correlated across tissues ( $p_{\text{FDR}} < 0.05$ ), we conducted bivariate analysis to partition the correlation into *cis*-genetic, *trans*-genetic and environmental effects. The majority (47 or 89%) of these transcripts shared significant *cis*-genetic determinants, while 13% shared significant *trans*-effects, and non-genetic factors were significant for 45%. On average, 46% of the cross-tissue correlation was due to *cis*-eQTL, 17% due to *trans* effects and 37% to non-genetic effects. These analyses suggest that *cis*-eQTL are major genetic determinants of cross-tissue correlation in transcript levels, and that lessons learned by identification of *cis*-eQTL may often generalize across tissues.

Evaluating the contribution of alternative splicing in the liver to variation in lipid levels

Lipid levels are heritable traits associated with cardiovascular disease risk, and previous genome-wide association studies (GWAS) have identified more than 150 loci associated with these traits. However, the underlying genetic mechanism(s) for the majority of lipid loci are not well understood. While intense effort has been devoted to the identification of genetic variants that causally affect complex traits via gene expression (eQTLs), recent research indicates that changes in the abundance of alternatively spliced transcripts may be another contributing mechanism (Zhang et al., 2015). Consequently, identifying genetic loci that associate with alternative splicing (*i.e.*, sQTLs) in primary liver tissue - an organ highly relevant for lipid traits - would be ideal, but has not been described to date.

To address this gap, we present results from an sQTL discovery effort using data from more than 300 primary liver and stem cell-derived hepatocyte samples. Gene ontology analysis confirms that the alternatively-spliced genes associated with identified sQTLs are enriched for liver-specific processes including alcohol and lipid metabolism. To evaluate the contribution of our sQTLs to variation associated with lipid levels, we present the results of co-localization analysis using GWAS data generated by the Global Lipid Consortium (Global Lipids Genetics Consortium et al., 2013). We demonstrate that sQTLs co-localize with lipid loci previously unexplainable using eQTL data alone. Finally, given that liver-dependent gene regulation has been shown to impact lipid levels, we compare the enrichment of presumed tissue-restricted sQTLs in GWAS lipid loci to the enrichment of multi-tissue sQTLs (identified using 44 tissues from GTEx) in GWAS lipid loci. Given that relatively few studies have evaluated the relationship between alternative splicing and complex traits, our efforts provide an important contribution to understanding genetic mechanisms influencing both cardiovascular disease risk and complex traits in general.

**Meta-analysis of >150 genome-wide studies for association with blood lipid levels.** S.E. Graham<sup>1</sup>, G. Hindy<sup>2,3</sup>, W. Zhou<sup>4</sup>, G. Abecasis<sup>5</sup>, G. Peloso<sup>2,6,7</sup>, S. Kathiresan<sup>3,6,8,9</sup>, C.J. Willer<sup>1,4,10</sup>, Global Lipids Genetics Consortium. 1) Department of Internal Medicine, Division of Cardiovascular Medicine, University of Michigan, Ann Arbor, MI; 2) Department of Clinical Sciences, Lund University, Malmö, Sweden; 3) Program in Medical and Population Genetics, Broad Institute, Cambridge, MA; 4) Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 5) Center for Statistical Genetics, Department of Biostatistics, University of Michigan School of Public Health, Ann Arbor, MI; 6) Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA; 7) Department of Biostatistics, Boston University School of Public Health, Boston, MA; 8) Department of Medicine, Harvard Medical School, Boston, MA; 9) Cardiovascular Research Center, Massachusetts General Hospital, Boston, MA; 10) Department of Human Genetics, University of Michigan, Ann Arbor, MI.

Cardiovascular disease is a predominant cause of death worldwide and is mediated by circulating levels of blood lipids. Approximately half of all cases of cardiovascular disease are attributed to inherited genetic risk factors, yet only ~10-12% of genetic variation is thought to be explained by previously identified variants. To further understand the genetic contributions to cardiovascular disease we are performing a meta-analysis of over 150 studies with an estimated final sample size of >500,000 individuals collected through the Global Lipids Genetics Consortium (GLGC). All samples were genotyped with a genome-wide array and were imputed using 1000 Genomes Phase 3 with European samples additionally imputed using the Haplotype Reference Consortium. We tested for association between single variants and indels with 5 lipid phenotypes: total cholesterol, HDL-cholesterol, LDL-cholesterol, non-HDL cholesterol, and triglycerides. We collected covariance matrices from all cohorts to allow for conditional analysis and rare variant burden testing. We will present our findings aimed at discovering novel lipid loci and uncovering biological mechanisms for association at these loci by integrating with epigenetics data. We will also determine the causal role of these lipid phenotypes in cardiovascular disease by performing multivariate Mendelian randomization studies and examining lipid genetic risk score associations with diseases in the UK biobank.

**1860F**

**Population and medical genetics of the Kibbutzim Family Study.** S. Carmi<sup>1</sup>, E. Granot-Hershkovitz<sup>1</sup>, D. Karasik<sup>2,3</sup>, I. Peter<sup>4</sup>, Y. Friedlander<sup>1</sup>, H. Hochner<sup>1</sup>. 1) Public Health, The Hebrew University of Jerusalem, Jerusalem, Israel; 2) Medicine, Bar Ilan University, Safed, Israel; 3) Institute for Aging Research, Hebrew SeniorLife, Boston, MA; 4) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY.

**Background:** The Kibbutzim Family Study (KFS) tracks large families living in long-term social stability and homogeneous environment in Northern Israel. Extensive information on anthropometric and cardio-metabolic phenotypes was collected on 1032 participants during two visits, eight years apart. We genotyped 901 individuals on an exome-chip array (500k SNPs), making the KFS one of the largest genotyped family-based cohorts in Israel. Here, we report results for the population-genetic characteristics of the KFS as well as for genotype-phenotype associations. **Population genetics:** The KFS participants are mostly self-reported Ashkenazi Jewish (AJ; 85%), with the remaining reporting various other Jewish ancestries. Principal Component Analysis of the KFS, jointly with Jewish and world-wide samples, confirmed self-reported ancestries and allowed precise assignment of ethnic origins to the remaining individuals. Interestingly, we observed, for the first time, a weak genetic distinction between AJ originating from Eastern and Western Europe. Using family-based phasing and shared haplotypes analysis, we confirmed claims of a recent severe AJ bottleneck (point estimates: effective size  $\approx 450$  individuals, 23 generations ago). **Complex traits:** We imputed the KFS using 1000 Genomes data and 128 AJ whole-genomes, reaching 6.9M variants with imputation quality  $>0.9$  and minor allele frequency  $>1\%$ . We used linear mixed models to conduct a genome-wide association study of 17 cardio-metabolic risk phenotypes. Our strongest associations, which replicated previously discovered regions, were for Lipoprotein (a) (rs56393506, upstream of *LPA*;  $P=9 \cdot 10^{-7}$ ), weight (chr.8p23.1;  $P=3.6 \cdot 10^{-9}$ ) and low-density lipoprotein (chr.16q22.1-2;  $P=8.8 \cdot 10^{-7}$ ). Effect sizes were largely correlated between baseline values and the differences across visits, suggesting shared genetic architecture. Finally, we observed, for some phenotypes, an enrichment of association signals at alleles with an elevated frequency in the KFS compared to Europeans, in line with the expected value of the AJ founder population for trait mapping. **Summary:** The KFS is a valuable resource for the study of the population genetics of Israel as well as of cardio-metabolic traits under a homogeneous environment.

**1861W**

**Regulatory activity and deletion of rs3780181 suggests a molecular mechanism at the VLDLR lipid GWAS locus.** J. Davis, T. Roman, S. Vadlamudi, M. Zeynalzadeh, A. Iyengar, K. Mohlke. Department of Genetics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

Blood lipids, including total cholesterol (TC) and low-density lipoprotein cholesterol (LDL-C), are heritable risk factors for cardiovascular disease. The molecular mechanisms underlying the majority of blood lipid-associated GWAS signals remain elusive. One association signal is located in intron 3 of *VLDLR*: rs3780181-A is associated ( $P \leq 2 \times 10^{-9}$ ) with increased TC and LDL-C. rs3780181 is also associated with the expression level of *VLDLR* in liver samples. To investigate the variants and genes underlying the association signal, we evaluated allelic differences in functional regulatory assays and used genome editing to delete the putative regulatory element. We tested a 222-bp DNA element surrounding rs3780181 for enhancer activity using transcriptional reporter assays in human HepG2 hepatocytes, THP-1 monocytes, and SGBS preadipocytes. We generated 3-4 independent clones for each allele in both forward and reverse orientations with respect to a minimal promoter. We observed the highest enhancer activity in THP-1 cells, 5-fold more than an empty vector (EV) control. In HepG2 and THP-1 cells, the risk allele rs3780181-A had decreased enhancer activity than the non-risk G-allele element in the both orientations. The allelic difference in enhancer activity was significant ( $P \leq 0.009$ ) in both orientations in HepG2 cells, and significant ( $P=0.02$ ) in the forward orientation in THP-1 cells. In electrophoretic mobility shift assays using nuclear extracts of THP-1 and HepG2 cells, the risk allele rs3780181-A showed stronger specific protein binding than the G-allele. To determine if the enhancer containing rs3780181 affects expression of nearby genes *in vivo*, we used CRISPR-cas9 to engineer a deletion of the DNA surrounding rs3780181 in HEK293T kidney cells, and we measured the effect of the homozygous deletions on expression of nearby genes: *VLDLR*, a lipoprotein receptor, and the adjacent gene, *SMARCA2*, a chromatin-remodeler. All expression levels were normalized to the housekeeping gene *ACTB*. The enhancer deletion cell lines ( $n=8$ ) showed 1.2-fold significantly ( $P < 0.04$ ) decreased *VLDLR* and *SMARCA2* expression when compared to the wild-type ( $n=3$ ) and mock-edit control cell lines ( $n=6$ ). Together, these results suggest that altered binding of a transcriptional repressor to the A-allele of rs3780181 decreases activity of an enhancer of *VLDLR* and/or *SMARCA2*, leading to increased TC and LDL-C.

**Heritability and genetic correlation of 25 complex traits in Taiwanese population.** C. Lin<sup>1,2</sup>, M. Su<sup>1,2</sup>, C. Hsiung<sup>1,2</sup>, C. Shen<sup>1,2</sup>. 1) Taiwan Biobank, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

Recent studies have shown that the heritability variation across a wide range of multiple traits, which is always specific to a particular population. Taiwan Biobank (TWB) provides a unique opportunity to evaluate the heritability of multiple traits in Han Chinese population. We estimated the proportion of phenotypic variance explained by the common variants for 25 complex traits derived from the TWB. The genetic correlation between pairs of traits in Taiwanese population were estimated by Genome-wide Complex Trait Analysis (GCTA). More than 16,000 samples were genome-wide genotyped using the Affymetrix Axiom TWB array, which was specifically designed for Taiwanese population. After data quality control, genotype data of 598,060 single nucleotide polymorphisms (SNPs) in 13,231 unrelated individuals were analyzed. We found the highest heritability (0.47) estimated by common SNPs is body height among 25 complex traits. Based on the phenotypic correlation and genetic correlation between 25 traits, triglyceride and uric acid show a relatively high correlation with multiple traits such as systolic blood pressure (SBP), Hemoglobin A1c (HbA1c), and high-density lipoprotein (HDL). It is indicated that triglyceride and uric acid may play an important role in most of common disease such as hypertension, type 2 diabetes, and hyperlipidemia. We also noticed that increased triglyceride or increased uric acid might causally increases SBP and HbA1c and decreases HDL. Our study describes the phenome-wide heritability and genetic correlation in Taiwanese population, and reveals that triglyceride and uric acid may play an important role in the causal relationship among type 2 diabetes, hypertension, and hyperlipidemia. The purpose of these results may demonstrate a good model of potential of TWB how to make good use of TWB information to estimate heritability of common diseases.

**1863F**

**Genome-wide association study of HDL efflux phenotypes in 5,143 French Canadians.** K.S. Lo<sup>1</sup>, C. Low-Kam<sup>1</sup>, D. Rhoads<sup>1</sup>, M.-P. Dubé<sup>1,2</sup>, G. Lettre<sup>1,2</sup>, J.-C. Tardif<sup>1,2</sup>. 1) Montreal Heart Institute, Montreal, Quebec, Canada; 2) Faculty of Medicine, Université de Montréal, Montreal, Quebec, Canada.

High-density lipoproteins (HDL) are the centerpiece of reverse cholesterol transport by which cholesterol is removed from peripheral cells and transported to the liver for excretion. Despite this potent anti-atherosclerotic role, neutral clinical trials and Mendelian randomization studies have shed doubt on the "good" cholesterol hypothesis (Barter et al. 2007; Schwartz et al. 2012; Voight et al. 2012). These results have shifted the interest of the community from merely increasing HDL-cholesterol (HDL-C) concentration to understanding HDL composition and functions. Then, recent studies have shown that cholesterol efflux of serum HDL (the capacity of HDL particles to accept cholesterol from macrophages) is an independent risk predictor of coronary artery disease (CAD) (Khera et al. 2011; Rohatgi et al. 2014). Here, we attempted to identify the genetic determinants of HDL efflux in the French Canadian population. In a subset of 2,002 participants (~50% with myocardial infarction (MI)), we obtained HDL-related measures (HDL-C, apoA-I and LCAT concentrations), nuclear magnetic resonance spectroscopy data, and HDL efflux using 3 different cellular assays (J774, BHK, HepG2). We observed significant correlations between HDL-C concentration and triglyceride levels ( $r=-0.47$ ), large HDL particle concentration ( $r=0.87$ ), HDL particle size ( $r=0.7$ ), and HDL efflux (J774 basal efflux,  $r=0.65$ ; J774 stimulated,  $r=0.4$ ). HDL efflux was independently associated with reduced MI risk after adjustment for traditional risk factors ( $P=6 \times 10^{-11}$  for J774 basal efflux). We measured HDL efflux in an additional 3,397 participants. We combined low-pass whole-genome sequencing and genome-wide genotyping followed by imputation to test the association between HDL efflux phenotypes and genotypes at >31M variants. The strongest hits included loci previously associated with HDL-C concentration (e.g. *CETP*, *LIPC*, *LPL*, *APOA1*). We repeated the association analyses, correcting for HDL-C and triglyceride levels. We saw no enrichment of association results for HDL efflux when focusing on variants previously associated with CAD. Also, there was no enrichment of association signals when considering regulatory sequences from the liver or hepatocytes. Overall, our initial results suggest that HDL effluxes are typical human complex traits controlled by variants of weak effect sizes. This highlights the importance of increasing sample size to define the genetic determinants of this promising CAD biomarker.

**Genetic effect assessment of functional variants on blood lipid traits by exome-wide association study.** S. Moon, S. Han, M.Y. Hwang, K.H. Yoon, Y.J. Kim, B.-J. Kim. Division of Genome Research, Korea National Institute of Health, Cheongju-si, Chungcheongbuk-do, South Korea.

Dyslipidemia of high density lipoprotein cholesterol (HDLc), low density lipoprotein cholesterol (LDLc), triglyceride (TG) and total cholesterol (TC) involved in the lipid metabolism has a crucial role in the pathogenesis of metabolic syndrome emerging as a major public health issue. Although large-scale genome-wide association identified many genetic loci associated with the metabolic syndrome and related traits, there is a few studies on the effect of coding polymorphisms. Here, we evaluated the role of exonic variants related the lipid traits (HDLc, LDLc, TG, and TC) to discover exonic variants associated with the development of metabolic syndrome. We performed exome-wide analysis using about 14,000 individuals (7,442, 3,407 and 3,037 in discovery, replication 1 and 2, respectively) from Korean Genome and Epidemiology Study genotyped with the Illumina HumanExome Beadchip (hereafter referred to as the ExomeChip). Using the Exome Aggregation Consortium browser, we examined genetic effects of all functional variants including missense, loss-of-function in the ExomeChip. Consequently, a total of 3,474 functional variants of 24 genes which have at least a functional variant associated with lipid traits. From the results, we confirmed that 45 common variants listed in GWAS catalog are replicated in our study regardless of ethnic difference. Moreover, we assessed genetic effects of 3,474 functional variants. Of these, 138 variants were significantly associated with lipid traits ( $P < 5 \times 10^{-6}$  in discovery,  $P < 5 \times 10^{-2}$  in each replication stage). Of 138 associated variants, 53 variants showed a pleiotropic effect in at least two traits. Some of variants were significant only in Asian population. Our results provide researchers with the useful evidence to understand causal variants and risk factors associated with lipid-related traits.

**1865T**

**A multi-trait genetic association approach to identify genetic loci not identified before in single-trait GWAS of lipid traits.** M. Preuss<sup>1,2</sup>, G. Nadkarni<sup>1</sup>, R. Loos<sup>1,2,3</sup>. 1) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai; 2) The Genetics of Obesity and Related Metabolic Traits Program, Icahn School of Medicine at Mount Sinai; 3) The Mindich Child Health and Development Institute, Icahn School of Medicine at Mount Sinai.

Obesity, combined with a poor lipid profile, increases the risk of cardiovascular disease substantially. Large-scale genome-wide association studies (GWAS) have identified more than 360 genetic loci associated with body mass index (BMI), and circulating triglyceride, HDL- and LDL-cholesterol (HDL-C, LDL-C) levels. These GWASs have mainly focused on one single trait at a time, and the loci identified may not fully represent the biology that underlies these correlated traits. Here, we performed a multi-trait genome-wide association analysis that considers those four traits simultaneously in one analysis. We speculate that such multi-trait approach will identify genetic loci that highlight a more comprehensive biology to further elucidate the link to cardiovascular disease. We used mtSet (Casale FP et al. 2015), a multi-trait LMM set test that enables joint analysis across multiple correlated traits and multiple sets of variants while accounting for population structures and relatedness. MtSet uses as a sliding window (of 30kb) approach, resulting in ~174,000 windows and a Bonferroni corrected genome-wide significance (GWS) of  $P = 2.9 \times 10^{-7}$ . Each trait was adjusted for age, and residuals were log- and rank-transformed to normality in men and women separately. Phenotype data was extracted from electronic health records (EHRs) for 1,560 African ancestry (AA) and 1,982 Hispanic ancestry (HA) participants of the Mount Sinai BioMe BioBank for whom 1000 Genomes (Phase 3) imputed data was available. No loci reached genome-wide significance, but six reached suggestive significance ( $P < 10^{-5}$ ), covering *NAALADL2* ( $P = 1.5 \times 10^{-6}$ ), *KIAA1324L* ( $P = 8.5 \times 10^{-6}$ ) and a CNV at 5q14 ( $P = 1.2 \times 10^{-6}$ ) in individuals of African ancestry AA, and *LMCD1* ( $P = 8.7 \times 10^{-7}$ ), a *lincRNA at 4q28* ( $P = 1.8 \times 10^{-6}$ ), and *ZNF431* ( $P = 2.9 \times 10^{-6}$ ) in individuals of Hispanic Ancestry. Even though our study has still insufficient power, results are promising despite the small sample size. We are now increasing the sample size to confirm our observations and to subsequently narrow-down the loci and interpret their biological relevance. None of the suggestive loci have been previously implicated in obesity and lipid-related traits. We believe that a multi-trait genome-wide analysis provides an alternative approach to further and more comprehensively elucidate the broader biology that underlies correlated traits and diseases.

**1866F****Low LDL cholesterol concentrations are associated with increased risk of type 2 diabetes.**

Q. Feng<sup>1</sup>, W.Q. Wei<sup>2</sup>, C.P. Chung<sup>3</sup>, R.T. Levinson<sup>4</sup>, A.C. Sundermann<sup>5</sup>, J.D. Mosley<sup>1</sup>, L. Bastarache<sup>2</sup>, J.F. Ferguson<sup>6</sup>, N.J. Cox<sup>4</sup>, D.M. Roden<sup>1</sup>, J.C. Denny<sup>2</sup>, M.F. Linton<sup>4,5</sup>, D.R.V. Edwards<sup>4,5</sup>, C.M. Stein<sup>1,6</sup>. 1) Division of Clinical Pharmacology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN; 3) Division of Rheumatology, Vanderbilt University Medical Center, Nashville, TN; 4) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN; 5) Vanderbilt Epidemiology Center, Institute for Medicine and Public Health, Vanderbilt University, Nashville, TN; 6) Division of Cardiovascular Medicine, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN.

**Background** Observations from Mendelian randomization studies and statin clinical trials suggest that low LDL-C levels may be associated with increased risk of type 2 diabetes (T2DM). **Methods** We used de-identified electronic health records (EHRs) at Vanderbilt University Medical Center to compare the risk of T2DM among individuals with very low ( $\leq 60$  mg/dL, N=8,943) and normal (90-130 mg/dL, N=71,343) LDL-C levels. LDL-C measurements associated with statin use, hospitalization, or a serum albumin level  $< 3$  g/dl were excluded. We used a two-phase approach; in 1/3 of the sample (discovery) we used T2DM phenotype-wide association (PheWAS) codes, and in the remaining 2/3 (validation) we identified T2DM cases and controls using a validated algorithm. The prevalence of T2DM in the low and normal LDL-C groups was compared using logistic regression with adjustment for age, race, sex, body-mass index (BMI), HDL-C, triglycerides, and duration of care. Sensitivity analyses included exclusion of subjects with a previous medical condition representing a possible indication for statin therapy (diabetes or myocardial infarction) and those with advanced renal disease and organ transplantation. Secondary analyses included stratification of sex, race, BMI, and LDL-C level. **Results** In the discovery cohort, PheWAS code 250.2 (T2DM) was significantly more frequent in the low LDL-C group ( $p = 1 \times 10^{-33}$ ). In the validation cohort, the risk of T2DM was increased in the low compared to normal LDL-C group (OR 2.4, 95% CI 2.1-2.8;  $P < 2 \times 10^{-16}$ ). The findings were near identical in sensitivity analyses. The association between low LDL-C levels and T2DM was significant in males (OR 2.4, 95% CI 2.0-3.0) and females (OR 1.7, 95% CI 1.4-2.1), and in normal weight (OR 2.2, 95% CI 1.6-3.0), overweight (OR 2.2, 95% CI 1.7-2.8) and obese (OR 2.0, 95% CI 1.7-2.4) individuals, and in individuals with LDL-C  $< 40$  mg/dL (OR 2.3, 95% CI 1.7-3.1) and LDL-C 40-60 mg/dL (OR 2.0, 95% CI 1.7-2.3); P-values all  $< 10^{-6}$ . The association was significant in whites (OR 2.7, 95% CI 2.3-3.2;  $P < 2 \times 10^{-16}$ ) but not blacks (OR 1.1, 95% CI 0.8-1.5;  $p=0.56$ ). **Conclusions** Low LDL-C concentrations occurring in the absence of statin treatment were significantly associated with T2DM risk in a large EHR population; this increased risk was present in both sexes and all BMI categories, and in whites but not blacks. The findings suggest special attention be paid to T2DM risk with therapies aiming to markedly lower LDL-C.

**1867W****Whole exome sequencing identifies coding variants associated with NMR-based lipid phenotypes in a large cardiovascular cohort.**

S. Giambardino<sup>1</sup>, R. McGarrath<sup>1</sup>, L.C. Kwee<sup>1</sup>, J. Overton<sup>2</sup>, J. Reid<sup>3</sup>, S.G. Gregory<sup>1</sup>, A. Baras<sup>3</sup>, C.B. Newgard<sup>1,3</sup>, W.E. Kraus<sup>1</sup>, S.H. Shah<sup>1</sup>. 1) Duke Molecular Physiology Institute, Duke University, Durham, NC; 2) Regeneron Genetics Center, Tarrytown, NY; 3) Sarah W. Stedman Nutrition and Metabolism Center, Duke University, Durham, NC.

Although high density lipoproteins (HDL) are known colloquially as “good cholesterol,” with lower HDL levels associated with higher cardiovascular (CV) risk, increasing evidence suggests that more granular HDL determinations around HDL particle size are better predictors of risk. Studies have shown that higher levels of small HDL particles exhibit strong CV protective effects. And while genetic studies of lipids have identified novel therapeutic targets, they have not focused on these more refined evaluations which may provide better signals. Utilizing the CATHeterization GENetics (CATHGEN) cohort, a cohort of patients who received cardiac catheterization, we measured HDL subclasses using NMR in frozen, fasting plasma. Whole exome sequencing was performed and resulted in 8,557 individuals for analysis. Given prior studies showing the strongest association between the molar sum of concentrations of small and medium HDL subclasses (HMSP) with CV risk, analyses were focused on this lipid phenotype. After quality control measures were applied, single variant association testing was performed using linear regression models adjusting for within-ancestry population stratification, batch, age and sex, stratified by ancestral groups. With a MAF threshold of 0.01, stratified analysis datasets contained 5,882 individuals and 170,081 autosomal variants for the European ancestral group and contained 1,671 individuals and 294,165 autosomal variants for the African ancestral group. Results from these stratified tests were then combined and meta-analyzed. Five exomic variants met genome-wide significance ( $p \leq 5 \times 10^{-8}$ ) for association with HMSP in the meta-analysis and localized to three genomic regions: chr2:27.3-27.5Mbp (rs1260326 and rs4665972 in *GCKR* and *EIF2B4*, min.  $p=1 \times 10^{-16}$ ), chr19:44.9Mbp (rs7412 in *APOE*,  $p=4 \times 10^{-98}$ ) and chr20:45.9-46.0Mbp (rs3918251 and rs7679 in *SLC12A5-AS1* and *PCIF1*, min.  $p=1 \times 10^{-8}$ ), with a consistent direction of effect across ancestral groups. Using a large CV cohort, we have identified genetic loci strongly associated with the HDL subclass biomarker HMSP, a more granular marker of HDL cholesterol and a stronger predictor of CV risk than conventional HDL. These loci highlight potential novel lipid loci mediating inter-individual variation in HDL cholesterol phenotypes but also identify a known lipid and CV locus (*APOE*).

Peter<sup>1</sup>. 1) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Department of Epidemiology, University of North Carolina, Chapel Hill, NC; 3) Department of Statistics & Biostatistics, Rutgers University, New Brunswick, NJ; 4) Keck School of Medicine, University of Southern California, Los Angeles, CA; 5) University of Hawaii Cancer Center, Honolulu, HI; 6) School of Medicine & Health Sciences, George Washington University, Washington, DC; 7) Information Sciences Institute, University of Southern California, Los Angeles, CA; 8) Icahn School of Medicine at Mount Sinai, New York, NY; 9) Vanderbilt University Medical Center, Nashville, TN; 10) Department of Genetics, Rutgers University, New Brunswick, NJ; 11) Cancer Prevention Institute of California, Fremont, CA.

Lipid levels are heritable polygenic traits associated with cardio-metabolic outcomes. Extensive genome-wide association studies (GWAS) have been conducted in European-ancestry populations, identifying >150 loci. However, few studies included African Americans (AAs) or Hispanics, who are characterized by distinct genetic backgrounds and lipid profiles. In this study, we performed a GWAS for high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), triglycerides (TG) and total cholesterol (TC) in a multi-ethnic population from the PAGE Study, consisting of 10,137 AAs, 17,856 Hispanics, 2,387 Asians, 1,915 Hawaiians, 604 Native Americans and 360 other individuals. Participants were genotyped using the Multi-Ethnic Genotyping Array, followed by imputation using all 1000 Genomes Phase 3 data. Lipid levels were adjusted for medication by adding a constant, and TG values were log-transformed. All participants were pooled for association testing, adjusted for age, sex, study, self-identified ethnicity, center, household membership and the first 10 principal components (PCs). Stratified analyses within each ethnic group, conditional analyses adjusting for previously defined loci and interaction analyses between SNPs and PCs were also performed. We identified two novel loci for HDL (8q22-rs11782435 and 14q22-rs75405126,  $P=2.94E-9$  and  $2.07E-8$ , respectively), one novel loci for TG (SLC4A5-rs186278890,  $P=3.34E-10$ ) and one novel loci for TC (CREB3L2-rs73729087,  $P=1.52E-8$ ), with consistent directions and comparable effect sizes across ethnic groups ( $P_{\text{heterogeneity}}>0.05$ ). Multiple novel independent signals were identified in reported loci (CETP, LCAT, LIPG, SCARB1, TOM1, LDLR, HRP, LPL, APOE and SAMM50), and substantial refinement was observed at APOA5 for TG, reducing the number of SNPs in high LD ( $r^2>0.6$ ) with the top hit in AAs by 100%. Of the 40 reported loci replicated in our study ( $P\leq 5E-8$ ), 18 showed significant heterogeneity ( $P<0.05$ ). In addition, four AA-specific novel loci (MTA1-rs60255124, CDH3-rs564672295 and STEAP1-rs373140531 for HDL and MTHFD2-rs186278890 for TG,  $P\leq 3.52E-8$ ) and two Hispanic-specific novel loci (7q22-rs552830302 for HDL and RNF44-rs188713108 for TC,  $P\leq 4.30E-8$ ) were identified, showing disparate allele frequencies between ancestral populations. These results highlight the importance of conducting GWAS in diverse populations, in order to provide a more complete portrait of the genetics basis underlying lipid traits.

Kathiresan<sup>1</sup>, P.S. Tsao<sup>11</sup>, P.W.F. Wilson<sup>2</sup>, T.L. Assimes<sup>11</sup> on behalf of the VA Million Veteran Program. 1) Massachusetts General Hospital, Boston, MA; 2) Perlman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) VA Boston Healthcare System, Boston, MA; 4) University of Utah School of Medicine, Salt Lake City, UT; 5) Boston University School of Public Health, Boston, MA; 6) Penn State University, Hershey, Pennsylvania; 7) University of Michigan Medical School, Ann Arbor, MI; 8) Emory University School of Medicine, Atlanta, GA; 9) University of Michigan School of Public Health, Ann Arbor, MI; 10) VA Connecticut Healthcare, West-Haven, CT; 11) Stanford University School of Medicine, Stanford, CA.

**Background:** Large-scale biobanks that integrate biosamples with clinical phenotypes from an electronic health record (EHR) may catalyze better understanding of disease etiology, prevention, and treatment. The Million Veteran Program (MVP) is a national, voluntary research program to study how genes affect health in US veterans. Circulating plasma concentrations of high-density lipoprotein cholesterol (HDL), low-density lipoprotein cholesterol (LDL), triglycerides, and total cholesterol are known risk factors for cardiovascular disease, and represent the main therapeutic targets for disease prevention and treatment. **Methods:** For 353,323 participants genotyped using a custom MVP array, we extracted clinical phenotypes from the EHR spanning an average of 10 years per participant. We tested the association for up to 32 million genotyped and imputed DNA sequence variants for association with plasma HDL, LDL, triglycerides, and total cholesterol, and combined association results with published literature via meta-analysis. **Results:** Of 353,323 genotyped participants, 302,271 had lipid data available for analysis. 72% were of European ancestry, 20% were African American, and 8.3% were Hispanic. Genome-wide association testing in MVP and meta-analysis with published literature (combined  $N>600,000$ ) yielded 129 novel associations at genome-wide level of significance. For example, carriers of a rare missense mutation in Perilipin-1 (PLIN1 p. L90P, minor allele frequency = 0.08% in MVP) demonstrated a 2.65 mg/dL (0.233 standard deviation) higher plasma HDL after testing in 596,475 individuals. Perilipin-1 is required for lipid droplet formation, triglyceride storage, and free fatty acid metabolism. Frameshift loss of function mutations in Perilipin-1 have been reported to result in severe lipodystrophy. **Conclusions:** In a large-scale biobank leveraging the electronic health records of US veterans, we have identified 129 new genetic signals for blood lipid levels.

**1870W****Genome-wide association study of anthropometric, cardiovascular, and lipid biomarkers in an ethnically diverse cohort of sub-Saharan Africans.**

Sub-Saharan Africa is home to a diversity of cultures and ethnic groups whose complex history and regional adaptations have led to high levels of genetic and phenotypic variation across the continent. Sub-Saharan populations typically have low linkage disequilibrium as they did not undergo an out-of-Africa population bottleneck, allowing for fine-mapping of trait-associated loci. We present genome-wide association results across a cohort of up to ~2,000 individuals from ethnically diverse rural Central, Eastern, and Southern African populations encompassing a variety of lifestyles (hunter-gatherers, pastoralists, and agriculturalists). Genotypes are derived from array data augmented by imputation based on whole genome sequence data. The set of quantitative traits investigated include anthropometric measurements (including height, BMI, percent body fat), cardiovascular traits (including pulse, blood pressure), and circulating lipid biomarkers (including cholesterol, HDL, LDL). For many traits we find large variation among populations and ethnicities, including height, blood pressure, LDL, and BMI. Estimates of heritability, ethnic and regional variation in trait associations, and comparison to non-African associations are discussed. The association results are a unique resource for understanding the genetic architecture of quantitative traits relevant to human health in a diverse set of African populations under-represented in human genetic studies. NIH grant 1R01DK104339-01 and 1R01GM113657-01 to SAT. This work was supported in part by a pilot-project funded by the Center of Excellence in Environmental Toxicology at the University of Pennsylvania (NIH P30-ES013508) and by NIEHS Training Grant (T32-ES019851) to MH.

The transmembrane 6 superfamily member 2 (*TM6SF2*) loss-of-function variant, rs58542926, is a genetic risk factor for nonalcoholic fatty liver disease and progression to fibrosis, but is also associated with lower levels of hepatic-derived triglyceride-rich lipoproteins. *TM6SF2* is expressed predominately in liver and small intestine, sites for triglyceride rich lipoprotein biogenesis and export. In light of this, we explored whether *TM6SF2* may exhibit analogous effects on both liver and intestine lipid homeostasis. To test this, we genotyped rs58542926 in 983 bariatric surgery patients from the Geisinger Medical Center for Nutrition and Weight Management, Geisinger Health System (GHS) in PA and from 3,556 study participants enrolled in the Amish Complex Disease Research Program (ACDRP). Although these two cohorts have different metabolic profiles, carriers in both cohorts had improved fasting lipid profiles. Importantly, following a high fat challenge, carriers in the ACDRP cohort exhibited significantly lower postprandial serum triglycerides suggestive of a role for *TM6SF2* in the small intestine. To gain further insight into this putative role, effects of *TM6SF2* deficiency were studied in a zebrafish model and in cultured human Caco-2 enterocytes. In both systems *TM6SF2*-deficiency resulted in defects in small intestine metabolism in response to dietary lipids including significantly increased lipid accumulation, decreased lipid clearance and increased endoplasmic reticulum (ER) stress. Consistent with this, we also observed increased hepatic ER stress in human carriers of the variant. These data strongly support a role of *TM6SF2* in regulation of systemic lipids potentially through a role for *TM6SF2* in intracellular lipid metabolism in liver and intestine. .

## 1872F

**Gender differences in genetics of body composition and obesity traits after an intensive exercise intervention.** A.I. Vazquez<sup>1</sup>, F. Dong<sup>2</sup>, H. Kim<sup>1</sup>, Y.L. Bernal-Rubio<sup>1</sup>, J.R. Fernandez<sup>3</sup>, M.S. Bray<sup>2</sup>. 1) Epidemiology and Biostatistics, Michigan State University, East Lansing, MI; 2) Department of Nutritional Sciences, University of Texas, Austin, TX, USA; 3) Department of Nutrition Sciences, University of Alabama at Birmingham, Birmingham, AL, USA.

The genetic variation on body composition measures has been shown to differ across gender and race/ethnicity; however, little is known about how genes differentially influence body composition changes, particularly in the context of potential hormonal differences associated with gender. In the Training Interventions and Genetics of Exercise Response (TIGER) study genetic variation was examined in sedentary adults (18-35 y) who participated in a controlled aerobic exercise 15-week protocol. 1012 non-Hispanic white, 700 African American, and 332 Hispanic participants were genotyped using the MetaboChip (Illumina, Inc.). Measures of body weight, BMI, waist/hip ratio (WHR), lean mass (Lean-M), fat mass (Fat-M), bone mass (Bone-M) and percent fat (%Fat) were obtained pre- and post-intervention. We performed genome wide association studies (GWAS) for baseline traits, and change between pre and post-intervention. GWAS were done in within races and in the PC-adjusted multiethnic group. Genomic heritability (GH; inter-individual variation explained by SNPs) for baseline and change measures were estimated through Bayesian analysis. Weight, BMI, waist, hip, Fat-M and %Fat were reduced with the intervention, while there was an increase in Lean-M and Bone-M. Body changes after an exercise intervention have a large genetic component, with GH ranging between 0.2 and 0.4. GH of change measures was variable across genders. Females (F) had the highest GH for change in WHR (mean [95% Confidence Region]: 0.56 [0.33;0.79] for F vs 0.28 [0.07;0.52] for males [M]), an indicator of fat topography. Males had the highest GH for change in weight (0.37 [0.12;0.64] for M vs 0.17 [0.05; 0.3] for F), BMI (0.44 [0.18;0.72] for M vs 0.25 [0.08;0.44] for F), fat-M (0.45 [0.16;0.75] for M vs 0.19 [0.06;0.34] for F), lean-M (0.29 [0.08;0.53] for M vs 0.19 [0.06;0.34] for F), and Bone-M (0.38 [0.11;0.67] for M vs 0.21 [0.06;0.38] for F). Among the top genes and pathways represented by the significant genes in gender-specific analyses were the FTO pathway in females, and the Nuclear Receptors in Lipid Metabolism pathway in males. Our results establish the existence of gender-specific differences associated with change in weight and body composition and demonstrate that changes in body size/mass traits between gender differ in inter-individual variation and pathways, supporting the importance of examining genetic effects specific to genders.

Proprotein convertase subtilisin/kexin type 9 (PCSK9) is a secreted protease that has profound effects on plasma levels of LDL cholesterol (LDL-C) by mediating degradation of LDL receptor. Loss-of-function (LoF) mutations have been shown to associate with reduced risk for cardiovascular events. PCSK9 inhibitors have been developed and have been shown to effectively and safely induce more favorable lipid profile and to reduce the rate of cardiovascular events. To study whether carriers of the LoF variant had any adverse or beneficial health outcomes we analyzed life-long national health registry data in 44500 Finnish individuals. We examined the health data of 3340 carriers of the PCSK9 R46L (rs11591147) LoF variant (3270 heterozygotes and 70 homozygotes) and compared them to 41160 non-carriers. Our large harmonized phenome-wide association study data set comprises of 97 different quantitative traits, 440 disease endpoints and 174 drug categories derived from nationwide registries that include follow-up data from hospitalizations since 1969, cancers (1952), specialty clinic visits (1998), drug purchases (1995), and drug reimbursements (since 1964). By utilizing drug purchase data, we were able to analyze the usage of drugs from several categories (eg. cardiovascular system, metabolism, and systemic hormonal preparations). As expected, the variant carriers have lower levels of LDL-C (beta=-0.4 mmol/l, p=9x10<sup>-67</sup>), total cholesterol (beta=-0.38 mmol/l, p=4x10<sup>-64</sup>), apolipoprotein B (ApoB) (beta=-0.08 g/l, p=1x10<sup>-74</sup>), ApoB to ApoA1 ratio (beta=-0.07, p=6x10<sup>-46</sup>) and higher levels of HDL cholesterol (beta=0.02 mmol/l, p=6x10<sup>-6</sup>). Underscoring the validity of the Finnish registry data, variant rs11591147 carriers also had reduced risk of hyperlipidemia (OR=0.56 (0.44-0.7), p=2x10<sup>-9</sup>), myocardial infarction (OR=0.68 (0.55-0.82), p=6x10<sup>-6</sup>) and they were significantly less likely to have ever purchased lipid modifying agents (ATC C10A) (OR=0.57 (0.52-0.63), p<2x10<sup>-17</sup>). Most importantly, across a diverse set of disease endpoints covering neurodegenerative, gastrointestinal, cardiovascular, respiratory, cancer, allergy and immune mediated diseases, we did not observe any significantly increased risk for any diseases or increased use of prescribed medicines. Our study demonstrates the benefit of large population cohorts, biobank samples and decades of centrally aggregated health registry data in evaluating potential comorbidities or adverse effects of drug targets.

**Background:** Familial hypercholesterolemia (FH), characterized by inherited high levels of low-density lipoprotein cholesterol (LDL-C) and consequently premature coronary heart disease, is caused by many rare variants in a few genes, including *LDLR*, *APOB* and *PCSK9*. Hundreds of FH variants have been documented, but the impact of these variants at the population level is poorly studied due to their low frequencies. **Design and Methods:** Using genome-wide genotypes from a customized Affymetrix Axiom<sup>®</sup> array from 331,107 ethnically diverse participants of the Million Veteran Program (MVP), we identified FH variants based on clinical significance categories ("pathogenic" or "likely pathogenic") from ClinVar. We then determined the collective and individual impact of each of these variants on untransformed maximum available laboratory measures of LDL-C over up to 15 years (maxLDL). **Results:** Of the 62 "pathogenic" or "likely pathogenic" SNPs archived in ClinVar and genotyped in the MVP, we observed 58 variants from *LDLR* and *APOB* at least once. 1,616 individuals in total had at least one of these variants, resulting in an estimated carrier frequency of 1: 205 among the MVP participants, and 1:84 (1.2%) in those with maxLDL > 190 mg/dL. On average, FH variants in *APOB*, *LDLR* or both genes associate with greater maxLDL by 23.6 mg/dL ( $p=1.1 \times 10^{-24}$ ), 18.3 mg/dL ( $p=2.4 \times 10^{-22}$ ), and 20.4 mg/dL ( $p=1.5 \times 10^{-103}$ ), respectively. We then examined the genetic effects of 12 rare FH variants, each with more than 30 observed carriers (carrier frequency between 0.01% and 0.56%), and confirmed that carriers of seven variants had higher mean levels of maxLDL (6-80 mg/dL) than non-carriers. Phenotypic effects for European Americans and African Americans (AAs) were largely similar, but several variants, including rs201573863 and rs151207122, were predominantly observed in AAs. **Conclusion:** Putatively pathogenic FH variants have a wide spectrum of phenotypic effects on LDL-C, and have various frequencies in the population - some are race-specific. More robust evidence of genotype-phenotype associations of FH variants is needed to accurately infer at-risk individuals from genotype-based screening to aid in decisions regarding the intensity of LDL-lowering.

## 1875F

**Lipid loading in human liver cells induces differential expression of 88 genes.**

M. Alvarez<sup>1</sup>, K. Garske<sup>1</sup>, J. Benhammou<sup>1</sup>, Y. Bhagat<sup>1</sup>, P. Pajukanta<sup>1,2,3</sup>. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, USA; 2) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, USA; 3) Molecular Biology Institute at UCLA, Los Angeles, USA.

Fatty acids are building blocks of triglycerides (TG), associated with obesity and metabolic disorders, such as type 2 diabetes and non-alcoholic fatty liver disease. The liver plays a key role in metabolizing free fatty acids (FFAs), and this process is highly regulated to ensure an appropriate energy balance. In insulin resistance and metabolic diseases, FFAs are continually released from adipose tissue into the blood, inducing the liver to ectopically accumulate lipids by taking in fatty acids. It is therefore important to understand the human hepatocyte transcriptomic response to lipid uptake. To this end, we explored the effect of uptake of the saturated fatty acid, palmitic acid (PA), on global mRNA transcription in the human liver cell line, HepG2. We incubated HepG2 cells with PA conjugated to BSA, in serum-depleted media for 24 hours. We also incubated HepG2 cells with BSA as a vehicle-only control in serum-depleted media. We prepared the RNA-seq libraries using the Illumina TruSeq Stranded mRNA library prep kit. Libraries were sequenced at a depth of 25-30 M paired-end reads on an Illumina HiSeq 4000 platform. Each group was conducted and sequenced in triplicates. We mapped the reads using the STAR 2-pass protocol, and counted against the Gencode version 26 annotation using HTSeq. Differentially expressed (DE) genes were identified using the edgeR pipeline, employing FDR<0.05. Of the 11,408 expressed genes, 9 were significantly down-regulated while 79 genes were up-regulated in response to lipid loading. After running DAVID pathway analysis, the most enriched pathways passing the multiple testing correction were glycolysis/gluconeogenesis, steroid biosynthesis, and pentose phosphate pathways. Sixteen genes encoding mitochondrial respiratory chain enzymes were also up-regulated. Noteworthy, we identified several DE genes with no previous implication in fatty acid metabolism, including 3 metallothionein genes and 3 ribosomal genes. Next, we investigated how much the +/- 500 kb local *cis* regions of these genes explain of heritability of TG levels using LD Score. We found that these *cis* regions explained 3.3% of the TG heritability, a significant 4.3-fold enrichment ( $p=0.019$ ). Overall, the 88 DE genes induced by lipid loading help elucidate the cellular responses to environmental dietary cues in the human liver, and provided 88 candidate genes of which 39 are novel for exploring gene-environment interactions in metabolic diseases.

**1876W**

**Human liver transcriptomes reveal potential new cholesterol genes under tight co-regulation with statin-targeted cholesterol synthesis pathway genes.** A. Ko<sup>1,2</sup>, D. Kaminska<sup>1,3</sup>, E. Nikkola<sup>1</sup>, J. Pihlajamäki<sup>3,4</sup>, P. Pajukanta<sup>1,2,5</sup>. 1) Department of Human Genetics, David Geffen School of Medicine at UCLA, Los Angeles, CA; 2) Molecular Biology Institute at UCLA, Los Angeles, CA; 3) Institute of Public Health and Clinical Nutrition, University of Eastern Finland, Kuopio, Finland; 4) Clinical Nutrition and Obesity Center, Kuopio University Hospital, Kuopio, Finland; 5) Bioinformatics Interdepartmental Program, UCLA, Los Angeles, CA.

Obesity may perturb cholesterol synthesis and other key liver functions by inducing ectopic fat deposition to the liver, which can cascade to non-alcoholic fatty liver disease (NAFLD), non-alcoholic steatohepatitis (NASH), cirrhosis, and cancer. To identify genes affected in liver due to obesity, we performed RNA-sequencing (RNA-seq) on liver biopsies and cataloged metabolic and histological traits from 259 obese bariatric surgery patients. Using 15,670 expressed genes, we carried out weighted co-expression network analysis to identify co-regulated genes critical to liver's main functions as well as differential expression (DE) analysis between healthy and NASH livers (n=69 and 43) to uncover disease-perturbed genes. Overall, 19 signed co-expression modules were identified of which 11 are significantly associated (FDR<0.05) with fatty liver, fibrosis, an aggregated NAFLD phenotype, and lipid traits. Notably, a 75-gene module that positively correlates with statin usage (FDR=2.0x10<sup>-16</sup>) displays enrichment for cholesterol biosynthesis pathway (FDR=9.68x10<sup>-14</sup>) and protein-protein interactions (P<0.00001), implying statin's strong effect on cholesterol synthesis pathway at both mRNA and protein levels. Importantly, the module is highly preserved in an independent liver RNA-seq cohort from GTEx (n=96, Z-score>10), suggesting their consistent liver mRNA co-regulation. The module comprises the statin target gene, *HMGCR*, and 19 other known cholesterol genes (e.g. *SREBF2*, *LDLR* and *PSCK9*) in high correlation with new candidates for cholesterol regulation (e.g. *DERL3*, *SLC29A2*, *C14ORF1*, and *DNHD1*). The flanking (±500kb) variants of the 67 module genes that are individually associated with statin usage (P<6.67x10<sup>-4</sup>) show high enrichment for LDL-cholesterol (LDL-C) GWAS signal (P=0.0012) and account for 5% of LDL-C heritability using LD Score, indicating their genetic effect on LDL-C. Based on the DE analysis, 13 statin-module genes are significantly up-regulated in NASH subjects, including key members from cholesterol biosynthesis and fatty acid pathways (e.g. *SQLE*, *MVK*, *FADS1*, and *ACLY*), suggesting possible disruption of their co-regulation with other statin-module genes by NASH. As statins can induce adverse side effects, such as liver damage or type 2 diabetes, the novel statin-associated genes we identified by integrating phenotype, liver histology, and transcriptomic data provide potential targets for new therapeutic agents of hypercholesterolemia.

**1877T**

**Genetic regulation of adipose tissue transcript expression is involved in modulating serum triglyceride and HDL-cholesterol.** S.K. Das<sup>1</sup>, S.P. Sajuthi<sup>2</sup>, N.K. Sharma<sup>3</sup>, M.E. Comeau<sup>2</sup>, J.W. Chou<sup>2</sup>, D.W. Bowden<sup>2</sup>, B.I. Freedman<sup>4</sup>, J.S. Parks<sup>5</sup>, C.D. Langefeld<sup>2</sup>. 1) Internal Medicine-Endocrinology, Wake Forest School of Medicine, Winston-Salem, NC; 2) Department of Biostatistical Sciences, Division of Public Health Sciences, Wake Forest School of Medicine, Winston-Salem, NC; 3) Department of Biochemistry, Wake Forest School of Medicine, Winston-Salem, NC; 4) Department of Internal Medicine, Section on Nephrology, Wake Forest School of Medicine, Winston-Salem, NC; 5) Department of Internal Medicine, Section on Molecular Medicine, Wake Forest School of Medicine, Winston-Salem, NC.

Dyslipidemia is a major contributor to the increased cardiovascular disease and mortality associated with obesity and type 2 diabetes. We hypothesized that variation in expression of adipose tissue transcripts is associated with serum lipid concentrations in African Americans (AAs), and common genetic variants regulate expression levels of these transcripts. Fasting serum lipid levels, genome-wide transcript expression profiles of subcutaneous adipose tissue, and genome-wide SNP genotypes were analyzed in a cohort of non-diabetic AAs (N=250). Serum triglyceride (TRIG) and high density lipoprotein-cholesterol (HDL-C) levels were associated with expression level of 1458 and 2089 adipose tissue transcripts, respectively, but poorly associated with total cholesterol or LDL-C levels. Serum HDL-C-associated transcripts were enriched for salient biological pathways, including branched-chain amino acid degradation, and oxidative phosphorylation. Genes in immuno-inflammatory pathways were activated among individuals with higher serum TRIG levels. We identified significant cis-regulatory SNPs (cis-eSNPs) for 449 serum lipid-associated transcripts in adipose tissue. The cis-eSNPs of 12 genes were associated with serum lipid level in genome wide association studies in Global Lipids Genetics Consortium (GLGC) cohorts. Allelic effect direction of cis-eSNPs on expression of *MARCH2*, *BEST1* and *TMEM258* matched with effect direction of these SNP alleles on serum TRIG or HDL-C levels in GLGC cohorts. These data suggests that expressions of serum lipid-associated transcripts in adipose tissue are dependent on common cis-eSNPs in African Americans. Thus, genetically-mediated transcriptional regulation in adipose tissue may play a role in reducing HDL-C and increasing TRIG in serum.

**1878F**

**The X-factor of complex disease: Development of methods and software for analysis of the X chromosome in GWAS and RVAS reveals X-autosomal gene-gene interactions and X-linked associations underlying lipid levels and their sexual dimorphism.** A. Keinan<sup>1,2,3,4</sup>, S. Carmi<sup>5</sup>, F. Gao<sup>1</sup>, L. Lo<sup>1</sup>, L. Ma<sup>6</sup>, R. Ma<sup>1</sup>, Y. Qiu<sup>1</sup>, A. Slavney<sup>1</sup>, K. Ye<sup>1</sup>. 1) Department of Biological Statistics & Computational Biology, Cornell University, Ithaca, NY; 2) Cornell Center for Comparative and Population Genomics, Cornell University, Ithaca, NY; 3) Center for Vertebrate Genomics, Cornell University, Ithaca, NY; 4) Center for Enervating Neuroimmune Disease, Cornell University, Ithaca, NY; 5) Braun School of Public Health and Community Medicine, The Hebrew University of Jerusalem, Jerusalem, Israel; 6) Department of Animal and Avian Sciences, University of Maryland, College Park, MD.

A unique role of ChrX in complex disease and quantitative traits is expected from its role in model organisms, human Mendelian disorders, and sexual dimorphism. However, its role remains poorly tested as GWAS largely ignored or incorrectly analyzed it. A similar picture emerges for sequence-based association studies (lit. review). For several years, we developed methods and software for X that span all GWAS stages (XWAS), including QC, genotype calling, stratification correction, and statistical tests that both account for and exploit X-inactivation, which is becoming commonly used. In a first large-scale XWAS, we analyzed 27 GWAS datasets of different autoimmune diseases and reported 22 X-linked replicated associations, most with sex-specific effect size and related functions. However, we were puzzled by association of a locus in *COSMC* with 2 IBDs. Recently, this result led to a functional mouse study, revealing *COSMC* loss leads to IBD-like microbiota disruption and results in gut inflammation, mostly in males, and to extensive mechanistic insight. This example stresses the importance of studying X's role in complex diseases as a stepping stone toward sex-specific diagnosis and treatment. I will present results from the following efforts, with only brief examples below: 1) Beyond sex-specific X-linked effects, we test sex-specific X-linked modulation of previously associated autosomal loci, using lipid levels as initial testbed, partly due to our experience with these in GWAS, pharmacogenomics, and nutrigenomics; 2) Large-scale XWAS meta-analysis of lipid levels based on >50 datasets; 3) XWAS of several psychiatric disorders since they are highly sexually dimorphic and X genes play key roles in neurological development; 4) We develop methods for sequence-based association studies, including X-tailored variant and genotype calling, as part of and in coordination with GATK, and optimizing statistics for testing a region or a set of X-linked rare variants; 5) We broadly apply these newly-developed methods, initially to lipid levels. 1) We discovered 4 such X-Auto interactions underlying HDL levels alone. 2) One association with both diastolic and systolic BP is within *GRIA3*, which product interacts with a  $\beta$ 2-adrenergic receptor encoded by *ADRB2*, which has been implicated in BP response to inhibitors 5) In RVAS of UK10K, we optimized SKAT's weight function based on theoretical predictions to be steeper for X, which greatly improved power (but not for autosomes).

**Common and rare genetic variants for asthma, hay fever and eczema.** W. Ek, T. Karlsson, M. Rask-Andersen, A. Johansson. Department of Immunology, Genetic, Science for Life, Uppsala University, Uppsala, Uppsala, Sweden.

**Purpose** The heritability for asthma has been estimated to 82 % and for hay fever and eczema to 60-80% <sup>1</sup>. Previous genome-wide association (GWA) studies have reported a number of common variants explaining part of this heritability. This study, aims to investigate the effect of common as well as rare genetic variants behind asthma, hay fever and eczema using the UK Biobank (UKBB) including more than 500,000 participants with ~70 million densely imputed genetic variants. **Methods** We performed GWA studies for asthma and for the combined diagnose hay fever/eczema, using 116,137 non-related Caucasian participants with self-reported diagnosis. We used logistic regression models, adjusted for a number of covariates and performed conditional analysis to explore secondary signals. We further estimated the SNP heritability for each disease using GCTA, and investigated the shared genetic contribution to the diseases. **Summary of results** The SNP heritability was estimated to 35 % for asthma and 30 % for hay fever /eczema. Our study resulted in 30 loci for asthma and 29 loci for hay fever/eczema, passing a genome wide significance level ( $P < 5 \times 10^{-8}$ ). We confirmed many previously reported loci and report a number of novel loci for each disease including *RTEL1*, *TRIM26* and *RAD51L* for asthma. *RTEL1* is biologically interesting due to its involvement in lung function. For hay fever/eczema, examples of novel loci were *ZBTB38*, *EVI5*, *NR* and *LCE1E*. Interestingly, some previously reported loci seem to be more than one independent loci, For example, both the epidermal differentiation complex harboring the *FLG* gene and the MHC region, contains more than one independent loci associated to atopic diseases. Interestingly, many genes seem to overlap between the diseases, while others seem to be disease specific. <sup>1</sup> *Allergy Eur J Allergy Clin Immunol* 2016.

**1880T**

**Multi-omic approaches to identifying clinical biomarkers of asthma exacerbations in African Americans.** *H. Gui<sup>1</sup>, S. Xiao<sup>1</sup>, A.M. Levin<sup>1</sup>, M. Yang<sup>1</sup>, J.J. Yang<sup>2</sup>, D. Rynkowski<sup>1</sup>, E.G. Burchard<sup>3</sup>, L.K. Williams<sup>1</sup>.* 1) Henry Ford Health System, Detroit, US; 2) University of Michigan, Ann Arbor, US; 3) University of California San Francisco, San Francisco, USA.

Severe asthma exacerbations, which result in rescue medication use, emergency department visits, and hospitalizations, contribute to significant disease-related morbidity and account for a large proportion of asthma-related expenditures. Until now there are few measures that can be used clinically to predict impending events and thereby guide treatment. Multi-omic approaches may provide complementary information when attempting to identify exacerbation biomarkers. The Study of Asthma Phenotypes and Pharmacogenomic Interactions by Race-ethnicity (SAPPHIRE) is a longitudinal asthma study; study participants had detailed electronic medical records data on severe exacerbations (oral steroid use, ER visits, or hospitalizations). In total 875 participants had genome-wide SNP array data (518341 common variants), 199 had RNA-sequence expression data (15,022 protein-coding genes), and 185 had both. Cox proportional hazard regression models were used to test the influence of single nucleotide polymorphism (SNP) genotypes (additive genetic model) and gene expression levels (normalized read counts) on time-to-exacerbation. Models accounted for potential confounders. Top hits from both data sets were used to search for cis-eQTL within 2Mb of top (SNP) associations. The top SNP association, rs16944353, showed a hazard ratio (HR) of 1.55 ( $P=1.73E-07$ ) but did not reach the pre-defined Bonferroni threshold ( $P<5.00E-08$ ) in the genome-wide association study (GWAS). The top association from the RNASeq analysis was for *AHR*, which showed a HR=3.56 ( $P=1.39E-05$ , FDR < 0.25) for time-to-exacerbation, but this did not reach the pre-defined threshold of  $P<5.74E-06$ . There were no overlapping genes in the top 10 signals from both analyses. In addition, none of the top 10 GWAS SNP associations were eQTL loci for the top genes identified in the transcriptomic analysis. In conclusion, we discovered one GWAS SNP and one gene transcript that were of borderline significance in their relationship to asthma exacerbations. Multi-omic approaches may identify different, and potentially complementary, predictors of disease outcomes. Future analyses with additional samples are needed to validate these initial findings. .

**1881F**

**Shared genetic etiology and ancestry variations between asthma and major complex diseases.** *T. Mersha<sup>1</sup>, Y. Gauta<sup>1</sup>, S. Ghandikota<sup>1</sup>, D. Lin<sup>2</sup>.* 1) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Karlstad University, Karlstad, Sweden.

Although epidemiological and clinical evidence supports the observation that subjects with asthma often have other complex diseases such as autoimmune, infectious, and metabolic disorders, little is known about genetic architecture for such comorbidities. The objectives of this study were twofold: a) determine the shared genetic risk factors and biological pathways between asthma and other complex diseases in the context of GWAS data; b) analyze racial ancestry variations among the shared GWAS risk variants. We explore over 20,000 unique GWAS SNPs associated with 1,480 diseases or traits to extract shared risk variants among asthma and other disease ontologies (i.e., asthma, metabolic, autoimmune, cardiovascular, inflammation, infection, mental and cancer). We calculated Jaccard similarity index to determine relatedness and pathways to identify shared functional enrichments at the gene and pathway level. We found more shared genetic loci than expected by chance alone (significant hypergeometric p-value for asthma-metabolic ( $<3 \times 10^{-15}$ ), asthma-autoimmune ( $<2 \times 10^{-29}$ ), asthma-cardiovascular ( $<1.1 \times 10^{-7}$ ), asthma-inflammation ( $<1.9 \times 10^{-23}$ ), asthma-infection ( $<5 \times 10^{-7}$ ), asthma-mental ( $<6 \times 10^{-10}$ ) and asthma-cancer ( $<4 \times 10^{-16}$ ). The Jaccard index for asthma-complex disease etiology pairs ranged 7%-20%. Significantly over-represented pathways include the T Helper cell differentiation (fold enrichment = 13.7, p-value =  $2.1 \times 10^{-14}$ ). Ancestry variation in allele frequency was found for multiple diseases particularly for infection, metabolic and autoimmune-related risk variants. Our results show that the degree of interconnection between asthma and specific complex disease genetic loci couldn't be explained by random chance, suggesting a shared molecular mechanisms linking asthma with the rest of complex diseases. An improved understanding of these pathways in shared genomic regions could provide valuable insights into the causal pleiotropic effects that may contribute to comorbidity between asthma and other diseases. Future research is warranted to explore further to identify underlying shared mechanism and novel therapeutic targets associated with the genetic pathways. .

**Mapping human airway smooth muscle cell transcriptional and epigenetic responses to asthma-promoting cytokines reveals enrichments for asthma-associated SNPs.** *E.E. Thompson<sup>1</sup>, Q. Dang<sup>2</sup>, B. Mitchell-Handley<sup>1</sup>, K. Rajendran<sup>2</sup>, S. Ram-Mohan<sup>2</sup>, J. Solway<sup>3</sup>, R. Krishnan<sup>2</sup>, C. Ober<sup>1</sup>.* 1) Department of Human Genetics, The University of Chicago, Chicago, IL; 2) Center for Vascular Biology Research, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; 3) Department of Medicine, The University of Chicago, Chicago, IL.

Airway hyperresponsiveness (AHR) to inhaled stimulants is a key feature of asthma. AHR has a strong genetic component; however, the genetic architecture of AHR is largely unknown. We used cell models of AHR to discover functional single nucleotide polymorphisms (SNPs) that have direct effects on transcriptional and epigenetic responses to two asthma and AHR-promoting cytokines, IL-13 and/or IL-17, in cultured airway smooth muscle cells (ASMCs) from 71 individuals. We hypothesized that some of these SNPs will be associated with asthma and, therefore, enriched for small *p*-values among SNPs included in asthma GWAS. Expression and DNA methylation data were obtained using Illumina Human HT-12 v4 arrays and Infinium MethylationEPIC BeadChip, respectively; samples were genotyped with the Illumina OmniExpress BeadChip. We conducted expression quantitative trait locus (e)QTL and methylation (me)QTL mapping using Matrix eQTL in cytokine-treated samples. Genes regulated by eQTLs in IL-13-exposed ASMCs were enriched for T cell activation involved in immune responses (GO:0002286; *p*=0.0072), and genes regulated by eQTLs in IL-17-exposed ASMCs were enriched for microtubule organization (GO:0031122; *p*=0.0023). We then asked whether SNPs that were QTLs at a FDR 5% were more likely to have small *p*-values (*p*<0.05) in asthma GWAS. Indeed, eQTLs (SNPs  $\pm$ 250Kb of the transcription start site of each gene) in IL-13, IL-17 and IL-13+IL-17-exposed ASMCs were enriched for asthma-associated GWAS SNPs (*p*=1.48 $\times$ 10<sup>-5</sup>, 7.91 $\times$ 10<sup>-8</sup>, and 4.63 $\times$ 10<sup>-8</sup>, respectively); meQTLs (SNPs  $\pm$ 5kb of a CpG site) in IL-17 and IL-13+IL-17-exposed ASMCs, but not in IL-13-exposed ASMCs, were enriched for asthma-associated GWAS SNPs (*p*=0.00042, 0.011 and 0.43, respectively). Overall, 249 asthma-associated GWAS SNPs were associated with gene expression (eQTLs: mean of 15 SNPs, 7 genes per exposure) or with methylation (meQTLs: mean of 88 SNPs, 76 CpGs per exposure) levels in ASMCs. These results indicate that IL-13 and IL-17-exposed cultured ASMCs serve as a model for elucidating the function of asthma-associated SNPs identified in GWAS, and for identifying additional candidates that did not meet stringent criteria for genome-wide significance in GWAS. Moreover, our data suggest that IL-13- and IL-17-mediated arms of asthma pathogenesis and AHR may be influenced by genetic variation in different sets of genes. This work was supported by R01 HL113395.

**Unraveling the genetic architecture of generalized vitiligo in a homogeneous, isolated Romanian village.** *G. Andersen<sup>1</sup>, S. Birlea<sup>1,2</sup>, S. Santorico<sup>1,3</sup>, R. Spritz<sup>1,4</sup>.* 1) Human Medical Genetics and Genomics, University of Colorado, Anschutz Medical Campus, Aurora, CO; 2) Department of Dermatology, University of Colorado School of Medicine, Aurora, CO, USA; 3) Mathematical and Statistical Sciences, University of Colorado, Denver, CO, USA; 4) Department of Pediatrics, University of Colorado School of Medicine, Aurora, CO, USA.

Vitiligo is a genetically complex disease in which patches of depigmented skin result from autoimmune destruction of melanocytes. By genome-wide association studies (GWAS) of vitiligo in individuals of European ancestry (EUR), we identified 48 vitiligo susceptibility loci. While proteins encoded at these loci highlight a framework for melanocyte-directed autoimmunity, the overall picture of vitiligo pathobiology remains incomplete. Here, we report analyses of an isolated, inbred Romanian village with vitiligo prevalence ~8 times higher than in the general EUR population, suggesting an enrichment of genetic and/or environmental risk factors. Due to the small number of ancestral founder genomes (~23), villagers are expected to have reduced causal allele heterogeneity and perhaps fewer causal alleles overall, thus constituting a less genetically complex subset of the general EUR population. We have genotyped 50 cases and 120 unaffected villagers for 591,361 SNPs genome-wide, and we have used these genotypes to compare genetic architectures under three alternative models of vitiligo pathogenesis: (1) a polygenic model with unusually high prevalence of common EUR risk variants detected by GWAS; (2) a mono- or oligogenic model in which a highly-penetrant variant rare in the general EUR population explains most vitiligo risk; or (3) both. Specialized association analyses of the 48 known susceptibility loci are being used to assess common, genetic risk variants under hypothesis 1, and genome-wide linkage analysis is being used to identify variants consistent with hypothesis 2. Our combined approach of association and linkage within this remarkable isolated village provides a unique opportunity to ascertain the genetic architecture of vitiligo in a relatively simple, homogeneous population. Implications of this study will be to highlight key pathobiological pathways, either by identifying a combination of common risk variants that confer particularly high risk, or by identifying a novel vitiligo susceptibility locus that confers unusually high disease risk.

**Polygenic risk score predicts development of HCV-associated mixed cryoglobulinemia and response to interferon-free therapy.** *M. Artemova<sup>1</sup>, N. Mukhin<sup>1,2</sup>*. 1) Fundamental Medicine, Moscow State University, Moscow, Russian Federation; 2) Tareev Clinic for Nephrology, Internal and Occupational Diseases, Moscow, Russian Federation.

Mixed cryoglobulinemia (MC) can be detected in 40-60% of patients chronically infected with hepatitis C virus (HCV). Overt MC vasculitis (MCV) appears in a minority (5-10%) of patients and includes a spectrum of symptoms from mild to life-threatening. Despite the success of new direct acting antivirals, several recent studies demonstrate persistent MC or MCV following virus eradication after interferon-free treatment (PMID: 27943361; 19571811). Recent GWAS confirmed importance of the host genetic background as a predisposing factor in MCV development (PMID: 25030430). Here, we present a method for quick evaluation of genetic predisposition to MC among HCV patients, using polygenic risk score (PRS). We focused on cases with only HCV and no other infections or autoimmune diseases to ensure cohort is genetically-enriched. Study included 54 affected samples diagnosed with HCV-associated MC (31 MCV and 23 asymptomatic MC) and 26 well-matched controls with long duration of HCV infection without notable production of cryoglobulins. Using qPCR, we screened the two independent SNPs most associated with MCV: rs2071286 and rs9461776. PRS was calculated as a sum of alternative alleles for these two SNPs weighted by their logistic regression coefficients. Individuals with asymptomatic MC and MCV had similar PRS (1.1 and 0.816, respectively); thus, we consolidated these cohorts for further analysis. Samples with MCV and asymptomatic MC on average had a 3.2-fold increase in risk ( $p=3.4 \times 10^{-6}$ ) compared with controls. Analysis of the clinical data demonstrated that immunological response to the interferon-free treatment depends on interaction of HCV duration and inherited risk (PRS),  $p=0.033$  and on the rate of rheumatoid factor production ( $p=0.03$ ). Patients with long duration of HCV, high PRS and rheumatoid factor kept cryoglobulins production for at least 11 weeks longer than controls.

**Identification of several genes modifying multiple sclerosis risk conferred by tobacco smoke: A case-only analysis.** *F.B.S. Briggs*. Neuroimmunological Disorders Gene-Environment Epidemiology Lab, Department of Population and Quantitative Health Sciences, Case Western Reserve University, School of Medicine, Cleveland, OH.

**Background:** Multiple sclerosis (MS) is an idiopathic neuro-inflammatory disease with prominent genetic and environmental risk components. It is likely specific genetic variants contribute to MS risk for a given environmental condition. Thus, exploring genetic heterogeneity in the context of environmental risks presents a unique opportunity to further characterize the heritable component of MS. Tobacco smoke (TS) is an established risk factor, and prior work demonstrated *NAT1* conferred MS risk in the presence of TS exposure. Thus, a gene-centric, multi-stage analysis was conducted to identify novel genetic variants modifying MS risk due to TS. **Methods:** Genetic and survey data for 1,056 European Americans cases (onset age  $\geq 18$  yrs) from the Accelerated Cure Project for MS were available. DNA samples were genotyped on an Illumina HumanExome BeadChip with custom content (~270,000 autosomal SNPs). The study population was divided into a discovery (N=795) and replication (N=261) set. Detailed TS history was available and cases were classified as a smoker if they were an active smoker within 5 years prior onset. Power calculations were conducted for the discovery data assuming a 2-sided  $\alpha$  and TS prevalence of 33% for a range allele frequencies and effect sizes. A total of 42,346 variants (MAF $\geq 5\%$ ) in 11,500 genes were interrogated in the discovery data with smoking status as the outcome. Models were adjusted for gender, onset age, birth year, education, disease subtype, and ancestry. Discovery associations (2-sided  $p < 0.05$ ) for which there were sufficient power ( $> 70\%$ ) were pursued in the replication data where a 1-sided  $p < 0.05$  determined significance. The discovery and replication data were combined to determine final associations. **Results:** 1,386 discovery associations were pursued in the smaller replication data. In the replication data, there were 63 SNPs in 40 genes with significant associations. In the combined data, the most significant associations were for missense SNPs in *DNAH9* (odds ratio [OR]=1.5,  $p=9 \times 10^{-6}$ ) and *ADRB2* (OR=1.5,  $p=1 \times 10^{-4}$ ). The strongest effects were observed for an *OR2L8* missense SNP (OR=0.43,  $p=8 \times 10^{-4}$ ) and a *TLR4* intronic SNP (OR=0.45,  $p=8 \times 10^{-4}$ ). TS alters *DNAH9* and *TLR4* expression in airway epithelium, and *DNAH9* x TS contributes to bronchial hyperresponsiveness and *TLR4* x TS contributes to the accrual of neutrophils in airways of smokers. Thus, the results suggest genetic variation in physiological response to TS contributes to MS risk.

Multiple sclerosis (MS [MIM 126200]) is a demyelinating autoimmune disease with genetic and environmental risk factors. To date, over 2.5 million individuals worldwide have been diagnosed with MS. Disease prevalence is highest in North America and northern Europe at ~100 cases per 100,000 individuals. MS is a multifactorial disease, and a majority of established genetic risk factors have been discovered in white populations. However, it is not known to what extent these genetic risk factors originated from European ancestral populations. We hypothesize that the genetic risk of MS is largely driven by European ancestry, contributing to the observed prevalence disparity among different populations. We performed admixture mapping and tested more than 200 established major histocompatibility complex (MHC) and non-MHC genetic risk factors for increased European ancestry in cases compared to controls. We collected genotype data from 1,589 admixed cases and 11,980 admixed controls representing the black, Hispanic, and Asian populations recruited through Kaiser Permanente Northern and Southern California, the U.S. Pediatric MS Network, Genetic Epidemiology Research on Aging cohort, UC San Francisco and the International MS Genetics Consortium. Using fastStructure, we estimated the average global admixture proportions of black (74% African, 26% European), Hispanic (6% African, 52% Native American, 42% European), and Asian (92% East Asian, 8% European) study subjects. We inferred local ancestry from genotype data for each subject using RFMix to map the admixture proportions across the genome. For each admixed population, we performed hypothesis testing with a non-parametric test statistic (Pritchard and Montana, 2004) that adjusts for global admixture differences between cases and controls. We found no evidence supporting increased European ancestry for the non-MHC genetic risk loci in MS cases. However, we found evidence for increased European ancestry in regions within the MHC in black MS cases. The difference in European ancestry within the Class I MHC region is 1.8% greater than the difference in genome average between cases and controls ( $p < 0.05$ ). Our findings support the hypothesis that the non-MHC genetic risk factors are not exclusively European but that some MHC risk alleles may originate from European ancestry.

**Immune-phenotypes among patients with systemic lupus erythematosus and their association with HLA-DRB1 alleles.** L.M. Diaz-Gallo<sup>1</sup>, E. Lundström<sup>2</sup>, V. Oke<sup>3</sup>, K. Elvin<sup>2</sup>, Y.L. Wu<sup>2</sup>, J. Gustafsson<sup>1</sup>, A. Jönsson<sup>4</sup>, D. Leonard<sup>5</sup>, A. Zickert<sup>6</sup>, G. Nordmark<sup>6</sup>, A.A. Bengtsson<sup>7</sup>, L. Rönnblom<sup>8</sup>, E. Gunnarsson<sup>1</sup>, C.Y. Yu<sup>2</sup>, E. Svenungsson<sup>1</sup>, L. Padyukov<sup>1</sup>. 1) Department Medicine Solna, Rheumatology Unit, Karolinska Institutet, Stockholm, Stockholm, Sweden; 2) Department of Clinical Immunology and Transfusion Medicine, Unit of Clinical Immunology, Karolinska Institutet/Karolinska University Hospital, Stockholm, Sweden; 3) The Research Institute at Nationwide Children's Hospital, Columbus, Ohio 43205, USA; 4) Department of Clinical Sciences, Section of Rheumatology, Lund University, Skåne University Hospital, Lund, Sweden; 5) Department of Medical Sciences, Section of Rheumatology, Uppsala University, Uppsala, Sweden.

Systemic lupus erythematosus (SLE) is a remarkably heterogeneous autoimmune disease, with a broad display of autoantibodies and there is a need to define SLE sub-phenotypes. Therefore, we set out to investigate whether there are phenotypic clusters in SLE, based on autoantibody profile, and to investigate their association with one of the most important genetic risk factors for SLE, *HLA-DRB1* alleles. We evaluated a total of 908 SLE patients of European Caucasian origin, and 3654 age- gender- and ethnicity-matched healthy controls (HC). Blood samples from the patients were used to determine 13 autoantibodies: dsDNA, nucleosomes, ribosomal P, RNP68, RNPA, Sm, Sm/RNP, SSA52, SSA60, SSB, aCL-IgG/IgM and ab<sub>2</sub>GP1. *HLA-DRB1* typing was performed by sequence-specific primer polymerase chain reaction assay. Cluster analysis was done using Gower distance matrix, followed by partition around medoids cluster calculation and Silhouette metric for number of clusters validation. Chi-square test, odds ratios and 95% confidence intervals were calculated for the association tests. Our results demonstrate that there are differential associations between the four defined clusters and specific *HLA-DRB1* alleles. A cluster where the anti-SSA52/60/SSB are dominating was specifically and strongly associated with *HLA-DRB1\*03* when compared with HC (OR=4.1 95%CI=3.4-4.9, PFDR=6.4E-56) and other clusters (OR=2.9 95%CI=3.3-3.6, PFDR=1.1E-19). A second cluster, dominated by anti-SmRNP/Sm/DNA/RNPA/RNP68/nucleosome, was specifically associated with *HLA-DRB1\*15* when compared with HC (OR=1.7 95%CI=1.6-2.1, PFDR=5.7E-6) and other clusters (OR=1.5 95%CI=1.1-1.9, PFDR=0.01), suggesting that the overall association of these alleles with SLE comes from these autoantibodies clusters. The third cluster, dominated by anti-B2GP1/aCL-IgG/IgM, was associated with *HLA-DRB1\*04* when compared with other clusters (OR=1.8 95%CI=1.4-2.4, PFDR=2E-4). No significant association was detected between the fourth cluster, negative for the 13 tested autoantibodies, and *HLA-DRB1* alleles. Previous reports and empirical observations from the clinic support that SLE subgroups, based on autoantibody profile, are associated with specific clinical manifestations, damage accrual and long term prognosis. Our approach confirms these observations and frame them into the genetic background. These results could be used in the definition of predictive biomarkers and inclusion criteria for clinical trials.

**GWAS polygenic model approach applied to primary biliary cholangitis (PBC) in a Japanese population.** O. Gervais<sup>1</sup>, K. Ueno<sup>1</sup>, K. Kojima<sup>1</sup>, Y. Aiba<sup>2</sup>, M. Kawashima<sup>2</sup>, Y. Kawai<sup>1</sup>, Y. Hitomi<sup>2</sup>, K. Tokunaga<sup>2</sup>, M. Nakamura<sup>3,4</sup>, M. Nagasaki<sup>1</sup>. 1) Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo, Tokyo, Japan; 3) Clinical Research Center, National Hospital Organization (NHO) Nagasaki Medical Center, Nagasaki, Japan; 4) Department of Hepatology, Graduate School of Biomedical Sciences, Nagasaki University, Nagasaki, Japan.

Primary Biliary Cholangitis (PBC) is an autoimmune liver disease which affects predominantly women over the age of 40 and is typically associated with anti-mitochondrial antibodies (AMA). Although the etiology of PBC is still unknown, genetic predisposition is well established, as exemplified by studies which have shown familial clustering and higher concordance in monozygotic twins than in dizygotic twins. A number of GWAS analyses have been conducted to elucidate the role of genetic variation in the development of PBC, and several susceptibility genes associated with PBC have been discovered, notably in the highly polymorphic HLA region. At the same time, the majority of the GWAS studies on PBC published so far solely focused on individuals of European descent. The first GWAS for PBC in the Japanese population revealed potential ethnic differences, for instance with regard to the *IL12A* locus, which was not found to be significantly associated with PBC, unlike previous research conducted in a North American cohort. This finding suggests a need for additional research to clarify the regional genetic characteristics of PBC. In this study, polygenic model analysis was used to examine data collected from Japanese individuals (>1300 PBC cases and >1500 healthy controls) genotyped for approximately 600,000 SNPs using the Affymetrix Axiom ASI Array, and to estimate the genetic parameters (heritability, etc.) associated with PBC in this population.

**Lupus-associated functional polymorphism in *PNP* causes cell cycle abnormalities and interferon pathway activation in human immune cells.** Y. Ghodke-Puranik<sup>1</sup>, J.M. Dorschner<sup>1</sup>, D.M. Vsetecka<sup>1</sup>, S. Amin<sup>2</sup>, A. Mako<sup>2</sup>, F. Ernste<sup>2</sup>, T. Osborn<sup>2</sup>, K. Moder<sup>2</sup>, V. Chowdhary<sup>2</sup>, E. Eliopoulos<sup>2</sup>, M. Zervou<sup>2</sup>, G.N. Goulielmos<sup>2</sup>, M.A. Jensen<sup>1</sup>, T.B. Niewold<sup>1</sup>. 1) Dept of Immunology and Division of Rheumatology, Mayo Clinic, Rochester, MN; 2) Division of Rheumatology, Mayo Clinic, Rochester, MN; 3) Department of Agricultural Biotechnology, Agricultural University of Athens; 4) Laboratory of Molecular Medicine and Human Genetics, Department of Internal Medicine, Medical School of Crete, Heraklion, Greece.

**Background:** Systemic lupus erythematosus (SLE) is frequently characterized by type I interferon (IFN) pathway activation. We previously found a missense SNP in the *purine nucleoside phosphorylase (PNP)* gene was associated with high IFN in SLE (rs1049564). *PNP* is a key enzyme in purine metabolism. In this study, we perform functional follow-up of this polymorphism in human cells. **Methods:** Type I IFN was measured in patient sera using a reporter cell assay. The *PNP* variant was modeled structurally using Pymol software. *PNP* mRNA and protein levels, and type I IFN-induced gene expression were measured in lymphoblastoid cell lines with known *PNP* rs1049564 genotypes. Cell cycle was assayed using flow cytometry. **Results:** Structural modeling indicated no major disruption in folding related to rs1049564. Human lymphoblastoid cells homozygous for rs1049564 TT had decreased *PNP* mRNA and protein levels. Rs1049564 TT cells had reduced PNP enzymatic activity even when the amount of PNP was controlled. TT cells had a ~2-fold increase in S-phase block as compared to homozygous CC cells. The S-phase block could be pharmacologically reversed with hypoxanthine and adenosine, supporting relative PNP deficiency as the cause of the S-phase block. Type I IFN-induced transcripts were increased in a dose-response fashion related to the rs1049564 T allele both at baseline and after type I IFN stimulation. **Conclusions:** The rs1049564 *PNP* T allele is a loss-of-function variant, inducing S-phase block and IFN pathway activation in lymphocytes. The S-phase block can be rescued in our in vitro experiments, suggesting a potential for personalized therapeutics.

**1890F****Association of protein tyrosine phosphatase non-receptor N22 gene functional variant R620W with systemic lupus erythematosus patients from Kuwait.**

*M.Z. Haider<sup>1</sup>, A.M. Al-Awadhi<sup>2,3</sup>, J. Sukumaran<sup>1</sup>, S. Balakrishnan<sup>1</sup>.* 1) Pediatrics Department, Faculty of Medicine, Kuwait University, Jabriya, Kuwait; 2) Department of Medicine, Faculty of Medicine, Kuwait University, Jabriya, Kuwait; 3) Al-Amiri Hospital, Kuwait.

Systemic lupus erythematosus (SLE) is a common, complex autoimmune disease with multiple-organ involvement, characterized by the production of pathogenic autoantibodies directed against cytoplasmic and nuclear cellular components. SLE is thought to result from multifactorial etiology, involving hormonal factors, environmental triggers and genetic susceptibility. The aim of this study was to investigate the role of protein tyrosine phosphatase non-receptor type 22 (*PTPN22*) gene functional variant R620W in genetic susceptibility of the SLE in Kuwaiti Arabs. The study included 134 SLE patients and 214 healthy controls from Kuwait. The genotypes of *PTPN22* gene functional variant R620W were determined by PCR-RFLP and confirmed by DNA sequencing and the genotype and allele frequencies were compared between SLE patients and controls. A relatively high frequency of the variant 620W (T-allele) of the *PTPN22* gene was detected in SLE patients from Kuwait. 35.7% of the SLE patients had at least one variant allele (T-allele) compared to 15.9% in the controls. A statistically significant difference was detected in the frequency of variant genotypes, TT and CT between SLE patients and the controls ( $p < 0.0001$ ). No association was detected between the *PTPN22* gene variant and the Raynaud's phenomenon, renal involvement and severity of the SLE. The frequency of *PTPN22* gene functional variant R620W reported in this study is amongst the highest compared to other world populations. A high prevalence of this variant in SLE patients in comparison to controls suggests its significant contribution in conferring susceptibility to SLE along with other factors.

**1891W****Transcription factors are associated with disease risk loci: Epstein-Barr virus nuclear antigen 2 (EBNA2) is an environmental factor associated with multiple autoimmune diseases.**

*J.B. Harley<sup>1,2,3,4</sup>, X. Chen<sup>1</sup>, M. Pujato<sup>1</sup>, D. Miller<sup>1</sup>, A. Maddox<sup>1</sup>, C. Forney<sup>1</sup>, A.F. Magnusen<sup>1</sup>, A. Lynch<sup>1</sup>, K. Chetal<sup>5</sup>, M. Yukawa<sup>6,7</sup>, A. Barski<sup>6,7</sup>, N. Salomonis<sup>5</sup>, K.M. Kaufman<sup>1,2,3,4,5</sup>, L. Kottyan<sup>1,6</sup>, M.T. Weirauch<sup>1,3,5</sup>.* 1) Center for Autoimmune Genomics and Etiology (CAGE), Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 2) Division of Immunobiology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 3) Division of Developmental Biology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 4) US Department of Veterans Affairs Medical Center, Cincinnati, OH, USA; 5) Division of Biomedical Informatics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 6) Division of Allergy & Immunology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA; 7) Division of Human Genetics, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA.

Mechanisms responsible for most complex disease genetic associations from GWAS projects appear to be regulatory. We reasoned that transcription factors (TFs) might operate across multiple loci in a given phenotype more frequently than expected by chance, which is now established by simulation for at least 92 disease and physiological human phenotypes involving 2,264 associations from 1,544 TF ChIP-seq data sets at a Bonferroni corrected  $P < 10^{-8}$ . Among these, an environmental factor, Epstein-Barr virus (EBV) nuclear antigen 2 (EBNA2) ChIP-seq data identify multiple environment-risk gene locus interactions with autoimmune phenotypes, such as **Multiple Sclerosis** (44 of 109 loci evaluated, OR=4,  $P < 6 \times 10^{-30}$ ), **Systemic Lupus Erythematosus** (26 of 53 loci, OR=6,  $P < 1 \times 10^{-25}$ ), **Rheumatoid Arthritis** (25 of 84 loci, OR=4,  $P < 2 \times 10^{-14}$ ), **Inflammatory Bowel Disease** (38 of 112, OR=3,  $P < 1 \times 10^{-12}$ ), and **Type 1 Diabetes** (20 of 57, OR=4,  $P < 6 \times 10^{-12}$ ), and others. These associations were also present when restricted to the open chromatin (DNase-seq) of EBV transformed B cells were considered. No association with EBNA2 was found with >150 other phenotypes. For each disease we observe a partially shared set of human TFs clustering with the EBNA2 associated loci that are also immunoprecipitated in EBV transformed B cells, but not generally in other cell types nor in B cell lines not infected with EBV. These relationships are genetic if and only if differential allelic mechanisms operate with respect to EBNA2. The data available to test this hypothesis are very sparse. However, the vitiligo risk locus at CD44 provides an example and a possible proof of principle. The EBNA2 ChIP-seq DNA binding at rs3794102 favors the risk allele, as evidenced by having >2-fold more risk than non-risk allele reads. In addition, CD44 gene expression favors the risk allele only when Ramos cells are EBV infected. This locus has properties of an "allelic switch" with more open chromatin (ATAC-seq) and activating TF ChIP-seq reads (EBF1, BATF, ATF2, & BCL3 in addition to EBNA2) on the risk allele, while suppressive TF reads (MTA3 & FTIC) dominate on the non-risk allele. Our approach nominates potentially important molecular relationships occurring in specific cell types that have the potential to reveal mechanisms of disease and, moreover, reveals a potentially important class of gene by environment interactions for a subset of autoimmune disorders that suggest molecular mechanisms involving EBNA2.

## 1892T

**Identification of the primary functional variants in primary biliary cholangitis susceptibility gene loci *NFKB1/MANBA*.** Y. Hitomi<sup>1</sup>, K. Nakatani<sup>1</sup>, K. Kojima<sup>2,3</sup>, N. Nishida<sup>4</sup>, Y. Kawa<sup>2,3</sup>, M. Kawashima<sup>5</sup>, Y. Aiba<sup>6</sup>, M. Nagasaki<sup>2,3,7</sup>, M. Nakamura<sup>6,8,9</sup>, K. Tokunaga<sup>1</sup>. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 3) Graduate School of Medicine, Tohoku University, Sendai, Japan; 4) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine, Ichikawa, Japan; 5) Japan Science and Technology Agency (JST), Tokyo, Japan; 6) Clinical Research Center, National Hospital Organization, Nagasaki Medical Center, Omura, Japan; 7) Graduate School of Information Sciences, Tohoku University, Sendai, Japan; 8) Department of Hepatology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan; 9) Headquarters of PBC Research in NHOSLJ, Clinical Research Center, National Hospital Organization Nagasaki Medical Center.

Primary biliary cholangitis (PBC) is a chronic and cholestatic liver disease that is caused by the autoimmune destruction of intrahepatic small bile ducts, which eventually leads to liver cirrhosis and hepatic failure. We recently identified a susceptibility gene region for PBC in the Japanese population by our previous genome-wide association study (GWAS), including *nuclear factor kappa B subunit 1 (NFKB1)* and *mannosidase beta (MANBA)*. However, the primary functional variants in *NFKB1/MANBA* and their molecular mechanisms for disease susceptibility in PBC have not yet been clarified. In the present study, we attempted to identify the primary functional variants in *NFKB1/MANBA* by performing high-density association mapping based on an SNP imputation analysis by IMPUTE2 (ver. 2.3.1) using whole-genome sequence data from a reference panel of 1,070 Japanese individuals (1KJPN) and genotype data from our previous GWAS (PBC patients:  $n = 1,389$ ; healthy controls:  $n = 1,508$ ). From among the 83 SNPs in *NFKB1* and 52 SNPs in *MANBA* that showed a  $P$  value  $< 5.0 \times 10^{-7}$  on high-density association mapping, candidate functional SNPs that potentially regulate gene expression efficiencies were selected by *in silico* analysis using the Regulome DB database and the UCSC Genome Browser. Two primary functional variants for disease susceptibility were identified by *in vitro* functional analysis (luciferase assay and electrophoretic mobility shift assay) using the human liver cell line HepG2 and the human T-cell line Jurkat. Additionally, e-QTL data from the GTEX portal database supported the potential role of these functional variants in regulating gene expression efficiencies ( $P = 6.5 \times 10^{-5}$  in spleen;  $P = 7.2 \times 10^{-6}$  in visceral adipose tissue). These results suggested that high-density association mapping based on SNP imputation analysis and on *in silico/in vitro* functional analysis can be used to identify primary functional variants in disease susceptibility genes. This study illustrated a systematic methodology for the identification of primary functional variants from a pool of suggestive SNP associations, and this methodology may eventually contribute to the development of novel diagnostic and therapeutic methods for PBC.

## 1893F

**TYK2 correlates with multiple sclerosis symptomatology at onset.** J. Jiangyang<sup>1</sup>, J. Yu<sup>1</sup>, E. Utigard<sup>2</sup>, D. Ontaneda<sup>2</sup>, F.B.S. Briggs<sup>1</sup>. 1) Neuroimmunological Disorders Gene-Environment Epidemiology Lab, Department of Population and Quantitative Health Sciences, School of Medicine, Case Western Reserve University, Cleveland, OH; 2) The Mellen Center for Multiple Sclerosis, Cleveland Clinic, Cleveland, OH.

**Background:** Multiple sclerosis is a complex autoimmune diseases with inflammatory and neurodegenerative phases. The etiologic processes are not clear, but failures in endogenous repair mechanisms are thought to contribute to the manifestation of symptoms and disease progression. Tyrosine kinase 2 (*TYK2*) is an established MS risk locus, and functional analyses of the MS risk allele suggest a shift in T cell differentiation in favor of a Th2 phenotype. Interestingly, *TYK2* is ubiquitously expressed, and likely to have functional roles in other systems, as evident by research demonstrating strong correlation between attenuation of *Tyk2* and enhanced CNS repair. **Hypothesis:** We hypothesize genetic variation in *TYK2* contributes to the presentation of symptoms at onset in persons with MS (PwMS), especially considering it is a known MS risk locus (therefore may also temporally affect early clinical manifestation). **Methods:** Genetic and survey data for 1,056 European Americans PwMS (onset age  $\geq 18$  yrs) from the Accelerated Cure Project for MS were available. DNA samples were genotyped on an Illumina HumanExome BeadChip with custom content (~270,000 autosomal SNPs) including 16 *TYK2* SNPs (MAF $>0.01$ ) residing within 2 haplotype blocks (solid spline of LD;  $D'>0.8$ ). PwMS reported detailed symptoms experienced at onset (31 questions), which were classified into 11 impaired functional domain by two neurologists. We focused on the most prevalent impaired domains: sensory (50%), motor (46%), cerebellar (32%), brainstem/bulbar (31%), and optic nerve (28%); these domains minimally correlated ( $r^2<0.25$ ), except for motor and cerebellar ( $r^2=0.7$ ). Models were adjusted for gender, birth year, onset age, education, disease subtype, and genetic ancestry. A significance threshold of  $p<0.005$  was imposed (2 blocks by 5 domains). **Results:** Based on the significance threshold, no SNP was associated with sensory or brainstem/bulbar impairment at onset. 2 missense SNPs were associated with increased optic nerve impairment (OR~1.4,  $p<0.003$ , MAF $>0.25$ ). 3 intronic SNPs were associated with increased cerebellar impairment (OR~2.5,  $p=5 \times 10^{-4}$  to  $p=6 \times 10^{-5}$ , MAF $>0.06$ ), and marginally associated with motor impairment (OR~2.4,  $p<0.01$ ). **Conclusions:** Uncovering genetic variants contributing to MS presentation and progression has proven challenging. Using a hypothesis driven approach we have identified *TYK2* as a strong candidate for future studies of cerebellar dysfunction (i.e. loss of coordination) in MS.

**1894W**

**Genetic screening of Galectin-3 CRD variants in RA: A case-control association study.** T. Kaur<sup>1</sup>, J. Singh<sup>2</sup>, M. Kaur<sup>1</sup>. 1) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India; 2) Department of Molecular Biology & Biochemistry, Guru Nanak Dev University, Amritsar, India.

**Statement of Purpose:** Rheumatoid arthritis (RA) is a chronic, inflammatory, systemic disease condition characterized by destruction of peripheral joints, subsequently leading to deformity and disability. Various studies have demonstrated the pro-inflammatory role of galectin-3 in pathogenesis of RA. Human galectin-3 protein is encoded by a single gene *LGALS3* located on chromosome 14q22.3. Genetic variations in *LGALS3* can have profound effects on structure as well as function of galectin-3. So, the present study was designed for genetic screening of CRD variants of *LGALS3* in RA. **Methodology:** The present case-control study recruited 200 RA patients and a cohort of 200 age- and gender- matched controls. The study protocol was approved by Institutional Ethics Committee as per declaration of Helsinki. Genetic screening of rs2075602 and rs2075603 variants were carried out by Sanger sequencing. Serum galectin-3 were assessed in the studied participants using commercially available ELISA kits. Galectin-3 levels were stratified according to different genotypes and data thus obtained was subjected to suitable statistical analyses. **Results:** Comparison for both SNPs showed no significant ( $P > 0.05$ ) difference in genotypic as well as allelic distribution between the studied groups. Significantly ( $P < 0.001$ ) elevated serum galectin-3 levels were observed in cases ( $1.81 \pm 0.96$  ng ml<sup>-1</sup>) as compared to controls ( $0.95 \pm 0.51$  ng ml<sup>-1</sup>). Overall significantly ( $P < 0.05$ ) elevated galectin-3 levels were observed in cases with each genotype of both variants than respective controls. However comparison of galectin-3 levels among various genotypes of both variants showed no significant ( $P > 0.05$ ) difference in cases as well as in controls. **Conclusion:** The studied variants may not be associated with diseases susceptibility. Furthermore, studies involving other CRD variants are required to elucidate their association with disease susceptibility.

**1895T**

**Genetic variation in the estrogen receptor alpha gene (*ESR1*) and susceptibility to rheumatoid arthritis.** S.E. Lofgren<sup>1</sup>, I.A. Pereira<sup>2</sup>, M.N. Drehmer<sup>1</sup>. 1) Biologia celular, Embriologia e Genetica, Universidade Federal de Santa Catarina, Florianópolis, SC, Brazil; 2) Hospital Universitário, divisão de reumatologia, da Universidade Federal de Santa Catarina, Florianópolis, SC, Brazil.

**Background:** Estrogen is the main female hormone, which acts through its receptors ER- $\alpha$  and ER- $\beta$  (ERs), codified by *ESR1* and *ESR2* genes, respectively. Today, several lines of evidence suggest a pivotal role of this pathway in several immune-related responses in the context of autoimmune diseases. Here we analyzed the association of a genetic variant in the estrogen receptor  $\alpha$  gene (*ESR1*) in a group of Brazilian patients with Rheumatoid arthritis (RA) for susceptibility and detailed clinical manifestations of RA. **Methods:** A total of 449 individuals (268 healthy controls and 181 RA patients) were genotyped for the polymorphism rs2234693 in the *ESR1* gene. Allele and genotype frequencies were calculated and analyzed using Unphased software. **Results:** The rs2234693 variant was associated with RA by allelic and genotypic analysis (OR = 1.31,  $p = 0.048$  and OR = 1.57,  $p = 0.036$ , respectively). Stratifying by gender, in female RA patients and controls the association was more significant (OR = 1.43,  $p = 0.016$  for allelic association and OR = 2.29,  $p = 0.011$  by genotypic association). It was also associated with the presence of high blood pressure, osteoporosis and cardiopathy. A slight association was seen with anti-CCP antibodies when analyzing only females (OR = 1.19,  $p = 0.041$ ). **Conclusion:** The rs2234693 variant was associated with the presence of RA, especially in females, and potentially associated with anti-CCP antibodies in female patients, as well as with other rather unspecific clinical manifestations of the disease.

**1896F**

**Identification of rare variants in Italian multiplex families with multiple sclerosis using a next generation sequencing approach.** E. Mascia<sup>1</sup>, A. Zauli<sup>2</sup>, C. Guaschino<sup>1</sup>, M. Sorosina<sup>1</sup>, A.M. Osiceanu<sup>1</sup>, S. Santoro<sup>1</sup>, L. Ferrè<sup>1,2</sup>, S. Peroni<sup>1</sup>, D. Biancolini<sup>3</sup>, S. Bonfiglio<sup>3</sup>, D. Lazarevic<sup>3</sup>, C. Basagni<sup>4,5</sup>, N. Barizzone<sup>4,5</sup>, G. Meola<sup>6,7</sup>, V. Martinelli<sup>2</sup>, G. Comi<sup>2</sup>, G. Tonon<sup>3</sup>, F. Esposito<sup>1,2</sup>, S. D'Alfonso<sup>4,5</sup>, F. Martinelli Boneschi<sup>6,7</sup>. 1) Laboratory of Human Genetics of Neurological Diseases, CNS Inflammatory Unit & INSPE – IRCCS San Raffaele Scientific Institute, Milan, Italy; 2) Department of Neurology, IRCCS San Raffaele Scientific Institute – Milan, Italy; 3) Center for Translational Genomics and Bioinformatics, IRCCS San Raffaele Scientific Institute – Milan, Italy; 4) Interdisciplinary Research Center of Autoimmune Diseases (IRCAD), University of Eastern Piedmont, Novara, Italy; 5) Department of Health Sciences, University of Eastern Piedmont, Novara, Italy; 6) Laboratory of Genetics of Complex Disorders and Department of Neurology, IRCCS Policlinico San Donato, San Donato Milanese, Milan, Italy; 7) Department of Biomedical Sciences for Health, University of Milan, Milan, Italy.

Multiple Sclerosis (MS) is a multifactorial inflammatory and neurodegenerative disease in which both genetic and environmental factors contribute to the pathogenesis. More than 200 common variants and several signals in the HLA region have been already identified to be associated to MS susceptibility, however it is still unclear the role of rare/private variants in raising disease risk. This study is aimed to explore the role of rare functional variants in MS by studying multiplex families. We recruited a total of 30 families with  $\geq 3$  affected relatives (2 of them with first-degree relationship). Agilent SureSelect Human All Exon QXT V5 kit was used to generate WES data, while one family (4MS + 4 healthy controls (HC)) was sequenced at whole genome level (Illumina TruSeq DNA Sample Preparation Kit). Sequencing was performed with paired-end (2x101bp) protocol on Illumina HiSeq2500 platform. Until now, sequencing and analyses have been performed for 13 families (41 MS and 32 HC). WES data generation for the remaining families is ongoing. An internal pipeline based on BWA aligner and GATK UnifiedGenotyper was followed for the alignment and calling steps, while variants annotation was performed using SnpEff suite. For each family we selected variants with: (i) high or moderate impact, (ii) allele frequency (AF)  $\leq 5\%$  according to public databases, (iii) AF  $\leq 10\%$  in Italian population according to our internal database of 62 HC. We then followed two models: (i) "sharing model" by selecting those variants shared by all cases within each family, and (ii) "segregation model" by selecting those variants that segregates according to the family pedigree. We generated 2 lists of genes specific for each family that were intersected in order to identify genes in common between families. Pathway analysis was also performed using WebGestalt tool. Following the "sharing model", we identified variants in 1926 genes, 148 of which showing variants in at least 3 families. Pathways analyses revealed that the identified genes were mainly involved in immunity and in autoimmune diseases. Following the "segregation model", only 12 genes were identified in common between at least 2 families. The same strategy will be used for the remaining families. We conclude that the application of WES in familial cases can be useful in the identification of novel genes and pathways involved in MS pathophysiology.

**1897W**

**Genetic association between not related to HLA immune gene polymorphisms and development of specific autoantibody is limited to few genetic loci in patients with rheumatoid arthritis.** L. Padyukov<sup>1</sup>, B. Brynedal<sup>2</sup>, D. Ramsköld<sup>1</sup>, L. Israelsson<sup>1</sup>, M. Hansson<sup>1</sup>, R. Holmdahl<sup>3</sup>, L. Klareskog<sup>1</sup>, V. Malmström<sup>1</sup>, D. Gomez-Cabrero<sup>4</sup>, K. Shchetinsky<sup>1</sup>, RACI. 1) Rheumatology Unit, Karolinska Inst, Stockholm, Sweden; 2) Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden; 3) Department of Medical Biochemistry and Biophysics Karolinska Institutet, Stockholm, Sweden; 4) Unit of Computational Medicine, Department of Medicine, Karolinska Institutet, Stockholm, Sweden.

Development of anti-citrullinated peptide antibodies (ACPAs) is very specific event for rheumatoid arthritis (RA) and may inform about changes in biological pathways preceding the disease development. Since multiple genetic loci were found in relation to RA, we investigated association between genetic variations and development of several types of ACPAs in three big cohorts of RA patients from Sweden, USA and UK (EIRA, NARAC and WTCCC) with overall 5,668 individuals in relation to non-HLA genetic variations. Autoantibody detection for 16 ACPA specificities was performed by multiplex analytic microarray system and genotyping on Illumina ImmunoChip was used in our study. Logistic regression analysis in each cohort with following meta-analysis was employed as statistical method. We detected a limited number of associated loci that reached study-wide significant association with development of ACPAs. Development of multiple ACPAs associates with *PTPN22* genetic variants and development of anti-CEP1 antibody associates with locus at chromosome 13, corresponding to uncharacterized lncRNA gene *LOC105370177*. Most of RA associated loci, however, are not associated strongly with ACPA development in our study. Stratification by shared epitope alleles led to finding of residual association with *PTPN22* locus for vimentin peptide in SE positive cases, but no significant findings in SE negative cases, likely because of lack of statistical power. Our data suggest strong genetic regulation for development of multiple ACPA specificities in RA within *PTPN22* locus, but very specific regulation within locus at chromosome 13, which may characterise disease development in a subset of cases.

**1898T**

**Variants near *HLA-DQA1* contribute to the development of antibodies to anti-TNF in Crohn's disease.** A. Sazonovs<sup>1</sup>, N. Kennedy<sup>2</sup>, L. Moutsianas<sup>1</sup>, K. de Lange<sup>1</sup>, C. Anderson<sup>1</sup>, T. Ahmad<sup>2</sup>, J. Barrett<sup>1</sup>. 1) Wellcome Trust Sanger Institute, Hinxton, Cambridgeshire, United Kingdom; 2) Royal Devon and Exeter NHS Foundation Trust, Barrack Road, Exeter, Devon, United Kingdom.

Crohn's Disease (CD) is a chronic condition that causes inflammation of the gastrointestinal tract. While there is no cure for CD, the anti-TNF drugs infliximab and adalimumab are effective in treating patients with Crohn's disease refractory to conventional therapies. Clinical efficacy is associated with mucosal healing and improved quality of life. However anti-TNF drugs are expensive, 10-40% of patients fail to respond to 10-12 weeks of therapy (primary non-response - PNR), and a further 25-45% lose response (loss of response - LOR) within the 12 months of treatment. The PANTS (Personalised Anti-TNF Therapy in Crohn's Disease) study is a prospective observational UK-wide study designed to investigate the clinical, serological and genetic factors that determine primary non-response, loss of response and adverse drug reactions to anti-TNF drugs in patients with active CD. We have genotyped 1,404 patients to perform a genome-wide association study to uncover genetic variants that impact anti-TNF response. A comparison of patients who show no efficacy of anti-TNF (PNR) with those who achieve long-term remission did not show any significant associations. We next tested for association with the development of anti-drug antibodies, one of the key mechanisms of non-response. Using a Cox proportional hazards model, we uncovered two genome-wide significant associations with time from initial treatment to first detection of clearing anti-drug antibodies, as defined by a positive anti-drug antibody titre in the absence of detectable drug. One signal ( $p = 5.8 \times 10^{-9}$ ) was near *HLA-DQA1*, a region for which other variants have been previously implicated in adverse events in response to other drugs. We next imputed HLA alleles at 4-digit resolution using HIBAG, but no single allele reached genome-wide significance, suggesting that this signal may not be driven by a classical HLA allele. These results represent the first robust associations to immunogenicity to one of the most widely prescribed anti-inflammatory medications. We are now carrying out whole genome sequencing in the same set of patients in order to expand these analyses from common to rare variants.

**1899F**

**Longitudinal clinical, molecular, and immunohistochemistry changes during mycophenolate mofetil therapy in patients with systemic sclerosis.** D.M. Toledo<sup>1</sup>, M. Hinchcliff<sup>2</sup>, J. Taroni<sup>3</sup>, T.A. Wood<sup>1</sup>, J. Franks<sup>1</sup>, S. Shah<sup>1</sup>, R. Agrawal<sup>1</sup>, L. Beussink-Nelson<sup>4</sup>, M.A. Carns<sup>1</sup>, S. Podluskys<sup>1</sup>, B. Christensen<sup>1</sup>, P.A. Pioli<sup>1</sup>, M.L. Whitfield<sup>1</sup>. 1) Molecular & Systems Biology, Dartmouth College, Hanover, NH; 2) Feinberg School of Medicine, Northwestern University, Chicago, IL; 3) Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Northwestern University, Evanston, IL.

**Background:** Systemic sclerosis (SSc) is a rare autoimmune disease characterized by skin and internal organ fibrosis. The cause of SSc is largely unknown. We have shown that patients can be classified into four molecular gene expression subsets (inflammatory, fibroproliferative, limited, normal-like) based on gene expression from skin. In this study, we use gene expression data from a cohort collected as part of an investigator initiated clinical trial of mycophenolate mofetil/MMF to identify cell types and factors involved in disease progression and improvement during treatment. **Methods:** Skin biopsies and sera were obtained from controls and patients with SSc at base/MMF naïve, 6, 12, 24, 36 months. DNA microarray, differential gene expression analysis, and gene set enrichment analysis was performed. Immunohistochemistry/IHC was performed for CD163 (macrophage MΦ marker), and CCL2 levels measured by qRT-PCR and ELISA. MΦ migration in response to SSc sera was also performed. Differentiation state and genome-wide DNA methylation was analyzed for SSc-like MΦs. **Results:** Six completers showed two distinct gene expression patterns between 24-36mo determined by MMF status. From base to 24mo, all six subjects on MMF showed a decrease in the inflammatory signature, in immune cell gene signatures, in MΦ IHC counts, and in CCL2 mRNA. MMF cessation at 24mo in three subjects resulted in a return of the inflammatory signature, increased MΦ IHC counts, increased CCL2 mRNA and worsening skin disease. In contrast, three subjects who continued MMF showed a persistent decrease in the inflammatory signature through 36mo with improved/stable skin disease. MMF continuers had lower CCL2 levels and decreased ability to recruit monocytes during treatment compared to base. **Conclusion:** A subset of patients with SSc lose their inflammatory skin gene expression signature and show decreases in skin MΦs and CCL2 mRNA while on MMF. Upon cessation, patients show rebounding inflammation, worsening skin disease, and increases in skin MΦs, while patients who remain on MMF do not. These results implicate a role for MΦs in skin improvement during MMF treatment. Collectively, these data support the hypothesis that MΦs may be the disease-potentiating cell type in SSc and MΦ modulation may be the key to disease improvement. We are further investigating the role of these cells in SSc by characterizing the SSc MΦ DNA methylation signature and using this to predict MΦ numbers in any SSc tissue sample.

**1900W**

**Integrative analysis of genetic, gene expression and DNA methylation data on systemic lupus erythematosus (SLE).** *W. Yang, T.Y. Wang, M. Guo, Y.F. Wang, H. Zhang, J. Yang, Y.L. Lau.* Paediatrics & Adolescent Med, Univ Hong Kong, Hong Kong, 10000, Hong Kong.

SLE is a prototype autoimmune disease with extremely complex etiology. There is a strong genetic component for SLE with increased disease risk for family members of affected. Genome-wide association studies (GWAS) have revealed 80 susceptibility loci in both European and Asian populations, pointing to the involvement of both innate and adaptive immunity in SLE pathogenesis. Gene expression and DNA methylation studies in SLE have detected important molecular aberrations involved in the disease process, such as a strong interferon signature in most SLE patients. However, the complex interplay of molecular changes and their functional impact at the cellular and intercellular level remains elusive, hindering an in-depth understanding of the disease mechanisms, which is essential for identifying new treatment targets and precise medical interventions. In this study, we try to integrate findings from genetics, gene expression, and DNA methylation on SLE and to identify hidden mechanistic changes for the disease. Genetics data are based on GWAS datasets on two Chinese populations and another one on European populations. Gene expression and DNA methylation data were extracted from a number of studies from public domains, followed by quality control measures and meta-analyses. Both protein-protein interaction (PPI) databases and information on transcription factor (TF) binding peaks from ENCODE are used to detect the intrinsic connections among different molecules. PPI network analysis was able to identify distinguished clusters (pathways) from these genes that probably play important roles in the disease. Prominent TF enrichment were detected for these SLE genes, such as IKZF1, STAT2, EBF1, and IRF4 being enriched in multiple gene sets. Interestingly, 'STAT' and 'IRF' TFs are found enriched for genes with hypomethylation but not those with hypermethylation. Findings on the estrogen receptor targets in T cells are particularly intriguing given the role of sex in SLE prevalence.

**1901T**

**Identification of one novel IBD susceptibility locus through a genome-wide association study in Korean populations.** *B.D. Ye<sup>1</sup>, S. Jung<sup>2</sup>, M. Hong<sup>2</sup>, S.B. Lee<sup>2</sup>, B.M. Kim<sup>2</sup>, H.S. Lee<sup>2</sup>, S.H. Park<sup>1</sup>, S.K. Yang<sup>1</sup>, K. Song<sup>2</sup>.* 1) Department of Gastroenterology, Asan Medical Center, University of Ulsan Colleg, Seoul, South Korea; 2) Department of Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, Korea.

Recent meta-analysis of the genome-wide association studies (GWAS) identified over 200 IBD associated regions. However, identified common variants account for only a fraction of IBD heritability. Moreover, despite of observed differences in clinical characteristics of IBD among different ethnicities, there have been limited studies in non-European populations. In a recent Korean GWAS on IBD in 1505 cases (922 CD, 583 UC) and 4041 controls for the discovery stage followed by replication in an additional 1,989 cases (993 CD, 996 UC) and 3,491 controls, we have reported 2 novel IBD susceptibility loci: rs3766920 in *PYGO2-SHC1* at 1q21 and rs16953946 in *CDYL2* at 22q13. In this study, we identified one additional locus at genome-wide significance through validation in additional 574 cases and 542 controls: rs3731257 at 9p21 (combined  $P = 2.26 \times 10^{-8}$ ). rs3731257, located ~900 bp upstream of *CDKN2A-AS1*, is within a LD region of 173 kb that includes *CDKN2A-AS1*, *CDKN2A*, *CDKN2B-AS1*, and *CDKN2B*. This locus was reported to be associated with coronary artery disease, diabetes, and multiple cancers. The eQTL analysis showed marginal significance between rs3731257 and mRNA expression of *CDKN2A* ( $P = 0.021$ ), in Japanese derived lymphoblastoid cell lines (<http://www.genome.med.kyoto-u.ac.jp/SnpDB>). Using knock-out mice, it was shown that *CDKN2A* plays a role as a modulator of macrophage activation and polarization via the JAK2-STAT1 pathway with possible roles in inflammatory diseases. Our results provide additional biological insight to IBD in Koreans.

## 1902F

**The influence of human genetic variation on HIV related non-Hodgkin lymphoma.** C.W. Thorball<sup>1,2</sup>, C. Hammer<sup>1,2</sup>, P.J. McLaren<sup>3,4</sup>, J. Fellay<sup>1,2</sup>, the Swiss HIV Cohort Study. 1) School of Life Sciences, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; 2) Swiss Institute of Bioinformatics, Lausanne, Switzerland; 3) JC Wilt Infectious Diseases Research Centre, National Microbiology Laboratory, Public Health Agency of Canada, Winnipeg, Canada; 4) Department of Medical Microbiology and Infectious Diseases, University of Manitoba, Winnipeg, Canada.

**Background.** Despite effective antiretroviral treatment, individuals infected with human immunodeficiency virus (HIV) have a substantially increased risk of developing several cancers, especially non-Hodgkin lymphoma (NHL). This elevated cancer risk is partly due to virus-induced immunosuppression, co-infections with oncogenic pathogens and traditional risk factors such as smoking. However, all of these risk factors cannot entirely explain the excess cancer burden seen in the HIV-positive (HIV+) population. In this study, we sought to test whether common genetic variants contribute to the increased NHL risk in an HIV infected patient. **Methods.** To search for human genetic determinants of HIV-associated NHL, we performed genome-wide genotyping of HIV+ patients in the Swiss HIV Cohort Study (SHCS) with a positive NHL diagnosis. To avoid bias introduced by differential treatment, we restricted the samples to individuals enrolled after 2000 (n = 161). We compared them to a control group consisting of age-matched HIV+ patients from the SHCS diagnosed with HIV before 2005 and with no registered cancer diagnosis as of September 2016 (n = 1184). Genotype data were imputed using the 1000 Genomes phase 3 reference panel. We used logistic regression with PLINK2 to identify associations with NHL while adjusting for sex and the first 5 principal components. Transcriptomic changes due to associated variants were imputed using MetaXcan with the GTEx whole blood and EBV transformed lymphocytes transcriptome datasets. **Results.** Genome-wide associated variants ( $p < 5 \times 10^{-8}$ ) were observed at the *PAM16* locus with rs113974017 and rs201469434 having the lowest p-values ( $p = 3.90 \times 10^{-8}$ ). Analysis of publicly available transcriptomes with MetaXcan demonstrated that these variants significantly impact the expression of *PAM16* in whole blood ( $p = 3.82 \times 10^{-6}$ ) and *NMRAL1* in EBV transformed lymphocytes ( $p = 6.62 \times 10^{-4}$ ). **Discussion and conclusion.** We have identified a novel NHL risk locus in an HIV+ population. The transcriptomic impact on *NMRAL1* is interesting, since this gene has previously been found to be a negative regulator of *TRAF3* by inhibiting its ubiquitination. The involvement of *TRAF3* in lymphoma is well established, as knockdown of *TRAF3* in mice leads to the spontaneous development of B cell lymphomas. On the other hand, overexpression of *TRAF3* leads to B cells becoming hyperactive and thus promoting autoimmunity, inflammation and cancer.

## 1903W

***IL1RN* variants influence systemic juvenile idiopathic arthritis susceptibility and are a biomarker of non-response to treatment with anakinra.** E.G. Shuldiner<sup>1</sup>, V.L. Arthur<sup>1</sup>, A. Hinks<sup>2</sup>, P. Woo<sup>3</sup>, W. Thomson<sup>2</sup>, E.F. Remmers<sup>4</sup>, M.J. Ombrello<sup>1</sup>, International Childhood Arthritis Genetics (INCHARGE) Consortium. 1) Translational Genetics and Genomics Unit, National Institute of Arthritis and Musculoskeletal and Skin Diseases, Bethesda, MD; 2) Arthritis Research UK Centre for Genetics and Genomics, Centre for Musculoskeletal Research, University of Manchester, Manchester, United Kingdom; 3) Center of Paediatric and Adolescent Rheumatology, University College London, London, United Kingdom; 4) Inflammatory Disease Section, National Human Genome Research Institute, Bethesda, MD.

Systemic juvenile idiopathic arthritis (sJIA) is a chronic childhood inflammatory disease that is poorly understood. Early amelioration of inflammation in sJIA is thought to improve long-term prognosis, but heterogeneous responses to anti-cytokine agents, such as anakinra (recombinant IL1RA [interleukin-1 receptor antagonist]), can delay achievement of this goal. Until recently genetic investigations of sJIA have studied candidate genes in small patient collections. These studies found only modest associations, yet they are regularly included in discussions of sJIA pathophysiology. Therefore we examined the 11 reported sJIA candidate susceptibility loci (*IL1A/B*, *GLI2*, *IL1RN*, *IL1R2*, *IL10/20*, *IL6*, *MVK*, *CCR5*, *MIF*, *SLC26A2*, *TAPBP*) in the largest sJIA study population ever assembled. Single nucleotide polymorphism (SNP) genotypes were evaluated in 770 sJIA cases and 6947 controls from the INCHARGE sJIA dataset. We examined 5479 SNPs in 11 candidate regions, among which 500 SNPs were independent ( $r^2 < 0.5$ ), defining the study's significance threshold as  $p < 1E-4$ . Logistic regression was performed in 9 case-control strata and association results were meta-analyzed. Association meta-analysis revealed a single association signal in the *IL1RN* promoter region, where 3 linked SNPs showed significant association with sJIA. The effect of sJIA associated SNPs on *IL1RN* expression was evaluated *in silico* in paired whole genome and RNA sequencing data from lymphoblastoid cell lines (LCL) of 1000 Genomes Project subjects. Analysis of LCL data showed that *IL1RN* expression is inversely correlated with sJIA risk. Moreover, sJIA associated SNPs are among the strongest published determinants of *IL1RN* and IL1RA levels, linking low *IL1RN* expression with increased sJIA risk. The relationship between sJIA associated SNPs and response to anakinra treatment was evaluated in 38 sJIA patients. The presence of homozygous *IL1RN* high expression alleles correlated strongly with non-response to anakinra ( $p = 9.8E-4$ , OR 17.3). Although high expression *IL1RN* alleles were protective against sJIA, patients with 2 high expression alleles were significantly less likely to respond to anakinra treatment than those with 1 or 2 low expression alleles. This is the first report to link sJIA risk and response to anakinra treatment with genetically determined capacity to produce *IL1RN* or IL1RA. These SNPs are the first potential biomarker(s) capable of prospectively guiding therapeutic decision making in sJIA.

**First report of the mutational and phenotypic spectrum of hereditary spherocytosis in Indian patients.** A. Aggarwal<sup>1</sup>, M. Jamwal<sup>1</sup>, P. Sharma<sup>1</sup>, M.U. Sachdeva<sup>1</sup>, P. Malhotra<sup>2</sup>, D. Bansal<sup>2</sup>, R. Das<sup>3</sup>. 1) Hematology, Post Graduate Institute of Medical Education and Research, Chandigarh, India; 2) Internal Medicine, Post Graduate Institute of Medical Education and Research, Chandigarh, India; 3) Pediatrics (Hemato-Oncology Unit) Post Graduate Institute of Medical Education and Research, Chandigarh, India.

**Introduction** Hereditary spherocytosis (HS) is a common inherited hemolytic anemia characterized by the presence of microspherocytes. The pathogenesis involves defects in any of the several genes coding for membrane proteins that link the membrane skeleton to the overlying lipid bilayer. Membrane proteins include ankyrin, band 3,  $\beta$ - and  $\alpha$ -spectrin and protein 4.2. We studied the molecular spectrum and genotype-phenotype correlation of HS in Indian patients. **Methodology** Complete blood counts, incubated osmotic fragility test, antiglobulin test, eosin-5' dye-binding test were done in 76 cases from 50 families to diagnose HS. RBC membrane ghosts were prepared and were analysed on gradient gels (4-12%). Relative quantification of mRNA isolated from enriched reticulocytes was done by qRT-PCR. cDNA sequencing of *ANK1*, *SPTB*, *SLC4A1* and *EPB42* genes was done (ABI3130). TruSight One™ sequencing panel was used for preparing libraries in 11 cases that were sequenced on MiSeq™ (Illumina). MiSeq Reporter™ and VariantStudio™ were used for analysis, characterization and annotation of variants. Possible pathogenic variants were validated by Sanger sequencing in cases and family members. G6PD-deficiency,  $\alpha$ -thalassemia and *UGT1A1* polymorphism were studied as phenotype modifiers. **Result** SDS-PAGE, qRT-PCR and cDNA sequencing were not contributory in deciphering molecular pathologies due to instability of mutated RNA and compensatory protein production by normal allele. NGS uncovered novel pathogenic mutations in *ANK1* and *SPTB* out of which 30% were splice site, 30% were small indels and 40% were nonsense mutations in 10 out of 11 patients. Inheritance was non-dominant in 50% and autosomal dominant in 30% cases. G6PD Mediterranean variant in four HS patients led to greater transfusion requirements. Genotyping for Gilbert syndrome showed homozygosity (TA<sub>7</sub>/TA<sub>7</sub>) for promoter variant of *UGT1A1* in 38% of the HS patients with significantly higher mean bilirubin level of 8.44 mg/dl and higher frequency of cholelithiasis (36%) (p<0.001). **Conclusion:** This first ever study on the molecular spectrum of HS from India revealed predominantly sporadic and dominantly-inherited defects in *ANK1* and *SPTB* in North Indian HS patients. Most of the cases (70%) presented at an early age with jaundice and anemia. Co-inherited G6PD deficiency and other genetic modifiers led to phenotypic variability. NGS provided a sensitive, cost-effective and rapid tool for understanding the molecular pathology of HS patients.

**1905F**

**Autoimmunity genes are associated with acquired hypothyroidism in a large clinical cohort.** J. Freudenberg, C. Schurmann, C. O'Dushlaine, A. Li, N. Banerjee, RGC. GHS. DiscovEHR Collaboration, A.R. Shuldiner, J.D. Overton, J.G. Reid, A. Baras, T.M. Teslovich, O. Gottesman, F.E. Dewey, N.S. Abul-Husn. Regeneron Genetics Center, Tarrytown, NY.

Genome-wide association studies (GWAS) have identified a large number of genes as risk factors for a range of autoimmune diseases. Here, we evaluated the role of known autoimmunity genes in patients with Acquired Hypothyroidism from a large clinical care cohort. Autoimmune thyroiditis is a frequent and well established cause of hypothyroidism. Genes were evaluated based on their prior implication in Rheumatoid Arthritis, Type 1 Diabetes, Inflammatory Bowel Disease, Psoriasis, Multiple Sclerosis or Systemic Lupus Erythematosus in published GWAS. Exome sequencing and Illumina array genotyping data were analyzed for 12,040 hypothyroidism cases (defined by ICD-10 diagnosis code) and 41,318 controls of European ancestry from the Geisinger Health System DiscovEHR cohort. Genome-wide significant ( $P < 5 \times 10^{-8}$ ) associations were observed for common variants in *PTPN22* (rs2476601, OR=1.29,  $P=3.3 \times 10^{-24}$ ), the *CTLA4* locus (rs231726, OR=1.13,  $P=2.29 \times 10^{-14}$ ), the *SH3B3-PTPN11* locus (rs3184504, OR=1.14,  $P=4.36 \times 10^{-18}$ ), and the *IZKF4* locus (rs10876864, OR=1.1,  $P=7.68 \times 10^{-10}$ ). Within the HLA-region, significant associations were observed both in the class I region (rs3130977, OR=1.15,  $P=1.17 \times 10^{-18}$ ), as well as the class II region (rs1048372, OR=1.14,  $P=5.3 \times 10^{-18}$ ). These results indicate that Acquired Hypothyroidism, a diagnosis present in nearly 20% of individuals in our clinical care cohort, is driven to a notable extent by autoimmunity. Making use of the large sample size available for this trait, we further performed gene-based burden testing by aggregating rare (MAF<1%) protein-altering variants for each gene into a joint test. Interestingly, the strongest association was observed for the *IFIH1* gene, where 4.2% of chromosomes carry at least one such variant. In aggregate, these rare protein altering variants show a protective association with hypothyroidism (OR=0.85,  $P=4.61 \times 10^{-5}$ ) in our dataset. Rare *IFIH1* variants are already known to alter interferon signaling and to influence genetic risk for Type 1 Diabetes and Systemic Lupus Erythematosus. Our findings indicate that rare variants in *IFIH1* also contribute to hypothyroidism, consistent with autoimmunity as major underlying cause, and point to a role for interferon signaling in at least a subset of cases.

## 1906W

**Trans-ethnic meta-analysis of fetal hemoglobin genome-wide association results identifies common variants at the *KLF1* locus.** Y. Ilboudo<sup>1</sup>, C. Sidore<sup>2</sup>, F. Cucca<sup>2</sup>, G. Lettore<sup>1</sup>. 1) Department of Medicine, Université de Montréal, Montréal, QC H3T 1J4, Canada; Montreal Heart Institute, Montréal, QC H1T 1C8, Canada; 2) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche, Monserrato, Cagliari, Italy.

The clinical severity of sickle cell disease (SCD) and  $\beta$ -thalassemia, the major hemoglobinopathies that affect millions of patients worldwide, can be ameliorated by increased production of fetal hemoglobin (HbF). To date, genome-wide association studies have uncovered three main loci (*BCL11A*, *HBS1L-MYB*, and the *HBB* locus) that modulate levels of HbF in hemoglobinopathy patients as well as non-anemic individuals. Together, genetic variation at these three loci accounts for ~50% of HbF heritability. To identify new HbF regulators, we performed a meta-analysis of genome-wide association results obtained from ~3,400 SCD patients of African ancestry and ~6000 healthy Sardinians. All association results were corrected for age, sex, and the main principal components, and were also conditioned on genotypes at *BCL11A*, *HBS1L-MYB*, and *HBB*. Meta-analysis results were well-calibrated ( $\lambda_{GC} \sim 1.0$ ) and were not enriched among genetic variants that map to erythroid regulatory elements defined using DNase 1 hypersensitive site assays, histone tail modification profiling, or ATAC-seq experiments. We identified one novel genome-wide significant locus on chromosome 19p13 (rs4804210,  $P_{combined} = 6.1 \times 10^{-9}$ ,  $P_{Sardinia} = 1.6 \times 10^{-6}$ ,  $P_{SCD} = 6.4 \times 10^{-4}$ ). HbF association results at this locus are independent from the previously reported HbF signal at the nearby *NFIX* gene (Danjou et al., *Nature Genet.*, 2015). Using the GTEx resource, we found that rs4804210 (and its linkage disequilibrium proxies) is an eQTL for *DNASE2* and *KLF1*. Further, this region physically interacts with the promoter of *CALR* as determined by Hi-C methodology. Although additional functional work is required, *KLF1* represents a strong candidate causal gene at this locus: (1) it encodes a key erythroid transcription factor, (2) it is mutated in patients with hereditary persistence of fetal hemoglobin, and (3) it regulates the expression of *BCL11A*. Our results suggest that increasing sample size, even by combining individuals of different ancestry, is a promising strategy to find loci associated with HbF levels, a critical modifier of hemoglobin disease severity.

## 1907T

**An intergenic variant between HLA-DRA and HLA-DRB contributes to the clinical course and long-term outcome of ulcerative colitis in Asians.** H.S. Lee<sup>1</sup>, M. Hong<sup>1</sup>, S. Jung<sup>1</sup>, J. Hong<sup>1</sup>, B.M. Kim<sup>1</sup>, J.W. Moon<sup>1</sup>, S.H. Park<sup>2</sup>, K.J. Kim<sup>3</sup>, B.D. Ye<sup>2</sup>, S.H. Oh<sup>3</sup>, K.M. Kim<sup>3</sup>, Y.S. Yoon<sup>4</sup>, C.S. Yu<sup>1</sup>, J. Baek<sup>1</sup>, C.H. Lee<sup>5</sup>, B. Han<sup>5</sup>, J. Liu<sup>6</sup>, T. Haritunians<sup>7</sup>, D.P.B. McGovern<sup>7</sup>, S.K. Song<sup>1</sup>. 1) Department of Biochemistry and Molecular Biology, Department of Biochemistry and Molecular Biology, Seoul, South Korea; 2) Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 3) Department of Pediatrics, Asan Medical Center Children's Hospital, University of Ulsan College of Medicine, Seoul, Korea; 4) Colon and Rectal Surgery, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea; 5) Department of Convergence Medicine, University of Ulsan College of Medicine & Asan Institute for Life Sciences, Asan Medical Center, Seoul, Korea; 6) Human Genetics Group, Genome Institute of Singapore, Singapore; 7) The F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, California, United States of America.

Most currently known susceptibility loci for ulcerative colitis (UC) are not associated with the prognosis of UC. To define the contribution of human leukocyte antigen (HLA) to UC prognosis, we performed HLA imputation on three independent discovery cohorts of 1,336 UC patients (972 with poor prognosis and 364 with good prognosis) using the SNP2HLA with the Korean HLA reference panel. Associations between UC prognosis and binary markers in HLA were analyzed by logistic regression. Validation was performed on an additional 625 patients (496 with poor prognosis and 129 with good prognosis), and those data were also analyzed by logistic regression. The three discovery cohorts and the replication cohort were then meta-analyzed using the inverse-variance weighted method, assuming a fixed-effect model. We found that an intergenic variant between HLA-DRA and HLA-DRB was associated with poor prognosis of UC at genome-wide significance (odds ratio = 1.72; 95% confidence interval = 1.43–2.07;  $P_{combined-meta} = 1.04 \times 10^{-6}$ ), with effect size increasing incrementally according to worsening of prognosis, but showed no association with susceptibility. The presence of the risk variant had a sensitivity of 80.0% and specificity of 38.1% for colectomy. Our results provide new insights into prognosis-associated genetic variation in UC, which is distinct from the genetic contribution to disease susceptibility. These findings could be useful in identifying poor-prognosis patients who might benefit from early aggressive therapy.

Otitis media (OM) is a common disease of early childhood. Interrelated phenotypes include acute OM (AOM), recurrent AOM (rAOM) and OM with effusion (OME). Its etiology is one of complex associations between host, pathogen, environmental and genetic risk factors. To unravel the genetic component to the etiologies of OM we conducted genome-wide association studies (GWAS) per otitis phenotype to identify genetic susceptibility loci to OM, next to underlining possible differences between phenotypes. Our cohort includes children of European ancestry at the Children's hospital of Philadelphia (n=10,634) and the Generation R Study, Erasmus University Medical Center in the Netherlands (n=2,669). We established 3 otitis media phenotypes, including AOM, rAOM, and OME, and 2 combined phenotypes that were previously used in literature, namely Tympanostomy, and an OM combined phenotype consisting of all cases. GWASs were performed per phenotype at both centers and then results were meta-analyzed. We identified a genome-wide significant locus for phenotype AOM at chr16p12.3 with top SNP rs76488276 (P-value=4.533e-08) which is located in an intergenic region. The closest gene is Glycoprotein 2 (GP2) which is involved in innate immune response. For the other phenotypes, we found more than 40 SNPs associated with each phenotype at significance level P<0.00001, though we did not identify individual genome-wide significant loci. Only a limited number of significant SNPs were discovered in more than one phenotype, suggesting different genetic profile for these affiliated phenotypes. The difference in individual SNP association, pathway analysis and protein-protein interaction network analysis results for each phenotype underline genetic complexity of this common disease and its interrelated subtypes.

## 1909W

**Multiple HLA B\*57 alleles, sharing the amino acid residue valine<sup>97</sup>, are associated with drug-induced liver injury due to flucloxacillin in a European population.** P. Nicoletti<sup>1</sup>, G.P. Aithal<sup>2</sup>, S. Coulthard<sup>3</sup>, R. Andrade<sup>4</sup>, E. Bjornsson<sup>5</sup>, J.F. Dillon<sup>6</sup>, A.H. Maitland van der Zee<sup>7</sup>, J.H. **Background:** In Europe, flucloxacillin is a widely prescribed beta-lactam antibiotic but its use is associated with serious liver injury in approximately 1 in 12,000 patients. This liver injury shows strong genetic susceptibility driven by the *HLA-B\*57:01* allele with carriers at 80 times higher risk. **Methods:** DILIGEN/DILIC consortia collected 197 North European flucloxacillin-induced liver injury (Flu-DILI) cases between 2005 and 2013. The cases, matched with 6835 population controls, were genome-wide genotyped and SNPs, HLA alleles and amino acid residues were predicted to confirm and further investigate risk factors located within and outside the MHC region. **Results:** Our GWAS confirmed that *B\*57:01* is the major risk factor (OR = 36.62; 95% CI [26.14-51.29]; P = 2.67\*10<sup>-97</sup>) with a carriage frequency of 84%. Other HLA alleles belonging to the *B\*57:01* haplotype, like *C\*06:02*, *DQB1\*03:03*, *DRB1\*07:01*, *DQA1\*02:01* and *A\*01:01*, also showed a genome-wide significant risk effect while *C\*07:02*, *B\*07:02* and *DQB1\*03:01* were protective. Haplotype analysis showed that *B\*57:01*-containing haplotypes confer risk while *B\*57:01*-omitting haplotypes seems to be protective, suggesting that *B\*57:01* and no other alleles within the haplotype is the main risk factor. *B\*57:01* conditional analysis revealed that *B\*57:03* was the most significant independent risk factor (OR = 79.21; 95% CI [13.57-462.4]; P = 1.2\*10<sup>-6</sup>). Interestingly, valine in position 97, a residue shared by several *B\*57* alleles including *B\*57:01*, *B\*57:03* and *B\*57:02*, had the highest effect size (OR = 38.1, 95% CI [27.07-53.62], P = 9.7x10<sup>-97</sup>). Conversely, arginine<sup>97</sup> and serine<sup>97</sup> have significant protective effects (OR= 0.43 P= 5.13\*10<sup>-14</sup> and OR= 0.53, P=9.82\*10<sup>-7</sup>). Serine<sup>97</sup> is a characteristic residue for the protective *B\*07:02*. No other signal was identified outside the MHC region. **Conclusion:** We found that *B\*57:01* and *B\*57:03* were significant independent risk determinants for Flu-DILI. The shared amino acid valine<sup>97</sup> showed the strongest risk association, while arginine<sup>97</sup> and serine<sup>97</sup> showed a genome wide significant protective effect. Abacavir hypersensitivity is associated only with *B\*57:01*, but appears to have a different mechanism from Flu-DILI involving alteration of the peptide repertoire with aspartate<sup>114</sup> and serine<sup>116</sup>. The novel association between Flu-DILI and valine<sup>97</sup> could help explain the apparently different mechanisms involved in the adverse reactions to these two drugs.

**Transcriptome analysis of systemic lupus erythematosus reveals distinct susceptibility, activity and severity signatures.** N. Panousis<sup>1</sup>, G. Bertsias<sup>2</sup>, I. Gergiannaki<sup>3</sup>, M. Tektonidou<sup>3</sup>, M. Trachana<sup>4</sup>, A. Banos<sup>5</sup>, A. Fanouriakis<sup>5</sup>, C. Pamfil<sup>6</sup>, D. Boumpas<sup>5,6</sup>, E.T. Dermizakis<sup>1</sup>. 1) Department of Genetic Medicine and Development, University of Geneva Medical School, Geneva, Switzerland; 2) Department of Rheumatology, University of Crete, Faculty of Medicine, Crete, Greece; 3) Department of Rheumatology, University of Athens, Faculty of Medicine, Athens, Greece; 4) Department of Pediatrics, Aristotle University of Thessaloniki, Faculty of Medicine, Thessaloniki, Greece; 5) Biomedical Research Foundation of the Academy of Athens, Athens, Greece; 6) Department of Rheumatology, Attikon Hospital, Athens, Greece; 7) Iuliu Hațieganu University of Medicine and Pharmacy, Cluj-Napoca, Romania.

Systemic Lupus Erythematosus (SLE) is a multi-organ, complex autoimmune disease with immense immunological and clinical heterogeneity. Understanding the molecular mechanisms of this variability is essential to facilitate early diagnosis and personalized therapy. We report an RNA-seq analysis of whole blood in 142 SLE patients and 58 matched healthy individuals. We defined the global transcriptional signature of SLE by identifying differentially expressed genes between SLE and healthy individuals. Correcting for the estimated proportions of different immune cell types revealed that the well-established mediator in the pathogenesis of SLE the Interferon (IFN) signaling pathway is robust and prevalent across different immune cells. We also defined a cell specific signature of SLE in immune cells and found that naive and memory B cells, CD4 memory resting T cells, CD8 T cells, and neutrophils have different cell composition effects on gene expression between SLE and healthy individuals. By differential expression analysis between active SLE, inactive SLE and healthy individuals, we defined a 'core/susceptibility' and a 'flare/activity' disease expression signature with oxidative phosphorylation, ribosome regulation and cell cycle being the biological processes enriched for the latter. We propose a measurement of disease activity/severity by combining the validated Systemic Lupus Erythematosus Disease Activity Index 2000 (SLEDAI-2k) with a new pseudo-phenotype, derived from PCA analysis that explains most of the gene expression variability correlated with this index. We also reveal unique transcriptional signatures across disease sub-phenotypes, showing that granulocytes/neutrophils and NETosis play a crucial role in lupus nephritis pathogenesis. The substantial differences (6730 differentially expressed genes 5% FDR) in gene expression between SLE and healthy individuals allowed us to build multiple classifiers that can discriminate disease versus healthy status with a median sensitivity of 83% and median specificity of 100%. Finally, we estimate the tissues harbour genetic causality of SLE by integration of GWAS signals for SLE and eQTLs from 44 tissues available from the GTEx project. Our study defines for the first time, a distinct susceptibility and activity/severity signature in SLE that may facilitate the identification of patients at risk for severe SLE and facilitate patient selection and monitoring for targeted therapies.

**NKG2D variation and viral bronchiolitis.** A. Pasanen<sup>1</sup>, M.K. Karjalainen<sup>1</sup>, L. Kummola<sup>2</sup>, M. Ruotsalainen<sup>3</sup>, T. Jartti<sup>4</sup>, E. Goksör<sup>5</sup>, G. Wennergren<sup>5</sup>, I.S. Junttila<sup>6</sup>, M. Hallman<sup>1</sup>, M. Korppi<sup>7</sup>, M. Rämelt<sup>1</sup>. 1) PEDEGO Research Unit, Medical Research Center Oulu, University of Oulu, and Department of Children and Adolescents, Oulu University Hospital, Oulu, Finland; 2) Faculty of Medicine and Life Sciences, University of Tampere, Tampere, Finland; 3) Kuopio University Hospital, Pediatrics, University of Eastern Finland, Kuopio, Finland; 4) Department of Pediatrics, University of Turku and Turku University Hospital, Turku, Finland; 5) Department of Pediatrics, University of Gothenburg, Queen Silvia Children's Hospital, Gothenburg, Sweden; 6) Faculty of Medicine and Life Sciences, University of Tampere, Tampere, Finland and Fimlab Laboratories, Tampere, Finland; 7) Center for Child Health Research, Tampere University and Tampere University Hospital, Tampere, Finland.

Bronchiolitis is a lower respiratory infection that is most often caused by respiratory syncytial virus. Annually, 2-3% of an age cohort develop bronchiolitis that requires hospital treatment. Genetic background of bronchiolitis is not well known. In the present study, our aim was to identify susceptibility loci by comparing a matched subset (n=187) of our previous bronchiolitis GWAS with known quantitative trait loci (QTLs). A Finnish-Swedish population with 700,000 genotyped variants was tested for association. To reconsider potentially omitted true associations, the variants below a permissive p-value threshold ( $p < 10^{-4}$ ) were analyzed for colocalization with known QTLs. Expression QTLs (eQTLs) were screened from Genotype-Tissue Expression (GTEx) data, and protein QTLs were examined in pGWAS server. Fluorescence-activated cell sorting (FACS) was used to confirm allele specific expression levels of the identified QTLs. The association of candidate loci was tested in two additional Finnish bronchiolitis case sets (n=124 and 101) that were tested against the GWAS controls. Of the 36 bronchiolitis GWAS SNPs with  $p < 10^{-4}$  (MAF > 0.1), the variant rs10772271 resided within an eQTL associated to NKG2D expression ( $p = 2.2 \times 10^{-8}$ ,  $\beta = -0.36$ ), and within a pQTL associated to NKG2D protein levels ( $p = 7.8 \times 10^{-9}$ ,  $\beta = -0.26$ ). In the GWAS, the major allele (A) was the bronchiolitis susceptibility allele (OR=2.34,  $p = 9.9 \times 10^{-6}$ ). The association of NKG2D locus to bronchiolitis was nominally replicated in one population (OR=1.5,  $p = 0.049$ ), whereas the other showed directional consistency (OR=1.43). We confirmed the association of rs10772271 genotypes and NKG2D expression by FACS using NK cells extracted from healthy donors; the predisposing allele was associated to lower NKG2D expression ( $p = 6.0 \times 10^{-4}$ ). We identified NKG2D locus as a candidate for bronchiolitis susceptibility. The GWAS association was nominally replicated in one replication population. The susceptibility allele of rs10772271 of the NKG2D locus was associated to decreased gene and protein expression in QTL databases and in our flow cytometry experiments. NKG2D is a transmembrane receptor, of which ligands are expressed in response to stress, such as virus infection. We hypothesize that decreased NKG2D expression predisposes to bronchiolitis, but further studies are needed.

**Introduction.** Antibody isotype levels and humoral immune responses to latent infections and vaccines vary among individuals, and this is thought to be highly influenced by host genetics. To unravel the mechanisms of genetic control of antibody isotype levels and immunoglobulin G (IgG) responses to common pathogens and vaccines, we conducted genome-wide association studies (GWAS) in a well-characterized population of 1000 healthy individuals recruited by the *Milieu Intérieur* Consortium. **Methods.** The *Milieu Intérieur* (MI) project is a population-based study that aims at assessing the determinants of immunological variance within a healthy population. A total of 1000 individuals of French ancestry, with a 1:1 sex ratio, and stratified across five-decades of life (age 20 – 69), were recruited. Serum samples were used for measuring levels of four antibody isotypes (IgA, IgM, IgG and IgE) and for qualitative (serostatus: seropositive/seronegative) and quantitative assessment of IgG responses against Cytomegalovirus, Epstein-Barr virus (EBV), Herpes simplex virus 1 & 2, Varicella zoster virus, *Helicobacter pylori*, *Toxoplasma gondii*, Influenza A virus, Measles, Mumps, Rubella, and Hepatitis B virus. We used the Illumina OmniExpress and HumanExome arrays for genotyping. After imputation with IMPUTE2, logistic or linear regressions were performed to detect associations between 5 million human genetic variants and antibody levels. Association of rare variants was tested by using sequence kernel association test (SKAT). **Results and discussion.** Genome-wide significant associations ( $P < 5 \times 10^{-8}$ ) were observed between the levels of IgG mounted against EBV (EBNA antigen) and Rubella, and variants in the MHC locus on chromosome 6, confirming previous observations. By imputing classical HLA alleles and amino acids, we found that these associations rely on variations in amino acid composition of the HLA-DR $\beta$ 1 and HLA-DP $\beta$ 1 molecules. No genome-wide significant association was found for serostatus. Analysis of rare variants led to identification of seven new loci associated with levels of IgA. Together our results provide new possible insights into mechanisms determining IgA production and response to different viral antigens and encourage further genetic and functional work.

**Characterising copy number variation at the Crohn disease-associated gene intelectin 1 (*ITLN1*).** F. Almalki<sup>1,2</sup>, E.J. Hollox<sup>1</sup>. 1) University of Leicester, Leicester, United Kingdom; 2) Taibah University, Medina, Saudi Arabia.

Genome-wide association studies in Europeans have identified an allele at an intronic single nucleotide polymorphism (rs2274910) at *ITLN1* associated with Crohn disease (CD). The human intelectin protein 1 (hItln1), coded by the *ITLN1* gene, is expressed in the intestine and recognizes and binds with multiple glycans, in particular to the terminal acyclic 1,2 diol ligand that is found solely on bacteria. However the variant functionally responsible for the association with CD has not yet been identified. The Database of Genomic Variants (DGV) shows copy number variants overlapping *ITLN1* have been identified by either sequence read depth analysis of aligned short read sequences or by hybridisation intensity data from SNP chips. Our aim was to characterise these variants and explore their potential as variants that contribute to the risk of CD. We used a PCR-based method called the paralogue ratio test (PRT) or junction fragment PCR to characterise these copy number variants. A putative duplication and deletion was not validated, suggesting these were false positive calls from genome-wide data. However a 4 kb deletion reported from the 1000 Genome Project was validated and confirmed that it is an in-frame deletion arisen as a result of a non-allelic homologous recombination event between two Alu elements. This deletion has only been found in Africans so far, and is rare, so does not explain the GWAS signal found in Europeans. Nevertheless it may represent an independent susceptibility allele to CD in non-European populations.

**Genetic footprints and functional analysis of polymorphisms in the *PKLR* gene.** O.C.L. Bezerra<sup>1</sup>, N. Mabunda<sup>2</sup>, G. Salomé<sup>3</sup>, L.E. Alvarado-Arnez<sup>1</sup>, F.S.G. Kehdy<sup>1</sup>, F.S. Neves-Manta<sup>1</sup>, R.M. Silva<sup>1</sup>, L.P. Ferreira<sup>1</sup>, E. Tarazona-Santos<sup>3</sup>, L. Gusmão<sup>4</sup>, E.F. Carvalho<sup>4</sup>, R.O. Pinheiro<sup>1</sup>, A.G Pacheco<sup>5</sup>, I.V. Jani<sup>6</sup>, M.O. Moraes<sup>1</sup>. 1) Laboratory of Leprosy, IOC/FIOCRUZ, Rio de Janeiro (RJ), Brazil; 2) Laboratory of Molecular Virology, National Institute of Health, Maputo, Mozambique; 3) Department of Geral Biology, Institute of Biological Science, Federal University of Minas Gerais (UFMG), Belo Horizonte (MG), Brazil; 4) DNA Diagnostic Laboratory (LDD), State University of Rio de Janeiro (UERJ), Rio de Janeiro (RJ), Brazil; 5) Program of Scientific Computing (PROCC), FIOCRUZ, Rio de Janeiro (RJ), Brazil.

Pathogens exert a strong evolutionary force in humans. *PKLR* encodes for pyruvate kinase (PK), a key red blood cell enzyme that catalyzes the ATP output in glycolysis. PK defects, due to genetic mutations, cause nonspherocytic hemolytic anemia. This gene is under a strong selective pressure by Plasmodium in Africa, especially where malaria is endemic. Mutations responsible for PK deficiency have a dual role: association with resistance to malaria and susceptibility to *Salmonella typhimurium*. We hypothesized that malaria parasite selective pressure in Africa shaped *PKLR* resistant genotypes in humans and those could be an evolutionary trade off for intracellular pathogens. Thus, aiming to investigate the *PKLR* polymorphisms and its association to mycobacterial pathogens, we performed two independent case-control studies with two diseases caused by intracellular pathogens, leprosy and tuberculosis, in a Rio de Janeiro and Mozambique populations, respectively. Our results highlighted G allele of the four tested SNPs and the haplotype G/G/G/G as associated with leprosy susceptibility in individuals from Rio de Janeiro (haplotype frequency in cases – 0.39 – and controls – 0.27). Subsequently, association was confirmed for two of the four SNPs (G allele) in a Mozambican TB case-control study. The frequency of the haplotype G/G/G/G was higher in cases (0.48) than in controls (0.38), suggesting the same direction of association in Mozambique. Interestingly, the frequency of the susceptibility haplotype was augmented in African-ancestry cohorts from EPIGEN Consortium, Salvador (0.56), and 1000Genomes, YRI and LWK (0.87), compared to European-ancestry cohorts, Pelotas (0.32) and CEU (0.27). In addition, considering that iron overload is a secondary consequence of RBC lysis in PK deficient individuals, we evaluated the genotype-phenotype correlation by comparing iron parameters in association with *PKLR* SNPs. The GG-genotype (for all individual SNPs) was correlated to higher ferritin and haptoglobin loads in healthy subjects and leprosy patients. Our findings revealed a consistently genetic association between *PKLR* SNPs with leprosy and tuberculosis susceptibility and the functional analysis among G-carriers supported a relevance role of the *PKLR* gene with mycobacterial infections. Finally, we evidenced a locus of evolutionary trade off in which individuals carrying resistant selected genotypes to malaria infection were more susceptible to intracellular pathogens.

**Exome sequencing identifies variants of the alkylglycerol monooxygenase gene (*AGMO*) as a cause of relapses in visceral leishmaniasis in Sudan.** S. Marquet<sup>1</sup>, B. Bucheton<sup>1,2</sup>, C. Reymond<sup>1</sup>, L. Argiro<sup>1</sup>, SH. El-Safi<sup>3</sup>, JP. Desvignes<sup>4</sup>, C. Bérout<sup>4,5</sup>, A. Mergani<sup>6</sup>, A. Dessein<sup>1</sup>. 1) INSERM UMR906, GIMP, Labex ParaFrap, Aix-Marseille University, MARSEILLE, France; 2) IRD-CIRAD 177, Montpellier, France; 3) Dept of Microbiology and Parasitology, Faculty of Medicine, Khartoum, Sudan; 4) INSERM UMR910, GMGF, Aix-Marseille University, Marseille, France; 5) AP-HM, Dept de génétique Médicale, Marseille, France; 6) College of Applied Medical Sciences, Taif University, Turabah, Saudi Arabia.

Visceral leishmaniasis (or Kala-azar, KA) is the most severe form of leishmaniasis. It is characterized by fever, weight loss, hepatosplenomegaly and lymphadenopathy. It is caused by *Leishmania* parasite that multiplies in liver macrophages. During an outbreak of KA in Babar El Fugara, a Sudanese village, 5.7% of cured patients displayed relapses, with familial clustering in half the cases. We performed whole-exome sequencing on a total of 10 relapsing individuals and 11 controls from five families. Rare homozygous and compound-heterozygous nonsense (c.1213C/T, rs139309795, p.Arg405\*) and missense (c.701A/G, rs143439626, p.Lys234Arg) mutations of the alkylglycerol monooxygenase gene (*AGMO*) were associated with KA relapse in three families. Sequencing in additional family members confirmed the segregation of these mutations with relapse and revealed an autosomal dominant mode of transmission. Moreover, these mutations were detected heterozygous in two subjects among 100 unrelated individuals with KA who never relapsed after cure, suggesting incomplete penetrance of *AGMO* deficiency. *AGMO* is expressed in hematopoietic cells in particular, and is strongly expressed in the liver. *AGMO* modulates PAF production by mouse macrophages, suggesting that it may act through the PAF/PAF receptor pathway previously shown to have anti-*Leishmania* activity. This is the first demonstration that relapses after a first episode of KA, are due to difference in human genetic susceptibility and not to modifications of parasite pathogenicity.

**De novo mutations implicate novel genes with burden of rare variants in systemic lupus erythematosus.** A. Roberts<sup>1</sup>, V. Pullabhatla<sup>2</sup>, M. Lewis<sup>3</sup>, D. Mauro<sup>3</sup>, D. Morris<sup>1</sup>, C. Odhams<sup>1</sup>, P. Tomblinson<sup>1</sup>, U. Liljedahl<sup>4</sup>, S. Vyse<sup>1,7</sup>, M. Simpson<sup>1</sup>, S. Sauer<sup>5,8</sup>, E. de Rinaldis<sup>2</sup>, A. Syvänen<sup>4</sup>, T. Vyse<sup>1,6</sup>. 1) Medical & Molecular Genetics, King's College London, London, United Kingdom; 2) NIHR GSTFT/KCL Comprehensive Biomedical Research Centre, Guy's & St. Thomas' NHS Foundation Trust, London, UK; 3) Centre for Experimental Medicine and Rheumatology, William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 4) Department of Medical Sciences, Uppsala University, Uppsala, Sweden; 5) Max Planck Institute for Molecular Genetics, Berlin, Germany; 6) Division of Immunology, Infection and Inflammatory Disease, King's College London, London, UK; 7) Division of Cancer Biology, The Institute of Cancer Research, London, UK; 8) Max Delbrück Centre for Molecular Medicine (BIMSB/BIH), Berlin, Germany.

**Background:** The heritability of most complex diseases, including autoimmune disease Systemic Lupus Erythematosus (SLE), remains largely unexplained by common variation, and few examples of rare variant associations have been identified. Here, using complementary whole-exome sequencing (WES) and high-density imputation, we identify candidate genes through *de novo* mutation discovery and demonstrate collective rare variant associations at novel SLE-susceptibility genes. **Methods:** We selected SLE cases with a severe phenotype (young age of onset and clinical features associated with poorer outcome) and sequenced the exomes of 30 SLE parent-affected-offspring trios. Using conservative parameters across three bioinformatics tools, the WES data were scrutinized for *de novo* mutations. Genes with *de novo* mutations were used as candidate genes in subsequent analyses. In a follow-up cohort of 10,995 individuals of matched European ancestry, including 4,036 SLE cases, we imputed genotype data to the density of the combined UK10K-1000 genomes Phase III reference panel across the candidate genes and performed rare variant burden testing. In addition, we assayed the functional effects of the p.His198Gln *de novo* mutation within candidate gene *C1QTNF4* using HEK293-NF- $\kappa$ B reporter cell line and fibroblast L929 cell line. **Results:** We identified 14 genes with missense *de novo* mutations, none of which are within the >70 SLE susceptibility loci implicated through genome-wide association studies (GWAS). We identify a burden of rare exonic variants across *PRKCD* associated with SLE risk ( $P=0.0028$ ), and across *DNMT3A* associated with two severe disease prognosis sub-phenotypes ( $P=0.0005$  and  $P=0.0033$ ). We further show no common variant association across these 14 loci. Additionally, we show the p.His198Gln *de novo* mutation within the candidate gene *C1QTNF4* inhibits NF- $\kappa$ B activation following TNF exposure. **Conclusion:** Exome sequencing studies typically lack power to detect rare variant associations for complex traits. In light of recent studies which have demonstrated the limitations of large-scale exome-wide case-control studies in detecting rare variant contributions, our results support extreme-phenotype sampling and *de novo* mutation discovery to aid a hypothesis-driven search for rare variation contributing to the heritability of complex diseases.

**1917F**

**A long non-coding RNA in the rheumatoid arthritis risk locus at chromosome 18 is involved in T cell activities.** M. Houtman, K. Shchetynsky, L. Padyukov. Rheumatology Unit, Department of Medicine Solna, Karolinska Institute and Karolinska University Hospital, Stockholm, Sweden.

Rheumatoid arthritis (RA) is a relatively common autoimmune disorder that is characterized by joint inflammation and destruction. Genome-wide association studies have enabled the discovery of common genetic variations in over 100 loci contributing to RA, but the precise targets of the majority of these associations are unknown. We aimed to identify the molecular mechanisms that connect variations in the protein tyrosine phosphatase non-receptor type 2 (*PTPN2*) locus with RA. We have found that previously identified RA-susceptibility variants in the *PTPN2* locus are associated with the expression of a long non-coding RNA *LINC01882* located 30kb downstream of *PTPN2* (whole blood; GTEx). To identify the function of this long non-coding RNA, we suppressed the expression of *LINC01882* using antisense oligonucleotides and RNA interference in Jurkat T cells. Twenty-four and 48 hours after knock-down, total RNA was extracted and ribosomal RNA was depleted. Sequencing libraries were generated using the Illumina TruSeq Stranded Total RNA kit and sequenced on an Illumina HiSeq 2500 platform, yielding about 25 million paired-end reads per sample. Differential expression analyses were conducted using DESeq2. We identified 12 deregulated genes after *LINC01882* knock-down (6 upregulated and 6 downregulated; FDR < 0.05). One of the downregulated genes is the zinc finger E-box-binding protein 1 (*ZEB1*), a repressor of interleukin-2 (*IL-2*) gene transcription, that points towards the involvement of *LINC01882* in T cell differentiation. Our data suggest that *LINC01882* might contribute to the molecular mechanism underlying RA. Overall, these findings point towards the potential role of *LINC01882* in the RA-susceptibility association attributed to the *PTPN2* locus.

**WGS identifies rare variants influencing variation in blood cell traits in Mexican American families.** *N.B. Blackburn<sup>1</sup>, J.M. Peralta<sup>1,2</sup>, L. Almasy<sup>3,4</sup>, D.C. Glahn<sup>5</sup>, R. Duggirala<sup>1</sup>, J.E. Curran<sup>1</sup>, J. Blangero<sup>1</sup>.* 1) South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley School of Medicine, Brownsville, TX, USA; 2) Menzies Institute for Medical Research, University of Tasmania, Hobart, Tasmania, Australia; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 4) Department of Biomedical and Health Informatics, The Children's Hospital of Philadelphia, Philadelphia, PA; 5) Department of Psychiatry, Yale University School of Medicine, New Haven, CT, USA.

The process of blood cell production, hematopoiesis, is a continuous and dynamic process influenced by a range of genetic and environmental factors. Variation in blood cell traits exists between healthy individuals and, importantly, is clinically relevant with extreme variation indicating a range of pathologies from anemia to infection or chronic hematological disease. It is established that blood cell traits are highly heritable and there have been a number of successes in localizing QTLs that influence variation in blood cell levels. While the key genes involved in hematopoiesis have been extensively characterized the underlying genetic basis of individual variation in blood cell traits remains relatively unknown. Here, we examine for the first time 16 blood cell traits in 1,462 Mexican American individuals from large pedigrees, each with WGS data available. These traits include count measures of RBCs, WBCs and platelets as well as measures of hemoglobin concentration and cell volumes. Using empirically calculated kinship probabilities, estimated using IBDLD from 100,000 LD pruned sequence variants, we identify that each of these traits is significantly heritable, for example 53% and 62% heritability for total WBC and RBC counts respectively ( $P=2.13 \times 10^{-20}$  and  $P=1.51 \times 10^{-26}$ ). Using rare ( $MAF \leq 0.05$  in public databases) nonsynonymous WGS variants predicted to be deleterious ( $CADD \geq 15$ ) we conducted measured genotype associations for each blood cell trait in SOLAR. We identified multiple rare variants associated with variation in blood cell traits, including rs52833951 in *MMP24* (V344I) which was associated with a 2.38 SDU increase in RBC levels, with all carriers having RBC counts in the highest 1% of the sample. In addition, using this variant set, we assess previously identified genome-wide associations from population based cohorts. For example the variant rs34856868 in *BTBD8* (V60I) was previously associated with lower monocyte counts. In our study conversely, this variant was associated with a 0.48 SDU increase in monocyte levels ( $P=0.008$ ). From the same population based cohort, rs3746072 in *S1PR4* (R375L) was previously associated with a decrease in total WBC count. Further supporting *S1PR4*'s role in WBC production, in our study we identify that rs61731111 (R243C) is associated with a 0.41 SDU decrease in total WBC count ( $P=0.02$ ). Our results emphasize the utility of WGS in pedigrees for identifying rare variants influencing blood cell traits.

**1919T**

**Trans-ethnic meta-analysis of the Korean, East Asian and European ImmunoChip data identifies three novel IBD susceptibility loci.** *S. Jung<sup>1</sup>, H.S. Lee<sup>1</sup>, B. Kim<sup>1</sup>, S.B. Lee<sup>1</sup>, B.D. Ye<sup>2</sup>, S.H. Park<sup>2</sup>, S.K. Yang<sup>2</sup>, K. Song<sup>1</sup>.* 1) Department of Biochemistry and Molecular Biology, University of Ulsan College of Medicine, Seoul, Korea; 2) Department of Gastroenterology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Korea.

To date, the 241 IBD susceptibility loci were reported in Europeans. Previously, we reported three new IBD as *NCF4-CSF2RB*, *CIITA* and *PSMA6-NFKBIA* as an Asian-specific or Asian-dominant IBD susceptibility loci using a meta-analysis of Korean and East Asian IBD ImmunoChip. In this study, we performed a meta-analysis of European, Korean and East Asian ImmunoChip data sets including 42,311 IBD cases and 53,389 controls using Mantra/Metal. We identified three novel loci for IBD/CD at genome-wide significance (Bayes factor  $> 6$  and  $P < 5.0 \times 10^{-8}$ ): rs2624435 in *MYO10-BASP1* at 5p15 (Bayes factor=6.32; OR = 0.94,  $P_{\text{combined}} = 1.80 \times 10^{-8}$ ), rs2074023 in *TSPAN32* at 11p15 (Bayes factor=7.49; OR = 0.94,  $P_{\text{combined}} = 1.05 \times 10^{-9}$ ) for IBD and rs7170683 in *LRRK1* at 15q26 (Bayes factor=6.34; OR = 0.94,  $P_{\text{combined}} = 1.99 \times 10^{-8}$ ) for CD. Our results provide additional biological insight to IBD.

**1920F**

**Associations between a polymorphism of the gene encoding the Toll like receptor and response to infliximab in Japanese patients with Crohn's disease.** S. Ma<sup>1</sup>, Y. Fukumitsu<sup>1</sup>, Y. Noma<sup>1</sup>, T. Inamine<sup>1</sup>, S. Kondo<sup>1</sup>, S. Urabe<sup>2</sup>, K. Matsushima<sup>2</sup>, R. Uehara<sup>2</sup>, T. Honda<sup>2</sup>, H. Machida<sup>2</sup>, N. Yamaguchi<sup>2</sup>, K. Ohnita<sup>2</sup>, F. Takeshima<sup>2</sup>, H. Isomoto<sup>3</sup>, K. Nakao<sup>3</sup>, K. Tsukamoto<sup>1</sup>. 1) Dept Pharmacotherapeutics, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki; 2) Dept Gastroenterology and Hepatology, Nagasaki Univ Grad Sch Biomed Sci, Nagasaki; 3) Div Med and Clin Sci, Dept Multidisciplinary Int Med, Faculty of Med, Tottori Univ, Yonago.

**Purpose:** Infliximab (IFX) is a chimeric monoclonal antibody which neutralizes tumor necrosis factor alpha and is widely used for the treatment of Crohn's disease (CD). However, some CD patients show loss of therapeutic response to IFX in about 20-30% of those at the 1-year treatment period although these patients had achieved remission. Therefore, we investigated an association of *TLR2*, *TLR4* and *TLR9*, which encode the Toll like receptors related to multiple inflammation signals, with response to IFX at the 1-year treatment period in Japanese CD patients. **Methods:** A total of 116 CD patients, which showed good response to IFX at the early period in Nagasaki University Hospital, were divided into two groups, responders and non-responders for IFX, according to the presence of IFX effect at the 1-year treatment period after IFX administration. Eight tag single nucleotide polymorphisms (SNPs) in these 3 genes were analyzed by PCR-restriction fragment length polymorphism, PCR-high resolution melting curves analysis and PCR-direct DNA sequencing. The frequencies of alleles and genotypes of each SNP between responders and non-responders at the period were compared in three different inheritance models using chi-squared test or Fisher's exact test. **Results:** Statistical analyses indicated the frequency of an A/A genotype of rs13105517 in *TLR2* in the minor allele recessive model was significantly decreased in responders at the 1-year treatment period in comparison to that in non-responders ( $P = 0.004$ , odds ratio = 0.195), implicating ~5.1-fold loss of response. Conversely, a G/G and G/A genotype of rs13105517 indicated ~5.1-fold response to IFX. **Conclusions:** Our results implicate the A/A genotype of rs13105517 in *TLR2* may affect the gain-of-function of TLR2, thereby leading to the activation of the downstream signals in the TLR signal pathway and eventually resulting in chronic intestinal inflammatory process in the intestines of CD patients. This is why these patients with this polymorphism of *TLR2* showed loss of response to IFX at the 1-year treatment period. Therefore, the polymorphism of *TLR2* may have the potential for being a new genetic biomarker to predict the long-term therapeutic effect and loss of response to IFX in Japanese CD patients, and for being a target molecule for new drugs overcoming loss of response to IFX.

**1921W**

**GWA and MHC-fine mapping analyses of multiple sclerosis (MS) age at diagnosis (AAD) identify novel associations with an HLA-DQ heterodimer and GZMA.** P.G. Bronson<sup>1</sup>, C. Tian<sup>2</sup>, A. Dhroso<sup>1</sup>, F.B. Briggs<sup>3</sup>, K.D. Nguyen<sup>1</sup>, M. Seldin<sup>4</sup>, T. 23andMe Research Team<sup>2</sup>, D. Hinds<sup>2</sup>, A. Day-Williams<sup>1</sup>, M. Penny<sup>1</sup>, S. John<sup>1</sup>, K. Estrada<sup>1</sup>. 1) Computational Biology & Genetics, Biogen, Inc., Cambridge, MA, USA; 2) 23andMe, Inc., Mountain View, CA, USA; 3) Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH, USA; 4) Department of Biochemistry, School of Medicine, University of California, Davis, CA, USA.

**Background:** Genetic studies of MS have identified >100 non-MHC loci. The strongest association is with *HLA-DRB1\*15:01* (OR=3.9,  $P < 1e-600$ ). In Europeans, this risk allele is in almost perfect LD with *HLA-DQB1\*06:02*. The risk allele and *HLA-DQB1* are associated with younger age at onset (AAO) ( $\beta = -0.72$  years,  $P = 2e-8$ ). An association between non-MHC loci and AAO has not been established. **Objectives:** To conduct case-only imputed HLA and GWAS studies of self-reported AAD in 23andMe MS cases (N=2,339, EUR). **Methods:** We developed a novel method to test the DNA sequence of HLA peptide binding grooves, based on cis or trans heterodimer configurations. AAD was analyzed using linear regression adjusted for gender and ancestry principal components (estimated from non-HLA SNPs). We tested all alleles, amino acid residues and peptide binding grooves for the classical HLA loci using a dominant model, whereas the standard additive model was used for the GWAS. The HLA significance threshold was  $P < 1.7e-3$  (false discovery rate, 0.05), and the GWAS utilized the standard genome-wide threshold. **Results:** We validated the association between AAD and the risk allele (*DRB1\*15:01*) ( $\beta = -1.97$ ,  $P = 5.6e-5$ ). However, an *HLA-DQ* peptide binding groove (*HLA-DQA1\*05/DQB1\*06:02*, in cis or trans) was even more strongly associated ( $\beta = -3.49$ ,  $P = 1.3e-6$ ). When both the risk allele and *HLA-DQ* molecule were included in the same logistic regression analysis, association was much stronger for *HLA-DQ* ( $\beta = -2.72$ ,  $P = 5.3e-4$ ) than for the risk allele ( $\beta = -1.26$ ,  $P = 0.02$ ). *HLA-DQ* was still significant when tested only in the risk allele carriers ( $\beta = -2.68$ ,  $P = 4.4e-4$ ). HLA was the only genome-wide significant peak in the GWAS. However, we observed an association with older AAD that was close to genome-wide significance in granzyme A (*GZMA*, 5q11). The peak variant was a common deletion ( $\beta = 2.62$ ,  $P = 6.7e-8$ ; rs33995145), and the region of association extended from *CCNO* to *DHX29*. **Discussion:** This is the first genetic HLA study to test the biological molecules (peptide binding grooves) to our knowledge, and we identified a novel association with an *HLA-DQ* molecule. This association was significant even after including *HLA-DRB1\*15:01* as a covariate, and when examined only in *HLA-DRB1\*15:01* allele carriers. We also identified a novel near-significant non-HLA association with *GZMA*, a protein produced by CD8+ T cells to induce apoptosis of tumor cells and virus-infected cells. Further research is ongoing to confirm our findings.

**1922T****Pleiotropy analysis of penicillin and sulfa drug allergy in the Kaiser**

**GERA cohort.** A. Majumdar<sup>1</sup>, J. Hoffman<sup>1</sup>, R. Melles<sup>2</sup>, D. Ranatunga<sup>2</sup>, J. Witte<sup>1</sup>, E. Jorgenson<sup>3</sup>. 1) Department of Epidemiology and Biostatistics, University of California San Francisco, CA, USA; 2) Kaiser Permanente Northern California, Department of Ophthalmology, Redwood City, CA, USA; 3) Kaiser Permanente Northern California, Division of Research, Oakland, CA, USA.

Hypersensitivity reactions against drugs are governed by immunologic mechanisms. Penicillin and Sulfa are two common drug classes and allergies to these types of medications can cause skin rash, itching, breathing problems, headache, and anaphylaxis. Genome-wide association studies (GWAS) have identified genetic risk factors underlying drug allergies, but they have not been investigated as extensively as other complex traits, e.g., cancers, psychiatric disorders. GWAS have also detected loci associated with multiple different diseases (i.e. pleiotropy). Analyzing pleiotropy may provide a better understanding of pathways and biological mechanisms shared by different conditions. We undertake a GW pleiotropic association study of Penicillin and Sulfa drug allergy in the Kaiser Permanente GERA cohort. We consider 748 cases for Penicillin and 678 cases for Sulfa, with 95 common cases having both allergies and a shared pool of 15,894 controls. All the individuals studied here are of European ancestry. We computed the univariate summary statistics for each trait adjusting for relevant covariates, and considered 7,761,491 genotyped and imputed SNPs after various screening. Using the p-value cut-off  $5 \times 10^{-8}$ , the univariate GWAS for Penicillin detected a novel signal at rs111969675 ( $P = 1.4 \times 10^{-8}$ ) which is an intronic variant in the CSMD1 gene located at 8p23.2, but the GWAS for Sulfa did not identify any GW signal. We applied the subset-based meta-analysis ASSET for the two traits adjusting for the shared subjects. Including the univariate GW signal for Penicillin at 8p23.2, ASSET identified two more novel signals associated with both Penicillin and Sulfa that were missed by the univariate GWAS: rs143123254 at 7p11.2 ( $P = 4.3 \times 10^{-8}$ ) and rs141475569 at 16q12.1 ( $P = 6.5 \times 10^{-9}$ ). rs141475569 is a known eQTL for the ABCC11 gene in liver tissue. We then applied the conditional false discovery rate (cFDR) approach for the two traits. Considering Penicillin as the principal phenotype and Sulfa as the conditioning phenotype, the cFDR approach validated the three signals detected by ASSET using a 5% level of cFDR and Sulfa p-value cut-off as 0.01 and 0.001. The lead SNP of the largest associated LD block detected by the cFDR approach is rs57841279 at 1q23.3. ASSET also produced a suggestive evidence of association at rs57841279 ( $P = 2 \times 10^{-5}$ ). rs57841279 is an intronic variant in the SDHC gene and a well-known eQTL. We attempt to replicate these signals in a separate dataset.

**1923F****Genetic markers associated with leprosy susceptibility in a group of**

**incident household contacts from Brazil.** L. Arnez<sup>1</sup>, T. Gomes Toledo-Pinto<sup>1</sup>, I. de Oliveira Moraes<sup>1</sup>, T. Calvo Leal<sup>1</sup>, P.T. Santos<sup>2</sup>, P. Medeiros<sup>3</sup>, R. Raju<sup>1</sup>, N. Duppre<sup>1</sup>, A.M. Sales<sup>1</sup>, D. Garbin di Luca<sup>1</sup>, E. Nunes Sarno<sup>1</sup>, I. Goulart<sup>4</sup>, A.G. Pacheco<sup>5</sup>, A.C. Pereira<sup>2</sup>, M. Ozório Moraes<sup>1</sup>. 1) Leprosy Laboratory, Fiocruz Institute, Rio de Janeiro, Rio de Janeiro, Brazil; 2) Molecular Carcinogenesis Program, National Cancer Institute, Rio de Janeiro; 3) Lauro de Souza Lima Institute, Bauru, Brazil; 4) National Reference Center for Sanitary Dermatology and Leprosy, Clinics Hospital, Federal University of Uberlândia, MG, Brazil; 5) Program of Scientific Computing, Fiocruz, Rio de Janeiro, Brazil.

We performed a Genome Wide Association Study (GWAS) in household contacts that developed leprosy (N=67) compared to contacts equally exposed to bacilli but that remained healthy (N=319) and did not progressed towards the disease. Using logistic regression we tested ~230,000 polymorphisms (IlluminaHumanCore-12) for association with leprosy per se as outcome. We prioritized significant SNPs with OR > 2 or < 0.5 to perform enrichment analysis in the genes were these top associated polymorphisms mapped to. We returned to genotyping data and evaluated the SNPs located in genes from the enriched processes and performed a second logistic regression tests by means of mixed models to assess leprosy. A genetic risk score was obtained and tested as a predictor in two different Brazilian populations with the same study design. Differential expression of gene candidates was assessed in THP-1, ST88-14 cell lines, blood and nerve biopsy samples from contacts and leprosy patients. Our results based on the top markers from the preliminary logistic regression and the enrichment analysis of associated SNPs pointed towards 31 genes that represented biological processes of neuron generation, regulation of neuromuscular junction, neurological system process and cell recognition ( $P\text{-value}_{\text{enrichment}} < 0.001$ ). The second logistic regression using mixed models indicated that 17 polymorphisms distributed in this specific set of genes were significantly associated either with susceptibility (N= 11 SNPs) or protection (N=6 SNPs) towards disease development even after correction for multiple comparisons ( $P\text{-value}_{\text{FDR}} < 0.05$ ). Combinatorial SNP analysis indicated that the group of incident household contacts had a higher genetic risk score ( $P < 0.001$ ), further by applying this score in different populations that had the same contact groups under comparison (develop disease versus remain healthy), we obtained probabilities that ranked higher in risk for the contacts that developed leprosy. Functional analysis evaluating the set of associated genes revealed differences in gene expression in nerve biopsies, blood samples and M.leprae-infected cell lines (THP-1, ST88-14). Interestingly, we determined novel SNPs in a group that exhibits the highest risk to progress towards the disease (contacts) indicating that they participate in pathogenesis and can be used as markers for disease outcome.

**Genome-wide association study identifies *HLA-DR/DQ* region for childhood nephrotic syndrome in Japanese.** X. Jia<sup>1</sup>, T. Horinouchi<sup>2</sup>, Y. Hitomi<sup>3</sup>, A. Shono<sup>2</sup>, S.S. Khor<sup>1</sup>, Y. Omae<sup>1</sup>, K. Nozu<sup>2</sup>, K. Kojima<sup>3,4</sup>, Y. Kawai<sup>3,4</sup>, M. Nagasaki<sup>2,5</sup>, K. Tokunaga<sup>1</sup>, K. Iijima<sup>2</sup>. 1) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 2) Department of Pediatrics, Graduate School of Medicine, Kobe University, Kobe, Japan; 3) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University, Sendai, Japan; 4) Graduate School of Medicine, Tohoku University, Sendai, Japan; 5) Graduate School of Information Sciences, Tohoku University, Sendai, Japan.

Nephrotic syndrome (NS) is the most common cause of kidney disease in children, but the underlying genetic etiology is not well understood. So far, no genome-wide association study (GWAS) has been reported for childhood NS in the world. To identify common genetic variations conferring the risk of childhood nephrotic syndrome, we performed a two-stage GWAS in the Japanese population. A total of 285 patients with childhood-onset NS and 419 adult healthy controls were genotyped using Affymetrix 'Japonica Array' in the discovery stage. *HLA*-genotyping for *HLA-DRB1/DQB1* was performed by sequence-specific oligonucleotide primed PCR (PCR-SSO) method using Luminex platform. In addition, we conducted high-accuracy imputation for both *HLA* class I and class II genes (*HLA-A*, *-B*, *-C*, *-DRB1*, *-DQB1* and *-DPB1*) based on Japanese population-specific reference. Whole-genome imputation was conducted using a phased reference panel of 2,049 healthy Japanese individuals (2KJPN panel). An independent cohort including 288 cases and 719 healthy controls were collected in the replication stage. Candidate SNPs detected in the discovery stage were genotyped by DigiTag2 or TaqMan assay in the validation and replication studies. In GWAS, the most significant signal was detected in *HLA-DR/DQ* region (rs3134996,  $P=2.39 \times 10^{-12}$ , odds ratio (OR)=0.31). In the *HLA* allele analysis, *HLA-DRB1\*08:02* ( $P_c=1.25 \times 10^{-16}$ , OR=3.18,  $P_c$  denotes Bonferroni corrected probability value), *HLA-DRB1\*13:02* ( $P_c=5.57 \times 10^{-14}$ , OR=0.16) and *HLA-DQB1\*06:04* ( $P_c=9.17 \times 10^{-16}$ , OR=0.11) showed strong positive or negative associations with childhood NS in both GWAS and replication sample sets. *HLA-DRB1\*08:02-DQB1\*03:02* ( $P_c=6.25 \times 10^{-18}$ , OR=4.50) and *HLA-DRB1\*13:02-DQB1\*06:04* ( $P_c=2.00 \times 10^{-15}$ , OR=0.11) were identified as the strongest susceptible and protective haplotype, respectively. Moreover, the risk haplotype *HLA-DRB1\*08:02-DQB1\*03:02* also showed a higher frequency in patients with the history of steroid resistance than the ones without such history during the follow-up ( $P_c=2.01 \times 10^{-2}$ ). After whole-genome imputation, 9 loci in non-*HLA* region showed suggestive associations ( $P < 1 \times 10^{-5}$ ). 18 SNPs from the 9 loci were selected as candidate SNPs for validation and replication, but none of the associations was replicated in the independent cohort.

**1925T**

**A genome-wide association analysis identifies *NMNAT2* and *HCP5* as susceptibility loci for Kawasaki disease.** J. Kim, J. Lee. Asan Institute for Life Sciences, Ulsan College of Medicine, Seoul, South Korea.

Kawasaki disease (KD), a systemic vasculitis of infants and children, manifests as fever and mucocutaneous inflammation. Although its etiology is largely unknown, epidemiological data suggest that genetic factors are important in KD susceptibility. To identify genetic variants influencing KD susceptibility, we performed a genome-wide association study (GWAS) in 249 children with KD and 1,000 controls in the Korean population, with replication in an independent 666 cases and 3,553 controls. Six single nucleotide polymorphisms (SNPs) in three loci were associated significantly with KD susceptibility ( $P < 1.0 \times 10^{-6}$ ), including the previously reported *BLK* locus (odds ratio (OR) = 1.52,  $P = 2.52 \times 10^{-11}$ ). The other two loci were newly identified: *NMNAT2* on chromosome 1q25.3 (OR = 1.33,  $P = 1.15 \times 10^{-6}$ ) and the human leukocyte antigen (*HLA*) region on chromosome 6p21.3 (*HLA-C*, *HLA-B*, *MICA*, and *HCP5*) (OR = 1.33 – 1.51,  $P = 8.93 \times 10^{-6}$  –  $5.24 \times 10^{-8}$ ). In a meta-analysis with Japanese data of 428 cases and 3,379 controls using imputed genotype data, the variant in *NMNAT2* remained significantly associated (OR = 1.27,  $P = 5.90 \times 10^{-7}$ ), whereas the *HLA* locus was not replicated in the Japanese population. These results provide new insights into the pathogenesis and pathophysiology of KD.

**1926F****ImmunoChip v2.0 meta-analysis identifies shared genetic loci for inflammatory bowel disease in Korean population.**

S.B. Lee<sup>1</sup>, B.M. Kim<sup>1</sup>, H.S. Lee<sup>1</sup>, M. Hong<sup>1</sup>, S. Jung<sup>1</sup>, J. Hong<sup>1</sup>, J.W. Moon<sup>1</sup>, J. Baek<sup>1</sup>, S.H. Park<sup>2</sup>, B.D. Ye<sup>2</sup>, S.H. Oh<sup>3</sup>, B. Han<sup>4</sup>, T. Haritunians<sup>5</sup>, D.P.B. McGovern<sup>5</sup>, S.K. Yang<sup>2</sup>, K. Song<sup>1</sup>. 1) Biochemistry and Molecular Biology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea; 2) Department of Gastroenterology, Asan Medical Center, Seoul, South Korea; 3) Department of Pediatrics, Asan Medical Center Children's Hospital, Asan Medical Center, Seoul, South Korea; 4) Department of Convergence Medicine, University of Ulsan College of Medicine, Seoul, South Korea; 5) The F. Widjaja Foundation Inflammatory Bowel and Immunobiology Research Institute, Cedars-Sinai Medical Center, Los Angeles, California, USA.

Current genome-wide association studies (GWAS) on inflammatory bowel diseases (IBD) have revealed more than 241 susceptibility loci specific to Caucasian population. These studies however, do not completely reflect the heterogeneity in genetic makeup and thus the clinical outcomes of IBD between different ethnicities. With limited non-European GWAS on IBD, our study aimed to identify novel IBD associated loci in Koreans. We newly genotyped 1,498 IBD cases (750 Crohn's disease, 748 ulcerative colitis) and 491 controls on an ImmunoChip v2.0 to be used as the discovery cohort. Replication of the candidate loci was performed using previously published Korean GWAS dataset of an independent cohort consisting of 1,337 IBD cases (905 CD, 432 UC) and 3,801 controls. Meta-analysis of the two datasets revealed no novel IBD susceptibility loci that exceed genome-wide significance. We compared our Korean data to the 241 previously reported IBD susceptibility loci in the European population and found that 182 SNPs were available in our data ( $r^2 > 0.8$ ). A total of 20 loci exceeded a significant threshold of  $2.07 \times 10^{-4}$  ( $0.05/241$ ) and an additional 52 loci showed association at the nominal significance ( $P < 0.05$ ). Furthermore, rs76295456 in *CD28* at 2q33 (odds ratio = 1.25; 95% confidence interval = 1.17–1.32;  $P_{\text{combined-meta}} = 1.08 \times 10^{-6}$ ) reached genome-wide significance for the first time in the Korean population. Our study does not provide any new insights on IBD susceptible loci but successful replication of previously reported loci highlights the shared genetic characteristics of IBD in trans-ethnic populations.

**1927W**

**GWAS identified associations of *HLA-DRB1-DQB1* haplotypes and *BTNL2* gene with response to a hepatitis B vaccine.** N. Nishida<sup>1,2</sup>, M. Sugiyama<sup>1</sup>, H. Sawai<sup>2</sup>, J. Ohashi<sup>2</sup>, S-S. Khor<sup>2</sup>, T. Tsuchiura<sup>1</sup>, K. Tokunaga<sup>2</sup>, M. Mizokami<sup>1</sup>. 1) Genome Medical Science Project, National Center for Global Health and Medicine, Ichikawa, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Bunkyo-ku, Japan; 3) Department of Biological Sciences, Graduate School of Science, The University of Tokyo, Bunkyo-ku, Japan.

Approximately 5-10% of individuals, who are vaccinated with a hepatitis B (HB) vaccine designed based on the HBV genotype C, fail to acquire protective levels of antibodies. Host genetic factors behind low immune response to the HB vaccine were investigated by GWAS and *HLA* association tests. GWAS and *HLA* association tests were carried out using a total of 1,193 Japanese individuals including 107 low responders (HBsAb  $\leq 10$  mIU/mL), 351 intermediate responders (10 mIU/mL < HBsAb < 100), and 735 high responders (HBsAb  $\geq 100$  mIU/mL). Classical *HLA* class II alleles were statistically imputed using the genome-wide SNP typing data. GWAS identified independent associations of *HLA-DRB1-DQB1* haplotypes, *HLA-DPB1* alleles and *BTNL2* gene with immune response to the HB vaccine designed based on the HBV genotype C. Five *HLA-DRB1-DQB1* haplotypes and two *DPB1* alleles showed significant associations with response to the HB vaccine in a comparison of three groups of 1,193 HB vaccinated individuals. When frequencies of *DRB1-DQB1* haplotypes and *DPB1* alleles were compared between low immune responders and HBV patients, significant associations were identified for three *DRB1-DQB1* haplotypes, and no association was identified for any of *DPB1* alleles. In contrast, no association for *DRB1-DQB1* haplotypes and *DPB1* alleles was identified in a comparison between high immune responders and healthy individuals. The findings in this study clearly show the importance of *HLA-DR-DQ* (i.e. recognition of a HB vaccine related HBsAg by specific *DR-DQ* haplotypes) and *BTNL2* molecules (i.e. high immune response to the HB vaccine) for response to a HB vaccine designed based on the HBV genotype C.

**Reduced severity of collagen-induced arthritis in peptidylarginine deiminase type 4 knockout mice.** A. Suzuki<sup>1</sup>, Y. Kochi<sup>1</sup>, K. Yamamoto<sup>1,2</sup>. 1) IMS, RIKEN, Yokohama City, Japan; 2) Department of Allergy and Rheumatology, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan.

**Objective.** Rheumatoid arthritis (RA) is one of the most common autoimmune diseases, which affects approximately 1% of the world population. RA is a chronic systemic inflammatory disease characterized by the inflammation of synovial joint tissues. Previously, we identified peptidylarginine deiminase type 4 (PADI4) as a susceptibility gene for RA by genome-wide association studies. PADI4 is highly expressed in immune cells, such as bone marrow, macrophages, neutrophils, and monocytes. Peptidyl-citrulline is an important molecule in RA because it is a target antigen of anti-citrullinated peptide antibodies (ACPAs), and only PADs (translated protein from PADI genes) can provide peptidyl citrulline via modification of protein substrates. The aim of this study was to evaluate the importance of the PADI genes in the progression of RA. **Methods.** We generated Padi4 knockout (Padi4<sup>-/-</sup>) DBA1J mice. Padi4<sup>-/-</sup> DBA1J and wild-type mice were immunized with bovine type II collagen (CII) to develop collagen-induced arthritis (CIA). We compared the incidence and severity score, and performed measurements of expression levels of various inflammatory cytokines and Padi genes in immune cells by real-time TaqMan assay. Also cytokine concentration and CII antibodies in sera were measured by enzyme-linked immunosorbent assay. We investigated PADI4 effect on the transcriptional pattern of macrophage from Padi4<sup>-/-</sup> mice by microarray. **Results.** We demonstrated that the clinical disease score was significantly decreased in Padi4<sup>-/-</sup> mice and Padi4 expression was induced by CII immunization. In Padi4<sup>-/-</sup> mice sera, serum anti-type II collagen (CII) IgM, IgG, and inflammatory cytokine levels were also significantly decreased compared with those in wild-type mice sera. Interestingly, Padi2 expression was compensationally induced in CD11b<sup>+</sup> cells of Padi4<sup>-/-</sup> mice. We also identified Fus gene as a significant gene between WT and Padi4<sup>-/-</sup> mice by independent two microarray tests. **Conclusion.** On the basis of these studies, it appears that Padi4 enhances collagen-initiated inflammatory responses. Our results revealed that PADI4 affected on expression of various cytokines and also controlled Padi genes and Fus gene.

**A locus on chromosome 5 shows African-ancestry-limited association with alloimmunization in sickle cell disease.** L.M. Williams<sup>1</sup>, Z. Qi<sup>2</sup>, K. Batai<sup>3</sup>, S. Hooker<sup>3</sup>, R. Machado<sup>4</sup>, A. Chen<sup>5</sup>, J. Moulds<sup>5</sup>, S. Campbell-Lee<sup>4</sup>, Y. Guan<sup>2</sup>, R. Kittles<sup>5</sup>, N. Hanchard<sup>6</sup>. 1) Biological Sciences, University of Botswana, Gaborone, Botswana; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 3) University of Arizona, College of Medicine, Tucson, AZ; 4) University of Illinois at Chicago, College of Medicine, Chicago, IL; 5) Gulf Coast Pathology, Houston, TX; 6) LifeShare Blood Centers, Shreveport, LA.

Red Blood Cell (RBC) transfusion remains a critical therapeutic intervention in Sickle Cell Disease (SCD); however, the apparent propensity of some patients to develop RBC alloantibodies presents a significant clinical challenge. Such alloimmunization 'responders' often form alloantibodies following each transfusion, limiting the availability of compatible blood. Donor and recipient factors have been implicated in this phenomenon, but there are no definitive predisposing genetic loci. We undertook a genome-wide association study of alloimmunization responder status in 267 SCD chronic transfusion recipients, using genetic estimates of ancestral admixture to bolster our findings. Analyses revealed SNPs on chromosomes 2 and 5 approaching genome-wide significance (GWS; min  $P$ -values=  $2.0 \times 10^{-8}$  and  $8.4 \times 10^{-8}$ , respectively), with local ancestry analysis demonstrating similar levels of admixture in responders and non-responders at implicated loci. Association at chromosome 5 was nominally replicated in an independent cohort of 150 SCD transfusion recipients, with META-analysis surpassing GWS (rs75853687,  $P = 6.6 \times 10^{-9}$ ), and this association extended to individuals forming multiple (>3) alloantibodies (meta-analysis  $P = 9.4 \times 10^{-6}$ ). Orthogonal genome-wide haplotype analyses implicated a rare haplotype of African origin at the same locus reaching GWS. The associated locus includes putative binding sites for immunoregulatory transcription factors predicted to affect *cis*-transcription of *ADRAB1* and the lncRNA *LINC01847* - both members of larger ontologies associated with immune regulation. Our findings provide insights to the pathophysiology underlying the development of alloantibodies, implicate non-RBC ancestry-limited loci in the susceptibility to alloimmunization, and may help to identify SCD transfusion recipients who are likely to become alloimmunization responders.

**1930W****GWAS meta-analysis in Chinese and European populations identified a novel locus associated with systemic lupus erythematosus on Xp11.**

H. Zhang<sup>1</sup>, J. Yang<sup>1</sup>, Y.-F. Wang<sup>1</sup>, T.-Y. Wang<sup>1</sup>, W. Yang<sup>1</sup>, Y. Zhang<sup>2,1</sup>. 1) The University of Hong Kong, Hong Kong; 2) Guangzhou Institute of Pediatrics, Guangzhou Women and Children's Medical Center, Guangzhou Medical University.

Systemic lupus erythematosus (SLE) is a complex autoimmune disease with extremely higher prevalence in females, especially for those in childbearing age. Taking advantage of high throughput genotyping technology, more than 80 loci have been identified as with SLE susceptibility, but only five of them are located on the X chromosome. Previously, we have identified three of the five X-linked SLE susceptibility genes in Chinese Han populations. In this study, making use of existing X chromosome genotype datasets on three trans-ethnic populations in Chinese and European, following by replication in three Asian cohorts, totally including 7,995 cases and 14,598 controls, we have successfully identified a novel risk-associated variant in Xp11 surpassing genome wide significance. We also further explored the established susceptibility loci in *L1CAM- MECP2* region, and showed evidence of a potential independent signal in Asians.

**1931T****Targeted sequencing in 1000 SLE patients discovers regulatory alleles that downregulate DAP expression and promote autoimmunity.**

Systemic Lupus Erythematosus (SLE) is an autoimmune disease with strong genetic predisposition. Analysis of common variants in GWASs have identified over 60 loci that account for significant amount of genetic heritability. However, large proportion of genetic heritability is still missing. Here we propose that at least part of the missing heritability of SLE can be explained by the genetic component of intermediate phenotypes that are not detectable through common variants at the level of the main complex trait. The idea is that certain loci might contribute intermediate phenotype to disease through low frequency functional alleles which are not captured on classical SNP arrays. Locus containing Death associated protein (DAP) gene was implicated in susceptibility to autoimmune diseases in past but was not investigated further. We hypothesize that DAP contribute intermediate phenotype to SLE through low frequency alleles and if so, targeted sequencing of the locus could reveal those causal variants. We performed deep targeted sequencing across entire DAP locus in 1000 SLE patients and identified a regulatory haplotype that pose strong [OR=1.4, p=4.82E-03] risk for SLE. RNA sequencing in healthy individuals carrying risk haplotype demonstrated significant downregulation of DAP expression before and after TLR stimulation. Multiple *cis* eQTLs were found embedded in the risk haplotype with most notable effect observed with C allele of rs2930047 SNP showing significant (p<0.01) reduction in DAP expression in multiple cell lineages. Furthermore, we show that SLE risk haplotype demonstrate high titers of antinuclear antibodies (ANA), especially, anti-sm IgGs. Transcriptome analysis in our eQTL panel and 1000 genome study sample showed upregulated expression of TNF in carriers of DAP risk genotype. Taken together, present study discovers a novel SLE risk haplotype that downregulate the expression of DAP gene, a well known negative regulator of autophagy. We propose that reduced DAP expression could potentially impair autophagy and apoptotic processes leading to dysregulated cellular homeostasis and development of autoimmunity.

**1932F**

**Cross-genetic heritability of maternal and neonatal immune mediators during pregnancy.** *M. Traglia<sup>1</sup>, L.A. Croen<sup>2</sup>, K.L. Jones<sup>3,4</sup>, L.S. Heuer<sup>2,4</sup>, C.K. Yoshida<sup>4</sup>, R. Yolken<sup>5</sup>, M. Kharrazj<sup>6</sup>, G.N. DeLorenze<sup>2</sup>, P. Ashwood<sup>4,7</sup>, J. Van de Water<sup>2,4</sup>, L.A. Weiss<sup>1</sup>.* 1) Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA; 2) Division of Research, Kaiser Permanente Northern California, Oakland, CA; 3) Department of Internal Medicine, Division of Rheumatology, Allergy, and Clinical Immunology, University of California, Davis, CA; 4) MIND Institute, University of California, Davis, CA; 5) Stanley Division of Developmental Neurovirology, Department of Pediatrics, Johns Hopkins University School of Medicine, Baltimore, MD; 6) Division of Environmental and Occupational Disease Control, California Department of Public Health, 850 Marina Bay Pkwy, Bldg. P, Richmond, CA; 7) Department of Medical Microbiology and Immunology, University of California, Davis, CA.

Increasing evidence shows that during pregnancy, fetal genetics contributes to different aspects of maternal physiology, such as blood pressure, gestational diabetes, metabolism, and preeclampsia. We previously showed that maternal circulating toxicant levels in pregnancy are regulated in part by fetal genetic variation (Traglia et al., 2017). Here, we aim to clarify whether maternal and fetal genetics independently contribute to neonatal and maternal immune function. We measured circulating levels of 22 mid-gestational maternal and 42 neonatal soluble immune mediators (SIMs) in EMA (Early Markers of Autism), a multi-ethnic population-based nested case-control study of autism including 790 genotyped women and 764 of their genotyped newborns (Croen, *Autism Res* 2008; Tsang, *PLoS ONE* 2013). We identified 5 neonatal SIMs with significant maternal heritability and 2 maternal SIMs with significant SNP-based fetal heritability. Because mother-offspring pairs share alleles via inheritance, we need to distinguish whether both maternal and fetal genomes contribute independently or only one individual's genome exerts influence (and the other is estimated to contribute to heritability due to sharing). To differentiate between the contributions of the maternal and fetal-genome, we identified the fetal alleles not inherited from the maternal lineage (fetal-specific alleles) and the maternal alleles not transmitted to the offspring (maternal-specific alleles). Using these derived datasets, we observed that most of the SIMs with significant cross-generational heritability estimates are independently influenced by the non-measured individual. For the same SIMs, we found low (albeit significant) correlation between the maternal-specific and fetal-specific SNP-based BLUP (best linear unbiased prediction) values ( $p < 12\%$ ), suggesting that largely non-overlapping sets of maternal SNPs and fetal SNPs contribute to the heritability of the same SIM, consistent with our previous GWAS-identified loci (Traglia et al, *ASHG* 2016). Our results suggest that during pregnancy and immediately after birth, maternal and fetal genetics strongly mediate the variability of immune system status via distinct mechanisms, and that better understanding of the cross-generational regulation of maternal and neonatal phenotypes may shed light on healthy pregnancy and development of the immune system.

**Association analysis of rheumatoid arthritis through whole-exome sequencing in a Singapore Chinese cohort.** *V. Kumar<sup>1</sup>, E.T. Koh<sup>2</sup>, P. Cheung<sup>3</sup>, M. Lahari<sup>3</sup>, C.T. Ng<sup>4</sup>, M.Y. Yong<sup>5</sup>, C.M. Woo<sup>2</sup>, K.P. Leong<sup>2</sup>, S. Davila<sup>1,5</sup>.* 1) Cancer and Stem Cell Biology, DUKE-NUS Medical School, SINGAPORE, Singapore; 2) Department of Rheumatology, Tan Tock Seng Hospital, Singapore; 3) Department of Rheumatology, National University Health System, Singapore; 4) Department of Rheumatology, Singapore General Hospital, Singapore; 5) SingHealth Duke-NUS Institute of Precision Medicine, Singapore.

Rheumatoid arthritis (RA) is a chronic inflammatory joint disease characterized by progressive bone and cartilage destruction. The contribution of genetic and environmental factors to RA pathogenesis is evident but their complex interaction remains elusive. About 100 genes have been found to be associated with RA. We aim to verify the known genes and to discover new associations in a Singaporean Chinese population. For this, we have done whole-exome sequencing in 600 Singapore Chinese patients with RA and 900 controls. Logistic regression and gene-based association analysis is currently underway. Besides investigating the genes that increase the risk of developing RA, we determine those that predict bad outcomes or poor response to medications.

**Assessing the mechanisms of thymic involution in an animal model of multiple sclerosis.** S.G. Gregory<sup>1,2</sup>, S.N. Giamberardino<sup>1</sup>, S.K. Siecinski<sup>1</sup>, E.A. Hocke<sup>1</sup>, K. Abramson<sup>1</sup>, S.F. Arvai<sup>1</sup>. 1) Duke Molecular Physiology Institute, Duke University Medical Center, Durham, NC, USA; 2) Discovery MS, David H Murdock Research Institute, Kannapolis, NC, USA.

**Purpose:** The thymus is a primary lymphoid organ that plays a pivotal role in thymocyte differentiation and maturation into functional T-cells. The selection of the self-tolerant T-cell antigen receptor repertoire is important for establishing immune homeostasis and preventing autoimmunity. Interestingly, the thymus is a dynamic organ whose activities are influenced by pathophysiological challenge. These events can cause thymic involution that may affect its ability to appropriately mature T cells into self-tolerant mediators of immune system response. The purpose of this project was to assess the impact of an animal model of multiple sclerosis (MS), experimental autoimmune encephalomyelitis (EAE), on thymus cellularity and gene expression. **Methods:** EAE was induced in C57BL/6J wild type mice via injection of MOG<sub>35-55</sub> and Complete Freund's Adjuvant emulsion and severity scored according to ascending paralysis clinical scores (CS) '0' asymptomatic to '5' moribund. All analyses were performed in thymi from naïve and peak EAE (CS 3.0-3.5) mice. Immune histochemical staining was performed using hematoxylin and eosin, anti-B220 antibody, or anti-cytokeratin antibody; flow sorting involved thymic disaggregation and CD45- depletion with CD45+ cells stained antibodies against CD3ε, CD19, CD4 and CD8b. CD4+, CD8+, or CD4CD8 double positive T cells were visualized from the CD3ε+ T cell gate. The same disaggregation approach was used on the thymi to generate Single Cell 3' libraries on the 10X Genomics Chromium Controller, prior to analysis using standard parameters in Seurat single cell analysis software. **Results:** We have established that the thymus severely atrophies during EAE due to significant loss of cellularity and disruption of its structure, with loss of CD4CD8 double positive T cells and, unexpectedly, increasing CD19+ B-cell numbers. In the naïve state, our single cell gene expression data include discrete epithelial, thymocyte, CD4+, and maturing CD8+ cells populations, while in the involuted thymus identified replicating thymic epithelial, thymic stromal cells, as well as T-cells and the B-cells observed in our IHC staining. **Conclusions:** We have generated the first single cell gene expression profile of an EAE induced involuted thymus in a mouse model of MS. The profile provides a glimpse into normal thymus function and during physiological stress, and identifies novel pathways that might be important in immune cell dysfunction in the development of MS.

**1935F**

**Sex-specific transcriptional responses to lipopolysaccharide (LPS) in peripheral blood leukocytes (PBLs) in the Hutterite founder population.** M. Stein, K. Naughton, C. Billstrand, R. Nicolae, C. Ober. Department of Human Genetics, University of Chicago, Chicago, IL.

Many immune-mediated diseases show sex differences in prevalence, but the underlying genetic contributors to this phenomenon are still largely unknown. To address this question and characterize sex-specific differences in innate immune response, we studied the transcriptional response of PBLs to LPS in 47 male and 66 female members of the Hutterite community. Whole blood was incubated in a closed system (TruCulture®, Myriad RBM) for 30 hours with either media alone or media + 0.1µg/ml LPS, a component of the gram-negative bacterial cell wall. Genome-wide gene expression levels were measured by RNAseq. Genes were mapped to hg19 using STAR and normalized using voom, resulting in 10,425 autosomal genes detected as expressed. Using a linear model with age included as a covariate, and individuals as a random effect, we tested for differential gene expression between LPS-treated and untreated samples in males, females, and for differences between sexes. 6,933 (66.5%) genes were differentially expressed (DE) in response to LPS treatment in both males and females (FDR 5%). 1,479 DE genes significantly differed in magnitude and/or direction between males and females (FDR 5%). Notably, 89.4% (1,323) of these genes had a greater magnitude of response in males, including *IRF1* ( $P_{\text{ResponseDiff}}=2.73 \times 10^{-7}$ ), a gene located 2.8kb downstream of rs2549003, which was previously associated with sex-specific asthma risk in European American males. In this gene set, pathway analysis of genes with a greater response in males identified enrichments for downstream activators IFN $\gamma$ , IRF7, and STAT1. Additionally, 340 DE genes in males only included *MYD88*, a critical mediator in innate immune signaling ( $P_{\text{males}}=2.56 \times 10^{-6}$ ,  $P_{\text{females}}=0.33$ ). In contrast, 194 DE genes in females only included an enrichment for genes downstream of IL-5, a type 2 T cell cytokine. These data suggest that there is a more robust response to LPS at 30 hours in males compared to females, particularly in IFN-mediated pathways. These results are consistent with previous reports of *IFNG* genotype-sex interactions in asthma risk, and highlight the potential link between sex-specific differences in immune response and risk for asthma and potentially other immune-mediated diseases with sex differences in prevalence. This work was funded by R01 HL085197.

**Role of rare variants in progression from latent to active tuberculosis in Peruvian population.** S. Asgari<sup>1</sup>, Y. Luo<sup>1</sup>, R. Calderon<sup>2</sup>, L. Lecca<sup>2</sup>, S. Leon<sup>2,3</sup>, J. Jimenez<sup>2</sup>, M. Murray<sup>2</sup>, S. Raychaudhuri<sup>1</sup>. 1) Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts, USA; 2) Socios En Salud, Lima, Peru; 3) Department of Global Health and Social Medicine, Harvard Medical School, Boston, Massachusetts, USA.

**Background:** Common variants (> 0.01 minor allele frequency (MAF)) have been associated with susceptibility to pulmonary tuberculosis (TB). Yet common variants explain only a portion of the total trait variance. The impact of rare coding variation on susceptibility to pulmonary TB has not been as thoroughly investigated. Using a custom-designed genotyping chip, here we utilize 1668 cases and 1326 matching controls to look for rare, functional variants that affect susceptibility to pulmonary TB in Peruvian population. **Methods:** To discover rare variants we applied exome sequencing to 116 Peruvian TB cases. We conjectured that rare risk variants in Peruvian populations would be enriched among these cases. We then used the rare variant content from these samples, to design a genotyping array that included 712K markers including 320 markers derived from exome sequencing of 116 Peruvian TB cases. We used this custom array to then genotype 1668 Peruvians who developed active TB and 1326 matching controls from the same household who were positive for tuberculin skin test but did not develop active TB. We used Plink 1.9 for quality control. 8 cases and 4 controls were removed due to missingness > 0.05 or Hardy-Weinberg equilibrium p-value < 1e-5. Of the remaining individuals, 369 cases and 455 controls had identity by descent (IBD) > 0.2. Weighted sum method (Madsen and Browning, 2009) was used to collapse variants with MAF < 0.01 within each gene. Genetic relatedness matrix was calculated using GEMMA v0.94.1. We tested gene burden association, using GMMAT v0.7-1, by fitting a linear mixed model to the data with first 10 principal components and age as covariates. **Results:** Analyses aimed at detecting the burden of rare variants within a gene showed no significant associations. Restricting this analysis to only variants that modify protein sequence did not reveal further signals. Possibly larger sample sizes are required to fully explore the role of rare coding variants in susceptibility to pulmonary TB.

**1937T**

**Deciphering genetic susceptibility to tuberculous meningitis: Exome sequencing and a GWAS in a South African population.** M. Möller, N. Bowker, M. Salie, H. Schurz, P.D. van Helden, E.G. Hoal, C.J. Kinnear. 1SA MRC Centre for TB Research, DST/NRF Centre of Excellence for Biomedical TB Research, Division of Molecular Biology and Human Genetics, Faculty of Medicine and Health Sciences, Stellenbosch University.

Tuberculous meningitis (TBM) is a type of extrapulmonary tuberculosis (TB) which leads to inflammation of the meninges through small lesions called Rich foci. TBM represents 1% of total TB disease, with the age of onset being around 2-5 years of age. Disease development remains poorly understood, including the mechanism of dissemination across the blood-brain barrier. This study concentrated on the involvement of the host genome in TBM susceptibility. We hypothesised that multiple common variants of moderate effect size are more likely to influence TBM susceptibility than rare variants of large effect. Ten TBM cases and 10 healthy controls were exome sequenced. A total of 123 TBM cases, 400 pulmonary TB (pTB) cases and 477 healthy controls were genotyped on the Illumina® Multi-Ethnic Genotyping Array (MEGA). Gene set association tests SKAT-O and SKAT Common Rare were used to assess the association of rare SNPs and the cumulative effect of both common and rare SNPs with susceptibility to TBM, respectively. The SKAT-O analysis included 8 322 gene sets comprising 16 728 SNPs, which did not yield any associations with TBM susceptibility. Ingenuity Pathway Analysis (IPA) of the top-hits of the SKAT-O analysis showed that two genes are both important in TBM pathogenesis and highlighted these as targets for future study. The SKAT Common Rare analysis included 13 270 gene sets comprised of 53 239 SNPs and one gene was associated with TBM susceptibility. In addition, a number of top-hit genes ascribed to the development of the central nervous system (CNS) and innate immune system regulation were highlighted. The role of common variants (>5%) in TBM susceptibility were assessed by conducting a genome-wide association study (GWAS). A GWAS comparing 114 TBM cases to 395 healthy controls showed no association with TBM susceptibility. A second analysis comparing 114 TBM cases to 382 pTB cases was conducted to investigate variants associated with different TB phenotypes. No significant associations were found with progression from pTB to TBM. This study reports the first exome sequencing and GWAS of a TBM cohort and has identified a single previously undescribed association with TBM susceptibility. These results further our understanding of TBM in terms of both SNPs and genes that influence susceptibility. In addition, a number of candidate genes involved in innate immunity have been identified using IPA for further genotypic and functional investigation.

## 1938F

**Genome wide association in Peru demonstrates that progression to active tuberculosis is a polygenic and highly heritable trait.** S. Raychaudhuri<sup>1,2</sup>, R. Calderon<sup>3</sup>, L. Lecca<sup>3</sup>, S. Leon<sup>3</sup>, J. Jimenez<sup>3</sup>, B.D. Moody<sup>6</sup>, M. Murray<sup>3,4,5,6,7</sup>, Y. Luo<sup>1,2</sup>. 1) Division of Genetics and Rheumatology, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, MA, USA; 3) Socios En Salud, Lima, Peru; 4) Partners In Health, Boston, MA, USA; 5) Division of Global Health Equity, Brigham and Women's Hospital, Boston, MA, USA; 6) Department of Global Health and Social Medicine, Harvard Medical School, Boston, MA, USA; 7) Department of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 8) Division of Rheumatology, Immunology and Allergy, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA.

Since only ~10% of the 1.5 billion *Mycobacterium tuberculosis* (*Mtb*) infected individuals worldwide go on to develop active tuberculosis (TB), host genetic factors that control disease progression have emerged as a central question in TB pathogenesis. To dissect the genetic basis of TB progression, we conducted a genome wide association study (GWAS), comparing 1,676 primary pulmonary TB patients versus 1,330 individuals who did not develop TB despite *Mtb* exposure through a household contact. Contrasts with previous studies, here we explicitly control for *Mtb* exposure and infection status, thereby allowing us to investigate whether progression to active TB is indeed highly heritable. We first designed a customized array based on whole-exome sequencing data from 116 active TB cases to optimize the capture of genetic variations in Peruvians. This allowed detection of rare and low-frequency population-specific coding variants and those which predisposed to TB risk. We then genotyped 3,006 individuals at 712K genomic markers and imputed ~8 million variants using the 1000 Genomes Project Phase 3 reference panel. We used linear mixed models to test for single marker associations, which account for population stratification and relatedness in collected individuals. Our study identified a potentially new TB progression locus on chromosome 3q23, where 8 variants located in the downstream of the RASA2 gene had  $P$ -value  $< 10^{-7}$ . We also saw association in a previously reported TB locus at HLA-DQA1 ( $P=1.6 \times 10^{-7}$ , OR=1.27), but did not detect signals at other reported risk loci. This outcome suggests that previously reported loci may not be specific to TB progression, whereas HLA-association may affect both TB progression and *Mtb* infection. Next, we estimated genetic heritability of TB progression on the liability scale ( $h^2$ ) using LD score regression (Bulik-Sullivan et al 2015). In total, we report 14.5% (s.e. 0.02) variation can be explained for TB progression. One possible reason for the limited success of prior GWASes might be due to low heritability of traits pursued. Our study is the first to quantify  $h^2$  of TB progression, and indicates a strong genetic basis. This degree of heritability is comparable to other traits in which GWAS have been highly successful as sample size mounted. For example, estimated  $h^2$  for Crohn's disease in the WTCCC data is 22.0% (0.02). We are now undergoing a second phase of data collection, where this new risk locus will be further validated.

## 1939W

**Genetic variation in *GLS2* is associated with development of complicated *Staphylococcus aureus* bacteremia.** W.K. Scott<sup>1</sup>, F. Ruffin<sup>2</sup>, B.S. Kuinkel<sup>3</sup>, D.D. Cyr<sup>3</sup>, S. Guo<sup>1</sup>, D.M. Dykxhoorn<sup>1</sup>, R.L. Skov<sup>4</sup>, N.E. Bruun<sup>5</sup>, A. Dahl<sup>6</sup>, C.J. Lerche<sup>6</sup>, V.G. Fowler Jr.<sup>2</sup>, P.S. Andersen<sup>4</sup>, DANSAB Study Group. 1) Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Medicine, Duke University Medical Center, Durham, NC; 3) Duke Clinical Research Institute, Duke University Medical Center, Durham, NC; 4) Statens Serum Institut, Copenhagen, Denmark; 5) Gentofte University Hospital, Copenhagen, Denmark; 6) Rigshospitalet, Copenhagen, Denmark.

*Staphylococcus aureus* bacteremia (SAB) is a serious, common infection. Recent genome wide association studies (GWAS) have associated *S. aureus* infections with common variation in the HLA class II region. Rare variants are not well covered by GWAS and may be significant contributors to SAB risk or severity. We used whole exome sequencing (WES) to examine the cumulative effect of coding variants in each gene on risk of complicated SAB in a discovery set of patients, and then evaluated the nominally significant genes in a replication set of patients using custom-capture sequencing. The discovery set comprised 84 complicated SAB cases (endocarditis or bone/joint infection) frequency-matched by age (in deciles), sex, and bacterial clonal complex (CC5 or CC30 vs. CC8) to 84 uncomplicated SAB controls. All were white inpatients at Duke University. WES utilized Agilent SureSelect 72Mb capture kits, followed by sequencing on an Illumina HiSeq2000, alignment and base calling with a standard pipeline. The SKAT-O and EFACTS packages were used for gene-based association tests and logistic regression models with Firth bias correction, respectively. Both controlled for age, sex, and clonal complex as covariates. The replication set of 122 complicated SAB cases and 118 uncomplicated SAB controls was frequency matched by age, sex, and clonal complex. All were white Europeans collected by the Statens Serum Institut. An Agilent SureSelect 2Mb capture array captured genic sequence for 342 genes nominally associated with complicated SAB in discovery (SKAT-O  $p < 0.035$ ). Sequencing and data analysis proceeded as for WES. A Bonferroni-corrected gene-based test  $p$ -value of  $1.5 \times 10^{-4}$  determined significance in the replication set. One gene, *GLS2*, was significantly associated with complicated SAB in the replication set ( $p=1.2 \times 10^{-4}$ ). The strongest single-variant association in all 342 genes was rs2657878 in *GLS2* ( $p=5 \times 10^{-4}$ ). This variant is strongly correlated with a missense variant (rs2657879,  $p=4.4 \times 10^{-3}$ ) in which the minor allele (associated here with complicated SAB) has previously been shown to reduce circulating glutamine levels. Comprehensive examination of the coding sequence for association with complicated SAB in a two-stage discovery/replication design identified a novel candidate gene. *GLS2* is an interesting candidate for complicated SAB due to its role in regulating glutamine production, a key factor in activation of T-cell production.

Cramp<sup>13</sup>, S.M. Donfield<sup>14</sup>, B.R. Edlin<sup>15</sup>, G. Alexander<sup>6</sup>, D.L. Thomas<sup>1</sup>, P. Duggal<sup>1</sup>. 1) Department of Medicine, Johns Hopkins University, Baltimore, MD, USA; 2) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA; 3) University of California, San Francisco, CA, USA; 4) Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA; 5) RTI International, Research Triangle Park, NC, Atlanta, GA, San Francisco, CA, USA; 6) Blood Systems Research Institute, San Francisco, CA, USA; 7) Department of Epidemiology and Biostatistics, University at Albany, State University of New York, Rensselaer, NY, USA; 8) Department of Genetics, Stanford University School of Medicine, Stanford, CA, USA; 9) Division of Cancer Epidemiology and Genetics, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA; 10) Liver Unit, IRCCS "Casa Sollievo della Sofferenza", San Giovanni Rotondo, Italy; 11) University of Southampton, Southampton General Hospital, Southampton, UK; 12) Toulouse III University, Toulouse, France; 13) South West Liver Unit, Plymouth, PL6 8DH, UK; 14) Rho, Inc., Chapel Hill, NC, USA; 15) SUNY Downstate College of Medicine, Brooklyn, NY, USA; 16) Department of Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK.

The outcome of acute hepatitis C virus (HCV) infection is linked to variants in the MHC region and 2 variants in high LD in *IFNL4*. However, these two *IFNL4* variants do not fully explain the HCV outcomes and there is controversy about whether the *IFNL4* variants are associated with HCV outcome across ancestry groups. To address these issues, we performed a dense GWAS of spontaneous clearance of HCV compared to individuals who have persistent infection, in 4091 people in 3 different ancestry groups (1869 African Americans (AA, 340 clearance/1529 persistence), 1739 European Americans (EA, 701 clearance/1036 persistence) and 486 Hispanics (173 clearance/313 persistence). Samples were genotyped using the Illumina Human Omni-Quad and imputed to 1000genomes Phase 3 using Minimac3. Mach2dat was used to test the association of imputed SNP dosage with HCV clearance under a log-additive model. HIV infection status and 20 PCs were included as covariates, separately for each ancestry group and meta-analyzed. Significant associations were confirmed at the 2 known loci (*IFNL4*, 19q13.2 and *MHC*, 6p21.32) for all 3 groups. On chromosome 6, the top SNPs were located near genes for class II MHC and included rs2647006 (A/C) (Meta-Pvalue: 5.15x10<sup>-20</sup>). The most significant association on chromosome 19 was rs74597329 (Imputed; G/T; OR: 0.47, PValue: 9.8x 10<sup>-16</sup> for AA, OR: 0.44, PValue: 1.3x10<sup>-22</sup> for EA, OR: 0.30, PValue: 2.84x10<sup>-12</sup> for Hispanics, Meta-Pvalue: 8.17x10<sup>-46</sup>). The SNP codes for change of Ala→Glu in position 22 of the protein but in conjunction with the -T polymorphism (rs11322783) conforms the ΔG/TT polymorphism (rs368234815). The LD between previously identified *IFNL4* variants, rs12979860 and rs74597329 is high ( $r^2 > 0.87$  for all 3 populations), and conditioning on either SNP removed significance of the other SNP. Interestingly, rs4803221 another top SNP not in high LD with the previous ones, had attenuated significance but was still present (PValue: 6.2x10<sup>-6</sup>, 1.6x10<sup>-5</sup>) in EA after conditioning on either of the first 2 SNPs. The associations on chromosomes 19 and 6 were independently associated with HCV clearance and additive. The *IFNL4* finding was confirmed in EA and observed for the first time with GWAS significance for AA and Hispanics. This study finds that in EA, rs4803221 is independently associated with HCV clearance at *IFNL4*; however in AA, both rs74597329 and rs12979860 best explain the association of HCV clearance at this locus.

**Introduction** Albuterol, a bronchodilator medication, has been the standard of care for asthma treatment worldwide for the past three decades. Despite significant variation in bronchodilator response (BDR), albuterol is often the only medication prescribed for asthma, regardless of disease severity and the striking racial/ethnic disparity in BDR. Specifically, Puerto Rican and African American children with asthma have significantly lower BDR compared to Mexican American children. Previous studies have identified a genetic contribution to variation in BDR, yet much of the heritability of BDR remains to be explained. We hypothesize that rare, population-specific variants contribute to BDR in minority children with asthma. **Methods** We performed whole genome sequencing on 1,441 minority children with asthma from the tails of the BDR distribution. Our study included high and low drug responders from three racial/ethnic groups, African Americans (n=475), Puerto Ricans (n=483), and Mexican Americans (n=483). We performed logistic regression to identify associations with individual variants and BDR in each racial/ethnic group separately, and combined in a meta-analysis. We also performed association tests at pooled variants using SKAT-O in order to test for associations with both common and rare variants. All association models were adjusted for age, sex, BMI, and the top ten principal components. **Results and Conclusions** We identified population-specific and shared pharmacogenetic variants associated with BDR, including genome-wide significant and suggestive loci near genes previously associated with lung capacity (*DNAH5*), immunity (*NFKB1* and *PLCB1*), and β-adrenergic signaling pathways (*ADAMTS3* and *COX18*). Our study expands the understanding of pharmacogenetic analyses in racially and ethnically diverse populations and advances the foundation for precision medicine in at-risk and understudied minority populations.

## 1942W

**ITPKC and SLC11A1 gene variations are associated with Kawasaki disease patients.** Y. Bae<sup>1</sup>, K. Kim<sup>2</sup>, W. Ji<sup>3</sup>, D. Shin<sup>1</sup>, H. Kim<sup>2</sup>, D. Kim<sup>2</sup>, K. Kim. 1) Genome Research Center, Medizen Humancare, Seoul, South Korea; 2) Department of Pediatrics, Yonsei University College of Medicine, Severance Children's Hospital; 3) School of Medicine, Kyung Hee University, Seoul, Korea.

Kawasaki disease (KD) is an acute systemic vasculitis. Both the etiology of KD and erythema of Bacille Calmette-Guérin (BCG) injection site observed in the disease are poorly understood. The present study investigated the association between KD and single nucleotide polymorphisms (SNPs) in two candidate genes: inositol 1, 4, 5-triphosphate 3-kinase (*ITPKC*), one of the well-studied KD-associated genes, and solute carrier 11a1 (*SLC11A1*), which is associated with the hypersensitive reaction to the BCG strain in Koreans. Potential associations between BCG injection site erythema and SNPs in the *ITPKC* and *SLC11A1* genes were also evaluated. Gene-gene interactions between *ITPKC* and *SLC11A1* in KD and BCG injection site erythema were also analyzed. Three tagging SNPs in *ITPKC* and five tagging SNPs in *SLC11A1* were genotyped in 299 KD patients and 210 control children. SNP rs28493229 in *ITPKC* was associated with KD and coronary artery complications. SNP rs77624405 in *SLC11A1* was associated with KD. Comparisons of KD patients with and without BCG injection site erythema revealed that SNP rs17235409 in *SLC11A1* was associated with erythema, but no erythema-associated SNPs in *ITPKC* were identified. Interactions between *ITPKC* rs28493229\_GG and *SLC11A1* rs17235409\_GA and between *ITPKC* rs10420685\_GG and *SLC11A1* rs17235409\_AA were strongly associated with BCG injection site erythema. In conclusion, this study identified several important variations in the *ITPKC* and *SLC11A1* genes in Koreans.

## 1943T

**Location, location, location: Single cell gene expression of mucosal T cells vs peripheral blood T cells in Crohn's disease.** E.A.M. Festen<sup>1,2</sup>, W.T.C. Uniken Venema<sup>1</sup>, M.D. Voskuil<sup>1</sup>, R. Alberts<sup>1</sup>, A. Vich Vila<sup>1</sup>, R.K. Weersma<sup>1</sup>. 1) University of Groningen and University Medical Center Groningen, Department of Gastroenterology and Hepatology, Groningen, The Netherlands; 2) University of Groningen and University Medical Center Groningen, Department of Genetics, Groningen, The Netherlands.

**Introduction** Crohn's disease (CD) is a chronic inflammatory disease, that predominantly causes inflammation in the terminal ileum<sup>1</sup>. Genetic research has identified almost 200 genetic loci associated with CD, many of which are in genes involved in T cell pathways<sup>2,3</sup>. Furthermore, recent research has shown the importance of mucosa-specific T-cells<sup>4</sup>. Although studies have tried to characterize average expression of mucosal T cells using microarray expression data<sup>5</sup>, subtype-specific differences have not been researched. **Aims & Methods** Our aim is to assess which T cell subpopulations are present in the intestinal mucosa of CD patients, and how their transcriptome differs from peripheral blood T cells. We performed single cell RNA sequencing (scRNAseq) of 5292 CD3+ T cells isolated from peripheral blood and from ileal mucosal biopsies of CD patients (paired). Isolation of mucosal T cells was performed with a protocol from Raine et al.<sup>6</sup>. scRNAseq was performed with a locally developed, plate based method, with 3' library generation and unique molecular identifiers, sequenced with Illumina HiSeq2500. **Results** Findings from previously published microarray expression data were replicated<sup>5</sup>, identifying relative overexpression of *CXCR4*, *CD55*, *DUSP2*, *CD160*, *FASLG*, *ITGAE* and *TNFAIP3* in mucosal vs blood T cells. The relative overexpression of *TNFAIP3*, which promotes survival of CD4+ T-cells, is especially interesting, since variants near this gene are associated with CD and with response to anti-TNFa therapy<sup>6,7</sup>. Strikingly, a subgroup of mucosal CD8+ T-cells shows relative overexpression of three genes that are associated with CD: *TNFAIP3*, *FOS*, which promotes T-cell proliferation<sup>8</sup>, and *PTGER4*, which encodes the prostaglandin receptor EP4 that promotes the immune response through Th1 and Th17 activation<sup>6</sup>. **Conclusion** We show that CD associated genes are significantly overexpressed in ileal mucosal T cells, mainly in CD8+ cells. The characterization of expression patterns in individual cells is promising for development of cell-specific therapies in CD patients. **References** 1. Baumgart et al. (*Lancet*, 2012). 2. ## 1944F

**Comprehensive bioinformatic characterization around RASGRP1 gene identifies multiple potential functional variants for lupus susceptibility.**

J.E. Molinos<sup>1</sup>, C. Sun<sup>1</sup>, B. Singh<sup>1</sup>, K.M. Kaufmann<sup>2,3</sup>, J.B. Harley<sup>2,3</sup>, S.K. Nath<sup>1</sup>.

1) Oklahoma Medical Research Foundation, Division of Arthritis and Clinical Immunology, Oklahoma City, OK; 2) Cincinnati Children's Hospital Medical Center, Cincinnati, OH, 45229; 3) US Department of Veterans Affairs Medical Center, Cincinnati, OH, 45229.

Systemic Lupus Erythematosus (SLE) is a complex autoimmune disease with substantial genetic component. SLE disproportionately affects women and ethnic minorities. We recently identified a novel SLE susceptibility signal near Ras Guanyl releasing Protein1 (*RASGRP1*) in Asians [Sun et al, 2016, Nat Genet]. *RASGRP1* is a key signaling molecule, preferentially expressed in T-cells, and its deficiency in mice results in SLE due to improper splicing of the *RASGRP1* precursor transcript. However, the "true" functional variants and the genetic mechanisms by which the associated variants manifest SLE pathogenesis is largely unknown. The objective is to identify SLE functional variant(s) across multiple ethnically diverse populations that might influence *RASGRP1* expression. We conducted a comprehensive imputation-based (3347 SNPs) trans-ethnic meta-analysis from 6 cohorts (>9000 cases; 19000 controls) with Asian, European and African ancestries followed by additional genotyping, and selected 163 SNPs ( $P < 5 \times 10^{-3}$ ) for further evaluation. We then assessed co-localization of peak SNPs with active histone marks (H3K27ac, H3K4me1, H3K3me3) and DNase-I hypersensitivity sites across multiple tissues from ENCODE to further narrow the number of predicted functional SNPs associated with cis-regulatory modules. We further prioritized 91 SNPs ( $P < 5 \times 10^{-4}$ ) using a reported Bayesian refinement method that combines functional information at each SNP and accounting for ethnic-specific linkage disequilibrium (LD). To assess possible regulatory roles of the candidate SNPs, we correlated targeted SNP genotypes with multiple tissue-specific eQTLs from Blood eQTL, GTEx, GEUVADIS. Several SNPs are identified as eQTLs for *RASGRP1*, and the strongest eQTL was rs7173565 ( $P < 10^{-16}$ ). Finally, we assessed enhancer-promoter interactions via capture Hi-C data from multiple cell types. In summary, using comprehensive bioinformatics, we identified 3 distinct signals ( $P < 5 \times 10^{-8}$ ) from 3 LD-blocks containing several functional SNPs. While the first signal is intronic, the other 2 signals are intergenic. The rs7173565 was the most promising SNP identified as an eQTL and located in a super-enhancer region in CD4 and CD8 cells. Two signals were linked to enhancer-promoter interactions, as assessed by capture Hi-C. These results suggest that the susceptibility variants modulate *RASGRP1* expression through promoter-enhancer interaction, and its dysregulation and aberrant expression could increase the risk for SLE.

## 1945W

**Male-specific association of the FCGR2A His167Arg polymorphism with Kawasaki disease.**

Kawasaki disease (KD) is an acute systemic vasculitis that can potentially cause coronary artery aneurysms in some children. KD occurs approximately 1.5 times more frequently in males than in females. To identify sex-specific genetic variants that are involved in KD pathogenesis in children, we performed a sex-stratified genome-wide association study (GWAS), using the Illumina HumanOmni1-Quad BeadChip data (249 cases and 1,000 controls) and a replication study for the 34 sex-specific candidate SNPs in an independent sample set (671 cases and 3,553 controls). Male-specific associations were detected in three common variants: rs1801274 in *FCGR2A* [odds ratio (OR) = 1.40,  $P = 9.31 \times 10^{-6}$ ], rs12516652 in *SEMA6A* (OR = 1.87,  $P = 3.12 \times 10^{-4}$ ), and rs5771303 near *IL17REL* (OR = 1.57,  $P = 2.53 \times 10^{-5}$ ). The male-specific association of *FCGR2A*, but not *SEMA6A* and *IL17REL*, was also replicated in a Japanese population (OR = 1.74,  $P = 1.04 \times 10^{-2}$  in males vs. OR = 1.22,  $P = 0.191$  in females). In a meta-analysis with 1,461 cases and 5,302 controls, a very strong association of KD with the nonsynonymous SNP rs1801274 (p.His167Arg, previously assigned as p.His131Arg) in *FCGR2A* was confirmed in males (OR = 1.48,  $P = 1.43 \times 10^{-7}$ ), but not in the females (OR = 1.17,  $P = 0.055$ ). The present study demonstrates that p.His167Arg, a KD-associated *FCGR2A* variant, acts as a susceptibility gene in males only. Overall, the gender differences associated with *FCGR2A* in KD provide a new insight into KD susceptibility.

**RATIONALE:** Asthma is a complex disease with striking disparities across racial/ethnic groups, which may be partly attributable to genetic factors. One of the main goals of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to discover genes conferring risk to asthma in populations of African descent. **METHODS:** We performed a genome-wide meta-analysis of asthma association across CAAPA studies, genotyped on the African Diaspora Power Chip (ADPC), and imputed using the WGS reference panel from CAAPA itself. RFMix was used to infer local ancestry of 6,686 African American and African Caribbean subjects. The 1000 Genomes Project CEU and YRI populations were specified as reference populations. A total of 273,738 phased SNPs passing quality control filters and overlapping in all the CAAPA and reference population data sets were used as input for local ancestry inference. SNPs with  $p$ -values  $<1e-5$  were tested for interaction with the number of copies of segments of local African ancestry. The interaction  $p$ -value indicates whether a difference in allele frequency between cases and controls is observed in one class of local ancestry background more than another. **RESULTS:** An African-specific interaction that involved SNP rs11264909 on chromosome 1q23.1 was identified. This SNP is intronic to the KIRREL gene. A difference in allele frequencies was observed only in those subjects carrying 2 copies of African ancestry at this region, with the minor A allele being observed more frequently in cases (0.12) compared to controls (0.10),  $p=2.8e-5$ . SNP rs11264909 is ~0.9MB downstream from 2 SNPs intronic to the PYHIN1 gene previously identified by the NHLBI-supported EVE Consortium's asthma meta-analysis. Although the EVE SNPs were not polymorphic in Europeans, the A allele at SNP rs11264909 has a frequency of 0.20 in CAAPA and a much higher frequency (0.61) in Europeans. This A allele was observed more frequently in CAAPA cases (frequency of 0.22) compared to CAAPA controls (frequency of 0.19), and on average, cases have more European ancestry at this region compared to controls. These observations suggest the association observed with asthma is not due to an excess of African ancestry at this locus, but the association is specific to subjects of African ancestry at this region. **CONCLUSIONS:** SNP rs11264909 may have an African ancestry specific effect on risk to asthma, where the combination of African ancestry and the A allele increases risk.

## 1947F

**A genome-wide association analysis of Hashimoto's thyroiditis.** V. Boraska Perica<sup>1</sup>, L. Brčić<sup>1</sup>, A. Barić<sup>2</sup>, S. Gračan<sup>2</sup>, D. Kaličanin<sup>1</sup>, I. Gunjača<sup>1</sup>, V. Torlak Lovrić<sup>2</sup>, M. Brekalo<sup>2</sup>, M. Radman<sup>2</sup>, V. Škrabić<sup>3</sup>, A. Miljković<sup>4</sup>, I. Kolčić<sup>5</sup>, S. Tokić<sup>5</sup>, M. Štefanić<sup>6</sup>, Lj. Glavaš-Obrovac<sup>6</sup>, O. Polašek<sup>6</sup>, T. Zemunik<sup>6</sup>, M. Barbalčić<sup>6</sup>, A. Punda<sup>6</sup>. 1) Medical Biology, University of Split School of Medicine, Split, Croatia; 2) Department of Nuclear Medicine, University Hospital Split, Split, Croatia; 3) Department of Pediatrics, University Hospital Split, Split, Croatia; 4) Department of Public Health, University of Split School of Medicine, Split, Croatia; 5) Department of Medical Chemistry, Biochemistry and Clinical Chemistry, Faculty of Medicine, University of Osijek, Osijek, Croatia; 6) Department of Nuclear Medicine and Oncology, Faculty of Medicine, University of Osijek, Osijek, Croatia.

**Background:** Hashimoto's thyroiditis (HT) is the most common autoimmune thyroid disease characterized by chronic inflammation and reduced function of the thyroid gland. HT is the major cause of hypothyroidism in iodine-sufficient areas and it is highly prevalent in women. Although strong genetic susceptibility to HT has been proposed, underlying genetic factors are poorly known. Moreover, HT has never been analyzed on the genome-wide level. The aim of our study was to identify genetic variants associated with HT by performing the first genome-wide association analysis of this disease. **Methods:** A total of 869 individuals from Croatia, comprising of 430 HT cases and 439 controls, were included in this study. All HT cases met ETA recommendations and guidelines for Management of Subclinical Hypothyroidism. Control individuals were derived from the population-based "10,001 Dalmatians project" of which 349 individuals already had genome-wide data scanned by Illumina HumanOmni-ExpressExome array whereas additional 90 controls and HT cases were typed using Illumina Infinium HumanCoreExome array. Following quality control, two datasets were merged on an overlapping set of variants and imputed using 1000 Genomes reference panel. Association analysis was performed on 8,633,733 genetic variants under the univariate linear mixed model using GEMMA software. Binary disease status was treated as quantitative trait, and model was adjusted for age, sex, population stratification and relatedness. Reported investigations have been carried out following the principles of the Declaration of Helsinki. **Results:** We identified a missense variant inside *TET1* gene at the genome-wide significance level ( $\beta=0.365$ ,  $se=0.066$ ,  $p=4.21 \times 10^{-9}$ ) and a missense variant inside *UGT8* gene just below genome-wide significance ( $\beta=0.365$ ,  $se=0.072$ ,  $p=5.25 \times 10^{-7}$ ). A replication of these two signals along with 10 other suggestively associated variants ( $p < 10^{-5}$ ) is currently underway in an independent dataset of 303 HT cases and 302 controls. **Discussion:** *TET1* is a methylcytosine dioxygenase that is involved in DNA demethylation and gene activation indicating a role of epigenetic events in HT susceptibility. *UGT8* is an UDP-glycosyltransferase that has a role in the biosynthesis of galactocerebrosides of the nervous systems. **Conclusion:** In this first genome-wide analysis of HT to date, we have identified promising associations of biologically interesting genes pointing to a novel mechanisms underlying HT development.

## 1948W

**HLA-DPB1 and Graves disease in Han Chinese.** Y. Lee<sup>1,2,3,4,5</sup>, C. Huang<sup>1,4,6</sup>, W. Ting<sup>1,4,6</sup>, C. Lin<sup>2</sup>, W. Lin<sup>2</sup>, T. Chang<sup>2</sup>, H. Yang<sup>2</sup>. 1) Department of Pediatric Endocrinology, MacKay Children's Hospital; 2) Department of Medical Research, MacKay Memorial Hospital Tamsui District; 3) Department of Pediatrics, School of Medicine, College of Medicine, Taipei Medical University; 4) Department of Medicine, Mackay Medical College; 5) Institute of Biomedical Sciences, Mackay Medical College; 6) MacKay Junior College of Medicine, Nursing, and Management, Taipei, Taiwan.

Graves disease (GD) is a multifactorial disease that appears to involve a complex interplay of multiple genetic and environmental influences. It affects up to 0.5% of general population. The risk to a female sib of a proband with GD (As) is 10-15. The concordance rate is 20-35% in monozygotic twins but only 3-7% in dizygotic twins. These suggest that genetic factors play a role in the pathogenesis of this disorder. Because T-lymphocyte activating is dependent on recognition of MHC class II molecules. We reported association between DPB1 gene and GD in Han Chinese living in Taiwan. **Patients** The subjects were 256 GD patients (45 boys and 211 girls) aged 10.6 (SD 3.4), 2.7-19.0 years. GD was diagnosed on the basis of clinical manifestations and laboratory evidence. **Controls** The 381 control subjects consisted of 135 males and 246 females. They included hospital personnel and individuals who underwent routine health examinations or minor surgery. None had a history of autoimmune disease. All patients and controls were Han Chinese in Taiwan. Our institutional review board approved this study and all subjects or their guardians gave informed consent. **Genotyping of the DPB1 gene** We used sequencing-based typing to genotype the DPB1 gene. **Statistical analysis** Statistical difference in genotype, allele, and carrier distributions between patients and controls were assessed by the chi-square test. Odds ratios (OR) and 95% confidence intervals were also calculated. The Bonferroni correction,  $P_c = 1 - (1 - P)^n$ , was used for multiple comparisons where  $P_c$  is the corrected P value, P the uncorrected value, and n the number of comparisons. In this study, n is 13 for each allele, or carrier. A  $P_c$  value of less than 0.05 was considered statistically significant. **Results** The DPB1\*05:01 allele was the most frequent in patients (59.0%) and controls (46.7%). It was also significantly more frequent in patients than in controls, OR (95%CI)=1.64 (1.31-2.06),  $P_c = 2.27E-04$ . No other alleles were significantly different in frequency between patients and controls. **Conclusion** DPB1 was associated with T1D in Han Chinese in Taiwan. DPB1\*05:01 conferred susceptibility to GD. Extensive genotyping of other loci in the HLA complex is necessary to resolve the mechanism of the association between HLA and GD.

## 1949T

**Genome-wide association study identifies candidate loci associated with intraoperative remifentanyl requirements during laparoscopic-assisted colectomy.** D. Nishizawa<sup>1</sup>, T. Mieda<sup>2</sup>, M. Tsujita<sup>3</sup>, H. Nakagawa<sup>3</sup>, S. Yamaguchi<sup>4</sup>, S. Kasai<sup>5</sup>, J. Hasegawa<sup>1</sup>, K. Fukuda<sup>2</sup>, A. Kitamura<sup>3</sup>, M. Hayashida<sup>1,3,6</sup>, K. Ikeda<sup>1</sup>. 1) Psychiatry and Behavioral Science (Addictive Substance Project), Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Anesthesiology, Saitama Medical University Hospital, Saitama, Japan; 3) Department of Anesthesiology, Saitama Medical University International Medical Center, Saitama, Japan; 4) Department of Gastroenterological Surgery, Saitama Medical University International Medical Center, Saitama, Japan; 5) Department of Oral Health and Clinical Science, Tokyo Dental College, Tokyo, Japan; 6) Department of Anesthesiology & Pain Medicine, Juntendo University School of Medicine, Tokyo, Japan.

**Purpose:** Opioid analgesics are commonly required during and after laparoscopic surgery. Further, opioid requirements during and after laparoscopic surgery are highly variable among patients. We conducted a genome-wide association study (GWAS) in patients undergoing laparoscopic-assisted colectomy (LAC) to identify potential candidate single nucleotide polymorphisms (SNPs) that may significantly contribute to such individual differences. **Methods:** We conducted a three-stage GWAS by using whole-genome genotyping arrays with more than 900,000 markers in 351 patients, who underwent LAC under general anesthesia using sevoflurane and remifentanyl, and received intravenous fentanyl patient-controlled analgesia for postoperative pain control. During surgery, the end-tidal concentration of sevoflurane was fixed at 1.2 %, and the infusion rate of remifentanyl was titrated so as to maintain systolic blood pressure between 90 and 120 mmHg, heart rate below 75 beats per minute, and electroencephalographic bispectral index between 40 and 60. We further investigated whether some of the best candidate SNPs identified with the GWAS significantly affects opioid sensitivity in 355 patients undergoing mandibular sagittal split ramus osteotomy (SSRO) to corroborate potential associations found in patients undergoing LAC. **Results:** As a result of GWAS in surgical patients, a nonsynonymous SNP in the *TMEM8A* gene region, rs199670311, and intronic SNPs including rs4839603 SNP in the *SLC9A9* gene region, had highly significant associations with the intraoperative average remifentanyl infusion rate; the subjects with the A and T alleles required higher average remifentanyl infusion rates for intraoperative anesthesia, compared with those without these alleles in the rs199670311 and rs4839603 SNPs, respectively. In patients undergoing SSRO, the postoperative and total perioperative fentanyl requirements were greater in the A and T allele carriers compared with non-carriers in the rs199670311 and rs4839603 SNPs, respectively. **Conclusions:** Our findings provide valuable information for personalized pain control by opioids during LAC and during/after SSRO, in which the A and T alleles of the rs199670311 and rs4839603 SNPs, respectively, are associated with lower opioid sensitivity and require more opioids during LAC and during/after SSRO.

## 1950F

**NELFCD and CTSZ loci are associated with jaundice-stage progression**

**in primary biliary cholangitis in the Japanese population.** M. Kawashima<sup>1,2</sup>, N. Nishida<sup>2,3</sup>, Y. Hitomi<sup>4</sup>, K. Kojima<sup>4,5</sup>, Y. Kawai<sup>4,5</sup>, Y. Aiba<sup>6</sup>, H. Nakamura<sup>6</sup>, M. Nagasaki<sup>4,5,7</sup>, K. Tokunaga<sup>8</sup>, M. Nakamura<sup>6,8,9,10</sup>. 1) National Bioscience Database Center, Japan Science and Technology Agency, Chiyoda-ku, Japan; 2) Department of Human Genetics, Graduate School of Medicine, the University of Tokyo; 3) The Research Center for Hepatitis and Immunology, National Center for Global Health and Medicine; 4) Department of Integrative Genomics, Tohoku Medical Megabank Organization, Tohoku University; 5) Graduate School of Medicine, Tohoku University; 6) Clinical Research Center, National Hospital Organization, Nagasaki Medical Center; 7) Graduate School of Information Sciences, Tohoku University; 8) Department of Hepatology, Nagasaki University Graduate School of Biomedical Sciences; 9) Headquarters of PBC Research in NHOSLJ, Clinical Research Center, National Hospital Organization Nagasaki Medical Center; 10) Headquarters of PBC Consortium in Japan (PBCJPN), National Hospital Organization (NHO) Study Group for Liver Disease in Japan (NHOSLJ), and gp210 Working Group in Intractable Liver Disease Research Project Team of the Ministry of Health and Welfare in Japan.

**Aim and Methods:** Approximately 10-20% of patients with primary biliary cholangitis (PBC) progress from early stage to jaundice stage regardless of treatment with ursodeoxycholic acid. In this study, we performed a GWAS and validation study to identify genetic factors associated with progression to jaundice stage in PBC using a total of 1,125 PBC patients (975 early-stage and 150 jaundice-stage). Then, a high-density association mapping for the surrounding region of the top SNP detected from the GWAS and validation study was performed using 1,375 PBC patients (1,202 early-stage and 173 jaundice-stage), including GWAS set samples. Functional variants were predicted by in silico analysis using the Regulome DB database, UCSC genome browser, the SNP Function Prediction (FuncPred), and the PolyMiRTS database. To assess the biological effects on mRNA expression, we compared the endogenous expression levels in whole blood, transformed fibroblasts, liver, spleen, and EBV-transformed lymphocytes of CTSZ and NELFCD using the GTEx portal database. **Results and discussion:** A SNP located in the 3'UTR of cathepsin Z (CTSZ) showed the strongest association (odds ratio [OR] = 2.15, 95% confidence interval [CI] = 1.58-2.94,  $P = 7.62 \times 10^{-7}$ ) with progression to jaundice stage in GWAS, and this association reached borderline significance in the validation study (OR = 2.15, 95% CI = 1.61-2.87,  $P = 1.36 \times 10^{-7}$ ). High-density association mapping around CTSZ and negative elongation factor complex member C/D (NELFCD), which are located within a strong linkage disequilibrium block, revealed that another intronic SNP-X of CTSZ showed statistical significant association with jaundice-stage progression (OR = 2.16, 95% CI = 1.62-2.87,  $P = 8.57 \times 10^{-8}$ ). Among SNPs that are strong linkage disequilibrium ( $r^2 > 0.8$ ) with the SNP-X, four SNPs and two SNPs were predicted to be located in transcriptional regulatory elements and microRNA binding sites, respectively. Additionally, an eQTL analysis indicated that SNP-X was correlated with both NELFCD and CTSZ mRNA levels in whole blood and transformed fibroblasts. These results indicate that SNPs at *NELFCD/CTSZ* loci might be involved in progression to jaundice stage in PBC via alteration of these mRNA levels.

## 1951W

**Exome-wide association study of kidney function in 55,041 participants**

**of the DiscovEHR cohort.** C. Schurmann<sup>1</sup>, M.K. Puurunen<sup>1</sup>, S. Bruse<sup>1</sup>, A. Li<sup>1</sup>, N. Banerjee<sup>1</sup>, J. Penn<sup>1</sup>, A. Lopez<sup>1</sup>, K. Baras<sup>1</sup>, F.E. Dewey<sup>1</sup>, O. Gottesman<sup>1</sup>, T.M. Teslovich<sup>1</sup>, N.S. Abul-Husn<sup>1</sup>, Geisinger-Regeneron DiscovEHR Collaboration. 1) Regeneron Pharmaceuticals, Tarrytown, NY; 2) Geisinger Health System, Danville, PA.

**Background:** Chronic kidney disease (CKD), a progressive loss of renal function, is a major health burden affecting 5-10% of the world's population. Risk factors include diabetes mellitus, hypertension, cardiovascular disease, and family history. Serum creatinine levels and estimated glomerular filtration rate (eGFR) are established measures of kidney function. Genome-wide association studies (GWAS) mainly focusing on common variants have identified more than 60 loci associated with renal function, but less than 4% of the estimated heritability of eGFR has been explained so far. **Aim:** The aim of our study was to evaluate the impact of rare sequence variation on kidney function in a large clinical care cohort. **Methods:** We utilized exome sequencing and phenotypes derived from electronic health records for up to 55,041 European samples [60% female, median age 61 years, 26% type 2 diabetic, 64% hypertensive] from the DiscovEHR cohort. We tested single variants and genes for association with median serum creatinine and eGFR levels using linear regression models with adjustment for age, age<sup>2</sup>, sex, and genetic ancestry. **Results:** Preliminary association results for serum creatinine and eGFR include the replication of previously reported GWAS loci (*GCKR*, *GATM*, *UMOD1PDLT*, *CCDC158*, *ALMS1*, and *SLC47A1*). Furthermore, we identified ten gene-based associations at suggestive significance level ( $P < 1 \times 10^{-5}$ ), all of which were shared between serum creatinine and eGFR. These associations include aggregates of rare variants in known CKD-associated genes *SLC22A2* (Serum creatinine:  $B = 0.14$  standard deviations [SD],  $P = 2.3 \times 10^{-5}$ ; eGFR:  $B = -0.12$  SD,  $P = 5.6 \times 10^{-4}$ ) and *SLC47A1* (Serum creatinine:  $B = 0.15$  SD,  $P = 4.8 \times 10^{-13}$ ; eGFR:  $B = -0.17$  SD,  $P = 6.5 \times 10^{-16}$ ). The *SLC47A1* gene-based signals for serum creatinine and eGFR are largely driven by a single rare variant (rs111653425, MAF=0.9%) with  $B = 0.19$  SD and  $P = 2.9 \times 10^{-9}$  for serum creatinine and  $B = -0.20$  SD and  $P = 2.6 \times 10^{-10}$  for eGFR, respectively. The *SLC47A1* gene, previously associated with eGFR, creatinine levels, and CKD, is highly expressed in the kidney and liver and plays a role in treatment response to metformin, a drug used to improve blood glucose control in individuals with type 2 diabetes. **Conclusion:** These findings extend our understanding of the genetic architecture of renal function.

**1952T**

**Alternative splicing of *ICAM3* in Crohn's disease.** I. Arijis<sup>1,2</sup>, S. Verstockt<sup>3</sup>, M. Vancamelbeke<sup>2</sup>, B. Verstockt<sup>3</sup>, F. Schuit<sup>1</sup>, M. Ferrante<sup>2</sup>, S. Vermeire<sup>2</sup>, I. Cleynen<sup>2</sup>. 1) Department of Physiology - Biochemistry - Immunology, UHasselt - Jessa Hospital, Diepenbeek, Belgium; 2) Department of Clinical and Experimental Medicine, Translational Research Center for Gastrointestinal Disorders, KU Leuven, Leuven, Belgium; 3) Department of Human Genetics, KU Leuven, Belgium; 4) Department of Cellular and Molecular Medicine, Gene Expression Unit, Leuven, Belgium.

Crohn's disease (CD) is reflected by differential mucosal expression of genes involved in immune response, antimicrobial response, tissue remodeling and cell adhesion. The majority of protein-encoding genes, including those underlying susceptibility to CD, undergo alternative splicing, hereby influencing human physiology, development and disease. As differential splicing patterns on a genome-wide scale have not yet been studied in CD, we wanted to search for CD-associated alternative splicing events. Genome-wide alternative splicing was studied with Affymetrix Human Exon 1.0 ST Arrays on total RNA from mucosal biopsies from inflamed colon of 19 CD patients, and from normal colon of 6 controls. Data were analyzed with R/Bioconductor (aroma.affymetrix and limma packages), and with Exon Array Analyzer (EAA). Significant (false discovery rate <5% and >2-fold change) alternative splicing events from both programs were compared. Bio-functional analysis was performed with Ingenuity Pathway analysis (IPA). We identified 350 differential splicing events, representing 243 different genes, in both R and EAA. IPA analysis highlighted cellular movement, cell death and survival, and immune cell trafficking among the most enriched biological functions. When comparing only the top 50 most significant splicing events from both analysis programs, 20 were overlapping. Of these, five are known alternative splicing events, located in *ICAM3*, *AKAP9*, *AKAP13*, *SDR16C5* and *IGSF9*. Cluster analysis based on the expression of the corresponding exon probe sets distinguished CD patients from controls. We found alternative splicing of many transcripts in colonic biopsies of CD patients, many of which are involved in biological functions related to the pathogenesis of CD. *ICAM3* encodes an adhesion molecule regulating leukocyte trafficking. It represents a very promising alternative splice event in CD, as it is located in a known susceptibility region for CD. Currently, we examine the role of the identified *ICAM3* genetic variants on alternative splicing by quantitative RT-PCR.

**1953F**

**Chronic obstructive pulmonary disease subtyping through multiple -omics data integration.** B.D. Hobbs<sup>1,2</sup>, J.D. Morrow<sup>1</sup>, B.R. Celli<sup>2</sup>, R. Bueno<sup>2</sup>, G.J. Criner<sup>1</sup>, D.L. DeMeo<sup>1,2</sup>, C.P. Hersh<sup>1,2</sup>, E.K. Silverman<sup>1,2</sup>, M.H. Cho<sup>1,2</sup>. 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 2) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 3) Division of Thoracic Surgery, Brigham and Women's Hospital, Boston, MA; 4) Division of Pulmonary and Critical Care Medicine, Temple University School of Medicine, Philadelphia, PA.

**Rationale:** Chronic obstructive pulmonary disease (COPD), the third leading cause of death in the United States, is a highly heterogeneous disease. Some therapies for COPD appear to be most beneficial in specific subsets of patients. However, these subsets have often been based on a limited set of clinical factors and expert opinion. We hypothesized that biologically similar COPD subtypes can be identified by leveraging machine learning on integrated gene expression (transcriptomic), DNA methylation (epigenomic), and genetic variation data. Further, we hypothesized that subtypes derived from integrated -omics will associate with COPD clinical and radiographic features. **Methods:** We performed gene expression and methylation profiling and genome-wide genotyping on 105 lung tissue samples from former smokers of European ancestry with severe COPD. After quality control, in 84 samples with overlapping -omic data, we constructed subject distance (similarity) networks for each -omic data type (limiting genetic data to only the top 64 COPD-associated regions from a recent COPD GWAS) and merged them using the similarity network fusion (SNF) method. We used spectral clustering to identify subtypes of COPD patients from the fused patient similarity network. We performed differential gene expression and genetic association studies of the COPD subtypes to evaluate the gene expression and genetic differences between clusters. **Results:** We identified 4 clusters (subtypes) of subjects sharing molecular information. Although all groups had severe emphysema, clusters were significantly different in quantitative lung density (percent emphysema) on CT scan. The most severe subtype (cluster 2) had 38% emphysema and the least severe group had 28% emphysema. Lung function was not significantly different across clusters. A variant (rs17015027) at the *FAM13A* locus was significantly associated ( $P = 2.03 \times 10^{-4}$ ) with cluster 2 membership (compared to all other clusters). Cluster 2 showed differential expression (FDR < 10%) of *KPNA7*, *MMP10*, *LINC00479*, *GOLM1*, and *KRT17* compared to all other clusters where *MMP10* levels have been associated with quantitative imaging emphysema subtypes. **Conclusions:** An integration of multi-omic data from lung tissue of severe COPD cases identified four subtypes with significant clinical and genetic differences. Multi-omic integration has the potential to discover novel subtypes of COPD patients with similar underlying disease pathogenesis.

## 1954W

**Identifying genetic determinants of age at menarche and age at menopause in the Japanese population.** M. Horikoshi<sup>1</sup>, F.R. Day<sup>2</sup>, Y. Kamatani<sup>1,3</sup>, K. Matsuda<sup>4</sup>, M. Hirata<sup>4</sup>, K.K. Ong<sup>2</sup>, M. Kubo<sup>1</sup>, J.R.B. Perry<sup>2</sup>. 1) RIKEN Centre for Integrative Medical Sciences, Yokohama Japan; 2) University of Cambridge, Cambridge, UK; 3) Kyoto University Graduate School of Medicine, Kyoto, Japan; 4) University of Tokyo Institute of Medical Science, Tokyo, Japan.

Population genetic studies over the past decade have been highly successful in elucidating the genetic architecture of reproductive ageing. However, those studies have been largely limited to individuals of European ancestry, restricting the generalizability of findings and benefits of trans-ethnic approaches. To address this, we performed the largest genome-wide association study (GWAS) to date outside of European ancestry groups, comprising up to 67,030 women of Japanese ancestry collected by the Biobank Japan, for the ages at menarche (a marker of puberty timing) and menopause, imputed to 1000 Genomes reference variants. Genotyping array estimated heritabilities for age at menarche (13%) and age at menopause (10%) are 3-times smaller than those reported in Europeans. For menopause, 16 independent signals reached genome-wide significance ( $P < 5 \times 10^{-8}$ ), 8 of which are novel and not previously reported in Europeans. For menarche, 10 independent signals reached genome-wide significance, 2 of which are novel regions, and a third represents a novel Japanese-specific signal in a known European region ( $r^2 \sim 0$ ) near *PTPRD*. Of the 12 novel signals for the two traits, 5 showed significantly larger effects in Japanese than in Europeans ( $P_{\text{heterogeneity}} < (0.05/12)$ ). A further 3 signals were likely not identified in previous GWAS due to markedly lower allele frequencies in Europeans: *EIF4E* (rs199646819, minor allele frequency in Japanese vs. Europeans: 39% vs. 2%), *NKX2-1* (rs2076751: 25% vs. 7%) and *THOC1* (rs77001758: 40% vs. 0.1%). Highlighted mechanistic insights include a SIFT-predicted deleterious missense variant in *GNRH1* (encoding gonadotrophin releasing hormone, and a known signal for menarche) newly associated with age at menopause ( $P = 3 \times 10^{-13}$ ) and enrichment of menarche signals near genes that encode for receptor tyrosine phosphatases. Furthermore, genes involved in basic molecular processes: histone modification (*H1FX*), mRNA translation (*EIF4E* and *EIF4EBP1*) and DNA damage response (*RAD21*) were implicated in menopause timing. In summary, we report the first genomic study outside of Europeans to identify genome-wide significant loci for reproductive ageing. Widespread differences in allele frequencies and effect estimates present challenges for such large-scale trans-ethnic approaches, but allow new mechanistic insights.

## 1955T

**Markers of the adaptive immune response are associated with progressively worse chronic kidney disease status.** D.C. Crawford<sup>1</sup>, W.S. Bush<sup>1</sup>, J.N. Cooke Bailey<sup>1</sup>, K. Miskimen<sup>1</sup>, P. Miron<sup>1</sup>, J. O'Toole<sup>2</sup>, J.R. Sedor<sup>2,3</sup>. 1) Institute for Computational Biology, Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 2) Department of Medicine, Case Western Reserve University, Cleveland, OH; 3) Department of Physiology and Biophysics, Case Western Reserve University, Cleveland, OH.

Germline and somatic genomic variation represent the bulk of 'omics data available for precision medicine research. These data, however, may fail to capture the dynamic biological processes that underlie disease development, particularly for chronic diseases of aging such as chronic kidney disease (CKD). To demonstrate the value of additional dynamic precision medicine data, we sequenced somatic T-cell receptor rearrangements, markers of the adaptive immune response, from genomic DNA collected during a clinical encounter from 15 participants with CKD and associated co-morbidities. Participants were consented as part of a larger precision medicine research project at the MetroHealth System, a large urban public hospital in Cleveland, Ohio. Genomic DNA was extracted from whole blood, and T-cell receptors were sequenced with six replicates per sample using Adaptive Biotechnologies' immunoSEQ assays coupled with the Illumina NextSeq PE. All sequences were assembled using Adaptive Biotechnologies' ANALYZER bioinformatics pipeline. Demographic and clinical data closest to the time of blood draw were extracted from the electronic health record. Overall, the average age of patients was 61.73 years, more than half (60%) were female, and the majority were African American (80%). T-cell receptor diversity was estimated using productive clonality, a measure ranging from 0 (polyclonal samples) to 1 (monoclonal or oligoclonal samples). Productive clonality in this sample ranged from 0.0151 to 0.2565 with a mean of 0.1030 (standard deviation or SD=0.0669). Average productive clonality did not statistically differ by sex: females = 0.0811 (SD=0.0533) and males = 0.1358 (SD=0.0764). We then tested for correlations between T-cell receptor diversity and biomarkers of CKD, including disease status calculated using the CKD-EPI equation. Reduced T-cell diversity was associated with increased creatinine ( $R^2=0.0995$ ), BUN ( $R^2=0.0258$ ), and eGFR ( $R^2=0.066$ ), but not with white blood cell count ( $R^2=0.0004$ ). Reduced T-cell diversity was also associated with worsening CKD status ( $R^2=0.2362$ ), with a higher on average productive clonality (0.0488) among stage 4 patients ( $n=5$ ) compared with stage 3 (0.0330;  $n=8$ ) and stage 2 patients (0.0149;  $n=2$ ). These data suggest an association between advanced CKD and premature aging of the adaptive immune system and highlight the potential of dynamic 'omic data to generate novel hypotheses about disease mechanisms.

**1956F**

**Effect of CAG repeat length in the *androgen receptor* gene on hirsutism among healthy Israeli women of different ethnicities.** S. Ben-Shachar<sup>1,3</sup>, M. Slakman<sup>2</sup>, G. Israeli<sup>2</sup>, O. Eyal<sup>2,3</sup>, N. Weintrob<sup>2,3</sup>. 1) Genetic Institute, Tel Aviv Medical Center, Tel Aviv, Israel; 2) Pediatric Endocrinology and Diabetes unit, Dana Hospital, Tel Aviv Medical Center, Tel Aviv, Israel; 3) Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv, Israel.

**Introduction:** The differences in the levels of hirsutism between women of different ethnicities may stem from multiple etiologies. Polymorphism of the CAG repeats of the *androgen receptor* (*AR*) gene is common. Shorter length of the repeats are associated with increased activity of the receptor. We hypothesized that there are ethnic differences in the degree of hirsutism among Israeli women, and that the CAG repeat length may contribute to these differences. **Methods:** Healthy Israeli Jewish women age 18–45 years of Ashkenazi and non-Ashkenazi (North African and Near-Eastern) origin were recruited. Hirsutism was assessed using the simplified Ferriman–Gallwey (sFG) score. Demographic data (weight, body mass index [BMI], and age) were collected, and serum total testosterone levels were determined. The CAG repeat length was measured by PCR. Methylation-sensitive methods were used to detect the fractional activity of each allele in blood, and the weighted arithmetic mean was calculated for the CAG repeat length. **Results:** One-hundred and eight women were recruited (49 Ashkenazi and 59 non-Ashkenazi). There was a significant negative correlation between the number of CAG repeats in the *AR* gene and the sFG score. The number of repeats was not related to testosterone levels. Ashkenazi women had a lower degree of hirsutism ( $p < 0.001$ ), a lower BMI (21.4 vs 24 for non-Ashkenazi women,  $p = 0.003$ ), and lower testosterone levels (0.015 vs 0.022 ng/ml, respectively,  $p = 0.017$ ). The length of the shorter CAG repeat allele and the weighted CAG repeat length were greater among the Ashkenazi women ( $21.1 \pm 2.3$  vs  $19.6 \pm 2.6$ ,  $p = 0.03$  and  $22.2 \pm 2.4$  vs  $21.1 \pm 2.3$ ,  $p = 0.015$ , respectively). **Conclusions:** There is a significant difference in the degree of hirsutism between Ashkenazi and non-Ashkenazi women in Israel. The length of CAG repeats partially explains some of these differences. These results suggest that the ethnic difference in the degree of hirsutism is the result of a complex genetic trait.

**1957W**

**Rare variation associated with immunosuppressant drug concentrations: Moving beyond common SNPs in predicting drug metabolism.** A.A. Seyerle<sup>1</sup>, D. Schladt<sup>2</sup>, W. Guan<sup>3</sup>, R. Remmel<sup>4</sup>, W.S. Oetting<sup>5</sup>, C. Dorr<sup>6</sup>, B. Wu<sup>6</sup>, A. Israni<sup>6</sup>, P.A. Jacobson<sup>6</sup>. 1) Division of Epidemiology and Community Health, University of Minnesota, Minneapolis, MN; 2) Department of Nephrology and Chronic Disease Research Group, Minneapolis Medical Research Foundation, Hennepin County Medical Center, Minneapolis, MN; 3) Division of Biostatistics, University of Minnesota, Minneapolis, MN; 4) Department of Medicinal Chemistry, University of Minnesota, MN; 5) Department of Experimental and Clinical Pharmacology, University of Minnesota, Minneapolis, MN; 6) Department of Nephrology, Minneapolis Medical Research Foundation, Department of Medicine, University of Minnesota, Minneapolis, MN.

Tacrolimus (TAC), an immunosuppressive agent commonly used in solid organ transplant recipients, has a narrow therapeutic index requiring therapeutic drug monitoring in clinical care. Common genetic variants in cytochrome P450 3A4/5 are well known to affect the TAC metabolism and blood concentrations. Common variants and clinical factors explain ~50% of interpatient variability in blood trough concentrations. We examined whether rare genetic variants were associated with TAC troughs to explain additional variability. Among European American (EA; N=1,354) and African American (AA; N=299) kidney transplant (tx) recipients in the Deterioration of Kidney Allograft Function (DeKAF) Genomics study, longitudinal TAC troughs were measured in the first six months post-tx in each subject. A simple spline method was used to model a day 9 TAC trough concentration. Genotyping on recipient DNA was performed on a custom exome-plus Affymetrix TxArray SNP chip. For SNPs with a minor allele frequency < 5%, race-stratified statistical analyses were done using both gene-based burden testing and sequence kernel association testing (SKAT). Among EAs, the burden test identified ten genes on chromosome seven associated with TAC residuals (*PDAP1*, *ARPC1B*, *CYP3A5*, *ZNF655*, *ZSCAN25*, *ATP5J2*, *ZNF394*, *CYP3A4*, *ARPC1A*, *PTCD1*) and one gene on chromosome 21 (*CNN2P7*). SKAT identified *CYP3A43* and *CNN2P7* associated with TAC residuals in EAs. Burden testing in AAs identified the genes *ZNF138* and *ZNF107* associated with TAC residuals while SKAT testing did not identify any genes significantly associated with TAC residuals. Adjustment for common, well-known variants associated with TAC, *CYP3A5\*3* and *CYP3A4\*22* in EAs and *CYP3A5\*3*, \*6, and \*7 in AAs, eliminated significant findings on chromosome seven, although *CNN2P7* remained. These results suggest that low frequency variants in the genome may modify TAC blood concentrations. Our results also indicate that better characterization of the low frequency variants surrounding the *CYP* genes is needed to fully account for the role of genetics in TAC metabolism. Better understanding the role low frequency variants play in TAC metabolism could ultimately aid in more personalized and effective TAC dosing and may be relevant to hundreds of other *CYP3A* drug substrates.

**1958T**

***NUDT15* variants contribute to thiopurine-induced myelosuppression in European populations.** M.D. Voskuil<sup>1</sup>, G.J. Walker<sup>2,3</sup>, J.W. Harrison<sup>4</sup>, G.A. Heap<sup>2,3</sup>, J. Koskela<sup>5,6</sup>, E.A.M. Festen<sup>1</sup>, M.J. Daly<sup>5,6</sup>, R.K. Weersma<sup>1</sup>, R. Ward<sup>4</sup>, M.N. Weedon<sup>1</sup>, J.R. Goodhand<sup>2,3</sup>, N.A. Kennedy<sup>2,3</sup>, T. Ahmad<sup>2,3</sup>, IBD Pharmacogenetics Study Group. 1) Department of Gastroenterology and Hepatology, University of Groningen, University Medical Center Groningen, Groningen, Netherlands; 2) Department of Gastroenterology, Royal Devon and Exeter Hospital NHS Foundation Trust, Exeter, UK; 3) IBD Pharmacogenetics Group, University of Exeter, Exeter, UK; 4) University of Exeter Medical School, Exeter, UK; 5) Broad Institute of Harvard University and MIT, Cambridge, MA, USA; 6) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA.

Thiopurines are commonly used in the maintenance treatment of inflammatory bowel disease (IBD) but this is limited by myelosuppression in 7% of patients. Thiopurine S-methyltransferase (*TPMT*) variants only explain 26% of thiopurine-induced myelosuppression (TIM) in Europeans suggesting the presence of other genetic determinants. We aimed to identify the clinical features of TIM and to identify novel variants associated with TIM through a genome wide association study (GWAS) and whole exome sequencing. We recruited 491 IBD patients with TIM from 82 hospitals. Inclusion criteria included drug exposure in the 7 days prior to TIM, white blood cell count  $<2.5 \times 10^9/L$ , or neutrophil count  $<1.0 \times 10^9/L$  and that TIM necessitated dose reduction/drug withdrawal. After expert adjudication, 329 cases assigned a high likelihood of causality were genotyped and exome sequenced with 635 thiopurine-tolerant IBD controls for use in the final analyses. We first confirmed an association of TIM with *TPMT* in an initial GWAS. We then, using exome sequencing, discovered a novel 6bp in-frame deletion (rs746071566; AGGAGTC/A, p.Gly17\_Val18del) at position 48611918 of chromosome 13 in exon 1 of *NUDT15* (5.8% of cases, 0.2% of controls OR = 38.2;  $P = 1.3 \times 10^{-9}$ ). We replicated this in an independent cohort (2/73 [2.7%] cases vs. 2/840 [0.2%] thiopurine-tolerant IBD controls; OR=11.8,  $P=0.034$ ). All *NUDT15* coding variants were validated by Sanger sequencing. Multivariable logistic regression demonstrated that weight adjusted dose (OR=2.2,  $P=9.4 \times 10^{-11}$ ), *NUDT15* genotype (OR 21.7,  $P=2.8 \times 10^{-9}$ ) and *TPMT* genotype (OR 2.2,  $P=2.6 \times 10^{-4}$  for MUT/WT and OR 51.2,  $P=1.8 \times 10^{-4}$  for MUT/MUT) were independently associated with TIM. These are the largest ever clinical and genetic analyses of thiopurine-induced myelosuppression. We identified *NUDT15* coding variants, including a novel 6bp deletion; carriage of any coding variant confers a 22-fold increase in the odds of TIM, independent of *TPMT* genotype and thiopurine dose. Although *NUDT15* variants are less common than *TPMT* variants, their effect size for heterozygotes is greater. The number of patients needed to genotype to prevent TIM due to *NUDT15* coding variant heterozygosity is 100. The estimated absolute risk of TIM in *NUDT15* heterozygotes is 59%. A future clinical decision tool incorporating *NUDT15* and *TPMT* genotypes will offer personalized thiopurine therapy and prevent the considerable morbidity and costs associated with severe bone marrow toxicity.

**1959F**

**Exome sequencing highlights novel DNA variants with a potential role in polycystic ovary syndrome.** S.G. Wilson<sup>1,2,3</sup>, R.S. Smith<sup>1,4</sup>, P.J. Campbell<sup>1</sup>, K.A. Burns<sup>1,2</sup>, B.H. Mullin<sup>1,2</sup>, R.J. Mead<sup>4</sup>, E.M. Lim<sup>1,5,6</sup>, B.G.A. Stuckey<sup>1,2</sup>. 1) Endocrinology & Diabetes, Sir Charles Gairdner Hospital, Nedlands, WA, Australia; 2) School of Medicine and Pharmacology, University of Western Australia, Crawley, WA, Australia; 3) Department of Twin Research and Genetic Epidemiology, King's College London, London, UK; 4) School of Biological Sciences, Murdoch University, Murdoch, WA, Australia; 5) PathWest Laboratory Medicine, Nedlands, WA, Australia; 6) School of Pathology and Laboratory Medicine, University of Western Australia, Nedlands, WA, Australia.

Polycystic ovary syndrome (PCOS) is the leading cause of anovulatory infertility in women and affects 5%–10% of women in the developed world. Symptoms include hyperandrogenism, metabolic disturbances and chronic anovulation. The pathophysiology of PCOS is complex, but there is strong evidence of a genetic component. There is substantial heterogeneity in the clinical presentation of PCOS suggesting that the disorder is multifactorial, with multiple gene and environmental factors contributing to disease susceptibility. Numerous genome-wide association studies (GWAS) of PCOS have highlighted variants (MAF > 0.05) at 20 potentially relevant loci, however these common SNPs are unlikely to be the causal variants and together explain only a fraction of the heritability of PCOS. The aim of this project was to focus on variants at the lower end of the allelic frequency spectrum, which had predicted functional consequences on the protein product of the gene. We recruited first degree relative pairs and trios with physician diagnosed PCOS from a clinical practice using the NIH diagnostic criteria. Genomic DNA was extracted from the blood of 33 study subjects and Human exome capture and sequencing was undertaken using Agilent SureSelect XT Human All Exon +UTR v5 on Illumina HiSeq 2500. Targeted mapped coverage was 50x and SNV and Indel detection were performed. Data was then processed using ANNOVAR to annotate functional consequences of the genetic variants. We studied individual PCOS families, retaining only those variants that were present in all available affected individuals in the pedigree. Loci were filtered based on the following criteria: SIFT  $\leq 0.05$ , PolyPhen-2 > 0.85, MAF < 0.01 and mutation of the murine ortholog reported to cause a reproductive phenotype (where data was available). Among the missense variants that were observed, SNV in the genes *DNAH11*, *INSR*, *FZD1* may be of particular interest. In summary, exome sequencing appears to be an efficient technique for the study of rare variants segregating in families with PCOS. The study identified a number of variants of potential relevance to disease susceptibility and sets the stage for future functional studies aimed at increasing understanding of the pathophysiology of the disorder. If these data can be replicated, or functional relevance established, the findings may be of potential direct clinical value in molecular screening protocols and in the creation of genetic risk scores for patients.

**1960W**

**Search for genetic factor associated with right-sided colonic diverticula in Korean population: Genome-wide association study.** E. Choe<sup>1</sup>, E. Shin<sup>2</sup>, J. Kim<sup>2</sup>, S. Chung<sup>3</sup>, S. Yang<sup>3</sup>, Y. Kim<sup>3</sup>, J. Bae<sup>3</sup>. 1) Surgery, Seoul National University Hospital, Healthcare System Gangnam Center, Seoul, South Korea; 2) DNA Link, Inc., Seoul, South Korea; 3) Internal Medicine, Seoul National University Hospital, Healthcare System Gangnam Center, Seoul, South Korea.

**Background :** Diverticular disease is one of the most frequent problem in gastrointestinal tract. But since most of the colonic diverticula are asymptomatic, the exact prevalence is not well known and as such, single nucleotide polymorphism (SNP) based genetic study is scarce. In Asian population, diverticula is more frequently found in right colon with younger age, compared to western population. This early onset feature implies the high genetic predisposition for the diverticula in right colon. We performed a genome-wide association study to identify genetic factors associated with right-sided colonic diverticula in Korean population. **Method :** Genome-wide association study was conducted in 8,072 Korean population, who had colonoscopy during routine health check-up, using the Affymetrix Axiom® Customized Biobank Genotyping Arrays for right-sided colonic diverticula. After excluding those in age under 50 years and did not have diverticula, data from total 5444 samples were analyzed. Control group (test set, n=3396; replication set, n=1003) was defined as those in age≥50 years and did not have diverticula; case group (test set, n=678; replication set, n=367) was defined as those in any age and had right-sided colonic diverticula. Multiple logistic regression was used for analysis with age and gender adjustment. **Result :** In the test set (age = 57±6.68 years; Male : Female = 2588 : 1486), there were no SNPs that had significant association with right-sided colonic diverticula after the bonferroni correction (threshold for P value were < 10<sup>-8</sup>). So we investigated the regional plotting for SNPs that had P value less than 10<sup>-3</sup>. There were 3 blocks that had SNPs aggregated regionally with distances less than 100 base pair apart. 31 SNPs were identified in 3 blocks. In the replication set, 17 SNPs among 31 SNPs were replicated and the genes associated with each block were CDC42BPA; RPS6KA2; and TEX10, MSANTD3 gene. Most significant SNPs in each block were rs2718207 (CDC42BPA, P=9.2x10<sup>-4</sup>), rs79706510 (RPS6KA2, P=6.5x10<sup>-4</sup>) and rs2417084 (TEX10, MSANTD3; P=7.4x10<sup>-4</sup>). **Conclusion :** We demonstrated that the CDC42BPA, RPS6KA2, TEX10 and MSANTD3 are associated with the presence of right-sided colonic diverticula in Korean population. These findings are a novel finding that provide the genetic role in the pathogenesis of colonic diverticula. This should be validated in a larger size of diverticula cohort with variable ethnicity.

**Dysregulated gene and miRNA expression in different stages of Crohn's disease.** I. Cleynen<sup>1</sup>, S. Verstockt<sup>1</sup>, G. De Hertogh<sup>2</sup>, J. Van der Goten<sup>3</sup>, M. Vancamelbeke<sup>3</sup>, B. Verstockt<sup>3</sup>, L. Van Lommel<sup>4</sup>, F. Schuit<sup>4</sup>, P. Rutgeerts<sup>3,5</sup>, M. Ferrante<sup>3,5</sup>, S. Vermeire<sup>3,5</sup>, I. Arijis<sup>3,6</sup>. 1) Department of Human Genetics, KU Leuven, Leuven, Belgium; 2) Department of Morphology and Molecular Pathology, University Hospital Gasthuisberg, Leuven, Belgium; 3) Translational Research Center for Gastrointestinal Disorders (TARGID), Department of Clinical and Experimental Medicine, KU Leuven, Leuven, Belgium; 4) Gene Expression Unit, Department of Cellular and Molecular Medicine, KU Leuven, Leuven, Belgium; 5) Department of Gastroenterology and Hepatology, University Hospital Gasthuisberg, Leuven, Belgium; 6) Faculty of Medicine and Life Sciences, Hasselt University, Hasselt, Belgium; Jessa Hospital, Hasselt, Belgium.

Crohn's disease (CD) is characterized by chronic inflammation of the gut, progressing to stricturing and/or penetrating complications in most patients. Effective intervention before bowel damage, and thus in the early phase of the disease, will be required to optimize patient outcomes. We therefore aimed to define the molecular landscape of early CD, by performing transcriptomics on ileal mucosal biopsies of CD patients with early (<18 months after ileo-colonic anastomosis) post-operative recurrence (POR; Rutgeerts' score i2b, i3 or i4; n=24). We also included biopsies of newly diagnosed (<18 months) CD patients (n=19); late (>3 years after diagnosis or ileo-colonic anastomosis) CD patients with active disease (n=14); and 12 normal controls. Gene and microRNA (miRNA) expression was studied using Affymetrix Human Gene 1.0 ST and miRNA 2.0 arrays, and validation using quantitative reverse transcriptase-PCR. mRNA dysregulation was most pronounced in new and late CD with 608 and 614 significantly (false discovery rate (FDR) <5% and >2-fold change) differentially expressed gene probe sets, while 353 in POR CD versus controls, and an overlap of 261. The top dysregulated gene in POR CD was *FOLH1* (p=8.07x10<sup>-23</sup>; FC=42.15). In contrast, miRNA expression was most pronounced in POR CD, with 13 significantly (FDR<5% and >1.5-fold change) differential signals, while five and one in new and late CD. Integrating dysregulated genes and miRNAs found 64 miRNA-mRNA pairs with negative correlation in expression in POR CD, five of which experimentally supported in literature: hsa-let-7g-5p/*PRDM1* and hsa-let-7g-5p/*PTGS2*, hsa-miR-30d-5p/*SLC7A11* and hsa-miR-30d-5p/*WNT5A*, and hsa-miR-196a-5p/*ANXA1*. To be sure that POR expression is not influenced by previous disease (before surgery), we looked at gene expression in three CD patients with uninfamed post-operative ileum (i0), and six with POR i1 (≤5 aphthous lesions after surgery). There was only one significantly dysregulated gene (*WNT5A*) in i0, and 123 (including *WNT5A*) in i1 CD. *WNT5A* moreover had an increased expression with an increasing Rutgeerts' score (p<0.0001), and was dysregulated throughout different disease stages. *WNT5A* is a secreted glycoprotein that signals through the non-canonical pathway, and promotes crypt regeneration after tissue injury. Immunohistochemical staining for *WNT5A* is currently ongoing to narrow down which ileal regions show increased expression to help elucidate its role in early CD.

**Background and Goal:** Gallstone disease (GSD) is one of the most common gastrointestinal disorders in Taiwan. This complex disorder most resulting from interactions between genetics and environmental factors. The incidence of GSD is about 5-14.3% in adult and correlated with age positively. It costs a lot in clinical and surgical treatment. Previous research indicated that lifestyle and other environmental factors are one of the risk factor in GSD. Recently, genetic factors are also affecting in pathogenesis of gallstone. Cholesterol-, mixed- and pigmented-stone are major types in GSD. Mixed- and pigmented-stone may correlate with bacterial infection. But, the relationship between bacteria communities and bile in GSD are not well discussed in Taiwan. In this study, we try to find the possible risk factors in bacteria affect in GSD. **Methods:** We enrolled 60 patients (40 females) in this study. Gallbladder bile and gallstone total DNA were extracted by QIAamp DNA stool mini kit. 16S rDNA sequencing will be performed by MiSeq. Preliminary analysis using MiSeq reporter. Statistical analysis using SPSS. **Results:** Although the majority of identified bacteria were diminished in bile samples, Enterobacteriaceae genera and Pyramidobacter were abundant in bile. **Conclusion:** Our study provides database for the potential source of gallbladder bile and gallstone bacteria, and illustrates the influence of GSD formation on bacterial communities.

## 1963W

**101 novel loci and novel associations with gene expression detected in transethnic genome-wide study of estimated glomerular filtration rate in over 270,000 participants: The Million Veteran Program.** A.M. Hung<sup>1</sup>, A. Giri<sup>2</sup>, J. Hellwege<sup>2</sup>, O. Wilson<sup>1</sup>, E. Torstenson<sup>2</sup>, C. Kovesdy<sup>2</sup>, K. Birdwell<sup>1</sup>, M. Li<sup>2</sup>, E. Estimated glomerular filtration rate (eGFR) is a measure of kidney function and defines renal dysfunction and stages of chronic kidney disease (CKD). CKD affects over 14% of the US population, with higher prevalence in African Americans than non-Hispanic Whites. We have conducted the largest trans-ethnic genome-wide association study (GWAS) of eGFR to date in a well-defined cohort of African American (N = 56,253) and European American (N = 216,585) veterans participating in the Million Veteran Program (MVP). Genotypes were imputed based on the 1000 Genomes reference. eGFR was regressed onto additively encoded genetic variants, age, body mass index, sex, and 5 principal components. All analyses were performed in strata of hypertension status, diabetes status, and race, followed by fixed effects meta-analysis. We identified 13,261 SNPs in 157 loci at the significance threshold of  $p=5 \times 10^{-8}$  explaining 4.3% of the phenotypic variance, with the strongest signal replicating the previously detected association at *UMOD/PDILT* ( $p$ -value =  $4.3 \times 10^{-166}$ ). Of these, 56 represented previously reported loci from GWAS of kidney function or CKD, and 101 are novel and explain 2.1% of eGFR variance. The strongest evidence for novel signals were near *TPPP* (rs454190;  $p$ -value =  $2.26 \times 10^{-19}$ ) and near *NR1P1* (rs2823139;  $p$ -value =  $1.61 \times 10^{-18}$ ). Mutations in *NR1P1* have been implicated in congenital anomalies of the kidney and urinary tract. We also performed genome-wide association analysis of genetically predicted gene expression (GPGE) and eGFR using the MetaXcan method in multiple tissues derived from the Genotype-Tissue Expression (GTEx) project. Predicted expressions of 209 genes were significantly ( $p$ -value  $< 5 \times 10^{-8}$ ) associated with eGFR in one or more tissues. Predicted expression of previously suspected genes *GATM* and *SPATA5L1* were strongly associated with eGFR in many tissues, notably in thyroid ( $p$ -value =  $1.27 \times 10^{-82}$ ). Corresponding to novel signals from GWAS, associations between GPGE of nearby genes such as *TMUB1* in stomach, *SLC28A2* in nerve, and *SLC30A4* in subcutaneous adipose tissue were observed. As the largest transethnic GWAS of eGFR to date, we replicate over 50 previously identified loci, identify 101 novel loci and associate predicted expression of genes across several tissues with kidney function.

**1964T**

**An analysis of Crohn's disease genes in the French-Canadian population.** *B.E. Avila<sup>1,2</sup>, M. Rivas<sup>1,3</sup>, C. Stevens<sup>1</sup>, J. Rioux<sup>4,5</sup>, P. Goyette<sup>4</sup>, G. Boucher<sup>1</sup>, A. Bitton<sup>6</sup>, M. Daly<sup>1,2</sup>, NIDDK IBD Genetics Consortium.* 1) Medical and Population Genetics, Broad Institute, Cambridge, MA; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA; 3) Department of Biomedical Data Science, Stanford, CA, USA; 4) Montreal Heart Institute, Montreal, Quebec; 5) Université de Montréal, Montreal, Quebec; 6) McGill University Health Centre, Montreal, Quebec.

Exome sequencing has been powerful in determining variants with increased prevalence and effect size in contributing to risk of Inflammatory Bowel Disease (IBD) among population isolates. The French-Canadian population of Quebec has seen an intense founder effect more recently than many population isolates commonly studied today. In this study, we analyse 2,701 samples (with 667 cases, 1,020 controls, and 1,014 samples from complete trios) of French-Canadian origin for exome variants associated with Crohn's Disease in this population. Further, enrichment analysis based on a categorical Bayesian model allows us to determine which risk alleles are present in increased or decreased frequency due to the recent founder effect. The 338 complete trios give us the first opportunity to look sensitively at ultra-rare de novo variation in IBD, dissected by tolerance of genes to mutation and whether the gene has been potentially implicated based on proximity to one of the 250 confirmed IBD-associated loci discovered by GWAS. Similarly, we identify thousands of alleles which are specifically enriched from the founding population bottleneck, and explore their contribution to IBD in the same fashion.

**1965F**

**Evaluation of candidate genes for Hirschsprung disease using target sequencing.** *W.Y. Lam<sup>1</sup>, C.S. Tang<sup>1</sup>, P.C. Sham<sup>2,3</sup>, P.K.H. Tam<sup>1</sup>, S.S. Cherny<sup>6</sup>, M.M. Garcia-Barcelo<sup>1</sup>.* 1) Department of Surgery, The University of Hong Kong, Hong Kong; 2) Department of Psychiatry, The University of Hong Kong, Hong Kong; 3) Center for Genomic Sciences, The University of Hong Kong, Hong Kong.

Hirschsprung Disease (HSCR), or congenital aganglionic megacolon, is a relatively rare and complex genetic disorder characterised by the congenital absence of enteric neurons along a variable length of the distal intestine. Patients present with bowel obstruction and the disease may be fatal unless treated surgically. There is significant population variation in the incidence of the disease, and its incidence in Chinese is one of the highest in the world (1.4/5,000 live-births). Through the International Hirschsprung Disease Consortium exome sequencing project, candidate genes recurrently mutated with either *de novo* and/or inherited damaging variants were identified. In this follow-up study, we investigate if these genes are definitive genetic risk factors for HSCR in a larger number of patients. We screened 12 newly identified genes for mutations in 1200 Chinese and Caucasian HSCR patients, performed target sequencing using xGen@Lockdown@ Custom Probes for enrichment of the sequences of the selected genes and high-throughput sequencing with depth 700X. Latest findings of this study will be presented to provide insights on whether the mutated genes identified through our exome study really involved in the pathogenesis of HSCR. This project is supported by the HMRF grant 02131866 to MMGB.

**1966W****Identification of blood UMOD and HER2 as causal mediators of chronic kidney disease using Mendelian randomization in the ORIGIN trial.**

J. Sjaarda<sup>1,2</sup>, H. Gerstein<sup>1,2</sup>, S. Yusuf<sup>1,2</sup>, J. Mann<sup>3</sup>, D. Treleaven<sup>1</sup>, M. Walsh<sup>1,2</sup>, S. Hess<sup>4</sup>, G. Pare<sup>1,2</sup>. 1) McMaster University, Hamilton, Ontario, Canada; 2) Population Health Research Institute, Hamilton, Ontario, Canada; 3) University of Erlangen-Nuremberg, Bavaria, Germany; 4) Sanofi Aventis, Frankfurt, Germany.

**BACKGROUND:** Identification of biomarkers for chronic kidney disease (CKD) may lead to important advances in both prevention and treatment, particularly if they are causally linked. Many biomarkers have been epidemiologically linked with CKD, however, the possibility that such associations may be due to reverse causation or confounding limit their utility. This limitation can be overcome using a Mendelian randomization (MR) approach. We therefore used this technique to identify novel, causal mediators of CKD. **METHODS:** MR was performed by first identifying genetic determinants of 227 protein biomarkers assayed in 4,147 ORIGIN trial (Outcome Reduction with Initial Glargine Intervention) participants, and assessing their effects on CKD in the CKDGEN consortium (N=117,165, 12,385 cases) using the inverse-variance weighted method. The relationship between the serum concentration of each biomarker identified using this approach and incident CKD in ORIGIN participants was then estimated. **FINDINGS:** Uromodulin (UMOD) and human epidermal growth factor receptor 2 (HER2) were identified as novel, causal mediators of CKD using MR (UMOD: OR=1.30 per SD; 95% CI 1.25 to 1.35;  $p < 5 \times 10^{-20}$ ; HER2: OR=1.30 per SD; 95% CI 1.14 to 1.48;  $p = 8.0 \times 10^{-8}$ ). Consistent with the MR findings, blood HER2 was also associated with CKD events in ORIGIN (OR=1.07 per SD; 95% CI, 1.01 to 1.13;  $p = 0.01$ ). Additional exploratory MR analyses identified angiotensin converting enzyme (ACE) as a regulator of HER2 levels ( $\beta = 0.13$  per SD, 95% CI 0.08 to 0.16,  $p = 2.5 \times 10^{-7}$ ). This latter finding was corroborated by an inverse relationship between ACE-inhibitor use and HER2 levels ( $\beta = -0.25$  SD, 95% CI -0.30 to -0.20,  $p < 5 \times 10^{-16}$ ). **INTERPRETATION:** UMOD and HER2 are independent causal mediators of CKD in humans, and HER2 levels are regulated in part by ACE. Both these biomarkers are potential therapeutic targets for CKD prevention.

**1967T****Mendelian randomization shows non-linear causality between vitamin D levels and kidney function.**

A. Teumer<sup>1,2</sup>, G. Gambaro<sup>3</sup>, C. Pattaro<sup>4</sup>, A. Köttgen<sup>5</sup>, P.M. Ferraro<sup>3</sup> on behalf of the CKDGen Consortium. 1) Institute for Community Medicine, University Medicine Greifswald, Greifswald, Germany; 2) DZHK (German Center for Cardiovascular Research), partner site Greifswald, Greifswald, Germany; 3) Division of Nephrology, Fondazione Policlinico Universitario A. Gemelli, Catholic University of the Sacred Heart, Rome, Italy; 4) EURAC Research Institute for Biomedicine, Bolzano, Italy; 5) Institute of Genetic Epidemiology, Medical Center - University of Freiburg, Germany.

Vitamin D is important for regulating the concentration of calcium in the bloodstream and for healthy growth of bones. The prohormone vitamin 25(OH)D (calcidiol) is produced in the liver and converted in the kidney to the active form 1,25(OH)<sub>2</sub>D (calcitriol). Vitamin 25(OH)D is measured in serum as a marker for vitamin D. Observational studies suggest an association between lower levels of vitamin D and impaired kidney function, although the observed effect direction varied. Confounding might at least partly explain such findings. We performed Mendelian randomization (MR) analysis to assess whether circulating vitamin D levels are causally associated with renal function, quantified by the estimated glomerular filtration rate (eGFR) and urinary albumin-to-creatinine ratio (UACR). We applied a two-sample MR triangulation analysis with standard errors estimated by the delta method (Thomas *et al.*, AEP 2007) using rs10741657 (*CYP2R1*), rs12785878 (*DHCR7*) and rs2282679 (*GC*) as instruments. Effect estimates of these SNPs were obtained from published GWAS meta-analysis results of vitamin D (Wang *et al.* 2010, n=33,868), eGFR (Pattaro *et al.* 2016, n=133,723) and UACR (Teumer *et al.* 2015, n=54,450), respectively. All traits were log-transformed. Overall, a significant inverse causal effect of vitamin D levels on kidney function could be shown for eGFR ( $\beta = -0.013$ ,  $p = 0.003$ ). This result was validated in a one-sample 2-stage least-squares MR analysis in 15,481 individuals not included in the published vitamin D meta-analysis. Stratification of observational data by chronic kidney disease (CKD), defined as eGFR  $< 60$  ml/min/1.73m<sup>2</sup>, revealed an inverse vitamin D - eGFR association in 16,902 non-CKD individuals ( $\beta = -0.022$ ,  $p = 6.6 \times 10^{-6}$ ) and a positive association in the 1,275 CKD individuals ( $\beta = 0.015$ ,  $p = 6.5 \times 10^{-4}$ ). Vitamin D was not causally associated with UACR ( $\beta = 0.059$ ,  $p = 0.179$ ). The overall finding of an inverse causal relationship between vitamin D and eGFR is opposite to findings from observational studies, but the causal effect is very small: 10% vitamin D increase leads to 0.1% eGFR decrease. The direction of observational associations of vitamin D and eGFR changed in those with low kidney function, validating the contradicting results of the MR analyses and former observational studies. Our study gives insight into the relation of vitamin D and kidney function. Further investigation is warranted to fully understand the biology leading to the causal association.

**1968F****Differential metagenomic analysis associated between alcoholic and non-alcoholic fatty liver disease using 16S rRNA gene sequencing.**

Y. Yun<sup>1</sup>, H. Kim<sup>1</sup>, Y. Chang<sup>2</sup>, S. Ryu<sup>2</sup>, H. Shin<sup>2</sup>, H. Kim<sup>1</sup>. 1) Department of Biochemistry, Ewha Medical Research Institute, School of Medicine, Ewha Womans University; 2) 2Center for Cohort Studies, Total Healthcare Center, Kangbuk Samsung Hospital, School of Medicine, Sungkyunkwan University, Seoul, South Korea.

Alcoholic liver disease (ALD) and non-alcoholic fatty liver disease (NAFLD) share similar histological findings and many common pathogenic mechanisms, however which occur as a result of different causes, alcohol and obesity, respectively. Therefore, it's important to identify the differential disease progress which ends up to the same consequence. Emerging data demonstrate dysbiosis of the gut microbiota to be linked with ALD and NAFLD. But there is no report of comparing gut microbiota of these two condition in human. We used the data from a cross-sectional study of the Kangbuk Samsung Hospital Health Screening Center, between 23 June 2014 and 5 September 2014, which comprise three groups of 760 normal control, 297 NALFD, and 162 ALD. The fecal microbiota community of total 1219 samples was analyzed by pyrosequencing of the V3-V4 domain of the 16S rRNA genes. Alpha-diversity of ALD and NAFLD by phylogenetic diversity (PD) whole tree analysis was similar, while both were significantly lower compared to control ( $p < 0.001$ ). Three group showed significant far distant phylotypes between each other by ANOSIM test ( $p < 0.001$ ) of weighted UniFrac analysis. The decrease of Cyanobacteria and the increase of *Fusobacterium* were commonly associated in ALD and NAFLD. In contrast, *Paraprevotellaceae* and *Desulfovibrio* in ALD and *Methanobrevibacter* in NAFLD showed negative association uniquely. This might suggest a key distinguishable pathogenic mechanism between ALD and NALFD, which will contribute therapeutic development. [This research was supported by the National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2017R1D1A1B03035501, NRF-2016R1A6A3A1193 2719), Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI) funded by the Ministry of Health & Welfare (H14C0072), and Intramural research support program of Ewha Womans University School of Medicine.].

**1969W****Discovery of health disparities among African American patients at Vanderbilt University Medical Center.**

K. Atkins<sup>1,2</sup>, P. Straub<sup>2,3</sup>, N. Cox<sup>2,3</sup>, L. Davis<sup>2,3</sup> on behalf of the Precision Medicine and Health Disparities Collaborative. 1) Department of Physiology, Meharry Medical College, Nashville, TN; 2) Division of Genetic Medicine, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 3) Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Nashville, TN.

Knowledge of population-specific disease risk is critical to the mission of personalized medicine. Health conditions known to disproportionately affect African Americans including stroke, heart disease, and type 2 diabetes are not only more common, but are also more likely to result in complications and morbidity. Unrecognized health disparities pose a significant challenge to the promise of personalized medicine. We sought to discover novel health disparities in an African American patient population using the VUMC biobank (BioVU), a repository of DNA extracted from discarded blood collected during routine testing and linked to de-identified electronic medical records (EMR). We conducted a study of 29,370 individuals genotyped on the Illumina Human Exome Bead Chip and EIGENSTRAT was used to calculate principle components based on 4,388 ancestry informative markers. The first principal component (PC1) was found to represent the proportion of African ancestry. We performed a genome-wide association study (PheWAS), with PC1 as the dependent variable (smaller values indicating greater African ancestry) and sex as a covariate, to determine the association between African ancestry and 924 clinical phenotypes (each with at least 100 cases) extracted from the EMR. Individuals were considered "cases" if their EMR included least 3 occurrences of a qualifying ICD code. A total of 232 phenotypes exceeded the Bonferroni corrected p-value ( $5.41E-5$ ) for statistical significance. Hereditary hemolytic anemias (including sickle cell anemia) (OR = 0.92,  $p = 1.76E-100$ ) were the most significantly associated phenotypes. Additional known associations with African ancestry included asthma (OR = 0.97,  $p = 1.57E-57$ ) and, among adults aged 18 or older, end stage renal disease (OR = 0.96,  $p = 9.03E-70$ ), and chronic renal failure (OR = 0.97,  $p = 1.74E-68$ ) were also confirmed. We also identified a protective effect of African ancestry for "malignant melanomas" (OR = 1.07,  $p = 8.00E-39$ ). Finally, we discovered several novel associations with African ancestry including "fever of unknown origin" (OR = 0.98,  $p = 8.97E-78$ ), "acute upper respiratory infections" (OR = 0.99,  $p = 2.02E-72$ ), and "inflammatory diseases of female pelvic organs" (OR = 0.96,  $p = 9.91E-42$ ). An important limitation is the inability to distinguish genetic from environmental mediators of our reported associations. Future directions include incorporation of socioeconomic variables which may be mediating our results.

## 1970T

**Fetal but not maternal APOL1 genotype is associated with increased risk for preeclampsia among African-Americans.** C.L. Simpson<sup>1</sup>, K.J. Reidy<sup>2</sup>, R. Horton<sup>3</sup>, A.Z. **Background:** African Americans are at increased risk for preeclampsia. Genetic variants in the apolipoprotein L1 (*APOL1*) gene account for a substantial fraction of increased risk of kidney disease among African Americans. *APOL1* is expressed in human placenta, and transgenic mice expressing *APOL1* developed preeclampsia. The role of *APOL1* variants in human preeclampsia has not been studied. **Methods:** Two studies were performed evaluating maternal and fetal *APOL1* genotypes in African American women with preeclampsia. At Albert Einstein College of Medicine (AECOM) Affiliated Hospitals, we studied 122 pregnancies in African American women with preeclampsia. At University of Tennessee Health Science Center (UTHSC), we studied 93 pregnancies in African American women with preeclampsia compared to 793 control birth mothers and infants. **Results:** In both studies, fetal *APOL1* high risk (HR) genotype comprising 2 risk alleles was associated with preeclampsia in their mothers, relative risk at AECOM 1.65 (95% CI 1.11, 2.44) and odds ratio at UTHSC 1.92 (1.05, 3.49). In both studies, maternal *APOL1* HR genotypes were not associated with preeclampsia. Gestational age, birth weight and Cesarean section did not vary by *APOL1* genotype. Fetal *APOL1* HR genotype births with preeclampsia were not more likely to have severe preeclampsia, but those mothers were more likely to have cerebral or visual disturbances (63% versus 37%,  $p = 0.04$ ) and infants had lower APGAR scores at 5 minutes (8.0 versus 9.0,  $p = 0.01$ ). **Conclusion:** Fetal *APOL1* high-risk genotype confers an increased risk for preeclampsia, likely by adversely affecting placental function. *APOL1* genetic testing may have a clinical role to predict and perhaps improve pregnancy outcomes.

## 1971F

**Patterns of APOL1 G1 association with kidney function in young adults in five African diaspora populations.** B. Tayo<sup>1</sup>, H. Kramer<sup>1</sup>, A. Luke<sup>1</sup>, P. Bove<sup>2</sup>, T. Forrester<sup>3</sup>, E. Lambert<sup>4</sup>, J. Plange-Rhule<sup>5</sup>, R. Cooper<sup>1</sup>, R. Durazo-Arvizu<sup>1</sup>. 1) Public Health Sciences, Loyola Univ Chicago, Maywood, IL; 2) Institute of Social & Preventive Medicine, Lausanne University Hospital, Lausanne, Switzerland & Ministry of Health, Republic of Seychelles; 3) Tropical Medicine Research Institute, University of the West Indies, Mona, Kingston, Jamaica; 4) Research Unit for Exercise Science and Sports Medicine, University of Cape Town, Cape Town, South Africa; 5) Kwame Nkrumah University of Science and Technology, Kumasi, Ghana.

**Introduction:** The excess risk of end-stage renal disease in African Americans is now known to be attributable in part to *Apolipoprotein L1* gene (*APOL1*) risk variants G1 and G2 which are associated with higher risk of chronic kidney disease (CKD) initiation and progression in African Americans. Although these variants are specific to African ancestry populations, their frequencies vary among Afro-origin populations. It can be assumed that native African and other African diaspora populations share the increased predisposition to CKD as result of a common genetic background. **Goal:** The aim of the present study was to evaluate association of *APOL1* G1 with urine albumin and estimated glomerular filtration rate (eGFR) as markers for CKD in young adults from five African Diaspora populations. **Methods:** We measured urine albumin, serum creatinine and serum cystatin C in a cohort of 1561 non-diabetic unrelated adults from Ghana ( $n=211$ ), Jamaica ( $n=383$ ), Seychelles (263), South Africa (302) and the USA (402). Urine albumin-to-creatinine ratio (UACR), creatinine-based eGFR (eGFR-Scr) and cystatin C-based eGFR (eGFR-Scys) were calculated. All subjects were genotyped for *APOL1* rs73885319 and rs60910145 that were used to determine G1 haplotype. We tested for association of *APOL1* G1 with natural logarithm transformed UACR and eGFR under recessive genetic model using linear regression and controlled for age, sex and study site. Population stratification was controlled for by inclusion of principal components estimated from ancestry informative markers. CKD could not be analyzed as a dichotomous variable because there were few cases. **Results & conclusion:** Mean age and range in the cohort were  $34.4 \pm 6.2$  and 23–45 years. Mean UACR, eGFR-Scr and eGFR-Scys were  $12.9 \pm 71.3$  mg/g,  $143.7 \pm 18.5$  and  $124.3 \pm 15.4$  mL/min/1.73m<sup>2</sup>, respectively. Frequency of *APOL1* G1 was 21.2% overall; and 46.1%, 28.4%, 4.6%, 10.0% and 21.2%, in Ghana, Jamaica, Seychelles, South Africa, and USA, respectively. Associations with *APOL1* G1 in the cohort were significant for eGFR-Scr ( $p=1.2 \times 10^{-4}$ ) and UACR ( $p=0.0281$ ), and marginally for eGFR-Scys ( $p=0.0697$ ). There were significant associations ( $p<0.05$ ) with eGFR-Scr and UACR in the Ghana samples. These data represent the first report of patterns of *APOL1* G1 associations among young non-diabetic adults in African Diaspora populations. Additional studies that include both *APOL1* G1 and G2 risk variants are required to confirm these findings.

**1972W****Integrated linkage and rare variant association tests reveal rare variants associated with elevated androgen levels in polycystic ovary syndrome.**

M. Dapas<sup>1</sup>, R. Sisk<sup>1</sup>, R.S. Legro<sup>2</sup>, M. Urbanek<sup>1</sup>, A. Dunai<sup>1,3</sup>, M.G. Hayes<sup>1</sup>. 1) Northwestern University, Chicago, IL; 2) Penn State College of Medicine, Hershey, PA; 3) Icahn School of Medicine at Mount Sinai, New York, NY.

Polycystic ovary syndrome (PCOS) is a common endocrine disorder affecting up to 15% of premenopausal women worldwide. Common genetic susceptibility variants for PCOS account for little of the observed heritability. To test whether rare genetic variants were responsible for this heritability deficit, we implemented a novel bioinformatics pipeline that integrated linkage and rare variant association tests using whole genome sequencing data from 76 two-generation families with  $\geq 1$  daughters with PCOS. Variants were filtered according to allele frequency (MAF $\leq 2\%$ ), call quality, observed inheritance, predicted deleteriousness, and evidence for linkage. Associations between sets of rare variants and PCOS and its quantitative hormonal traits were assessed using burden tests, grouping variants at the gene-level (including 3' UTR and 7.5kb upstream of 5' TSS) and in sliding windows across the genome, accounting for relatedness, and adjusting for age and BMI. After correcting for multiple testing ( $P_c$ ), associations with dehydroepiandrosterone levels were found for rare variants in *FANCL* ( $P=2.61 \times 10^{-6}$ ,  $P_c=0.030$ ), *PTCH1* ( $P=6.57 \times 10^{-6}$ ,  $P_c=0.0081$ ), and an intergenic region upstream of *SFRP5* ( $P=2.38 \times 10^{-6}$ ,  $P_c=0.0029$ ). Associations were also found with luteinizing hormone levels for rare variants in *RHOD* ( $P=3.54 \times 10^{-6}$ ,  $P_c=0.041$ ). The strongest association of rare variants with testosterone (T) levels was found in the PCOS candidate gene *SRD5A2* ( $P=1.03 \times 10^{-5}$ ,  $P_c=0.12$ ). No significant associations were found with PCOS diagnosis, fasting insulin or sex hormone binding globulin levels. *FANCL* encodes a protein that is part of the Fanconi anemia (FA) core complex. The FA core complex also includes *FANCC*, whose gene is located in a PCOS GWAS susceptibility locus on chr. 9. The GWAS risk alleles in the *FANCC* locus are also in linkage disequilibrium with the rare variants we identified in nearby *PTCH1*, suggesting these variants contribute to that GWAS signal. *SFRP5*, which encodes a Wnt inhibitor, is differentially expressed in women with PCOS. *RHOD* is a regulator of actin cytoskeleton dynamics, a pathway linked to PCOS insulin resistance. *SRD5A2*, which metabolizes T, has previously been implicated in PCOS pathogenesis. Our study is the first to find evidence that rare variants contribute to elevated androgen levels in PCOS. Moreover, the variants identified in this study all lie in regions that correspond with relevant disease pathways, GWAS loci and/or established PCOS candidate genes.

**1973T****Genome-wide CNV analysis identifies *TGFBR3* as a candidate causal gene for endometriosis and infertility.**

E. Hatchwell<sup>1</sup>, K.T. Zondervan<sup>2,3</sup>, P.S. Eijs<sup>1</sup>. 1) Population Bio, Inc., Melville, NY; 2) Endometriosis CaRe Centre, Nuffield Department of Obstetrics & Gynaecology, University of Oxford, John Radcliffe Hospital, Oxford, UK; 3) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, UK.

Endometriosis is a gynecological complex disease characterized by chronic inflammation, pelvic pain, and reduced fertility. It is estimated to occur in 5-10% of women during their reproductive years and is frequently undiagnosed (e.g., the degree of pain does not necessarily correlate with the severity of the disease). Endometriosis heritability has been estimated at ~50%. Linkage studies on  $>1,100$  affected sister-pair families with a history of endometriosis revealed significant linkage peaks mapped to chromosomes 7 (in 2007) and 10 (in 2005) but the variants underlying these signals have not yet been found. The most recent GWAS on  $>17,000$  cases vs. 191,000 controls revealed 14 genetic loci, but the associated non-coding SNPs have small effect sizes, that collectively account for only 5% of disease risk, and leave as yet unanswered questions regarding the associated causal mechanisms. We used a copy number variant (CNV) method to identify additional genes/variants underlying the pathogenesis of endometriosis. Our CNV-based disease gene discovery method has two advantages over SNV-based methods: 1) variant interpretation is simpler because there are  $>1,000$ -fold fewer CNVs in the population as compared to SNVs, and 2) the large size of CNVs often unambiguously results in loss of function of the implicated gene. We performed genome-wide CNV analysis of blood-derived genomic DNA from endometriosis patients (all diagnosed via laparoscopic surgery) using array-based comparative genomic hybridization (aCGH). Interpretation of benign vs. potentially pathogenic CNVs was performed using our in-house CNV database and algorithms. The top gene that carried a potentially pathogenic CNV identified in our study was transforming growth factor, beta receptor III (*TGFBR3*, aka betaglycan). An intronic 8Kb deletion, which impacts predicted transcription factor binding sites, was found in 5 of 911 cases vs. 0 of 1,000 controls (OR = 12.1 (95% CI: 0.67-219.9),  $P_{\text{exact}} = 0.024$ ). In the subset of moderate/severe cases, the deletion was found in 4 of 449 cases (OR=20.2 (95% CI: 1.08-376.2;  $P_{\text{exact}}=0.009$ ). Segregation analysis of the *TGFBR3* deletion correlated with disease in at least 3 of 4 families that could be tested. Supporting biology for *TGFBR3* includes high gene expression in reproductive tissues (uterus, ovary, and placenta), involvement in the activin/inhibin pathway, and links to infertility, reproductive tissue cancers (breast, endometrial, and ovarian), and pain.

**Identification of lung cell populations from single-cell RNA-seq profiling of murine emphysema model.** J.H. Yun<sup>1,2</sup>, C.H. Lee<sup>3</sup>, R. Kirchner<sup>4</sup>, S. Boswell<sup>5</sup>, P. Castaldi<sup>6</sup>, L. Pinello<sup>5</sup>, X. Zhou<sup>2</sup>. 1) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 3) Department of Genetics, Harvard Medical School, Boston, MA; 4) Harvard Chan Bioinformatics Core, Boston, MA; 5) Single Cell Core, Harvard Medical School, Boston, MA; 6) Department of Pathology, Massachusetts General Hospital, Boston, MA.

**Background:** Emphysema is a chronic lung disease characterized by destruction of alveolar space and capillaries that constitutes chronic obstructive pulmonary disease (COPD) along with chronic bronchitis. *Hhip* (Hedgehog Interacting Protein) is a well-replicated GWAS-identified gene associated with COPD, and we have shown that *Hhip* haploinsufficient mice (*Hhip*<sup>-/-</sup>) developed age related emphysema and increased lymphocyte aggregates, similar to emphysema in human patients. The lung is composed of over 40 cell types, and multiple cell types are implicated in the development of emphysema. As traditional bulk RNA profiling approaches are limited in understanding the specific role of each cell types in emphysema pathogenesis, we performed single cell RNA sequencing (scRNA-seq) in wild type and *Hhip* heterozygous mice before and after the onset of emphysema. **Methods:** Lungs isolated from 2 and 8 months old *Hhip*<sup>-/-</sup> and its littermate C57BL/6 wild type mice (n=2 each) were mechanically minced, enzymatically dissociated and gradient centrifuged to generate epithelial-cell enriched single cell suspension. scRNA-seq was then performed on 3,000 unsorted cells per murine lung using inDrops, where the cell capture, lysis and reverse transcription of RNA from single cells occurs in droplets. cDNA libraries were constructed and paired end sequencing was performed with Illumina NextSeq. Reads were filtered and aligned using established inDrops processing pipeline. Data analysis was performed in R using the Seurat package. **Results:** Unsupervised clustering revealed clusters with expression patterns consistent with known lung tissue cell types such as alveolar cell types (Type I, II), endothelial cells, fibroblasts, and immune cells (macrophages, myeloid cells) as well as distinct clusters of apparently novel cells types with distinct molecular cell profiles. With the relatively large number of cells profiled, potential rare and novel cell populations may be identified and validated by histology. Older *Hhip*<sup>-/-</sup> mice exhibited a higher proportion of immune cell types than their wildtype controls, consistent with pathologic observations of increased lymphoid aggregates in the older *Hhip*<sup>-/-</sup> mice. In addition, cell types enriched with *Hhip* expression could be identified. **Conclusion:** Unbiased single cell RNAseq in murine lung identifies known and potentially novel cell types and confirms an increased proportion of inflammatory cells in the aged lung of *Hhip* heterozygous mice.

## 1975W

**The multi-phenotype derived Nephrotic Syndrome Severity (NS2) score empowers genomic discovery.** C.E. Gillies<sup>1</sup>, K. Yasutake<sup>1</sup>, X. Wen<sup>2</sup>, M.G. Sampson<sup>1</sup>. 1) Department of Pediatrics-Nephrology, University of Michigan, Ann Arbor, MI; 2) Department of Biostatistics, University of Michigan, Ann Arbor, MI.

**Background:** Among patients with nephrotic syndrome (NS), we are interested in discovering genomic factors associated with disease severity over time. This requires creating accurate models to represent NS biology and a statistical strategy that takes advantage of deep phenotypic data but accounts for modest sample sizes and multiple testing. Thus, we developed a Nephrotic Syndrome Severity ("NS2") score for patients in the Nephrotic Syndrome Study Network (NEPTUNE). **Methods:** NEPTUNE is a prospective, longitudinal study of NS enrolling affected adults and children receiving a clinically indicated biopsy. Rich demographic and clinical data are collected at baseline and over time. Genomic and histologic data are collected at baseline. We used the following parameters to create the multi-phenotype NS2 score: interstitial fibrosis, eGFR, protein-to-creatinine ratio, eGFR slope, time to complete remission, and time to a composite endpoint. We modeled the relationships between these variables and meaningful covariates using a Bayesian network (BN). The NS2 score represents a latent factor explaining the correlations in the observed data. The BN's parameters were inferred from 616 patients NEPTUNE participants using Markov chain Monte Carlo. **Results:** Compared to existing multi-phenotype methods, NS2 score increased power for discovery without inflating Type I error. With regards to known biomarkers of NS severity, a worse NS2 score was significantly associated with the *APOL1* high-risk genotype in black patients ( $p < 2.2 \times 10^{-5}$ ) and lower tubulointerstitial expression of *EGF* ( $p < 5.7 \times 10^{-10}$ ). After FDR control, 1,040 glomerular transcripts were significantly associated with NS2 score. Using geneset enrichment analysis, kidney development genes were among the most enriched NS2-associated glomerular transcripts in adults ( $p < 5.3 \times 10^{-9}$ ), including 15 known Mendelian SRNS genes. In children, "TNF alpha induced protein 3" was the gene whose expression was most associated with NS2 score. **Conclusion:** The NS2 score is a robust metric created by capitalizing on extensive clinical data and NS-specific knowledge. As a robust multi-phenotype method, it improved statistical power for discovery without inflating false positives and replicates known genomic associations. Thus, using NS2 score as an outcome measure in analyses ranging from gene expression correlation to GWAS may empower genomic discoveries.

**1976T**

**Transcriptomic analysis of the ratio of serum aspartate transaminase to serum alanine transaminase (Ast/Alt ratio) using a genotype-by-diet interaction model identifies a number of potentially important genes for liver disease in the San Antonio Family Heart Study.** *V.P. Diego, J.M. Peralta, M. Almeida, H.H.H. Göring, M. Johnson, J.E. Curran, S. Williams-Blangero, J. Blangero.* South Texas Diabetes and Obesity Institute, University of Texas Rio Grande Valley, Brownsville, TX.

The ratio of serum aspartate transaminase to serum alanine transaminase (Ast/Alt ratio) is a well-known biomarker of liver function in general and non-alcoholic fatty liver disease (NAFLD) in particular. The latter, NAFLD, has risen in prevalence largely in conjunction with the rise of metabolic syndrome, type 2 diabetes (T2D), and obesity, and this is especially true in Mexican Americans. We therefore sought to better understand the genetic determinants of NAFLD in the Mexican American study participants of the San Antonio Family Heart Study. Several studies have shown that diet significantly modulates liver function and Ast/Alt ratio. Thus, in our model we accounted for any potential diet effect by way of a genotype-by-diet interaction (GDI) model. To model a dietary effect we estimated the Mahalanobis distance (MD) kernel over all vectors of dietary data in our study, and used this MD kernel to estimate a corresponding dietary variance component (VC). The dietary variables consist of major macronutrients (i.e. mono- and polyunsaturated fats; saturated fats; carbohydrate; proteins; alcohol; and simple sugars) measured by percent of caloric intake and by estimated grams of the macronutrient. Under the GDI model, we modeled interaction by taking the Hadamard product of our genetic relationship kernel with the MD kernel and using this new kernel to estimate a GDI VC. With this model as our foundation, we then tested for the significance of a transcript by adding a single transcript to the model as an independent predictor variable. This analysis was performed over 22,353 gene transcripts found to be significantly heritable in our previous work. We found 10 gene transcripts to be significantly associated with Ast/Alt ratio, where their p-values fell under the corrected significance threshold. Under a less stringent correction, we found 29 more gene transcripts to be suggestively associated with Ast/Alt ratio. These results show that there are important genetic determinants underlying the variation in Ast/Alt ratio and, presumably, are involved in the progression to NAFLD.

**1977F**

**Chromatin interactions reveal novel gene targets for drug repositioning in rheumatic diseases.** *P. Martin<sup>1</sup>, K. Duffus<sup>1</sup>, A. McGovern<sup>1</sup>, A. Yarwood<sup>1</sup>, A. Barton<sup>1,2</sup>, J. Worthington<sup>1,2</sup>, S. Eyre<sup>1</sup>, G. Orozco<sup>1</sup>.* 1) Arthritis Research UK Centre for Genetics and Genomics, University of Manchester, Manchester, United Kingdom; 2) NIHR Manchester Musculoskeletal Biomedical Research Unit, Central Manchester Foundation Trust, Manchester Academic Health Science Centre, Manchester, United Kingdom.

The treatment of rheumatic diseases can be both expensive and ineffective with up to 1/3 of patient's failing to respond to current treatments and costing the NHS around \$4.5 billion annually. There is therefore a need to identify new treatments and to target these to individual patients. Although genetic studies have been successful in identifying common variation associated with disease susceptibility, a large proportion of these lie outside protein-coding regions. Many show enhancer activity but it is often unclear which gene(s) they regulate and how they contribute to disease. Chromatin folding brings linearly distant areas of the genome, such as promoters and enhancers, into close proximity, driving gene expression. Capture Hi-C (CHI-C) interrogates these interactions in a high-throughput, high-resolution manner, linking implicated enhancers to causal genes. We explored our existing CHI-C data on 3 rheumatic diseases, rheumatoid arthritis, juvenile idiopathic arthritis and psoriatic arthritis, targeting all known genetic associations, for the potential to identify candidate causal genes that are targets for existing drugs, which could be repositioned for use in these diseases. Chromatin interaction data for T- and B-cells in the 3 diseases was analysed using CHiCAGO v2, interactions between disease enhancer regions and active promoters were identified using BEDTOOLS v2.21.0 and intersected with drug targets from DrugBank v5.0.1. Overall 454 genes were identified as interacting with a disease associated region showing enhancer activity. Of these, 41 are existing drug targets (92 drugs), defined by the presence of the relevant name in the 'indication' field, and 9 are existing therapies used in the treatment of RA. Following pathway analysis of the implicated genes we identified a potential 275 drugs (202 genes) which could be repositioned. Importantly, over 90% of the drugs currently used to treat RA were identified showing the effectiveness of this approach. Our study also identified potential new targets within enriched pathways. We have identified genes which are implicated in disease, are the target of existing drugs and offer the potential for drug repositioning as well as targets involved in the same pathway. This data shows a novel insight into how functional annotation of genetic associations in rheumatic diseases can provide gene targets for re-positioned therapies.

**Genetic burden contributing to extremely low or high bone mineral density in a senior male population from MrOS study.**

S. Chen<sup>1</sup>, M. Jain<sup>2</sup>, S. Jhangiani<sup>3</sup>, Z. Coban Akdemir<sup>4</sup>, P. Campeua<sup>5</sup>, B. Klein<sup>4</sup>, C. Nielson<sup>4</sup>, D. Muzny<sup>6</sup>, E. Boerwinkle<sup>7</sup>, R. Gibbs<sup>1,5</sup>, E. Orwell<sup>4</sup>, J. Lupski<sup>1,5,6</sup>, J. Posey<sup>7</sup>, B. Lee<sup>1</sup>.

1) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Osteogenesis Imperfecta Clinic at Kennedy Krieger Institute, Baltimore, MD; 3) University of Montreal Medical Genetics Service, Montréal QC Canada; 4) Oregon Health & Science University Portland, Oregon; 5) Human Genome Sequencing Center Baylor College of Medicine, Houston, TX; 6) Department of Pediatrics, Baylor College of Medicine and Texas Children's Hospital, Houston, TX; 7) Human Genetics Center and Dept. of Epidemiology, UTHealth School of Public Health, Houston, TX.

**Purpose of the study** Worldwide, 1 in 5 men aged over 50 will experience osteoporosis and a clinical bone fracture and suffer from a greater fracture related mortality rate than women. However, the mechanism(s) underlying osteoporosis in men remains unknown. We aimed to identify genes associated with extremely low or high bone mineral density (BMD) as a potential means to elucidate contributing gene variants involved and possibly gain an understanding of biological processes underlying bone density loss that may point to potential therapeutic targets for increasing bone mass. **Methods** Subjects (<75) from the MrOS cohort were screened for BMD abnormalities consistent with phenotypic extremes. Low BMD is defined as having both hip DXA and vertebral QCT values in the 1st or 2nd decile while high BMD is defined as having both values in the 9th or 10th decile. To reduce inadvertent inclusion of low BMD resulting from a Mendelian disease, those with BMD beyond 3 sd were excluded. Controls were from CEU population of 1000 Genomes. In total, 90 low BMD, 99 high BMD and 82 controls were identified for WES at the Baylor HGSC as part of the BHCMBG program. WES data were filtered and parsed for rare variants with allele frequency < 1% in Caucasian population. Fisher's Exact test was performed to compare low BMD or high BMD subjects to controls for single-gene associations. Additionally, sets of genes causative of either Osteogenesis Imperfecta (OI) or Ehlers-Danlos syndrome (EDS) were grouped together for multi-gene analyses. **Results** No single gene associations with rare variants were found for either low BMD (n=30) or high BMD (n=18). Of note, rare variants in *FKBP10*, *SERPINF1*, *SERPINH1*, *SP7*, *TMEM38B* and *WNT1* were only detected in low or high BMD individuals but not in controls. By grouping 'OI genes' (*CRTAP*, *FKBP10*, *LEPRE1*, *PPIB*, *SERPINF1*, *SERPINH1*, *SP7*, *TMEM38B*, *WNT1*) together, we were able to detect a significant 3-fold increased accumulation of rare variants in low BMD subjects compared to controls (p=0.009). Additionally, genes associated with EDS (*SLC39A13*, *B4GALT7*, *COL3A1*, *COL5A1*, *COL5A2*) demonstrated a significant 2-fold increased frequency in low BMD subjects compared to controls (p=0.03). Overall, our study demonstrated an association between the accumulation of rare variants with low BMD, by using a multi-gene signature implicated in OI or EDS. These findings can direct a gene-panel approach to screen for additional multi-variant associations in a larger cohort.

## 1979T

**An integrative analysis of gene expression profiling and genome-wide DNA methylation datasets shows a different underlying molecular mechanism between Kashin-Beck disease and osteoarthritis.**

Y. Wen, P. Li, W. Wang, J. Hao, J. Han, A. He, Y. Du, L. Liu, X. Liang, X. Guo, F. Zhang. School of Public Health, Health Science Center, Xi'an Jiaotong University, Xi'an, Shaanxi, China.

**Background:** Kashin-Beck disease (KBD) is an endemic and chronic osteochondropathy with unknown etiology, which mainly occurs to children aged from 3 to 13. Osteoarthritis (OA) is a kind of degenerative joint disease distributing worldwide, sharing some characteristics on the manifestation and pathological changes of the articular with KBD. This study is to investigate the differences in gene expression profiling and DNA methylation level of articular cartilage from KBD versus those from OA. **Methods:** In this study, we conducted a genome-wide DNA methylation study in the cartilage chondrocytes of KBD compared to those of OA with Illumina Infinium HumanMethylation450 BeadChip. Furthermore, by utilizing a gene expression profiling dataset in the articular cartilage of KBD compared to OA published previously, an integrative analysis was conducted using the two datasets in IncroMap. **Result:** By performing integrative enrichment analysis, 19 KEGG pathways were identified to be alerted in the cartilage chondrocytes of KBD relative to OA both in the gene expression and DNA methylation levels, including mTOR signaling ( $P = 0.0301$ ), glycosaminoglycan biosynthesis-chondroitin sulfate/dermatan sulfate ( $P = 0.0391$ ), glycosaminoglycan biosynthesis-keratan sulfate ( $P = 0.0278$ ) and PI3K-Akt signaling ( $P = 0.0243$ ). Several genes, such as *TGB3* (expression ratio = 0.6643,  $P_{\text{methy}} = 0.0164$ ), *TGFBR2* (expression ratio = 1.5432,  $P_{\text{methy}} = 0.0370$ ), *JAK1* (expression ratio = 1.5282,  $P_{\text{methy}} = 3.97E-03$ ) were also found to be commonly differently methylated and expressed in KBD relative to OA. **Conclusion:** Our study results illustrated a different molecular mechanism and biological networks underlying KBD compared to OA.

**1980F**

**Identification of genetic variants associated with knee OA in patients with knee replacement surgery.** Y. Zhang<sup>1</sup>, S.A. Lietman<sup>2</sup>, S.A. Pendergrass<sup>3</sup>, G. Bang<sup>3</sup>, J.E. Miller<sup>3</sup>, D. Kim<sup>3</sup>, K.A. Kost<sup>4</sup>, M.T.M. Lee<sup>1</sup>. 1) Geisinger Genomic Medicine Institute, Geisinger Health System, Danville, PA; 2) Orthopedic Department, Geisinger Health System, Danville, PA; 3) Biomedical & Translational Informatics Institute, Geisinger Health System, Danville, PA; 4) Phenomics Core, Geisinger Health System, Danville, PA.

**Background:** GWAS have identified approximately 25 susceptibility loci associated with osteoarthritis (OA). However, only a few of them have been replicated. For knee OA, most studies used Kellgren and Lawrence (K-L) grade as a way to define cases ( $\geq 2$ ) and controls (0 and 1). However, the use of K-L grade is very subjective and neglects the variability of OA phenotypes. In addition, existing studies have not controlled for many risk factors during study design, such as injury or trauma history, hip dysplasia, and age. Thus, heterogeneity of the disease and inadequate study designs may cause the lack of replication. To overcome these limitations, we conducted a knee OA GWAS in patients with severe (end stage) OA who underwent knee replacement surgery from the Geisinger Health System MyCode® Community Health Initiative. **Method:** Illumina OMNI Express array genotyping data (MAF > 1%) from the DiscovEHR collaboration of the MyCode Community Health Initiative at Geisinger and Regeneron Genetics Center was used for this study. EHR data was used to retrospectively identify cases and controls. Patients with rheumatoid arthritis and knee trauma/injury were excluded from analysis. Cases were patients who had knee OA diagnosis and underwent total knee joint replacement. BMI and gender matched MyCode participants who were > 65 years old and without any history of OA in any joints were selected as controls. 1938 cases and 3293 controls from 59,499 genotyped participants in MyCode were identified. Models were adjusted for age, sex, BMI, smoking, diabetes status, and the first two principle components. **Results:** Seven SNPs with suggestive association ( $p < 1 \times 10^{-5}$ ) were identified. The most significant SNP (rs2174299,  $p = 4.97 \times 10^{-7}$ ) was in an intergenic region overlapping a long noncoding RNA. One SNP (rs743742,  $p = 4.28 \times 10^{-6}$ ) was found near the gene *TIMP3*. *TIMP3* belongs to the TIMP gene family, which are inhibitors of the matrix metalloproteinases, a group of peptidases involved in degradation of the extracellular matrix. This may involve in the degradation of cartilage in OA. Additionally, some SNPs reside in gene regulatory regions as defined by RegulomeDB, thus providing insight as to how the genetic variants may have functional consequences. **Conclusion:** Our results highlight the importance of performing GWAS for OA using different phenotypic information that better reflects OA. Future work will include larger sample size and further exploration of OA phenotypic variability.

**1981W**

**Evaluation of shared genetic aetiology between osteoarthritis and bone mineral density identifies SMAD3 as a novel osteoarthritis risk locus.** S. Hackinger<sup>1</sup>, K. Osteoarthritis (OA) is a common complex disease with a high public health burden and no curative therapy. The risk of developing OA is correlated with high bone mineral density (BMD), suggesting a shared underlying biology. However, despite a large body of epidemiological research into this association, the genetic overlap between OA and BMD has not yet been assessed on a genome-wide scale. Here, we investigated the shared genetics of OA and BMD using data from the arcOGEN and GEFOS consortia – the two largest genome-wide association studies (GWAS) for these respective traits published to date. We performed pairwise comparisons of summary statistics from the GEFOS consortium for lumbar spine ( $n = 31,800$ ) and femoral neck ( $n = 32,961$ ) BMD, and from the arcOGEN consortium for three OA phenotypes (hip,  $n_{\text{cases}} = 3,498$ ; knee,  $n_{\text{cases}} = 3,266$ ; hip and/or knee,  $n_{\text{cases}} = 7,410$ ;  $n_{\text{controls}} = 11,009$ ). Using LD score regression to estimate genetic correlation on a genome-wide scale, we found a significant correlation between the combined OA phenotype (hip and/or knee) and lumbar spine BMD ( $r_g = 0.18$ ,  $p = 2.23 \times 10^{-2}$ ). To identify distinct variants exerting cross-phenotype effects, we searched for shared association signals across different p-value cut-offs and performed a Bayesian co-localisation analysis to search for genomic regions harbouring pleiotropic signals. From these analyses we took forward 143 variants with evidence of cross-phenotype association for replication in independent large-scale OA datasets, and subsequent meta-analysis with arcOGEN for a total sample size of up to 23,425 cases and 236,814 controls. We found robustly replicating evidence for association with OA at rs12901071 (OR 1.08 95% CI 1.05-1.11,  $p_{\text{meta}} = 3.12 \times 10^{-10}$ ), an intronic variant in the *SMAD3* gene, which is known to play a role in bone remodeling and cartilage maintenance. Our findings provide the first systematic evaluation of pleiotropy between OA and BMD, highlight genes with biological relevance to both traits, point towards shared biological mechanisms involving both cartilage and bone homeostasis, and establish a robust new OA genetic risk locus at *SMAD3*. This work exemplifies the added power that can be afforded by considering shared genetic determinants for complex traits of medical relevance.

**1982T**

**Identification of *IRF4*, *NOTCH4* and *RPS12* genes for non-syndromic sagittal craniosynostosis in a genome-wide association study using logistic regression.** H. Sung<sup>1</sup>, CM. Justice<sup>1</sup>, L. Brody<sup>2</sup>, PA. Romitti<sup>3</sup>, SA. Boyadjiev<sup>4</sup>, AF. Wilson<sup>1</sup>. 1) Genometrics Section, NIH/NHGRI/CSGB, Baltimore, MD; 2) Medical Genomics and Metabolic Genetics Branch, NHGRI, NIH, Bethesda, MD, USA; 3) Department of Epidemiology, College of Public Health, The University of Iowa, Iowa City, IA, USA; 4) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA, USA.

Craniosynostosis, the premature closure of the cranial vault sutures, is a common congenital anomaly with sagittal non-syndromic craniosynostosis (sNSC) being the most common form of craniosynostosis. Justice et al. [2012] identified candidate loci for sNSC near *BMP2* and in *BBS9* by performing a Transmission Disequilibrium Test (TDT) on case-parent trios, which were recruited through the International Craniosynostosis Consortium [genetics.ucdmc.ucdavis.edu/icc.cfm]. Because there is low correlation between association results from logistic regression analysis and the TDT [Sung et al. 2008 and Eu-ahsunthornwattana et al. 2014], logistic regression analysis was performed on case-control data with the affected probands from Justice et al. [2012] as cases and healthy individuals from GWAS Trinity study [Desch et al. 2013] as controls. Both the case and control data were previously genotyped on the Illumina 1M human Omni1-Quad array. Samples with a genotyping rate less than 80% and Single Nucleotide Polymorphisms (SNPs) with a call rate less than 98% and a Minor Allele Frequency (MAF) less than 1% were excluded from the combined data for further analysis. Logistic regression in PLINK was performed on 748,100 SNPs in 127 sNSC children and 2,359 Trinity controls. In addition to the SNPs in or near *BMP2* and *BBS9* found by TDT analysis, logistic regression analysis identified additional SNPs associated with sNSC at the genome-wide significance level after Bonferroni correction, in or near genes including *IRF4*, *NOTCH4* and *RPS12*. Each of these genes is located on chromosome 6 and the most significant SNP identified for each gene was rs12203592 in the intronic region of *IRF4* ( $p < 1e-18$ ), rs371156 in the intergenic region between *NOTCH4* and *c6orf10* ( $p < 1e-10$ ) and rs9493468 in the intergenic region of the *RPS12* and *LINC00326* ( $p < 1e-13$ ). The *IRF4* gene is known to be one of the top 50 genes which were differentially expressed by prematurely fused human sutures [Coussens et al. 2008]. The *NOTCH4* gene is involved in embryonic development where NOTCH plays a critical role in skeletal development and homeostasis [Zanotti and Canalis, 2010 and 2016]. The *RPS12* gene is found to be one of the enriched genes in expression analyzing transcription profiles of human pharyngeal arch 1 [Cai et al., 2005]. Further investigation of these genes will be necessary to better understand the etiology of sNSC.

Background As genomic study continues to develop recently, genetic variates related to the diseases of human-beings are widely reported, including the copy number variants (CNVs) and single-nucleotide polymorphisms (SNPs). Nonetheless, the association analysis does not ensure successful identification of the causal variants. Incurred by the coexistence of CNVs and SNPs in the same genomic region, the probable bias of pathogenicity assignment and bioinformatic analysis has not been carefully examined. Characterized with the compound inheritance model which includes a common hypomorphic allele and a deletion of the *TBX6* gene, congenital scoliosis (CS)'s genetic etiology has been reported recently. Methods To simulate the scenario, a data set which has been experimentally validated was adopted as a realistic model from a CS cohort, which including 161 unrelated sporadic CS patients enrolled from the Peking Union Medical College Hospital (PUMCH) in China between October 2010 and June 2014 and 166 unrelated healthy controls. Results Per the association analysis, the apparent prevalence of the *TBX6* hypomorphic haplotype can be enhanced by the deletion in the population of patients, which resulted in overestimation of the SNPs' pathogenic contribution in the same region. Moreover, we found that around 10% of significant SNPs as identified by genome-wide association studies were located in the same region with common CNVs (frequency > 1%) and 99.69% overlapping the pathogenic CNVs. It shows that miscalculation widely exists. In addition, a generalized model was introduced to show the mechanism through which CNVs result in the association power's miscalculation. Conclusion A conceptual pipeline is put forward about how to prevent miscalculation in the association analysis of SNPs. Also, to reveal the potential inheritance model, SNPs should be assessed in relation to other forms of genetic variates.

**Osteoporosis-associated risk variant in distal enhancer at 1p36.12 regulates expression of long noncoding RNA through long-range loop formation.** Y. Guo, X.F. Chen, D.L. Zhu, M. Yang, B.J. Lu, Y.Y. Duan, Y. Rong, S.S. Dong, T.L. Yang. School of Life Science and Technology, Xi'an Jiaotong University, Key Laboratory of Biomedical Information Engineering of Ministry of Education, Xi'an, Shaanxi, China.

Genome-wide association studies (GWASs) have reproducibly associated variants within noncoding regions of chromosome 1p36.12 with osteoporosis, but the molecular mechanisms of how specific risk variants functionally contribute to the underlying pathogenesis are unknown. Traditional identification of pathogenic genes usually focus on genes closest to the GWAS hits, which may not be the true target. The aim of this study was to identify the target gene(s) and the functional variant(s) underlying the association between SNPs at 1p36.12 and osteoporosis, through integrative analysis combining data from expression quantitative trait locus (eQTL), genomic chromatin interaction (Hi-C), epigenomic profiles and functional assays. We demonstrate that three functional intergenic SNPs (rs6426749, rs6684375, rs34963268) at 1p36.12 act as distal allele-specific enhancers regulating expression of a lncRNA (*LINC00339*) via long-range chromatin loop formation. This loop is regulated by CTCF occupied in the loop boundaries. Specifically, rs6426749-G allele could bind to transcription factor TFAP2A, which efficiently elevates the enhancer activity and increases the *LINC00339* expression. Downregulation of *LINC00339* significantly increase the expression of *CDC42* in osteoblast cells, which is a pivotal regulator involved in bone metabolism. Together, our findings elucidate a potential mechanistic basis that a functional noncoding SNP rs6426749 obliquely regulates *CDC42* via *LINC00339*. Our study provides a novel mechanistic insight into how a noncoding SNP affects osteoporosis by long-range interaction, which would be promising therapeutic targets for osteoporosis.

**Broad mutation spectrum of *FBN1* gene implicated in a cohort of idiopathic scoliosis and its related genotype-phenotype correlation study.** M. Lin<sup>1,2</sup>, Y. Chen<sup>1,2</sup>, W. Chen<sup>1,2</sup>, Y. Zuo<sup>2</sup>, J. Liu<sup>3,4,5</sup>, G. Liu<sup>2</sup>, S. Liu<sup>2</sup>, G. Qiu<sup>2,4</sup>, N. Wu<sup>2,4,5</sup>, Z. Wu<sup>1,4,6</sup>. 1) Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, Beijing, China; 2) Department of Orthopaedic Surgery, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China; 3) Breast Surgical Oncology, Cancer Hospital of Chinese Academy of Medical Sciences, Beijing 100021, China; 4) Beijing Key Laboratory for Genetic Research of Skeletal deformity; 5) Medical Research Center of Orthopaedics, Chinese Academy of Medical Sciences, Beijing China; 6) Department of Central Laboratory, Peking Union Medical College Hospital, Beijing 100730, China.

**Background** Idiopathic scoliosis (IS) causes spinal deformity in 3% of children. Notwithstanding a strong genetic basis, few genes have been reported associated with IS and the pathogenesis remains to be elucidated. Etiology of IS is still unclear. We previously demonstrated a compound heterozygous model in which a null allele mutation in combination with a common haplotype of *TBX6* causes congenital scoliosis, suggesting that genetic factors play a significant role in vertebral malformation (VM). Hence, we established an in silico designed target panel comprising genes previously known to cause VM. *FBN1* is included in the panel. Fibrillin-1 encodes a large glycoprotein, fibrillin constitutes a cluster of large extracellular proteins that form the core of highly ordered extended and universally distributed aggregates, termed microfibrils. In this study, we report that the loss of function mutations of *FBN1* gene may contribute to IS. **Methods** We enrolled 102 patients diagnosed as IS in Peking Union Medical College Hospital (PUMCH) in China between October 2010 and November 2015. The IS diagnosis were confirmed by radiological imaging. Whole genome sequencing (WGS) was performed in 102 sporadic IS cases with additional 325 Han Chinese patients radiologically confirmed with vertebral malformation Target sequenced by an in silico designed target panel. **Results** We identified two novel *FBN1* frameshift mutations (c.7785delC, p.Y2596Tfs\*86; c.8275\_8291delGAGAAGACGCCATCTT, p.E2759Cfs\*9) in two unrelated patients by panel sequencing, respectively. These two variants did not exist in ExAC, 1000 Genome, ESP6500 database, universal mutation database (UMD) or any literature. The variants were possibly contributing to the phenotypes, but of uncertain significance. Moreover, the two patients were diagnosed Marfan syndrome based on the revised Ghent criteria. Furthermore, we also identified three *FBN1* missense mutations in highly conserved domain and one novel rare *FBN1* splicing defect by WGS. **Conclusions** Up to our knowledge, our findings indicated that loss of function mutations in *FBN1* might contribute to spinal deformity formed of IS. Our data showed that IS patients were inclined to harbor *FBN1* mutations, recapitulating the vital role of *FBN1* in the pathogenesis of IS.

## 1986F

**PheWAS meta-analyses on bone microarchitecture phenotypes assessed by HR-pQCT and CRISPR/Cas9 gene-editing in zebrafish identify novel genetic risks of osteoporosis and fractures: The Bone Microarchitecture International Consortium (BoMIC).** Y.H. Bone microarchitecture assessed by high resolution peripheral quantitative computed tomography (HR-pQCT) has been reported to be heritable even after adjusting for DXA-based areal BMD (aBMD), and has been associated with fracture risks. Genetic studies of these phenotypes may reveal unique, novel genes that contribute to skeletal integrity not identifiable in previous genome-wide association studies (GWAS) of aBMD. Thus, our objective was to conduct such a whole genome association study. We performed an expanded whole genome association meta-analysis on both rarer functional variants and common variants in 5,692 adult Caucasians obtained from 7 cohort studies (FHS, Mayo Clinic, GeRiCo, Lyon OFELY, Lyon STRAMBO, MrOS Sweden and GOOD Study) and replicated on top associated SNPs in 2,100 independent samples (CaMOS and Lyon Qualyor studies). HR-pQCT (XtremeCT, Scanco Medical AG) bone structure traits were assessed (Table 1). All studies were genotyped by SNP chips and whole genome imputation to ~40 million SNPs was performed based on the Haplotype Reference Consortium. We used either linear regression or mixed-effects model (family-based) for single SNP-phenotype associations. Additive genetic effect models were applied and adjusted for age, sex, weight and genetic ancestry. For less common variants (MAF < 1%), we performed gene-based Optimal SKAT test in each study. Meta-analysis was performed to combine association results. Of the 17 genome-significant loci (386 SNPs with  $p < 5 \times 10^{-8}$ ), 12 were not reported by previous aBMD GWAS meta-analyses: SIX2, PNPT1, chr4q35.2, KCNIP1, chr5q11.2, chr7q31.31, CSMD1, NRG1, PTHLH-CCFC91, FAM155A, C3 and FMN2 loci. The majority of these loci were specifically associated with  $\mu$ FEA-FL, TtAr, CtTh, TbSp, TbN or CtBMD. The most significantly associated SNP, rs10254825, was positively associated with FL ( $p=2.6 \times 10^{-23}$ ) and previously associated with fracture in GWAS meta-analyses. The remaining 5 loci (ZBTB40, SPTBN1, MEF2C-AS1, WNT16-FAM3C and AKAP11-TNFSF11) were previously reported by aBMD GWAS and are associated with multiple HR-pQCT phenotypes at both radius and tibia (e.g., TbBMD, TtBMD, TbSp). Our findings suggest that the genetic control of bone microarchitecture may provide additional insights into the pathogenesis of skeletal integrity not available from aBMD. Genome editing in zebrafish using the CRISPR/Cas9 on selected genes from the novel loci is underway to dissect the potential functional involvement in bone biology.

**Novel genetic risk factors identified from a genome-wide association study for lumbar disc degeneration in Southern Chinese.** Y. Li<sup>1,4</sup>, P. Gao<sup>2</sup>, X. Zhou<sup>2,4</sup>, K.M.C. Cheung<sup>3</sup>, K.D.K. Luk<sup>3</sup>, J. Karppinen<sup>5,6</sup>, Y.Q. Song<sup>2</sup>, K.S.E. Cheah<sup>2</sup>, D. Chan<sup>2</sup>, P.C. Sham<sup>1,4</sup>. 1) Center for Genomic Sciences, The University of Hong Kong, Hong Kong, SAR, China; 2) School of Biomedical Science, The University of Hong Kong, Hong Kong, SAR, China; 3) Department of Orthopedics and Traumatology, The University of Hong Kong, Hong Kong, SAR, China; 4) Department of Psychiatry, The University of Hong Kong, Hong Kong, SAR, China; 5) Medical Research Center Oulu, University of Oulu and Oulu University Hospital, Oulu, Finland; 6) Finnish Institute of Occupational Health, Health and Work Ability, and Disability Prevention Center, Oulu, Finland.

**Background** Lumbar disc degeneration (LDD) is a major etiological risk factor for low back pain (LBP), which is a common and disabling condition, affecting 80% of the general population at some time in life. LDD has been reported to have a substantial genetic component with up to 74% heritability. Most reported LDD associated genes are from candidate gene studies, only one meta-analysis was published based on European individuals. There is much missing heritability need to be explained and all candidate genes need to be tested in Southern Chinese population using an unbiased genome-wide approach. **Method** This study aimed to identify genetic variants associated with LDD in Southern Chinese population. Both single and combined MRI phenotypes were used for genome-wide association study (GWAS) in 2,200 subjects with Southern Chinese origin. Moreover, to improve the power of GWAS, cross disorder analyses were employed to leverage on pleiotropy with bone mineral density. **Results** One genome-wide significant signal for modic change was identified on Chromosome 15 (rs10214211,  $p = 9.53 \times 10^{-9}$ ) at gene *ADRA1B*. Another genome-wide significant signal in Chromosome 15 (rs1902430,  $P = 1.57 \times 10^{-8}$ ) was identified while combining two most related phenotypes, disc bulging and signal intensity loss. Two genes, *SCG3* and *LYSMD2*, were significant in this region. An additional low frequency missense variant, which only exists in LDD cases, was further identified in *SCG3* from whole exome sequencing analysis (rs146162352,  $P = 0.005$ ). Moreover, two loci in gene *KCND3* and *SPC24* were identified to be pleiotropic between BMD and LDD (SFDR  $q < 0.05$ ). **Discussion** Phenotype definitions are essential for genome-wide association studies. This study has provided several successful cases that detailed definitions of LDD could boost the power of GWAS to identify disease associated markers. Using the definition of modic change, we identified one genome-wide significant signal. While combining highly correlated phenotypes, signal intensity loss and disc bulging, the power of GWAS also boosted. Leveraging on the pleiotropic effects from bone mineral density, small  $p$ -values enrichments were identified on two genetic loci. Together, this study presents a catalog of candidate genetic variants associated with lumbar disc degeneration in Southern Chinese population.

**1988T****The genetic architecture of osteoarthritis: Insights from UK Biobank.**

1) Wellcome Trust Sanger Institute, Hinxton, UK; 2) University of Sheffield, Sheffield, UK; 3) Dromokaiteio Psychiatric Hospital, Athens, Greece; 4) deCODE genetics, Reykjavik, Iceland; 5) Akureyri Hospital, Akureyri, Iceland; 6) University of Iceland, Reykjavik, Iceland; 7) The National University Hospital of Iceland, Reykjavik, Iceland; 8) National and Kapodistrian University of Athens, Athens, Greece.

Osteoarthritis (OA) is the most prevalent musculoskeletal disease and a leading cause of disability worldwide. It affects 40% of individuals over the age of 70 and is associated with an increased risk of comorbidity and death. The health economic burden of OA is rising, commensurate with longevity and obesity rates, and there is currently no treatment. Half of the variation in risk of OA is due to genetic factors. OA has been relatively refractive to GWAS approaches, with only 18 established loci to date. These traverse hip, knee and hand OA, with limited overlap. Here we conduct the largest OA GWAS to date, using genotype data from the UK Biobank and linkage to Hospital Episode Statistics data to define cases and controls. We compare and contrast this hospital diagnosed (HD, n=10,083 cases) GWAS to self-reported (SR, n=12,658 cases) OA GWAS drawn from the same UK Biobank dataset (non-OA controls selected to be ~4x the number of cases). We find power advantages with the SR dataset, indicating that the increase in sample size overcomes phenotype uncertainty. We identify nine novel OA loci, which robustly replicate in an independent dataset from Iceland (in up to 18,069 cases and 246,293 controls). For example, rs3771501 (OR 0.94 (95% CI 0.92-0.96), p=1.66x10<sup>-6</sup>) resides in an intron of *TGFA*, which has been associated with cartilage thickness, is differentially expressed in OA cartilage lesions and contributes to the development of chondrocyte clusters. rs11780978 (OR 1.13 (95% CI 1.08-1.17), p=1.98x10<sup>-9</sup>) resides in *PLEC*, which plays a role in skeletal muscle disorders. rs2521349 (OR 1.13 (95% CI 1.09-1.17), p=9.95x10<sup>-10</sup>) lies within *MAP2K6*, which is differentially expressed in OA synovial tissue. Several of the novel signals reside in the same regions as variants associated with metabolic and anthropometric traits. Through LD score regression, we find significant positive genetic correlation between OA and body mass index (rg=0.42, p=9.8x10<sup>-9</sup>), waist circumference (rg=0.34, p=2.0x10<sup>-8</sup>), hip circumference (rg=0.24, p=1.3x10<sup>-3</sup>) and a negative correlation with educational attainment (rg=-0.49, p=7.9x10<sup>-6</sup>). All constitute established epidemiologic risk factors for OA. All novel signals are at common frequency variants and confer small effects, in line with a highly polygenic model underpinning OA risk.

**1989F****Longitudinal genome-wide association analyses and heritability estimates of pediatric bone mineral density.**

D. Cousminer<sup>1,2</sup>, A. Chesir<sup>1</sup>, J. Mitchell<sup>1,2</sup>, H. Kalkwarf<sup>3</sup>, J. Lappe<sup>4</sup>, V. Gilsanz<sup>5</sup>, S. Oberfield<sup>6</sup>, J. Shepherd<sup>7</sup>, A. Kelly<sup>1,2</sup>, S. McCormack<sup>1,2</sup>, B. Voight<sup>1,2</sup>, B. Zemel<sup>1,2</sup>, S. Grant<sup>1,2</sup>. 1) Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Philadelphia, PA; 3) Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 4) Creighton University, Omaha, NB; 5) Children's Hospital Los Angeles, Los Angeles, CA; 6) Columbia University Medical Center, New York, NY; 7) University of California San Francisco, San Francisco, CA.

**Background:** SNP heritability ( $h^2_{\text{SNP}}$ ) assesses the trait variance attributed to genotyped genetic factors.  $h^2_{\text{SNP}}$  for bone mineral density (BMD) is known to vary across skeletal sites and with age, and assessments of  $h^2_{\text{SNP}}$  and genome-wide association studies (GWAS) have typically been performed using cross-sectional data in adults. In contrast, systematic longitudinal assessment of  $h^2_{\text{SNP}}$  in the pediatric context has not yet been conducted. Thus, we sought to determine  $h^2_{\text{SNP}}$  estimates for BMD and bone mineral content (BMC) across specific clinically important skeletal sites using modeled longitudinal pediatric growth curves. We also performed complementary GWAS in search of novel bone-related loci. **Methods:** In the multicenter, multiethnic Bone Mineral Density in Childhood Study (BMDCS) of healthy children aged 5 to 20 years old with up to 7 annual measurements each, BMD and BMC of the spine, total hip, femoral neck, distal radius and total body less head were measured in up to 1,876 boys and girls. We used GCTA-Restricted Maximum Likelihood (GREML) to estimate  $h^2_{\text{SNP}}$  for Super Imposition by Translation and Rotation (SITAR)-modeled longitudinal growth parameters (*size*, *tempo*, and *velocity*) at each skeletal site, adjusting for population ancestry. Subsequently, sex and ancestry-specific standardized SITAR-modeled growth parameters were subjected to GWAS analyses using GEMMA, which also accounts for population ancestry. **Results:** In general,  $h^2_{\text{SNP}}$  was higher for the *size* parameter than for the *tempo* and *velocity* parameters, and was comparable to previously published cross-sectional estimates.  $h^2_{\text{SNP}}$  for *size* ranged from 0.52 (SE=0.093,  $P=2.0 \times 10^{-8}$ ) for femoral neck BMD to 0.20 (SE=0.09,  $P=0.011$ ) for radius BMD. GWAS recapitulated the known signal at *CPED1* for female radius BMD as associated with the radius *size* parameter, but also yielded a number of novel genetic signals associated with *size*, *tempo*, and *velocity* that varied across skeletal sites. **Conclusions:** We generated skeletal site-specific longitudinal estimates of  $h^2_{\text{SNP}}$  for pediatric BMC and BMD that are comparable to previous estimates but expand to more detailed skeletal resolution and capture growth longitudinally. Both  $h^2_{\text{SNP}}$  and the most prominent GWAS-implicated loci vary across skeletal sites. These results provide new insights into the process of skeletal bone acquisition, which is vital to optimizing the reduction in later-life osteoporosis risk.

**1990W****Exome sequencing in idiopathic scoliosis families implicates cilia genes in disease etiology.**

*E.E. Baschal<sup>1</sup>, E.A. Terhune<sup>1</sup>, C.I. Wethey<sup>1</sup>, R.M. Baschal<sup>1,2</sup>, K.D. Robinson<sup>1</sup>, M.F. Tjandra<sup>1</sup>, S. Pradhan<sup>1</sup>, B.S. Sutphin<sup>1</sup>, M.R.G Taylor<sup>3</sup>, K. Gowan<sup>4</sup>, C.G. Pearson<sup>5</sup>, L.A. Niswander<sup>4</sup>, K.L. Jones<sup>4</sup>, N.H. Miller<sup>1,2</sup>.* 1) Department of Orthopedics, University of Colorado Anschutz Medical Campus, Aurora, CO; 2) Musculoskeletal Research Center, Children's Hospital Colorado, Aurora, CO; 3) Department of Cardiology, University of Colorado Anschutz Medical Campus, Aurora, CO; 4) Department of Pediatrics, University of Colorado Anschutz Medical Campus, Aurora, CO; 5) Department of Cell and Developmental Biology, University of Colorado Anschutz Medical Campus, Aurora, CO.

Idiopathic scoliosis (IS) is a structural lateral spinal curvature  $\geq 10^\circ$  that affects 3% of healthy children, with females at the greatest risk for severe progression. Severe progressive curvature can lead to life-long problems of cosmetic deformity, operative spinal fusion, back pain, and degenerative disease. IS frequently runs in families, with most cases strongly suspected to be genetic. Previous efforts to understand the genetic etiology of IS have led to the identification of multiple genes that may contribute to the IS phenotype, including *LBX1*, *GPR126*, *FBN1*, *HSPG2*, *POC5*, and musculoskeletal collagen genes. Despite these findings, the majority of genetic factors contributing to IS remain undiscovered. To identify rare variants associated with IS, we performed exome sequencing on 5 multigenerational families with IS (3-4 individuals per family). Illumina HiSeq reads were mapped to the human reference genome (hg38) using GSNAP, and variants were called using FreeBayes. Variants were annotated using SnpEff and dbNSFP. We filtered the list of variants, requiring that each variant was present in all sequenced members of the family, was predicted to be damaging, and had an ExAC frequency of less than 5%. This filter resulted in a total of 352 variants across the 5 families, with 23 to 120 variants identified in each family. Seventeen genes were shared by at least 2 families. We combined the variant lists from all 5 families, and entered the corresponding genes into PANTHER. We used PANTHER Gene Ontology (GO) term enrichment analysis, with the annotation dataset "Cellular Component Complete." This analysis revealed an enrichment of genes associated with the GO term "Cell Projection Part" ( $p = 0.0243$  with Bonferroni correction,  $p = 1.84E-5$  without Bonferroni correction,  $n = 34$  genes). The "Cell Projection Part" GO term includes genes involved in cilia, actin-based processes/projections (lamellopodia and filopodia), and neuronal projections. Previous studies of IS have implicated variants in cilia genes, including *PTK7* and *POC5*. We looked at cilia in more detail, and found that "Ciliary Part" was significantly enriched in our gene list without Bonferroni correction ( $p = 5.41E-4$ ,  $n = 16$  genes). Further investigation and functional studies will be required to fully elucidate the role of cilia in IS pathogenesis. Our studies highlight a new set of cilia genes for further consideration in the etiology of IS.

**1991T**

**Association of TGF  $\beta$ 1 gene polymorphisms with primary knee osteoarthritis in Asian Indians.** *Q. Hasan, S. Poornima, K. Subramanyam, G. Iyer, M. Darooei, K. Konda, S. Daram, A. Priya, S. Kumari.* Kamineni Hospitals, Hyderabad, India.

Primary Osteoarthritis (OA) is slowly progressive and irreversible pathology, which is considered as a part of the ageing process. It affects all the joints of the body like hip, spine but predominantly of the knee. It is estimated that ~10% of the world's aged population  $\geq 60$  years have symptomatic OA and present therapy for it includes the use of pain relieving medicines, physiotherapy and joint replacement surgery. Early onset OA is currently being observed frequently in Asian Indians, with individuals below 50 years presenting with the pathology. Current evidence indicates an important role of gene polymorphisms in the etiology of complex disease arthritis. Transforming Growth Factor  $\beta$ 1 (TGF $\beta$ 1) plays a role in development, homeostasis of various tissues by regulating cell proliferation, differentiation, apoptosis, migration and bone remodeling. Two SNPs of TGF $\beta$ 1 gene have been selected for the evaluation which were identified in GWAS. The aim of the study was to analyse TGF $\beta$ 1 -C509T and T869C polymorphisms in Asian Indian primary knee OA patients below the age of 50 years. This study was approved by Institutional Ethics Committee. The study involved 200 OA cases, which were clinically diagnosed and radiologically confirmed along with age and gender matched controls. Genomic DNA was isolated from blood, PCR amplification by specific primers after restriction digestion was carried out. Both SNPs appeared to be in HWE in Asian Indian. Results showed that TGF $\beta$ 1 T allele of rs1800469 (C509T) was significantly associated with the disease (OR =4.08,95% CI=3.03–5.50,  $p < 0.0001$ ). Dominant (OR=4.31,95% CI=2.84–6.56,  $p < 0.0001$ ) and recessive modes of inheritance (OR=4.15,95%CI=2.68–6.45, $p = 0.0001$ ) also showed statistical significance. In T869C polymorphism the C was significantly associated with the disease (OR=3.76, 95%CI = 2.79–5.06, $p < 0.0001$ ). Dominant (OR=4.54,95% CI = 2.98–6.93, $p < 0.0001$ ), recessive (OR=3.51,95%CI=2.24–5.49, $p = 0.0001$ ) and co dominant modes of inheritance (OR=1.81 95%CI=1.10–2.99, $p = 0.01$ ) were also associated with disease. These SNPs, rs1800469 and rs1982073, are associated with young onset primary knee OA and could be used as potential biomarkers to identify individuals/family members, who are at risk of developing knee OA to plan preventative strategies in our population, after confirming in a larger study group. This will help reduce morbidity and disability associated with this pathology.

Defects in the biosynthesis and/or function of primary cilia cause a spectrum of disorders collectively referred to as ciliopathies. A subset of these disorders is distinguished by profound abnormalities of the skeleton that include a long narrow chest with markedly short ribs, extremely short limbs, and polydactyly as a common finding. These include the perinatal lethal short-rib polydactyly syndrome (SRPS) phenotypes and the phenotypically less severe asphyxiating thoracic dystrophy (ATD), Ellis van Creveld (EVC) syndrome and cranioectodermal dysplasia (CED). To identify new genes and define the spectrum of mutations in the skeletal ciliopathies, we analyzed 152 unrelated families with SRP, ATD and EVC. Causal variants were discovered in three newly associated genes, *TRAF3IP1*, *FUZ*, and *LBR*, and in eleven known skeletal ciliopathy genes, in 120 of the families. The results established the molecular basis of SRPS type IV, in which we identified mutations were in four different ciliary genes. The data have provided systematic insight regarding the genotypes associated with a large cohort of these highly genetically heterogeneous phenotypes and identified the ciliary components required for normal skeletal development.

**Targeted sequencing of sagittal nonsyndromic craniosynostosis in regions on chromosomes 3, 7, and 20.** *C.M. Justice<sup>1</sup>, A. Cuellar<sup>2</sup>, W. Lattanzi<sup>3</sup>, P.A. Romitti<sup>4</sup>, S.A. Boyadjiev<sup>2</sup>, A.F. Wilson<sup>1</sup>.* 1) Genometrics Section, Computational and Statistical Genomics Branch, National Human Genome Research Institute, NIH, Baltimore, MD; 2) Section of Genetics, Department of Pediatrics, University of California Davis, Sacramento, CA; 3) Università Cattolica del Sacro Cuore, Rome, Italy; 4) Department of Epidemiology, University of Iowa, Iowa City, IA.

Craniosynostosis (CS) is a common congenital malformation where one or more of the infant skull sutures (metopic, coronal, sagittal, or lambdoid) fuse prematurely. The prevalence of the most common type of CS, sagittal non-syndromic craniosynostosis (sNCS), is estimated to be about 2 per 10,000 live births. We previously performed the first genome-wide association study (GWAS) for sNCS, and discovered robust associations to a 120 kb region located 345kb downstream from *BMP2* on 20p12.3 and in a 167kb region intronic to *BBS9* on 7p14.3. Analyses of 52 imputed variants in *DLG1* on 3q29 were found to be genome-wide significant. In order to identify variants in the coding and noncoding regions responsible for the sNCS phenotype, targeted Next Generation Sequencing (NGS) was used to sequence the associated regions on 3q29, 7p13.2, and 20p12.3 and two additional genes in close proximity to these associated regions (*BMP2* and *BMPER*) in 100 case-parent trios. Association analysis resulted in significant markers on chromosomes 3, 7 and 20, as expected, given our previous findings. The most significant association on chromosome 3 was for rs3773855 ( $p=1e^{-5}$ ), on chromosome 7 for rs10228486 ( $p=6.11e^{-6}$ ) and on chromosome 20 for rs1124471 ( $p=6.4e^{-6}$ ). Thirty-two exonic variants were identified, 16 of which were non-synonymous (7 in *DLG1*, 4 in *BBS9*, 4 in *BMPER* and 1 in *BMP2*). None appeared causative, because of either the lack of prediction of being a damaging allele (by Sift or Polyphen2), or because the variant was found in unaffected parents and not transmitted to the affected offspring. No *de novo* variants were located in exonic regions. Of the 32,604 interaction tests performed between variants on *BBS9* and *BMP2*, none reached significance after adjustment for multiple tests. The top three interactions ( $p < 0.004$ ) were between rs142092 on chromosome 20 and 3 SNVs on chromosome 7 (rs3823763, rs6944723 and rs4604335). Variation in regulatory region(s) may be involved in the phenotype, and allele frequency differences between cases and the reference genome may indicate which alleles may be of interest for functional studies using zebrafish.

**1994T****Shared and subtype-specific genetic variation define the genetic susceptibility of juvenile idiopathic arthritis.**

Y. Li<sup>1</sup>, J. Li<sup>1</sup>, J. Bradfield<sup>1</sup>, R. Chiaroni-Clarke<sup>2</sup>, M. Mohebbnasab<sup>1</sup>, D. Abrams<sup>1</sup>, C. Kim<sup>1</sup>, F. Mentch<sup>1</sup>, E.T. Luning Prak<sup>2</sup>, P. Sleiman<sup>1,4</sup>, J. Ellis<sup>3</sup>, E. Behrens<sup>1</sup>, H. Hakonarson<sup>1,4,5</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania, Perelman School of Medicine, Department of Pathology, Philadelphia, Philadelphia, PA; 3) Murdoch Childrens Research Institute, The Royal Children's Hospital, Flemington Rd Parkville, Victoria 3052, Australia; 4) Department of Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, 19104, USA; 5) Division of Genetics, The Children's Hospital of Philadelphia, Philadelphia, PA, 19104, USA.

Juvenile Idiopathic Arthritis (JIA) encompasses a heterogeneous group of rare, immune-mediated joint disorders that afflicts ~1 in 10,000 children in North America and Europe and causes severe pain and physical debilitation. There are 7 JIA subtypes, with the most prevalent being oligoarthritis (OLG) and Rheumatoid Factor-negative polyarthritis (PRFN), however this classification is controversial as it does not necessarily reflect disease biology, in part because known genetic risk factors explain only a fraction of total disease heritability (~20-30%). To identify genetic risk factors for JIA, we performed a heterogeneity-sensitive GWAS with over 1250 pediatric cases from all 7 clinical subtypes and over 9000 population-based pooled controls all genotyped on the Illumina 550/610 platforms and imputed, using IMPUTE2. We adapted a previously published method for pooled inverse-chi square analysis (Li and Hakonarson, 2014) to identify both shared and subtype-specific JIA susceptibility loci, adjusting for the use of disparate subtype sample sizes and common, population-based controls. After association testing and quality filtering, we identified 32 genome-wide significant (GWS;  $P_{meta} < 5E-8$ ) as well as several dozen loci reaching marginal significance (GWM;  $P_{meta} < 1E10-5$ ). Overall, we replicated 87.5% of GWS and 72.7% of GWM loci reported by prior publications ( $P_{GWS} < 0.05$ ). Twenty (21) of the GWS loci have been reported in one or more autoimmune or inflammatory diseases/traits including *ANKRD55* ( $P_{meta} < 4.6E-10$ ; previously reported in JIA) and *IL22RA1* ( $P_{meta} < 6.9E-11$ ; psoriasis and chronic rhinosinusitis). Many of the other novel candidates have relevant biological annotation, for example, *LPHN2*, which encodes a G-protein coupled receptors (GPCR) that mediates neutrophil chemotaxis and is associated with all 7 JIA subtypes. The most robust association was observed for OLG/PRFN and enthesitis subtypes,  $P_{meta} < 4.4E-22$ ,  $3.2E-15$  and  $5.6E-08$ , respectively. Another novel candidate is *RCN1* ( $P_{meta} < 4.2E-08$ ), encodes a calcium-binding protein in the lumen of the endoplasmic reticulum and expressed on bone endothelial cells in response to by TNF-alpha. Importantly, JIA-associated GWS candidate genes show enrichment for protein-protein enrichment as compared to a genome-wide background ( $p < 0.012$ ). Independent replication analysis is underway as well as gene network, functional and multi-omic analysis for expression enrichment in relevant disease tissues.

**1995F****Characterizing the molecular biology of systemic sclerosis with RNA-Seq of both skin and PBMCs.**

E. Roberson<sup>1,2</sup>, L. Cao<sup>1</sup>, D.J. Morales-Heil<sup>1</sup>, M. Carns<sup>3</sup>, B. Korman<sup>3</sup>, J. Varga<sup>3</sup>. 1) Department of Medicine, Division of Rheumatology, Washington University, St. Louis, MO; 2) Department of Genetics, Washington University, St. Louis, MO; 3) Feinberg School of Medicine Scleroderma Program, Northwestern University, Chicago, IL.

**Background:** Systemic sclerosis (SSc) is a complex and heterogeneous orphan disease with multiple organ involvement. Treatment is complicated by a highly variable clinical course, lack of biomarkers of disease activity, and absence of FDA approved treatments. In most patients, skin and subcutaneous tissue are affected, and circulating immune cells are activated. We performed one of the first RNA-Seq analyses on simultaneously obtained skin and peripheral blood mononuclear cells (PBMCs) from patients with clinically well-characterized SSc. **Methods:** We obtained 3mm skin biopsies and PBMCs from healthy controls (n=14) and individuals with systemic sclerosis (n=21 with n=10 6 month follow-ups), including both limited cutaneous systemic sclerosis (lcSSc), diffuse cutaneous systemic sclerosis (dcSSc), scleroderma sine scleroderma (SSS), and Very Early Diagnosis of Systemic Sclerosis (VEDOSS). We performed stranded, total RNA-Seq for transcriptome profiling. Modified Rodnan skin score (MRSS) was evaluated at each visit, and most cases also had longitudinal pulmonary function data and high-resolution CT scan data to detect interstitial lung disease. **Results:** In skin the most significant increases were in the genes *COMP*, *COL4A4*, and *IGFBP4*. Genes significantly increased in SSc skin are enriched for AP-2 alpha transcription factor sites in their promoter, and functional categories were enriched for both extracellular matrix and immune system processes. In contrast, we detected a marked decreased expression of *SPAG17*, part of the ciliary axoneme central pair complex, in SSc skin. Decreased genes were significantly enriched for POU4F1 binding sites, and modestly enriched for selenocysteine synthesis. **Conclusion & future directions:** SSc samples are clinically characterized by fibrosis, but little inflammatory cell infiltrate. The skin transcriptomes demonstrate increased expression of genes involved in extracellular matrix, but also immune system processes. Few changes are detectable in PBMCs, but the presence of some significant changes supports the possibility of a blood biomarker of activity. The increased inflammatory signaling is in contrast to the general lack of immune cell infiltrate. A future direction will be to use single-cell RNA-Seq of dissociated skin to identify the cell lineage driving inflammatory gene expression. Overall this study will provide a rich resource for continued study, matching in-depth clinical phenotyping with transcriptome data.

**1996W**

**Development of the scleroderma genotype-phenotype map for assessing phenotypic relationships and drug repurposing.** *K. Chesmore<sup>1</sup>, C. Guoshuai<sup>1</sup>, M. Whitfield<sup>1</sup>, S. Williams<sup>2</sup>.* 1) Department of Genetics, Dartmouth College, Hanover, NH; 2) Department of Population and Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH.

Scleroderma, an inflammatory disease of the skin, is a rare and often debilitating disorder thought to affect between 1/8,000 to 1/33,000 people, although this number can vary drastically based on race and gender. Little is known about the underlying genetic/molecular components that contribute to disease risk of scleroderma, and as such, efforts to develop or repurpose drugs for the treatment of scleroderma has yielded little. In this study, we explore the GWAS catalog to assess the relationships of phenotypes to scleroderma based on shared gene and pathway associations. Through the identification of closely related phenotypes, we gain insight into the disease etiology of scleroderma and from this we are able to predict the repurposing of drugs with potential therapeutic value in the treatment of this disease. Such methods can provide an invaluable tool to improve the treatments of many human diseases and can have a particularly profound effect on rare and understudied diseases for which little information is known about the underlying biology and potential drug targets.

**1997T**

**Polymorphisms of genes involved in extracellular matrix homeostasis may play a role in the risk to develop anterior cruciate ligament and medial meniscus tears.** *L. Casilla<sup>1,2</sup>, M.F. Lea<sup>1,2</sup>, A.M. Oliveira<sup>1,2</sup>, S.E.B. Santos<sup>3</sup>, A.K.C. Ribeiro-dos-Santos<sup>3</sup>, G. Arliani<sup>1</sup>, D. Astur<sup>1</sup>, C. Franciozi<sup>1</sup>, P. Debieux<sup>1</sup>, M.C. Smith<sup>1,2</sup>, A. Pochini<sup>1</sup>, C. Andreoli<sup>1</sup>, B. Ejnisman<sup>1</sup>, M. Cohen<sup>1</sup>.* 1) Ortopedia e Traumatologia, Universidade Federal de São Paulo, São Paulo, Brazil; 2) Morfologia e Genética, Universidade Federal de São Paulo, São Paulo, Brazil; 3) Laboratório de Genética Humana e Médica, Universidade Federal do Pará, Brazil.

Anterior cruciate ligament (ACL) and medial meniscus are the main injured structures in knee, mainly during high-impact sporting activities. The disequilibrium between extracellular matrix synthesis and degradation may be involved in the tear of ligament and meniscus. Recent studies suggest polymorphisms in genes of extracellular matrix in the ACL tear may be associated with the multifactorial etiology of tear. However, few studies evaluated polymorphisms in meniscus tear. We originally evaluated whether 32 polymorphisms in *COL1A1*, *COL1A2*, *COL2A1*, *COL3A1*, *COL5A1*, *COL12A1*, *FN1*, *TNC*, *TNXB*, *COMP*, *PLOD1*, *PLOD2*, *LOX*, *TGFβ1*, *TGFβR1*, *MMP2*, *MMP3*, *MMP9*, *MMP13* and *TIMP2* were associated with the risk of ACL or meniscus tears in a Brazil population. We genotyped 177 patients with ACL tear, 309 ACL paired controls, 132 patients with meniscus tear and 275 meniscus paired controls using TaqMan assays in a real-time PCR system. 62 molecular markers were used to determine the genetic ancestry in the studied admixed population. Univariate and multivariate logistic regression were used to investigate if the polymorphisms were associated with the risk to develop ACL and meniscus tears. The models were adjusted for gender, age and molecular ancestry. The distribution of genotypes was in Hardy-Weinberg equilibrium. We observed that the rs185819 (*TNXB*) CC carriers had a lower risk to develop ACL tear ( $p=0.034$ ). A *TNXB* TT haplotype ( $p=0.002$ ) and a *MMP9* AA haplotype ( $p=0.045$ ) may be a protective factor to ACL tear. Moreover, rs3106796 (*COL3A1*) GG carriers had an increased risk to develop meniscus tear ( $p=0.021$ ) and rs522616 C allele (*MMP3*) carriers may be a protective factor for meniscus tear ( $p=0.0023$ ). The *TGFβ1* GG haplotype ( $p=0.0055$ ) may be a protective factor for meniscus tear. The *MMP3* CT haplotype ( $p=0.009$ ), *COL5A1* CT ( $p=0.0098$ ) and AC ( $0.0073$ ) haplotypes may have a risk to develop meniscus tear. Therefore, while *TNXB* and *MMP9* genetic variants may play a role in the etiology of ACL tears, *COL3A1*, *MMP3*, *TGFβ1* and *COL5A1* genetic variants may be associated with meniscus tear etiology.

**1998F****Filaggrin variations associated to atopic dermatitis in Ecuadorian pediatric population.** V. Romero<sup>1</sup>, I. Inoue<sup>1</sup>, H. Nakaoka<sup>1</sup>, S. Palacios<sup>2</sup>, J. Cabezas<sup>2</sup>.

1) Human Genetics, National Institute of Genetics-Japan, Mishima, Shizuoka, Japan; 2) Centro de la Piel, Quito, Ecuador.

Atopic dermatitis (AD) is the most common form of eczema in childhood, manifestations as a chronic, relapsing itchy rash that usually starts in early life and, in many children, wanes in severity later in childhood. Early-onset AD is caused by a skin barrier abnormality frequently caused by filaggrin gene (*FLG*) mutations in Northern Europeans and Asians. AD was positively correlated with greater distance from the equator and negatively correlated with mean annual outdoor temperature. However, globally Ecuador has the second highest country prevalence (22.5%) for children between 6 to 7 years, and the eight highest one for children between 13 to 14 years (16.5%). Furthermore, within Latin America, Quito has the highest risk of current symptoms of eczema in children between 6-7 years and the fifth highest risk for children between 13-14 years; but there are no studies analyzing a genetic relationship. We obtained samples from Centro de la Piel of Ecuadorian pediatric population with and without history of atopic dermatitis and focused on the mutations between groups. We identified several variations found in cases that differed from the most common ones described in Europe and Asia. Furthermore, we analyzed the difference of distribution of disease-cause variations among these populations.

**1999W****Differential alternative splicing of *MAPT* in brains supports its role in the pathogenesis of Parkinson disease.** L. Wang<sup>1,2</sup>, S. Lang<sup>1</sup>, G. Garbiso<sup>1</sup>, S. Sivasankaran<sup>1</sup>, L. Wang<sup>1,3</sup>, J. Vance<sup>1,2</sup>, J. Young<sup>1,2</sup>.

1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Human Genetics, University of Miami, Miami, FL; 3) Department of Biostatistics, University of Miami, Miami, FL.

**Background:** Microtubule-associated protein tau (*MAPT*) is an abundant brain protein that binds to microtubule and plays an important role in axonal stability and dynamics. Aggregation of the protein Tau in the brain has been implicated in many neurodegenerative diseases including Alzheimer's disease and frontotemporal dementia (FTD). Genome-wide association studies (GWAS) have repeatedly identified *MAPT* as a susceptibility gene for Parkinson disease (PD). The molecular mechanisms underlying the genetic association, however, remain unclear. *MAPT* has multiple alternative transcripts: the majority of them are generated via alternative usage of exon 2 (E2), E3, and E10 in the adult human brain. Herein, we investigated the role of *MAPT* alternative splicing in PD etiology. **Methods:** The dorsal motor nucleus of the vagus nerve (DMV) region is where the earliest sign of PD pathology is observed in the brain. Postmortem DMV tissues from four PD cases (age: 72 +/- 6 years) and four sex-matched controls (age: 72 +/- 8 years) were obtained. Total RNA was extracted and measured by RNA-seq. Differential alternative splicing was analyzed using the rMATS software. Alternative splicing events with a false discovery rate < 0.05 were regarded as significant. Quantitative reverse transcript-PCR (qRT-PCR) were conducted in additional samples (10 cases and 4 controls) to validate significant RNA-seq findings. **Results:** In the comparison of cases and controls, we confirmed three significant alternative splicing events in *MAPT*: 1). Decreased inclusion of E2 (22.9% vs 56.2%); 2). Increased inclusion of E10 (52.2% vs 20.4%); 3). Decreased retention of a 136bp fragment of intron 2 (5.4% vs 12.7%). E2 encodes a repeat domain that reduces the filament length of Tau-aggregation. Therefore, less inclusion of E2 could lead to longer filament. E10 encodes a microtubule binding domain which further stabilizes microtubules. Increased inclusion of E10 has been reported in FTD patients and has been associated with the H1 haplotype, which is associated with increased genetic risk for PD. The intron 2 retention results in a premature stop codon (76 amino acids vs 352~441 amino acids in wild type Tau). The truncated Tau may play a protective role by reducing Tau aggregation. **Conclusion:** Our findings support a role of *MAPT* in the pathogenesis of PD. Future studies are needed to evaluate if alternative splicing is a mechanism to confer the genetic risk of *MAPT* in PD.

**2000T****Mapping functional regulatory variants at Alzheimer's disease risk loci.**

M. Allen<sup>1</sup>, X. Wang<sup>2</sup>, M.M Carrasquillo<sup>1</sup>, D.J Serie<sup>3</sup>, S. Lincoln<sup>1</sup>, T. Nguyen<sup>1</sup>, K. Malphrus<sup>1</sup>, D.W Dickson<sup>1</sup>, Y. Asmann<sup>2</sup>, N. Ertekin-Taner<sup>1,3</sup>. 1) Dept Neuroscience, Mayo Clinic, Jacksonville, Jacksonville, FL; 2) Dept Health Science Research, Mayo Clinic, Jacksonville, Jacksonville, FL; 3) Dept Neurology, Mayo Clinic, Jacksonville, Jacksonville, FL.

Genome-wide association studies have identified common variants associated with risk for Alzheimer's disease (AD). We and others have shown that some of these variants also associate with brain expression levels of near-by genes. Importantly these findings implicate the biological mechanism of action and the likely influenced gene(s), and nominate transcriptional regulation as an important factor in AD pathogenesis. Despite these advances, the precise regulatory mechanism and functional genetic variants are largely not yet known. Furthermore, much of the heritability of AD remains unexplained, indicating additional genetic risk loci remain to be identified. We hypothesize that a systems biology approach may nominate additional AD candidate genes, and when combined with in-depth sequence analysis, identify functional regulatory risk variants at both known and novel loci. We previously generated transcriptome-wide brain gene expression measures from two brain regions (temporal cortex and cerebellum), and genome-wide genotypes, for ~ 200 AD subjects and ~200 subjects with other pathologies (nonAD). Gene expression levels were measured using Illumina's WG-DASL array and genotypes were generated using the Illumina Hap300 chip. We performed eQTL analysis using PLINK, differential expression analysis using R statistical software, and co-expression network analysis using WGCNA, in both brain regions. We are performing targeted sequencing, in these same samples, across selected loci using the Agilent Haloplex target enrichment system and will annotate and test identified variants to validate the functional impact on gene expression. Our prior work indicated that AD index risk variants were associated with expression of *CLU*, *ABCA7* and *PILRB*. Transcription profiling analyses identified 10 genes that were consistently differentially expressed (DEG) between AD and nonAD subjects in both the temporal cortex, which is affected by AD pathology, and the cerebellum, which is largely spared. Co-expression network analysis identified 8 hub genes with high connectivity in "immune" networks enriched for AD candidate genes. Sequencing is being performed across both coding and non-coding regions for the 3 eQTL candidate loci and 12 genes nominated by the systems biology approach. The identification of functional, AD risk, regulatory variants is expected to provide novel insights into the pathophysiology of this disease and nominate therapeutic targets.

**2001F****Whole-exome sequencing analyses for late-onset Alzheimer's disease in Japanese.**

Y. Asanomi<sup>1</sup>, D. Shigemizu<sup>1,2,3</sup>, Y. Nagata<sup>1</sup>, R. Mitsumori<sup>1</sup>, T. Mori<sup>1</sup>, S. Niida<sup>1</sup>, K. Ozaki<sup>1,4</sup>. 1) Medical Genome Center, National Center for Geriatrics and Gerontology, Obu, Japan; 2) Department of Medical Science Mathematics, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 3) Laboratory for Medical Science Mathematics, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 4) Laboratory for Cardiovascular Diseases, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan.

Alzheimer's disease (AD), the most common form of dementia, has been thought to have familial and common form (late-onset AD; LOAD). With an aging population, the prevalence of LOAD is expected to dramatically increase. LOAD is thought to result from complex interactions among multiple genetic and environmental factors. Although recent advances in genetic studies have discovered several genetic risk factors for LOAD, more than the half of the heritability of the disease remains unclear. To explain the missing heritability, several efforts that identify rare variants to have strong genetic effect are currently underway. Although a risk rare-variant in *TREM2* was found with relatively strong effect in a Caucasian study, the carrier of this variant is hardly detectable in the Japanese population. To identify the rare variants that would explain a part of genetic architecture for LOAD in Japanese, we have performed whole-exome sequencing analyses with 202 LOAD individuals. We narrowed down the candidate variants and the corresponding genes that may relate to LOAD by the definitions as below; 1) the genetic variants to have minor allele frequency less than 1%, 2) the scores for combined annotation dependent depletion (CADD), a tool for scoring the deleteriousness of variants, are convincing, 3) the genes are ordinary expressed in the brain, 4) the genes carry a number of the candidate variants. All variants called from the exome data of the patients were filtered through these definitions. We filtered the data of allele frequencies in public database, such as 1000 Genomes Project, Exome Sequencing Project, Exome Aggregation Consortium, and Japanese population reference panel (2KJPN). We excluded the genes hardly expressed in the brain on Genotype Tissue Expression (GTEx) database. In addition, we excluded the variants identified from our in-house exome data of 176 normal-cognitive elderlies. We are now focusing on the candidate rare variants and investigating the genetic pathway implicated in LOAD.

**Identification and validation of novel key drivers of Alzheimer's disease from multiscale causal networks that integrate large-scale DNA, RNA, and proteomic data.** *N.D. Beckmann<sup>1,2</sup>, W.J. Lin<sup>3</sup>, M. Wang<sup>1,2</sup>, A. Cohain<sup>1,2</sup>, G.M. Belbin<sup>1</sup>, W. Ma<sup>1</sup>, P. Wang<sup>1</sup>, M. Ehrlich<sup>4,5</sup>, B. Zhang<sup>1,2</sup>, S. Salton<sup>3</sup>, E.E. Schadt<sup>1,2</sup>.* 1) Genetics and Genomics, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Icahn Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY; 3) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY; 4) Department of Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY; 5) Departments of Neurology, Icahn School of Medicine at Mount Sinai, New York, NY.

Alzheimer's Disease (AD) is the prevailing cause of dementia, affecting more than 28 million worldwide. Further, its incidence is projected to double in the next 20 years. Its phenotypic characteristics include progressive loss of cognitive function, memory, ability to think and reason. AD patients present with senile plaques in the brain that are composed of accumulated Amyloid Beta (ABETA) and neurofibrillary tangles (hyperphospho-TAU protein). To date, several genetic components of familial and late onset AD and many biological pathways have been implicated in the disease. Nonetheless, causal genes, pathways/networks and mechanisms of the disease continue to elude the scientific community, with no effective drugs developed over the last decade to prevent, halt or reverse the onset or progression of disease. Here, we study gene and protein expression from the anterior prefrontal cortex in a large cohort of post-mortem samples ( $n > 300$ ), across the complete range of neuropathologies (from controls to definite AD; AMP-AD consortium). Using whole exome sequencing (WES) with the multiscale expression data, we identified 4224 eQTLs and 158 pQTLs, with 74 gene and protein products having both eQTLs and pQTLs. Differential expression analyses revealed 788 differentially expressed (DE) genes and 1016 DE proteins between AD cases and controls, highlighting mitochondrial and immune processes. As expected, ABETA was the protein with the highest log fold change in AD patients versus controls. Coexpression network analyses highlighted 4 gene modules enriched for DE genes, which were enriched for known disease pathways. We then constructed 3 Bayesian Causal Networks (BN): a gene BN seeded with an expanded gene list from the DE genes and 4 modules of interest; a protein BN seeded with all 2694 proteins; and a multiscale BN, comprised of all genes and proteins present in the other networks. We ran key driver (KD) analyses for DE genes and DE proteins in all networks, and identified important regulators of the disease. Strikingly, we identified a novel KD not previously associated with AD that was the only KD conserved across all 3 networks. When overexpressed in AD mouse model, we find that this KD lowered overall Abeta plaque and phospho-Tau level, validating our network findings and the importance of this gene as a driver of AD. Additionally, the genes and clinical features linked to this KD provide novel insights into the mechanisms underlying AD risk and pathogenesis.

**2003T**

**Whole-genome sequencing in non-Hispanic white familial late-onset Alzheimer's disease identifies rare variation in AD candidate genes.** *G.W. Beecham<sup>1</sup>, B. Vardarajan<sup>2</sup>, E. Blue<sup>3</sup>, S. Barral<sup>4</sup>, J.L. Haines<sup>5</sup>, W. Bush<sup>6</sup>, C.M. van Duijn<sup>6</sup>, E.R. Martin<sup>1</sup>, G.D. Schellenberg<sup>6</sup>, R. Mayeux<sup>2</sup>, E. Wjisman<sup>3</sup>, M.A. Pericak-Vance<sup>1</sup>.* *Alzheimer's Disease Sequencing Project.* 1) Dr. John T. Macdonald Foundation Dept. of Human Genetics, Hussman Inst. for Human Genomics, University of Miami, Miami, FL, USA; 2) Columbia University, New York, NY, USA; 3) University of Washington, Seattle, WA, USA; 4) Case Western Reserve University, Cleveland, OH, USA; 5) Erasmus MC, Rotterdam, Netherlands; 6) University of Pennsylvania, Philadelphia, PA, USA.

The Alzheimer's Disease Sequencing Project (ADSP) is an initiative to identify rare genetic variation influencing Late Onset Alzheimer's Disease (LOAD) risk. As part of the ADSP, we performed whole-genome sequencing (WGS) in 44 non-Hispanic white (NHW) extended families multiply affected by LOAD, followed by extensive quality control, variant filtering, and gene-based association tests. WGS data were generated for 197 persons from 44 NHW families, including both AD and cognitively intact relatives. Alignment was performed using the Burrows-Wheeler algorithm, followed by genotype calling using a consensus calling pipeline that used both GATK genotype calls and ATLAS genotype calls. Variants were annotated for allele frequency and predicted functional impact, categorized into damaging (e.g., loss of function, high CADD scores, etc) and likely damaging (e.g., non-synonymous, moderate CADD, etc). We performed gene-based association testing of 32 known AD candidate genes, accounting for family structure using the FSKAT software. Association was performed using rare variants ( $MAF < 0.01$ ) and two models (damaging set only; damaging and likely damaging). Examination of the 32 known LOAD and EOAD genes (largely identified by GWAS-based meta-analyses) confirmed the role of rare functional variation in a number of genes, including FERMT2 ( $p = 0.001$ ) and SLC24A4 ( $p = 0.009$  in NHW). The association in FERMT2 survives a Bonferroni correction for 32 genes tested ( $p\text{-value} = 0.05/32 = 0.00156$ ). Both genes still showed association after adjusting for age, sex, and principal components (FERMT2  $p\text{-value} = 0.002$ ; SLC24A4  $p\text{-value} = 0.023$ ). The PICALM gene also showed nominal association after adjusting for age, sex, and principal components ( $p\text{-value} = 0.032$ ; unadjusted  $p\text{-value} = 0.111$ ). SLC24A4 also showed nominal association in the damaging variant only analysis ( $p\text{-value} = 0.026$ ). These three genes still showed evidence of association after including index SNP genotypes as covariates (FERMT2  $p\text{-value} = 0.002$ , SLC24A4  $p = 0.015$ , PICALM  $p\text{-value} = 0.021$ ). This indicates that the associated variation in the genes is likely independent of the common variants that initially implicated the genes. These results suggest rare, functional variation may influence LOAD risk in multiplex families, even among genes identified through common variation. Variants are currently being validated using other technologies, and follow-up and replication analyses are ongoing.

**2004F**

**Novel candidate AD-risk loci identified through whole exome sequencing in African Americans.** M.M. Carrasquillo<sup>1</sup>, C.C.G. Ho<sup>1</sup>, A. N'Songo<sup>1</sup>, X. Wang<sup>2</sup>, J.D. Burgess<sup>1</sup>, M. Allen<sup>1</sup>, T. Nguyen<sup>1</sup>, G.D. Bisceglia<sup>1</sup>, S.J. Lincoln<sup>1</sup>, K.G. Malphrus<sup>1</sup>, Y.W. Asmann<sup>2</sup>, S.G. Younkin<sup>1</sup>, R. Duara<sup>3</sup>, M.T. Greig Custo<sup>3</sup>, N.R. Graff-Radford<sup>4</sup>, N. Ertekin-Taner<sup>1,4</sup>. 1) Department of Neuroscience, Mayo Clinic, Jacksonville, FL; 2) Department of Health Science Research, Mayo Clinic, Jacksonville, FL; 3) Wien Center for Alzheimer's Disease and Memory Disorders, Mount Sinai Medical Center, Miami Beach, FL; 4) Department of Neurology, Mayo Clinic, Jacksonville, FL.

Alzheimer's disease (AD) is twice as prevalent in African-American individuals, yet most AD studies have been conducted in Caucasians. Whole exome sequence data from 131 African-American AD patients and 107 non-demented African-American elderly controls were tested for association with disease status, both at the single variant level using a linear regression model adjusted for appropriate covariates, and at the gene level using SKAT-O. The SKAT-O analysis was performed using default weights and various minor allele frequency (MAF) upper and lower bounds (none,  $MAF \geq 5\%$ ;  $5\% > MAF \geq 0.5\%$ ,  $MAF < 0.5\%$ ), and the test was only performed when 2 or more variants could be analyzed in each gene. We followed up in an independent set of African-American AD cases and controls (67 AD vs. 234 controls) associations that met any of the following criteria: 1) 25 variants that have the smallest AD association P-values; 2) AD association with  $P < 0.05$ , prioritizing 25 variants with the largest CADD Phred score; 3) variants not observed in our controls, prioritizing 25 variants with the largest minor allele counts in ADs and that have a  $MAF < 0.001$  in public datasets; 4) variants within the gene that had the best P-value for gene-based association. We identified several variants with nominally significant associations with AD status. A non-synonymous variant in the gene encoding the junction-mediating and -regulatory protein (*JMY*) had the best P-value in the single variant analysis in the replication cohort ( $p = 0.035$ , odds ratio=2.36), and remains significant after Bonferroni correction for all 97 variant tested when the discovery and follow-up cohorts were analyzed jointly ( $p = 0.00004$ , odds ratio=3.16). *JMY* has been determined to be a modulator of neurogenesis and more recently has been shown to play an important role in autophagy. Interestingly, *JMY* and 4 other genes with a variant whose AD-risk association improves in the joint analysis show significant differential gene expression (FDR q-value  $< 0.05$ ) in the cerebellum of AD vs. controls in the Mayo RNAseq AMP-AD cohort (syn7332090). Employing whole exome sequencing in a cohort of African-Americans, we have identified associations with potentially functional coding variants at genes not previously associated with AD-risk. Our results warrant replication in independent cohorts, given the paucity of studies in African-Americans, and the need to identify risk factors that may be more relevant to AD in this minority population.

**A patient-derived iPSC model of a rare *TTC3* mutation segregating with Alzheimer's disease.** H.N. Cukier<sup>1,2</sup>, F.S. Johnson<sup>1</sup>, C. Garcia-Serje<sup>1</sup>, R.M. Carney<sup>1,3</sup>, J.M. Vance<sup>1,2,4</sup>, M.L. Cuccaro<sup>1,4</sup>, M.A. Pericak-Vance<sup>1,2,4</sup>, D.M. Dykxhoorn<sup>1,4</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Department of Neurology, University of Miami, Miami, FL; 3) Miami Veterans' Affairs Medical Center, Miami, FL; 4) Dr. John T. Macdonald Foundation Department of Human Genetics, University of Miami, Miami, FL.

While 20+ loci have been associated with late onset Alzheimer's disease (LOAD), a large number of genetic factors still have yet to be revealed. We recently performed whole exome sequencing on a non-Hispanic white LOAD family with 11 AD individuals with a range of onset between 70–85 years old (average 75.7 years) that was negative for alterations in known AD candidate genes (Kohli, et al, 2016). A single rare, nonsynonymous variant was identified in all affected individuals in the *tetratricopeptide repeat domain 3* (*TTC3*) gene. This missense alteration, rs377155188 (p.S1038C), is predicted to be deleterious by five *in silico* algorithms and extremely rare in the ExAC database ( $1.96 \times 10^{-6}$ ). Studies have reported that *TTC3* expression is reduced in LOAD patients and negatively correlated with AD neuropathology, making this gene an interesting LOAD candidate to further investigate. To understand the mechanism by which the *TTC3* alteration may be acting to contribute to LOAD risk, induced pluripotent stem cells (iPSC) lines were developed to examine cellular consequences in neuronal tissue, which can otherwise only be collected post-mortem. Peripheral blood mononuclear cells (PBMCs) were extracted from the whole blood of two LOAD individuals bearing the *TTC3* change, as well as two aged, and ethnically matched control individuals. iPSC reprogramming was performed using Sendai virus. Each iPSC line generated was validated for pluripotency through immunocytochemical staining and shown to be negative for any large-scale chromosomal abnormalities via karyotyping. These iPSC lines will be differentiated into forebrain neurons to generate a disease relevant tissue to assess. There is evidence that modulation of *TTC3* affects neurite growth (Berto, et al, 2007); therefore, morphological measures of axon and synapse formation will be assessed in differentiating neuronal cultures using live cell imaging. Alzheimer-specific phenotypes such as the levels of secreted beta amyloid and intercellular whole and phosphorylated tau will also be measured. Utilizing patient-specific iPSC lines will permit assessing the cellular and molecular consequences of genetic alterations that may contribute to LOAD risk. We will present the morphological and cellular phenotypes of these lines carrying a potential risk factor for AD.

**Genome-wide association study of brain amyloid deposition as measured by PiB-PET imaging and assessment of the genetic variance of amyloid deposition.** F.Y. Demirci<sup>1</sup>, Q. Yan<sup>1</sup>, K. Nho<sup>2</sup>, J. del-Aguila<sup>3</sup>, X. Wang<sup>1</sup>, S. Risacher<sup>1</sup>, B. Snitz<sup>1</sup>, H. Aizenstein<sup>1</sup>, C. Mathis<sup>1</sup>, O. Lopez<sup>1</sup>, E. Feingold<sup>1</sup>, W. Klunk<sup>1</sup>, A.J. Saykin<sup>2</sup>, C. Cruchaga<sup>3</sup>, M.I. Kamboh<sup>1</sup>. 1) University of Pittsburgh, Pittsburgh, PA; 2) Indiana University, Indianapolis, IN; 3) Washington University, St. Louis, MO.

Genomic efforts mainly through large-scale genome-wide association studies (GWAS) have identified over 20 risk loci for late-onset Alzheimer's disease (AD). However, known common AD variants in these loci account for only ~30% of the AD genetic variance. Genetic studies focusing on AD-related quantitative endophenotypes may help to identify additional AD-related genes. One such AD-related endophenotype is deposition of amyloid-beta (A $\beta$ ) in the brain, which is one of the two main pathologic hallmarks of AD; the other being the formation of tau tangles in the brain. The *in vivo* detection of A $\beta$  deposition in the brain, as measured by PET scanning with <sup>11</sup>C-labeled Pittsburgh Compound-B (PiB) and the increased retention of PiB in AD than cognitively normal brains has been confirmed in many studies. Here we have used PiB-PET as an endophenotype to identify novel genetic loci for AD pathology using the GWAS approach, the first to our knowledge, using the largest sample (n=1,019) with the PiB-PET imaging from University of Pittsburgh (PITT), Washington University (WU), Alzheimer's Disease Neuroimaging Initiative (ADNI) and Indiana University (IU). In the GWAS meta-analysis, the PiB uptake values from 4 cortical regions were averaged in each subject to calculate a mean global score as the quantitative endophenotype. With the exception of *APOE*, none of the other known AD risk loci showed significant association with PiB score. The *APOE* region showed the most significant association where several SNPs surpassed the genome-wide significant threshold ( $P < 5 \times 10^{-8}$ ) with *APOE\*4* most significant ( $P$ -meta = 9.09E-30;  $\beta$  = 0.18). Interestingly, after conditioning on *APOE\*4*, 14 SNPs remained significant at  $P < 0.05$  in the *APOE* region that were not in linkage disequilibrium with *APOE\*4*, including *APOE\*2*. Outside the *APOE* region, the meta-analysis revealed 15 non-*APOE* loci with  $P < 1 \times 10^{-5}$  on 9 chromosomes, with two most significant SNPs on chromosomes 8 ( $P = 4.87 \times 10^{-7}$ ) and 3 ( $P = 9.69 \times 10^{-7}$ ). The top 15 non-*APOE* SNPs along with *APOE\*4* and *APOE\*2* explained 35%, 25% and 31% of the amyloid variance in the PITT, WU and ADNI/IU datasets, respectively; of which 14-17% was explained by *APOE\*4* alone. In conclusion, we have identified novel signals in the *APOE* and non-*APOE* regions, in addition to *APOE\*4* that affect the A $\beta$  deposition in the brain. Our data also highlights the presence of yet to be discovered variants that may be responsible for the unexplained genetic variance of A $\beta$  deposition.

**Complement receptor 1 (CR1) intragenic duplication and Alzheimer's disease.** E.J. Hollox<sup>1</sup>, E. Kucukkilic<sup>1</sup>, K. Brookes<sup>2</sup>, K. Morgan<sup>2</sup>. 1) University of Leicester, Leicester, United Kingdom; 2) University of Nottingham, Nottingham, United Kingdom.

Genomewide association studies have highlighted SNP alleles within and surrounding genes involved in the immune response with late-onset Alzheimer's disease (LOAD), suggesting an important role of the immune response in the etiology of Alzheimer's disease. One of the strongest associations surrounds the complement receptor 1 gene (*CR1*), which encodes a gene important in the innate immune complement pathway. The associated SNP alleles form a risk haplotype, and several variants on this haplotype have been suggested to be the causative variant underlying the increased risk of LOAD. One of these variants is a 18 kb duplication that affects several exons of the *CR1* gene, causing an in-frame insertion of coding sequence and a consequent extra protein domain binding complement C3/C4. Here, we develop a robust approach to type *CR1* intragenic copy number, including the common duplication (*CR1\*B*) and deletion (*CR1\*C*) alleles, using a PCR-based approach called the paralogue ratio test (PRT). We also develop a locked nucleic acid junction-fragment PCR approach to validate duplication *CR1\*B* alleles in European samples. Applying these methods, we fail to show association of the *CR1\*B* allele with early-onset Alzheimer's disease patients (EOAD,  $p = 0.755$  OR = 1.05, 95% CI 0.77 to 1.43) in a UK cohort of 449 cases and 184 controls, but confirm the association in LOAD patients ( $p = 0.015$  OR = 1.21 95% CI 1.04-1.42) in a UK cohort of 1180 cases and 1005 controls. We suggest that the *CR1\*B* allele is the functional basis of the association, perhaps by altering the number of C3/C4-binding domains encoded by the protein and thereby modulating the immune response to neurodegeneration. We suggest further functional comparison of proteins encoded by *CR1\*B* risk alleles with those encoded by *CR1\*A* non-risk alleles to understand the mechanism of this association.

**Genome-wide association study for Alzheimer's disease in a Puerto Rican dataset.** J. Jaworski<sup>1</sup>, B. Feliciano<sup>2</sup>, K. Celis<sup>1</sup>, F. Rajabli<sup>1</sup>, K.L. Hamilton-Nelson<sup>1</sup>, LD. Adams<sup>1</sup>, AR. Betancourt<sup>2</sup>, JM. Vance<sup>1</sup>, ML. Cuccaro<sup>1</sup>, GW. Beecham<sup>1</sup>, MA. Pericak-Vance<sup>1</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) PRADI and Universidad Central del Caribe, School of Medicine, Caguas, PR, USA.

**Background:** There are over 5 million individuals of Puerto Rican (PR) origin, making up over 1.5% of the US population and representing the 2<sup>nd</sup> largest Hispanic/Latino population in the continental US. The population is highly admixed, with average ancestry values of 64% European, 21% African, and 15% Native American, but individual ancestries are highly variable. The number of Alzheimer's disease (AD) cases on the island of PR is estimated at 65,000. Genetic studies have been limited to a few rare families with early onset AD (PSEN mutations). Our goal in this study is to identify the genetic risk factors associated with AD. **Methods:** We have ascertained 395 individuals into the PR AD Initiative (PRADI) study including 97 families and 124 unrelated individuals for a total of 271 affected and 124 cognitively intact individuals. We performed genome-wide genotyping on the IlluminaMEGA and GSA arrays. Association was tested using the GWAF geepack package in R which fit logistic regression via Generalized Estimation Equation (GEE) for the additive model, treating each family as a cluster. **Results:** The top SNP observed, rs35293463, had a p-value of  $2.4 \times 10^{-7}$  which passed a Bonferroni corrected significance level. This SNP is located on Chromosome 2 (2p12) in the intron region of the predicted gene LOC105374814. APOE was nominally significant with a p-value of 0.013 and OR of 1.5. This is not as strong an effect as seen in non-Hispanic Whites (NHW)(See Rajabli et al abstract). A look at GWAS candidate AD loci observed in NHW datasets showed two genes were nominally significant; SLC24A4 (rs7150295, p-value 0.004) and CASS4 (rs7274581, p-value 0.007). In addition, APP (rs3991, p-value 0.007) was also nominally significant. **Conclusions:** The Puerto Rican population is a growing yet understudied population in the US. Understanding the etiology of Alzheimer's disease in this unique population will unlock keys to the disease in the population as a whole. This preliminary analysis of GWAS association suggest that associations observed in AD, while present, are not as strong in PR AD. We observed a novel top SNP on Chromosome 2 in an intronic region of a predicted gene. Genotyping more families and replicating the analysis is warranted.

**2009T**

**A whole exome study of Alzheimer's disease which is augmented by population data found the noble AD risk genes.** J. Kim<sup>1,2</sup>, M. Fernandez<sup>1,2</sup>, J. Budde<sup>1,2</sup>, H. Oscar<sup>1,2</sup>, C. Cruchaga<sup>1,2</sup>. 1) Department of Psychiatry, Washington University School of Medicine, 660 S. Euclid Ave. B8134, St. Louis, MO 63110, USA; 2) Hope Center for Neurological Disorders, Washington University School of Medicine, 660 S. Euclid Ave. B8111, St. Louis, MO 63110, USA; 3) Department of Neurology, Ilsan hospital, Koyang-shi.

Alzheimer's disease (AD) has high heritability. The currently known risk genes includes ABCA7, APOE, BIN1, CD33, CD2AP, CLU, CR1, EPHA1, MS4A6A/MS4A4E, PICALM, PLD3, SORL1, and TREM2 between others, and explain only part of AD heritability. Recently, a large scale whole exome study called as Alzheimer's Disease Sequencing Project (ADSP), aimed to find additional AD risk genes harboring low frequency and rare coding variants. However, although ADSP includes as much as 10,909 participants, it may be still underpowered for very rare alleles. The ExAc database which includes genetic information on 60,706 individuals, and should be a good representation of the allele frequencies in the population. In this study, we augmented statistical power by using the ExAc database as comparison group for the ADSP cases and tried the noble AD risk and protective genes. In order to avoid the population bias, we included only Non-Finnish European population in ExAc. In ADSP, we used European ancestry and excluded outliers by the plot of the first two principal components. We selected variants with minor allele frequencies (MAF) between that of the ADSP cases and ADSP controls. The MAF differences were tested by Pearson's chi-square tests. The MAF of gene-based analysis were obtained by collapsing MAFs of variants within gene boundaries. In the variant level, the well-known AD risk genes—TOMM40, TREM2, and MS4A6A—are replicated. The noble genes with genome wide significant level ( $P = 5 \times 10^{-6}$ ) were 38 genes including C10orf2, CHR1, and CROCC. In the gene-based level using burden test, we selected genes with  $P < 1 \times 10^{-6}$ , considering the number of human genes. The well-known AD risk genes—ABCA7, SORL1, and TREM2—are replicated. The significant noble genes were 69 genes including AGAP1, ALYREF, and TYRO3. We not only replicate known AD risk genes—ABCA7, MS4A6A, SORL1, and TREM2, but also found the noble candidate AD risk genes. We need to replicate these noble risk genes in other genetic studies. Our augmentation methods can be applied to the whole exome sequencing studies on other diseases.

**Alzheimer's disease exome sequencing study in the Finnish population isolate.** M.I. Kurki<sup>1,2,3</sup>, S. Helisalmi<sup>4</sup>, K.M. Mattila<sup>5</sup>, A.S. Havulinna<sup>3,6</sup>, J. Krüger<sup>8,9</sup>, T. Lehtimäki<sup>5</sup>, M. Perola<sup>6,10</sup>, V. Salomaa<sup>6</sup>, A. Remes<sup>7,8,9</sup>, M. Hiltunen<sup>11</sup>, H. So-ininen<sup>12</sup>, M.J. Daly<sup>1,2,3,13</sup>, A. Palotie<sup>1,2,3</sup>. 1) Psychiatric & Neurodevelopmental Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA; 2) Stanley Center, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Institute for Molecular Medicine Finland (FIMM), University of Helsinki, Helsinki, Finland; 4) Institute of Clinical Medicine, University of Eastern Finland; 5) Faculty of Medicine and Life Sciences, University of Tampere, Finland; 6) THL-National Institute for Health and Welfare, Helsinki, Finland; 7) Department of Neurology, Institute of Clinical Medicine; 8) Medical Research Center, Oulu University Hospital, Oulu, Finland; 9) Unit of Clinical Neuroscience, Neurology, University of Oulu, Oulu, Finland; 10) Estonian Genome Center, University of Tartu, Tartu, Tartumaa 51010, Estonia; 11) Institute of Biomedicine, University of Eastern Finland; 12) Institute of Clinical Medicine, Internal Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland; 13) Analytical and Translational Genetics Unit, Massachusetts General Hospital, Boston, Massachusetts, USA.

Both common and rare variants contributing to Alzheimer's disease (AD) have been identified. High impact variants explaining the majority of the heritability for familial early onset Alzheimer's disease (EOAD) have been identified in genes related to amyloid- $\beta$  processing. For the most common late onset Alzheimer's disease (LOAD), genome wide association studies have identified mostly low effect common variants in > 20 genomic loci (APOE\* $\epsilon$ 4 being the only high risk exception) suggesting many different pathways like metabolism, inflammation, synaptic activity and intracellular trafficking. To enrich for deleterious low frequency variants in our study sample, we investigated AD cases in a population isolate. Finland is the largest genetic population isolate in Europe where multiple genetic bottlenecks and genetic drift have increased the frequency of some deleterious alleles with negative selection. Previously we have identified Finnish enriched variants associated with schizophrenia, intellectual disability and cardiovascular diseases. So far, whole exome and targeted sequencing studies have identified predisposing rare coding variants (e.g. *APP*, *TREM2*, *PLD3*) with risk increases on par with that of APOE\* $\epsilon$ 4. Still the majority of the estimated heritability of LOAD (60-80%) remains unexplained and further studies are needed to pinpoint specific pathomechanisms to identify novel targets for treatment development. Here we describe an ongoing exome sequencing case control study of AD in the Finnish population. To date we have sequenced 1592 Finnish AD cases and 18186 controls. 1501 cases and 14983 controls passed the quality control process. We identified rare (MAF < 1%) damaging missense variants in known AD genes (e.g. *TREM2* AF: 3.36E-05, OR : 20.9 , p: 0.02; *SORL1*, AF (controls): 0, p 6.4e-4; *CR1* AF (controls) :0, p: 6.7E-3; *APP* , AF (controls): 3.3e-3, OR: 0.17, p: 3.96E-3) nominally associated with AD as well as new candidates not previously implicated by GWAS. To identify novel genes we are increasing the number of samples exome sequenced or genotype imputed using cases and controls identified from Finnish electronic health care registries. Finnish registry data allows exploration of these rare AD variants across hundreds of disease endpoints and clinically relevant phenotypes, better articulating their biological impact.

**Performance of a genetically-based biomarker risk algorithm for an Alzheimer's disease prevention screening study.** M.W. Lutz<sup>1,2</sup>, C.L. Dunn<sup>3</sup>, J.S. Cranston<sup>3</sup>, D.J. Hatch<sup>2,4</sup>, D.K. Burns<sup>5</sup>, A.M. Saunders<sup>5</sup>, B.L. Plassman<sup>1,2,4</sup>, K.A. Welsh-Bohmer<sup>1,2,4</sup>. 1) Department of Neurology, Duke University School of Medicine, Durham, NC 27710; 2) Duke Bryan Alzheimer's Disease Research Center, Duke University School of Medicine, Durham, NC 27705; 3) Duke University, Durham, NC 27708; 4) Department of Psychiatry, Duke University School of Medicine, Durham, NC 27710; 5) Zinfandel Pharmaceuticals, Chapel Hill, NC 27517.

The efficiency of clinical trials for prevention or delay-of-onset of Alzheimer's Disease (AD) is greatly increased if an enrichment strategy successfully identifies individuals likely to convert from normal cognition to AD or mild cognitive impairment (MCI) due to AD in the time frame of the trial. A genetic biomarker risk algorithm (GBRA) has been developed to enrich a double-blind, delay-of-onset clinical trial of the efficacy of low dose pioglitazone, a thiazolidinedione used for the treatment of Type 2 diabetes, to delay the onset of MCI due to AD (TOMMORROW, ClinicalTrials.gov identifier, NCT00106899). The GBRA is based on age and two genetic variants that are easily genotyped in blood: APOE and TOMM40 '523. The GBRA has been designed to allow subject enrichment across the ages of 65-83 years and was calibrated with data from the Duke Bryan ADRC Memory, Health and Aging Study. Other studies have compared the performance of the GBRA with imaging and biofluid biomarkers. The present study evaluates the GBRA for a longitudinal community based AD prevention screening study with measures of cognitive function, e.g. Montreal Cognitive Assessment (MoCA). The GBRA was tested with data from the Duke Bryan ADRC Prevention Screening Study and Database/Repository (PREPARE); comprised of a non-demented socioculturally diverse volunteer cohort from Durham, NC. The GBRA was used to stratify subjects at baseline into high or low risk groups. Individuals who had baseline and follow-up neurocognitive evaluations were included, N=423, mean age 69 years, sd 9.5. 303 individuals were classified as low risk at baseline, 120 as high risk. The difference in change between baseline and follow-up MoCA scores between the risk groups was 0.5 with the high risk group showing the largest decline (mean 1.1, sd 0.2) compared to the low risk groups (mean 0.6, sd 0.1). This difference was statistically significant (p=0.02) after adjusting for different follow-up intervals. Individuals showing both cognitive decline and cognitive improvement were observed in both risk groups. Cognitive, genetic and demographic data are presented to characterize the risk groups. The results of this study characterize the performance of the GBRA for measures of cognitive decline. When used in the context of a clinical trial, the GBRA has potential to significantly reduce the numbers of study subjects required and, in the case of a delay-of-onset study, reduce trial duration.

## 2012T

**Novel Alzheimer disease loci identified in subsets of whole exome sequencing data stratified by APOE genotype.** Y. Ma<sup>1</sup>, X. Zhang<sup>1</sup>, J. Chung<sup>1</sup>, A.C. Naj<sup>2</sup>, K. Hamilton<sup>3</sup>, E.R. Martin<sup>3</sup>, B.W. Kunkle<sup>3</sup>, R. Mayeux<sup>4</sup>, J.L. Haines<sup>5</sup>, M.A. Pericak-Vance<sup>3</sup>, G.D. Schellenberg<sup>2</sup>, K.L. Lunetta<sup>1</sup>, L.A. Farrer<sup>1</sup>, Consortium for Alzheimer Sequencing Analysis, the Alzheimer Disease Sequencing Project. 1) Biomedical Genetics, Boston University, Boston, MA; 2) University of Pennsylvania, Philadelphia, PA; 3) University of Miami, Miami, Florida; 4) Columbia University, New York, New York; 5) Case Western Reserve University, Cleveland, Ohio.

**Background:** Previous genome-wide association studies identified novel Alzheimer disease (AD) loci that were detected only when stratified by presence or absence of the *APOE*  $\epsilon 4$  allele. We evaluated whole exome sequence (WES) data from the Alzheimer Disease Sequencing Project (ADSP) to identify additional *APOE*-stratified associations with infrequent and rare single nucleotide variants (SNVs). **Methods:** Association with SNVs in the ADSP WES sample of unrelated non-Hispanic white AD cases and controls was evaluated in subgroups of *APOE*  $\epsilon 4$  carriers and non-carriers:  $\epsilon 4+$  (2377 cases, 706 controls) and  $\epsilon 4-$  (3145 cases, 4213 controls). We used EPACTS score test adjusting for principal components of ancestry in Model 1 and with additional adjustment of age and sex in Model 2. Analyses were restricted to SNVs with a minor allele count (MAC)  $\geq 10$ , resulting in 87,405 and 123,178 tests in the  $\epsilon 4+$  and  $\epsilon 4-$  subgroups, respectively. Genotype data that were imputed using the Haplotype Reference Consortium panel for ADGC participants not included in the ADSP were used for replication. **Results:** Among  $\epsilon 4+$  subjects, novel associations reached genome-wide significance (GWS) ( $P < 6 \times 10^{-7}$ ) with *C4ORF17* (rs41275705,  $P = 5.6 \times 10^{-7}$  in Model 1) and *SNPH* (rs367658252,  $P = 5.0 \times 10^{-7}$  in Model 2), but neither of them were replicated. Two GWS ( $P < 4 \times 10^{-7}$ ) novel associations were found in *AC099552* (rs536940594,  $P = 2.2 \times 10^{-7}$  in Model 1) and *GPAA1* (rs138412600,  $P = 2.7 \times 10^{-7}$  in Model 2) among  $\epsilon 4-$  subjects. The effect of *GPAA1* rs138412600 was stronger in  $\epsilon 3/\epsilon 3$  (OR=2.28,  $P = 6.8 \times 10^{-7}$ ) than  $\epsilon 2/\epsilon 2$  and  $\epsilon 2/\epsilon 3$  subjects (OR=1.49,  $P = 0.25$ ). Association with this SNV was confirmed with the same model and effect direction in the  $\epsilon 4-$  replication sample ( $P = 0.03$  and meta- $P = 7.7 \times 10^{-6}$ ). Replication results were unavailable for the *AC099552* SNV because it was too rare (MAF=0.0007) to be imputed accurately. **Conclusion:** We identified a novel robust association with *GPAA1* in subjects lacking the *APOE*  $\epsilon 4$  allele. *GPAA1* encodes glycosylphosphatidylinositol (GPI) anchor attachment protein, which has a male-specific function in memory formation. Further studies are necessary to determine the functional consequence of this non-synonymous mutation and its mechanism of action in relation to *APOE* genotype.

## 2013F

**Ambidexterity and Alzheimer's disease risk.** E.E. Mlynarski<sup>1,2,3</sup>, M. Tang<sup>1,2,3</sup>, A. Amlie-Wolf<sup>1,2,3</sup>, L. Qu<sup>1,2,3</sup>, A. Kuzma<sup>1,2,3</sup>, L. Cantwell<sup>1,3</sup>, J.M. Ringman<sup>4,5</sup>, G.D. Schellenberg<sup>1,3</sup>, L.-S. Wang<sup>1,2,3</sup>. 1) Penn Neurodegeneration Genomics Center, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, Philadelphia, PA; 2) Institute for Biomedical Informatics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 3) Department of Pathology and Laboratory Medicine, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 4) Memory and Aging Center, Keck School of Medicine of University of Southern California, Los Angeles, CA; 5) Department of Neurology, University of Southern California, Los Angeles, CA.

Previous studies have investigated the association between left handedness and Alzheimer's disease, however these studies either excluded ambidextrous individuals, and/or did not include genome-wide genetic analyses. Therefore, we performed association analyses to examine the prevalence of ambidexterity and left handedness in late-onset Alzheimer's disease. More than 7000 individuals from the NACC database were included in the analysis, all of which were of European descent and had available handedness, Alzheimer's disease case/control status, birth year, sex and education level phenotype data. Interestingly, our analysis revealed an association between Alzheimer's disease and ambidexterity, but not left handedness. In fact, the results suggest that ambidexterity is protective for late-onset Alzheimer's disease (OR = 0.591, 95% CI = 0.396–0.875,  $P = 9.26 \times 10^{-3}$ ). A multi stage GWAS was then performed for each of the four different handedness splits: ambidextrous vs left or right (A vs L/R), left vs right or ambidextrous (L vs R/A), right vs left or ambidextrous (R vs L/A), and left vs right (L vs R). The discovery analysis consisted of 4151 individuals with handedness phenotype data from six previously published Alzheimer's GWAS datasets, the replication was a meta-analysis of more than 4000 additional subjects from several independent Alzheimer's disease cohorts, and a meta-analysis of the discovery and replication cohorts was also performed. In the discovery, only one locus in the A vs L/R analysis reached genome-wide significance ( $p < 10^{-8}$ ). The one genome-wide significant signal ( $p = 4.07 \times 10^{-9}$ ), located at 10p12.33, replicated in the A vs L/R meta-analysis ( $p = 3.35 \times 10^{-9}$ ). The top SNP from the meta-analysis mapped to an intergenic region ~16 kb distal to the 3' end of *ST8SIA6*. Notably, there were no significant signals for any of the other three handedness splits (L vs R/A, R vs L/A, and L vs R), and the few suggestive loci ( $p < 10^{-5}$ ) that were identified in the discovery analysis did not replicate. Together, these results indicate that ambidexterity is associated with a lower risk of AD and the locus on 10p12.33 may play a role. Additional functional analyses are currently underway to identify the specific causal variant for the GWAS signal and elucidate the underlying genetic mechanisms.

## 2014W

**Variant prioritization by pedigree-based haplotyping in an Alzheimer's disease pedigree.**

Disease-associated linkage regions contain large numbers of variants. This complicates determining which are associated with a disease. In the absence of recurrent mutation, a new risk allele will occur on a single haplotype. Identification of variants unique to a haplotype driving a linkage signal could therefore provide a solution to the problem. Existing population-based haplotype phasing methods, however, require large reference samples and dense SNP marker panels for optimal performance. These are often unavailable in family-based studies. To address a variant prioritization problem in a linkage region, we developed a pedigree-based haplotyping method and applied it to Alzheimer's disease (AD) data from the ADSP. Our study sample consisted of subjects from recent generations of a population isolate of European descent with deep shared ancestry. The subjects were grouped into two pedigrees (P1 and P2), with 30 of 189 and 5 of 47 members, representing AD cases, respectively, and with WGS data available on 30 AD subjects from P1 and P2, combined. Using the MORGAN package, inheritance vectors representing chromosomal descent within pedigrees were generated using sparse SNP array data on 25 and 5 subjects in P1 and P2, respectively, with subsequent computation of LOD scores. A LOD score of 3.3 on chr5 was identified in P1. A modified version of the GIGI program was used to perform pedigree-based phasing and imputation of 49,740 WGS variants from the linkage region. This yielded a most-likely haplotype across the region, shared by 10 AD cases in P1. Identification of the risk haplotype responsible for the linkage signal reduced the number of variants of interest to 24,521. Further reduction to 276 variants was achieved by identifying variants that were unique to the risk-haplotype as opposed to being on haplotypes from subjects who did not carry the risk-haplotype in P1 and P2. The number of variants potentially associated with AD can be reduced further to 38 or 21 by applying minor allele frequency thresholds of 5% or 1%, respectively. These results show that pedigree-based haplotyping with subsequent identification of a haplotype driving a linkage signal may be a useful tool for WGS variant prioritization and for follow up in other samples.

Alzheimer disease (AD) is a complex disorder with high genetic component. Exome-wide significant association of *TREM2*, *SORL1* and *ABCA7* rare variants with AD risk has recently been reported, however with limited panel of variants or sample sizes, restricting the possibility to fully assess their effect. We took advantage of the ADES-FR dataset made up of 1,779 AD cases and 1,273 controls from France. We focused on *TREM2*, *SORL1* and *ABCA7* but also included *PLD3*, *AKAP9* and *UNC5C* genes, for which association of rare variants with AD risk has recently been reported. We generated whole genome (n=955) or whole exome sequencing data (n=2,106) and performed multiple-sample calling followed by stringent individual and variant quality controls. We then performed gene-based burden association analysis from exome data of 927 late-onset AD (LOAD, onset >65years) cases, 852 early-onset AD (EOAD, onset ≤65) cases and 1,273 controls. When aggregating rare (MAF<1%) protein truncating (PT) and missense variants predicted damaging by three bioinformatic tools (strictly damaging, SD), we found exome-wide significant association (p<2.5e-6) between EOAD risk and rare variants in *TREM2* (OR=6.3, 95%CI=[2.9-13.9], p=2.3e-7), *SORL1* (OR=3.4 [2.1-5.6], p=1.6e-7) and *ABCA7* (OR=2.5 [1.7-3.8], p=9.3e-7). The association with *TREM2* rare variants was robust to the exclusion of the p.R47H variant, previously described as associated with AD risk. No exome-wide significant signal was obtained in the LOAD sample while significance of the order of 10<sup>-6</sup> was observed in the whole AD group for *TREM2* (OR=4.8 [2.3-10.1], p=6.2e-6). No association was found with *PLD3*, *UNC5C* and *AKAP9* rare variants. With a cumulative MAF of 0.63% among controls and an OR of 6.3, *TREM2* rare PT+SD variants explained 1.17% of EOAD heritability. *SORL1* rare PT+SD variants explained 1.42% of it (OR of 3.4, cumulative MAF of 1.89%), and *ABCA7* rare PT+SD variants, 1.33% (OR of 2.5 and cumulative MAF of 3.22%). In comparison, 9.12% of EOAD heritability was attributable to *APOEε4*. Our study confirms previous gene-level results for *TREM2*, *SORL1* and *ABCA7* and provides a clearer insight into the classes of rare variants involved, including enlargement of the association to *TREM2* PT+SD variants. Despite different effect sizes and cumulative MAFs, *TREM2*, *SORL1* and *ABCA7* PT+SD rare variants contribute similarly to EOAD heritability with 1.1 to 1.5% of EOAD heritability attributed to each.

Alzheimer's Disease (AD), the most common form of dementia, is known to have a strong genetic component. To evaluate the association of exonic variants with AD, we analyzed data from the Alzheimer's Disease Sequencing Project, which consists of whole exome sequence (WES) from 10,929 subjects generated by three large scale genomic sequencing and analysis centers (LSACs). WES fastq files obtained from dbGaP (phs000572.v4.p2) were processed using Mayo Clinic's GenomeGPS pipeline, which aligned reads with Novoalign, and variants were identified using GATK's Best Practices workflow. Quality scores were assigned to variants using the GATK's variant quality score recalibration (VQSR) tools. Pooling information from public databases, variants were annotated using BioR and ANNOVAR. Rigorous quality control (QC) measures were implemented to retain a set of high quality, unrelated samples with relatively homogenous population substructure. Samples were QCed for coverage, call rate, missingness, TiTv ratio, sample contamination, sex check, sample duplication, relatedness, principal component analysis and APOE genotypes. Autosomal variants that passed VQSR, had a 95% call rate, met HWE criteria in controls, and had a minor allele count of at least 20 were analyzed. After sample and variant QC, 9904 samples and 102,828 variants remained. Single variant analysis, conducted by logistic regression using an additive genetic model adjusting for sex, APOE4 dose, APOE2 dose, LSAC, and three principal components addressing population substructure, yielded 5 variants with study-wide significance. Remarkably, additional QC to assess heterogeneity in minor allele frequency (MAF) across the three LSACs revealed that four of the five variants were likely false positives with markedly different MAFs across the LSACs ( $P_{\text{Isac}} < 1E-34$ ). Only rs75932628 encoding TREM2 p.R47H, which is known to associate with AD, achieved study-wide significance after this additional QC measure, which left 102,150 variants ( $P_{\text{Isac}} > 4.8E-7$ ). Logistic regression was also performed on variants with  $r^2 < 0.2$  in random sample(s) of 4952 subjects. Using the resultant coefficients, polygenic risk scores analyzed using the remaining half of subjects showed highly significant association with AD. Polygenic scores from relatively rare exonic variants (MAF < 1%) and from common variants (MAF > 10%) were both significant. Polygenic scores from protein-altering variants and from synonymous SNVs were also both significant.

**The roles of CD33 and TREM2 in neurodegeneration associated with Alzheimer's disease (AD) and frontotemporal dementia (FTD).** A. Rendina<sup>1</sup>, S. Napolitano<sup>1</sup>, F. Tripodi<sup>2</sup>, D. Drongitis<sup>3</sup>, A. Postiglione<sup>4</sup>, G. Milan<sup>2</sup>, E. Vitale<sup>1</sup>. 1) Institute of Protein Biochemistry (IBP), National Research Council (CNR), Naples, Naples, Italy; 2) Geriatric Clinic "Frullone" ASL Napoli 1, Naples, Italy; 3) Department of Biology, University of Naples Federico II, Naples, Italy; 4) Department of Clinical Medicine & Surgery, University of Naples "Federico II", Naples, Italy.

Frontotemporal dementia (FTD) and Alzheimer's disease (AD) are two multifactorial, heterogeneous and genetically complex neurodegenerative disorders. Despite massive research and drug development efforts, there are still no therapies that slow down or stop their progression. Several genes have been associated with both pathologies, suggesting that an as yet unknown common molecular pathway could exist. Mutations in genes related to neuroinflammation may be predisposing factors in these diseases. Coding and non-coding polymorphisms in genes expressed in microglia, including CD33 and TREM2, are risk factors and could be entry points for therapeutic intervention. Two SNPs in CD33 and one in TREM2 were described to be risk factors associated with Late Onset Alzheimer disease (LOAD). Specifically, CD33 SNPs rs3856444 and rs12459419 in minor alleles were found to confer strong protection while conferring elevated risk of LOAD in major alleles. These SNPs directly modulate the CD33 exon 2 splicing efficiency. In addition, the rare heterozygous missense variant rs75932628-T in TREM2 exon 2 was strongly associated with the ability of TREM2 to activate microglial cells. In order to assess the presence of these polymorphisms in an FTD cohort, we analyzed 216 Caucasians, mean age 60–85 years, diagnosed with LOAD, and 50 age-matched healthy controls. We used High Resolution Melting analysis (HRM) on genomic DNA from the whole blood of patients as a screen for mismatches. We sequenced the DNA from individuals with different melting curves using the Sanger method and used these results as a reference in our analysis. Our patients exhibited the coinheritance of SNPs rs12459419 and rs3865444, being heterozygous in 40%, homozygous for the major allele in 56.48% and homozygous for the minor allele in 3.7% of individuals. In addition, we identified a third SNP in CD33 exon 2, rs2455069, which belongs to a previously identified LD SNP block associated with an increased rate of cognitive decline. We found that all patients analyzed for SNP rs75932628 in the TREM2 gene are homozygous for the wild-type allele. However, some individuals are heterozygous for the nearby SNP rs143332484, which could be potentially associated with AD in our population. Further investigations are in progress to understand the mechanism of action of these two genes.

**Targeted sequencing of deep-phenotyped individuals for Alzheimer's disease susceptibility prediction.** *J. Seo<sup>1</sup>, M. Byun<sup>2</sup>, D. Lee<sup>3</sup>, M. Choi<sup>1</sup>, The KBASE consortium.* 1) Biomedical Sciences, Seoul National University, Seoul, South Korea; 2) Institute of Human Behavioral Medicine, Medical Research Center Seoul National University, Seoul, Republic of Korea; 3) Department of Neuropsychiatry, Seoul National University Hospital, Seoul, Republic of Korea.

Alzheimer's disease (AD), the most common form of dementia, is often classified on the basis of the onset age; late-onset AD (LOAD) is defined as onset of 65-year-old and more. Although having multifactorial origins, LOAD is clearly a genetic disorder, with heritability known to be 60-80%. Therefore, understanding the genetic etiology of LOAD will provide valuable insights into the pathogenesis of AD. Attempts to identify common genetic variants that are associated with LOAD susceptibilities have generated a number of candidate genes and variants with questionable functional implications. Here, we set up a targeted sequencing analysis of the coding and UTR regions of 132 LOAD-associated genes to determine if they carry previously uncharacterized rare variants with minor allele frequency less than 5%. Prior to the data production, we optimized the variant calling pipeline through a series of pilot experiments to ensure 93.5% sensitivity and 94.0% specificity in variant calling. The evaluation of imaging, psychological, psychiatric and experimental assessments in the KBASE (Korean Brain Aging Study for Early Diagnosis and Prediction of Alzheimer's disease) cohort provided more than 46 traits that can be utilized for genetic association test for 336 control, 137 mild cognitive impairment (MCI) and 84 LOAD cases. The cohort was analyzed by the Ion Torrent panel sequencing at a mean coverage depth of more than 400x. The initial association tests yielded 38 novel signals that exceeded the multiple-test corrected cutoffs from 20 traits. To validate the results, a larger replication set containing 3,113 control, 606 MCI and 845 LOAD cases was recruited. This study is an efficient and powerful genome analysis on common complex diseases to understand disease-causing mechanism and provide early-on disease prognosis prediction.

**2019F**

**Genetic markers in LUZP2 and FXBO40 genes are associated with the normal variability in cognitive performance in the elderly.** *V.A. Stepanov<sup>1</sup>, K.V. Vagaitseva<sup>1</sup>, A.V. Bocharova<sup>1</sup>, A.V. Marusin<sup>1</sup>, V. Markova<sup>2</sup>, L.I. Minaicheva<sup>1,2</sup>, O.A. Makeeva<sup>1,2</sup>.* 1) Institute of Medical Genetics, Tomsk National Medical research Center, Tomsk, Russian Federation; 2) Nebbiolo LLC, Tomsk, Russian Federation.

Cognitive performance is an important endophenotype for various neurodegenerative and neuropsychiatric diseases. In the present study two genetic variants in leucine-zipper protein (LUZP2) and F-box 40 protein (FBXO40) genes, previously reported to be genome-wide significant for Alzheimer's diseases and schizophrenia, were examined for association with cognitive abilities in normal elderly from the Russian population. Rs1021261 in LUZP2 and rs3772130 in FBXO40 were genotyped by multiplex PCR and MALDI-TOF mass spectrometry in a sample of 708 normal elderly subjects tested for cognitive performance using the Montreal Cognitive Assessment (MoCA). Association of genetic variability with the MoCA scores was estimated by parametric and non-parametric analysis of variance and by frequency comparison between upper and lower quartiles of MoCA distribution. Significantly higher frequency of 'TT' genotype of rs1021261 in LUZP2 gene, as well as 'A' allele and 'AA' genotype of rs3772130 in FBXO40 gene were found in a subsample of individuals with MoCA score less than 20 comparing to fourth quartile's subsample (MoCA > 25). The data of the present study suggests that genetic variability in LUZP2 and FBXO40 loci associated with neurodegenerative and neuropsychiatric diseases is also contributed to normal variability in cognitive performance in the elderly. This work was funded by the Russian Science Foundation (project No. 16-15-00020).

**Background.** Late-onset Alzheimer's disease (LOAD), the most common form of dementia, lacks effective treatment and is an enormous emotional and financial burden to society. Genetic research in early onset forms of the disease were the basis for current treatment strategies, but genome-wide association and exome sequencing studies of late onset disease have identified several novel susceptibility loci clustering in unique pathways that could lead to additional approaches. In this study we aim to determine whether family-based sequencing can provide a comprehensive and detailed knowledge of rare genetic variation leading to LOAD. **Methods:** We analyzed whole genome sequencing in members of 115 Caribbean Hispanic families with multiple relatives affected by LOAD. Recruitment for the study was based in medical clinics in the Dominican Republic, Puerto Rico and New York. Family ascertainment and follow-up has been in progress since 1998. All patients met recommended research criteria for LOAD, and controls were tested to be dementia free. We investigated rare genetic variants segregating within families or associated with LOAD. Single variant and gene-based association tests were performed, accounting for family structure. **Results.** A variant in *AKAP9*, p.R434W, segregated in two large families and was nominally associated with disease (OR=5.75, 95% CI 1.07–31.06, p=0.040). In addition, missense mutations in *MYRF* and *ASRGL1* under previously reported linkage peaks at 7q14.3 and 11q12.3 segregated completely in one family and in follow-up genotyping were nominally significant (p<0.05) in association with LOAD. We also identified rare variants in a number of genes implicated by GWAS, including *CR1* (p=0.049), *BIN1* (p=0.0098) and *SLC24A4* (p-value=0.040). **Conclusions and Relevance.** These results suggest rare variants in multiple genes influence LOAD risk in multiplex families. The results also support the view that rare variants may underlie loci established by GWAS.

**A new CAG repeat disease responsible for X linked cerebellar ataxia? L. Parodi<sup>1</sup>, M.L. Monin<sup>1,2</sup>, M. Raynaud<sup>3</sup>, G. Stevanin<sup>1,2,4</sup>, A. Brice<sup>1,2</sup>, A. Durr<sup>1,2</sup>.** 1) ICM Institut du Cerveau et de la Moelle, INSERM U1127, CNRS UMR7225, Sorbonne Universités – UPMC Université Paris VI UMR\_S1127, Paris, France; 2) APHP Department of Genetics, Groupe Hospitalier Pitié-Salpêtrière, Paris France; 3) CHRU de Tours, Service de Génétique, 37000 Tours ; INSERM U930, 37000 Tours; 4) Ecole Pratique des Hautes Etudes (EPHE), Paris Sciences et Lettes (PSL) Research University, Neurogenetics team, 75013 Paris, France.

Spinocerebellar ataxias (SCA) are inherited disorders predominantly affecting afferent and efferent cerebellar connections, resulting in a loss of gait and coordination as a disease hallmark. Among dominantly inherited SCAs the most prevalent group is due to pathological coding CAG repeat expansions in *ATXN1*, 2, 3, *CACAN1A* and *TBP* genes. We present a French family in which known CAG repeat expansions have been excluded, presenting with a spastic ataxia in two brothers at age 25 and 30. There was also apallathesia, progressive dystonic head tremor and progressive cognitive impairment. Both manifested severe cerebellar atrophy. Both their mother and maternal grand-mother, even in absence of any functional complaint, manifested moderate cerebellar dysarthria. The less severe presentation in the mother was in favor of mitochondrial or X-linked transmission. Since mitochondrial work-up was negative (normal muscular biopsy and respiratory chain levels, mtDNA quantification and sequencing) we performed Whole Exome Sequencing of the affected brothers and their father. Bioinformatic analysis was carried out in order to detect maternally inherited mutations. We identified a duplication (p.Gln2109\_Gln2115dup) harbored in *MED12* C-terminal region, predicted to add 7 Gln residues to the Glutamine-rich Opa domain resulting in a stretch of 14 consecutive CAG codons. Situated on the X chromosome, *MED12* encodes for the subunit 12 of a multiprotein complex necessary for mRNA transcription, crucial during neuronal development and differentiation and playing a fundamental role in both, Wnt and Shh pathways. Sanger sequencing validation showed that the duplication was carried in an heterozygous state by the mother and in hemizygous state by the two affected brothers, being absent in the father and in an unaffected daughter. Moreover, it is not present in public databases (ExAc, gnomAD) and absent in 324 French additional controls. Polyglutamine expansions in known SCAs genes are larger (21 CAG repeats in *CACAN1A* as smallest) but polyalanine expansions responsible for *OPMD* exhibit only 10-15 repeats. We are suspecting another mechanism than polyglutamine toxicity in this family and functional studies are currently underway. *MED12* involvement in critical aspects of neural development and the absence of the duplication in large control populations, are strongly supporting the hypothesis that the detected *MED12* rearrangement is a new cause of X-linked SCA.

**Neurobehavioral traits in family members inform gene discovery in ASD.**

S. Luzi<sup>1</sup>, M.L. Cuccaro<sup>1,2</sup>, E.R. Martin<sup>1,2</sup>, L. Gomez<sup>1</sup>, A.J. Griswold<sup>1</sup>, H.N. Cukier<sup>1</sup>, P.L. Whitehead<sup>1</sup>, J.L. Haines<sup>3</sup>, J.P. Hussman<sup>4</sup>, M.A. Pericak-Vance<sup>1,2</sup>. 1) Human Genomics, University of Miami - Miller School of Medicine (HIHG), Miami, FL; 2) Dr. John T. Macdonald Department of Human genetics, university of Miami, Miami, FL; 3) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, Ohio; 4) Hussman Institute for Autism, Baltimore, MD.

Autism (AUT) is multi-dimensional phenotype with a complex genetic architecture. Prior studies have shown that both neuropsychiatric (NPD) and neurodevelopmental (NDD) disorders (e.g., schizophrenia, ADHD, and bipolar disorder) have overlapping features and may have a shared molecular basis. We hypothesize that the presence of NPD, NDD, and subclinical AUT features within the same family concentrates autistic liability across generations with common genetic drivers. Using items from the ADI-R, we developed the Quantitative Autism Score (QAS) and applied it to create a phenotypically homogenous AUT cohort. We divided this cohort (N=520 individuals with AUT from the Simons Simplex Collection and Hussman Institute for Human Genomics) into two groups, based on family history of NPD, NDD and subclinical autistic features in relatives. The High Burden group (HB; N=185) consisted of individuals with AUT from families with a strong presence of NPD, NDD, and subclinical AUT features. The Low Burden group (LB; N=335) consisted of individuals with AUT from families with no family history of NPD, NDD or subclinical features. Using the QAS as our outcome measure, we conducted a SKAT-O gene-based test on WES data. In the HB group, *LMAN1L*, *GREB1L* and *EIF4A2* were significant (33513 genes analyzed, p-value=9.7E-06; 6.4E-05 and 6.8E-05). *LMAN1L* was also the most significant when only damaging variants were analyzed, surviving Bonferroni correction (18917 genes; p-value=2.4E-05). *LMAN1L* exerts its function in glycoprotein transportation and organelle targeting. *EIF4A2* has been reported to be overexpressed in frontotemporal dementia and down regulated in schizophrenia. In the LB group *PMFBP1*, *MIS18A* and *RPL14* were significant (p-value=3.2E-06; 7.2E-05 and 9.9E-05). When only damaging variants were analyzed, *SLC35F1* was the most significant (p-value=5.7E-05). *PMFBP1* is involved in the general organization of the cellular cytoskeleton and localized in an AUT CNV enriched region. *RPL14* is reported to interact with other genes in mice models of AUT, whereas *SLC35F1* is highly expressed in the fetal brain. Our results show that when we held the autism phenotype constant through the QAS, we were able to detect differences in autistic liability derived from family history. Our results point towards the presence of different mechanisms/different genes leading to ASD and suggest that family liability may bolster AUT gene discovery.

## 2023W

**Genome-wide analysis in pediatric-onset multiple sclerosis (MS) confirms a role for adult MS risk variants and reveals new candidates.**

Multiple sclerosis (MS [MIM 126200]), a complex autoimmune disorder, is the leading cause of non-traumatic neurological disability in young adults. Disease onset typically occurs between the ages of 20 and 40; however, ~5% of all MS patients have symptoms before 18 years. Exact mechanisms involved in pediatric MS pathogenesis remain unclear; however, both genetic and environmental factors have been implicated in disease susceptibility. The largest GWAS performed in adult MS recently identified 200 non-MHC MS variants (IMSGC, unpublished). Here, we describe the first GWAS study in white pediatric-onset MS cases and controls using the Illumina and Affymetrix platforms. Whole genome profiles for 500 pediatric MS cases and 11,577 controls were studied. Genetic imputation was performed using IMPUTE2, using the 1000 Genomes Phase 3 integrated variant set (March, 2012). Similar to adult onset MS, *HLA-DRB1\*15:01* showed a strong association in pediatric MS (OR=2.71, 95% CI 2.34-3.14, p=6.9 x 10<sup>-60</sup>). Within the MHC region, after conditioning on *HLA-DRB1\*15:01*, strong associations within the class I region genes (*HLA-B*, *HCG27*, and *PSORS1C1*; OR=2.12, p= 1.78 x 10<sup>-6</sup>) and class II region genes (*HLA-DPA1* and *MIR689*; OR=2.31, p=1.0 x 10<sup>-5</sup>) remained. Top established non-MHC adult MS risk variants associated with pediatric MS included rs6498163 (OR=1.29, 95% CI 1.14-1.46, p=8.2 x 10<sup>-5</sup>) and rs2286974 (OR=1.28, 95% CI 1.12-1.48, p=2.3 x 10<sup>-4</sup>) within *CLEC16A*; rs2150879 within *VMP1* (OR=1.29, 95% CI 1.14-1.47, p=8.9 x 10<sup>-5</sup>) and rs9878602 within *FOXP1* (OR=1.24, 95% CI 1.09-1.42, p=0.0009). More than 20% of tested adult MS risk variants demonstrated p<0.05 and had a mean OR=1.2 in pediatric-onset MS compared to OR=1.1 in adult MS. Furthermore, we searched the entire genome for new risk variants in pediatric-onset MS. Several gene regions reached genome-wide significance: SNPs clustering in genes *CHRD* and *THPO* on chromosome 3q27.1 (OR=2.92, 95% CI= 2.13, 4.18, p=1.7 x 10<sup>-10</sup>) and SNPs near or within gene *NOD1* on chromosome 7p14.3 (OR= 3.14, 95% CI=2.12, 4.65, p= 9.9 x 10<sup>-9</sup>) were observed. Results overall suggest variants within genes involved in adult-onset MS are also risk factors in children and suggest that similar biological processes are present in both groups.

## 2024T

**Multiple sclerosis in Orkney: The contribution of common variants to excess prevalence.** C.L.K. Barnes<sup>1</sup>, P.K. Joshi<sup>1</sup>, T.S. Boutin<sup>2</sup>, C. Hayward<sup>2</sup>, H. Campbell<sup>3</sup>, J.F. Wilson<sup>1,2,3</sup>. 1) Usher Institute of Population Health Sciences and Informatics, University of Edinburgh, Edinburgh, United Kingdom; 2) MRC Human Genetics Unit, University of Edinburgh, Institute of Genetics and Molecular Medicine, Western General Hospital, Crewe Road, Edinburgh, EH4 2XU, UK; 3) Centre for Global Health Research, The Usher Institute, University of Edinburgh, 9 Little France Road, Edinburgh, EH16 4UX, UK.

The Orkney Islands, located north of mainland Scotland, have the highest prevalence of Multiple Sclerosis in the world (4.02 / 1000 individuals)<sup>1</sup>. The prevalence of MS in Orkney is significantly higher than that found in mainland Scotland (a maximum of 2.29 / 1000 in Aberdeen)<sup>2</sup>; and higher than Shetland, a group of islands 50 miles north of Orkney (3.02 / 1000)<sup>1</sup>. Although various genetic and environmental risk factors for MS have been established, the reason for this excess prevalence of MS in Orkney is not clear. Several causes have previously been studied in Orkney, including vitamin D deficiency<sup>2</sup> and homozygosity<sup>3</sup>, but neither explain this excess prevalence. Compston et al (1981)<sup>4</sup> suggested that the reason behind this excess prevalence was due to a higher frequency of common risk variants in Orkney, occurring by chance due to the founders of the islanders' gene pool having higher frequencies of these variants. Here, we aim to explore this suggestion by comparing the common risk variants in Orkney to those in mainland Scotland to ask if there is a difference in their frequency, and if so, how that translates into disease prevalence. We calculated polygenic risk scores (PGRS, from an MS GWAS not including Orcadians) in controls from Orkney and Shetland (using the ORCADES and VIKING cohorts) and compared these to controls from Lowland Scotland (using individuals from Generation Scotland). When comparing PGRS between Orkney, Shetland and mainland Scotland, there was a small, but significant difference between the means of each population, with Orkney having the highest risk. However, this did not translate into a meaningful difference in prevalence that would be expected if common risk variants were the cause of the excess prevalence of MS in Orkney. This suggests that another cause, possibly rare variants, are more likely to be behind the excess prevalence of MS in Orkney. **References** 1. Visser, E. Macdonald Department of Human Genetics, Miller School of Medicine, University of Miami, Miami, FL, USA; 3) Department of Neurology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA; 4) San Juan MS Center, Guaynabo, Puerto Rico, USA; 5) Multiple Sclerosis Division, Department of Neurology, Miller School of Medicine, University of Miami, Miami, FL, USA; 6) Department of Neurology and Ann Romney Center for Neurological Diseases, Brigham and Women's Hospital, Boston, MA, USA; 7) Department of Neurology, University of California at San Francisco, San Francisco, CA, USA.

The Major Histocompatibility Complex (MHC), located on chromosome 6p21.3, has long been known to demonstrate the strongest genetic association with multiple sclerosis (MS) risk, on its own explaining ~10% of the sibling recurrence risk. The most extensively studied and replicated association has been seen with HLA-DRB1\*15:01, demonstrating the strongest genetic effect in Europeans and African Americans. However, the complex genomic structure of the region has made it difficult to comprehensively identify risk alleles across populations. The region has been most studied in individuals of Northern European ancestry, with additive and dominant effects for at least 13 different alleles. However, MHC variation across populations is high, with various population-specific alleles and allele frequency differences noted, and so those alleles may not be the most relevant in all populations. To assess MHC variation in Hispanic populations, we performed association analyses using genotype data from a custom Illumina array which were available on 1222 Hispanic MS cases and 1339 controls from sites across Puerto Rico and both the east and west coasts of the United States. Single Nucleotide Polymorphisms (SNPs) which tag ( $R^2 > 0.2$ ) 9 of the 13 published alleles were available. Association with MS was confirmed for 5 of the 9 in this Hispanic sample ( $p \leq 0.05$ ) including HLA-DRB1\*15:01, HLA-DQA1\*01:01, HLA-DQB1\*03:02, HLA-A\*02:01, and rs9277565 (correlated with HLA-DPB1). However, association was not confirmed ( $p > 0.05$ ) for HLA-DRB1\*08:01, HLA-B\*55:01, HLA-B\*44:02, and rs2229092 (missense in *LTA*). Utilizing conditional linear modeling ( $p \leq 1.0E-05$ ) within the extended MHC on chromosome 6 from 27 to 34 Mb, the three most strongly associated independent signals observed were HLA-DRB1\*1501 (OR = 2.45,  $p = 1.06E-22$ ), rs9277565 (OR = 1.55,  $p = 5.80E-08$ ), HLA-A\*02:01 (OR = 0.75,  $p = 9.42E-07$ ), and an intronic SNP in NFKB inhibitor like 1 (*NFKB1*) which serves as an eQTL for both DEXD-box helicase 39B (*DDX39B*) and natural cytotoxicity triggering receptor 3 (*NCR3*) in lymphoblastoid cell lines (OR = 0.66,  $p = 5.80E-06$ ). Further work is being done to characterize the local ancestry across each of these loci. This detailed investigation of the MHC provides a first step towards uncovering the MHC risk for MS in admixed Hispanic populations and chronicling the ancestral lineage of MHC risk haplotypes.

**Genetics of vaccination related narcolepsy.** *H.M. Ollila<sup>1</sup>, A. Wennerstrom<sup>2</sup>, M. Partinen<sup>2</sup>, E. Mignot<sup>1</sup>, J. Saarela<sup>3</sup>, P. Saavalainen<sup>4</sup>, O. Vaarala<sup>5</sup>, P. Tienari<sup>6</sup>, M. Perola<sup>2</sup>.* 1) Psychiatry, Stanford University School of Medicine, Palo Alto, CA; 2) National Institute for Health and Welfare, Helsinki, Finland; 3) Institute for Molecular Medicine Finland, University of Helsinki, Helsinki, Finland; 4) Research Programs Unit, Immunobiology, University of Helsinki, Helsinki, Finland and Department of Medical and Clinical Genetics, University of Helsinki, Helsinki, Finland; 5) Research Programs Unit, Diabetes and Obesity, University of Helsinki, Helsinki, Finland; 6) Research Programs Unit, Molecular Neurology, Biomedicum, University of Helsinki, Helsinki, Finland; Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland.

Type 1 Narcolepsy is a severe hypersomnia caused by a specific loss of neurons producing hypocretin/orexin in the hypothalamus and affecting 1/3000 individuals. In 2009/2010 immunization towards pandemic H1N1 Influenza-A campaign was launched and the vaccine used in Northern European countries associated with increased risk for narcolepsy. We built a multilocus genetic risk score with established narcolepsy risk variants using whole genome sequencing and exome sequencing data from 7,000 individuals to examine the genetic load for narcolepsy in 81 individuals with vaccination related narcolepsy, a third of all cases from Finland. Previously discovered risk variants had strong predictive power ( $P < 2.2 \times 10^{-16}$ ) in the vaccine related narcolepsy cases with only 4.9% of cases being assigned into the low risk category. Furthermore, at genome-wide level the strongest association was seen in *IL12RB1* (rs17885060,  $P = 2.93 \times 10^{-7}$ ) and *ZXDC* a gene required for HLA class II transcription (rs11715293  $P = 7.06 \times 10^{-7}$ ). Our findings suggest that genetic risk factors have a major role in regulating predisposition for narcolepsy and genetic risk score gives high predictive power to detect individuals with high risk for narcolepsy.

**Assessment of genomic variations in multiple sclerosis patients identifies mutations in *ADAMTS14*, *IL22RA2*, *HNRNPA1* and *TNPO1* genes indicating the existence of molecular mimicry and cytokine/interferon receptor pathway disruption inducing autoimmunity.** *A.M. Veerappa.* Department of Studies in Genetics and Genomics, University of Mysore, Mysuru, India.

Multiple Sclerosis (MS) is a rare inflammatory autoimmune demyelinating and neurodegenerative disorder in which axonal injury, neuronal loss, and atrophy of the central nervous system leads to permanent neurological and clinical disability. Immune-mediated destruction of myelin is considered to be the major cause of MS. Etiology of MS involves the interplay between genetic and environmental factors. To understand the role of genetic factors; we performed Whole Exome Sequencing (WES) on five Relapsing Remitting Multiple Sclerosis (RRMS) cases using Illumina HiSeq 2500. Focusing on deleterious/damaging mutations, identified mutations in *HNRNPA1*, *TNPO1*, *ADAMTS14* and *IL22RA2* playing a role in pathogenesis of RRMS. Mutations in *ADAMTS14* and *IL22RA2* were found present in all samples. Mutations in *ADAMTS14* contributes to disruption of balance between disintegrating proteinases and the corresponding inhibitors in favor of proteolysis leading to pathologic brain ECM destruction and MRI lesions. *ADAMTS14* is also known to be involved in the regulation of inflammation and acquired immunity. *IL22RA2* on the other hand, is involved in cytokine and interferon receptor activities inducing neuro-inflammation. However, in one of the cases, along with *ADAMTS14* and *IL22RA2* mutations, damaging variants were also identified in *HNRNPA1* and *TNPO1* disrupting the binding of TNPO1 with nucleoporin, affecting the transport of HNRNPA1 leading to its accumulation in cytoplasm resulting in increased cellular stress causing cellular death. Further analysis revealed the presence of 62% homology between Glycoprotein E (gE) of VZV virus and M9 domain of HNRNPA1. This molecular mimicry prompts the production of auto-antibodies resulting in autoimmunity. Thus we hypothesize that the molecular mimicry between gE of VZV virus and M9 domain of HNRNPA1 leads to accumulation in cell's cytoplasm triggering the auto-reactive immune response in neuronal cells causing neuro-degeneration.

**2028F**

**Genomic and functional evaluation of the role of the TNFSF14-TNFRSF14 pathway in susceptibility to multiple sclerosis.** M. Zuccala<sup>1</sup>, N. Barizzone<sup>1</sup>, E. Boggio<sup>1</sup>, L. Gigliotti<sup>1</sup>, M. Sorosina<sup>2</sup>, R. Bordon<sup>3</sup>, F. Clarelli<sup>4</sup>, S. Anand<sup>5</sup>, E. Mangano<sup>3</sup>, D. Vecchio<sup>4</sup>, F. Esposito<sup>2</sup>, C. Basagni<sup>1</sup>, E. Corsetti<sup>1</sup>, G. Predebon<sup>1</sup>, R. Cantello<sup>4</sup>, V. Martinelli<sup>2</sup>, G. Comi<sup>2</sup>, M. Leone<sup>5</sup>, G. de Bellis<sup>3</sup>, U. Dianzani<sup>1</sup>, F. Martinelli-Boneschi<sup>2,6</sup>, S. D'Alfonso<sup>1</sup>. 1) Department of Health Sciences, Interdisciplinary Research Center of Autoimmune Diseases (IRCAD), University of Eastern Piedmont, Novara, Avogadro University, Novara, Italy; 2) Laboratory of Human Genetics of Neurological Diseases, San Raffaele Scientific Institute, Milano, Italy; 3) National Research Council of Italy, Institute for Biomedical Technologies, Segrate, Milano, Italy; 4) MS Centre, SCU Neurology, AOU Maggiore della Carità, Novara, Italy; 5) SC Neurologia, Dipartimento di Scienze Mediche, IRCCS Casa Sollievo della Sofferenza, San Giovanni Rotondo, Italy; 6) Department of Biomedical Sciences for Health, University of Milan, Milan, Italy.

Multiple Sclerosis (MS) is a complex disease. Over 100 MS susceptibility genes were identified. Among these, the strongest non-HLA signal in the Italian population maps in the Tumor Necrosis Factor (ligand) superfamily member 14 (*TNFSF14*) gene. *TNFSF14* encodes for LIGHT, a transmembrane glycoprotein expressed on various immune cells and involved in immune modulation and dendritic cells (DC) maturation. We demonstrated that an intronic variant (rs1077667) is the primarily associated one through a fine-mapping approach. Cis-eQTL analysis data from different public databases showed that carriers of MS risk allele have a lower *TNFSF14* RNA expression in EBV-transformed lymphoblastoid cell lines (Geuvaris, Bioportal, Gtex) and in PBMCs (Gtex), but not in brain cells (Braineac). These data are consistent with the observation that in heterozygous individuals the allelic expression is unbalanced in favor of the allele with higher eQTL expression ( $p < 0.0001$ , RNAseq on 97 lymphoblastoid cells, Geuvaris). We confirmed these data by RT-PCR expression analysis on PBMC of 84 Italian MS and 80 healthy controls (HC): individuals with the MS risk genotype produced lower levels of *TNFSF14* transcript ( $p = 1.1 \times 10^{-4}$ ). In addition, we observed that MS patients show significantly lower expression levels compared to HC ( $p = 0.031$ ). Preliminary analysis performed on peripheral blood of HC by flow cytometry showed that in myeloid DC (CD11c+) the homozygous individuals for the risk allele ( $N = 10$ ) had a higher percentage of LIGHT positive cells compared to the others ( $N = 10$ ,  $p$ -value = 0.02). We compared the expression of LIGHT and its receptor HVEM (*TNFRSF14*) in 5 populations of monocyte-derived DC (MDC). LIGHT is expressed in all types of immature MDCs and was substantially upregulated in the mature (LPS-activated) MDCs, particularly in those derived using GM-CSF+IL-15 ( $p = 0.04$ ). Conversely, in this same population, HVEM was downregulated ( $p = 0.04$ ). In conclusion, we propose that an altered *TNFSF14* expression in immune cells driven by the intronic variant can contribute to the pathogenesis of MS. In particular, this variant seems associated with a low *TNFSF14* RNA expression in a mixed population of PBMCs and with a higher percentage of LIGHT positive cells in myeloid dendritic cells (representing only 1 – 2% of PBMCs) suggesting a cell specific influence of this variant on LIGHT expression at the protein level, which might have distinct effects on the surface and secreted forms of the protein.

**2029W**

**Predicted expression of *TMEM163* is associated with traumatic brain injury risk in a biobank population.** J. Dennis, X. Zhong, N. Cox. Genetic Medicine, Vanderbilt University Medical Center, Nashville, TN.

Over 8 million Americans sustain a traumatic brain injury (TBI) annually, with sequelae ranging from persistent headaches to dementia and death. Identification of genes predisposing to TBI and its late effects could help identify those at highest risk of adverse outcomes. We report the first GWAS of TBI risk, conducted in the Vanderbilt University Biobank, BioVU, which includes DNA samples linked to electronic medical records in >270,000 patients. We conducted gene-based analyses in 9155 European-ancestry patients using PrediXcan, a computational tool that predicts gene expression levels across tissues from genome-wide genotype data in the target sample (BioVU) and a reference transcriptome dataset (GTEx). We tested 11005 genes in whole blood and 9164 genes in brain cortex for association with TBI defined by CDC criteria as one or more ICD codes for 'Cerebral laceration and contusion', 'Concussion', 'Intracranial hemorrhage following injury', 'Skull fracture', and 'Other intracranial injury'. Analyses were adjusted for sex, age (at first TBI or at last ICD code in the medical record), and principal components 1-3. TBI was diagnosed in 503 of 9155 patients. The median age at first TBI was 51.7 years, 6.8% of patients were <18 years of age at first TBI, and 57.8% of TBI patients were male. No genes expressed in whole blood were associated with TBI or any of its sub-categories after applying Bonferroni correction. Conversely, expression of *TMEM163* in cortex was associated with 1.59-fold increased risk of 'Other intracranial injury' ( $p = 2.13 \times 10^{-7}$ ), and was marginally associated with TBI overall ( $p = 0.001$ ). *TMEM163* is a transmembrane zinc transporter implicated by meta-GWAS in Parkinson disease (PD) risk. PD was diagnosed in 1.8% of TBI cases vs. 0.8% of controls ( $p = 0.04$ ), while 'Other neurodegenerative diseases' were diagnosed in 72.5% TBI cases vs. 35.1% of controls ( $p < 2.2 \times 10^{-16}$ ). Nonetheless, the association between *TMEM163* expression and TBI persisted when we stratified by neurodegenerative disease, and *TMEM163* expression was only marginally associated with other neurodegenerative disease (odds ratio=1.12,  $p = 0.08$ ) in 3755 cases and 5575 controls. Our analyses suggest that *TMEM163* expression in cortex is associated with the risk of TBI, and perhaps with the risk of neurodegeneration in general. Further research is warranted to determine whether *TMEM163* is independently associated with PD risk, or whether the association is mediated by TBI.

**2030T**

**A genome-wide screen to identify suppressors of neurodegeneration in Gaucher disease.** S.U. McKinstry, K. Adams, I. Tsai, N. Katsanis. Center for Human Disease Modeling and Department of Cell Biology, Duke University School of Medicine, Durham, NC.

Gaucher disease (GD) is the most common lysosomal storage disorder with a broad range of symptoms including hepatosplenomegaly, blood and skeletal disorders, and neurological defects, including neurodegeneration. Gaucher is caused by mutations in *GBA*, leading to a loss of its glucosylceramidase activity and an accumulation of glucocerebroside in the lysosome. *GBA* enzyme replacement therapy is effective for many GD symptoms, but the enzyme cannot cross the blood-brain barrier and thus the neurological symptoms are left as an unmet need. While the precise mechanisms through which lysosome dysfunction leads to neurological defects is unknown, the link of *GBA* to a more common neurodegenerative disorder, Parkinson disease (PD), offers an important clue. Data from idiopathic PD patients and pathogenic single-gene mutations in PD has highlighted defects in mitochondria quality control through mitophagy, the process by which cells degrade damaged mitochondria, as potential pathomechanism in neurodegeneration. Importantly, defects in mitochondria quality control have been identified in GD patient cells, suggesting this mechanism could underlie neurodegeneration in GD as well. Disease severity in GD can vary widely suggesting that modifier genes play an important role in disease penetrance. In some cases, additional mutations ameliorate the disease severity, suggesting that genetic suppressor could be viable therapeutic targets. In this study, we conducted a genome wide RNAi screen to identify suppressors of mitochondria dysfunction as potential therapeutic targets for GD neurological dysfunction. We employed a dual track approach of using human cell lines to identify genetic suppressors of mitochondrial dysfunction and developing *in vivo* zebrafish disease models for target validation.

**2031F**

**Genome editing by CRISPR-Cas9 followed by RNA sequencing to identify the transcriptional regulatory role of MEIS1 in restless legs syndrome.** F. Sarayloo<sup>1,2</sup>, H. Catoire<sup>2</sup>, D. Rochefort<sup>2</sup>, P. Dion<sup>2,3</sup>, G. Rouleau<sup>2,3</sup>. 1) Human Genetics, McGill University, Montreal, Canada; 2) Montreal Neurological Institute, McGill University, Montreal (QC), Canada; 3) Department of Neurology and Neurosurgery, McGill University, Montreal (QC), Canada.

Restless legs syndrome (RLS), a frequent movement disorder in the elderly in western populations, is characterized by an irresistible urge to move the legs and abnormal sensations in the lower limbs. A successful GWAS on RLS in 2007 identified common variants associated with this disorder located in intron 8 of *MEIS1* gene and the intergenic region between *MAP2K5* and *SKOR1*. These results were also replicated by other independent studies. Our group subsequently showed that *MEIS1* risk haplotype is associated with decreased mRNA and protein expression of this gene in RLS patients' LCL and thalamus samples. To further explain the role of other RLS associated genes, we examined the *SKOR1* mRNA expression in patient cells with the *MEIS1* risk haplotype and observed a significant decrease in its expression, suggesting a regulatory role of *MEIS1* on *SKOR1* expression. To further confirm this regulatory role, a luciferase reporter assay followed by electrophoretic mobility shift assay showed a direct interaction between *MEIS1* and *SKOR1* promoter in two different regions. Given the fact that *MEIS1* has a transcriptional regulatory function, we hypothesize that this gene has an indirect regulatory role in RLS pathways. To further investigate that, we are overexpressing *MEIS1* and also using CRISPR-Cas9 to knockout this gene, separately in different human cell lines (HEK293 and SK-N-SH cells, a neuroblastoma cell line). Whole transcriptome of these sets of cells as well as wild type cells with normal endogenous expression are extracted followed by RNA-Seq experiment. We believe that differential expression analysis of RNA-Seq data will lead to identify genes that are in fact regulated by these transcription factors, some of which might be novel genes with direct roles in RLS pathological pathways.

**2032W**

**Investigation of rare variations in four SLI candidate genes in Pakistani SLI population.** *E.M. Andres<sup>1</sup>, M.A.R. Basra<sup>2</sup>, H. Hafeez<sup>2</sup>, F. Kausar<sup>2</sup>, S. Riazuddin<sup>2</sup>, M.L. Rice<sup>1</sup>, M.H. Raza<sup>1</sup>.* 1) University of Kansas, 1000 Sunnyside Avenue, Lawrence, KS 66045; 2) Institute of Chemistry, University of the Punjab, Lahore 54590, Pakistan; 3) Alama Iqbal Medical Research Center, Lahore 54550, Pakistan.

Specific language impairment (SLI) refers to a language deficit, which cannot be explained by any other neurological disorder. Both receptive and expressive language are often impaired in people with SLI. The estimated prevalence of SLI is 7% in kindergarten children. The causes of SLI are not well understood but it is clear that genetic factors are involved. Twin studies have shown that SLI is highly heritable and aggregates in small to medium size families. Many candidate genes have been associated with language impairment but there has been very little replication of rare coding variations between populations. Four candidate genes previously reported for language impairment (*NFXL1*, *TM4SF20*, *ATP2C2*, and *CNTNAP2*) were selected to sequence for the coding exons in probands of 29 SLI families ascertained from Pakistan. The probands were classified for SLI based on their family history and performance on the Peabody Picture Vocabulary Test-4<sup>th</sup> Edition (PPVT-4). Coding exons of all four candidate genes were sequenced in 29 probands through Sanger DNA sequencing. The sequencing data were analyzed to report the rare coding variants (less than 0.5% in the 1000 Genome). In total, one predicted splice site and eight rare coding variations were found within Pakistani SLI probands across four genes: *TM4SF20* (rs137891000), *NFXL1* (rs370816326, rs749383964, rs775580487), *CNTNAP2* (rs150918383, rs138517537, an unknown SNP), and *ATP2C2* (rs531589939, rs551531561, rs758765955, rs757310826). Our data show that previously reported SLI genes *NFXL1*, *TM4SF20*, *ATP2C2*, and *CNTNAP2* might be implicated in SLI in the Pakistani population when the sample size is increased.

**Defining the critical region for brain malformations in 6q27 microdeletions.** *M.D. Dias Hanna<sup>1</sup>, P.N. Moretti<sup>1</sup>, R.S. Bonadio<sup>1</sup>, M.T.A.S. Rosa<sup>2</sup>, M.S. Cordoba<sup>3</sup>, S.F. Oliveira<sup>1</sup>, A. Pic-Taylor<sup>1</sup>, J.F. Mazzeu<sup>1</sup>.* 1) Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Brasil; 2) Secretaria de Estado de Saúde do Distrito Federal, Brasília, Brasil; 3) Hospital Universitário de Brasília, Universidade de Brasília, Brasília, Brasil; 4) Faculdade de Medicina, Universidade de Brasília, Brasília, Brasil.

Terminal microdeletions of the long arm of chromosome 6 have been rarely described and the phenotype includes multiple brain malformations, intellectual disability and epilepsy. A smaller region of overlap of 1.7 Mb has been proposed to contain a gene responsible for the brain anomalies. We studied a 10-year-old girl with moderate intellectual disability and multiple brain alterations including periventricular nodular heterotopia, hydrocephalus, incomplete hippocampal inversion, hypoplastic vermis and reduced mesencephalic volume. Chromosome microarray analysis was performed using Cytoscan 750K (Affymetrix). Array revealed a 325kbp deletion on chromosome 6q27, smaller than the previous microarray refined microdeletions described on the literature, comprising six genes: *DLL1*, *FAM120B*, *MIR4644*, *PSMB1*, *TBP* and *PDCD2*. The deletion was inherited from her affected mother. *THBS2*, *PHF10*, *DLL1*, and *C6orf70* genes mapped at 6q27 have been previously proposed as candidate genes for the brain malformations in 6qter deletion carriers. The patient here described has a smaller deletion including only one of the previous candidate genes: *DLL1*. *DLL1* is involved in cell adhesion regulation, cell-cell communication and cell-fate determination and *DLL1* haploinsufficiency has been linked to holoprosencephaly in humans. *TBP* is a possible candidate gene for its expression in the brain and association to spinocerebellar ataxia and Parkinson's disease. *TBP* knock-out mice are not viable but *tbp* heterozygous showed no abnormalities. However, its effect is possibly greater for intellectual disability, but not for brain development and its contribution could be due to position effect, which can span as far as 5 Mb. *PDCD2* is associated with programmed cell death in thymocytes and *PSMB1* is a subunit of a proteasome complex. Both are tightly linked to *TBP*. *FAM120B* is not considered a candidate due to its expression in all adult and fetal tissues. *MIR4644* is a microRNA and the only study suggested its potential use as a biomarker in pancreatobiliary tract cancer. Study using bioinformatics tools to prioritize candidate genes for brain development pointed *DLL1* as the best candidate, but *TBP* could also be considered as a potential candidate. **Genomic variants related to verapamil response in the treatment of migraine.** *F.M. Cutrer<sup>1</sup>, C.J. Klein<sup>1</sup>, E.J. Atkinson<sup>2</sup>.* 1) Neurology, Mayo Clinic, Rochester, MN; 2) Biomedical Statistics and Informatics, Mayo Clinic, Rochester, MN.

At present, there is no biologically based rationale for drug selection among at least five pharmacologically distinct classes of prophylactic treatment in migraine, a disorder that afflicts over 40 million people in the United States. Whole Exome sequencing (WES) was performed in 22 patients who were highly responsive to Verapamil (mean 77% decrease) and in 15 patients who were poorly responsive (mean 3% decrease). After filtering out synonymous variants, we identified 588 correlating SNP's with  $p < 0.01$ . We then genotyped 188 different patients from whom we had Verapamil monotherapy data using the 524 most significant SNP's identified by WES and tested for a correlation with reduction in headache days. We then used all SNP's that correlated with Verapamil treatment response ( $p < 0.05$ ) in a pathway analysis to identify potential functional molecular cascades carrying a disproportionate number of Verapamil-migraine implicated SNP's. We assessed the change in the number of headache days using the percentage change model (Pre-treatment – Post treatment / Pre-treatment values. The table shows the SNP's with a  $p$ -value  $< 0.01$ .) **Pre- Post Treatment change** (Percentage reduction) We carried out a pathway analysis using the SNP's which were most highly correlated with change in headache days after Verapamil monotherapy treatment ( $p < 0.05$ ). Two pathways were implicated. When SNP's with  $p < 0.05$  correlation is used, the myo-inositol pathway is implicated. When the SNP's are further restricted to those with a  $p < 0.01$  then the phospholipase C signaling cascade is implicated. We propose that response to prophylactic treatment is an element of phenotype that is informative of the molecular pathophysiology of migraine susceptibility in individuals whose migraine is suppressed by a specific drug. We have demonstrated that using WES in highly responsive vs non-responsive subjects we can identify variants that implicate functional molecular cascades that are relevant to the anti-migraine action of the drug investigated. To our knowledge, this is the first work of its kind in migraine.

**Targeted sequencing of migraine-epilepsy susceptibility locus on chromosome 12q.** *M.E. Hiekkala<sup>1</sup>, M.A. Kaunisto<sup>2</sup>, A. Siren<sup>3</sup>, V. Artto<sup>4</sup>, S. Vepsäläinen<sup>4</sup>, P. Häppölä<sup>2</sup>, P. Palta<sup>2</sup>, E. Hämäläinen<sup>2</sup>, S. Lindh<sup>1</sup>, M. Färkkilä<sup>4</sup>, A. Palotie<sup>2,5,6,7,8,9</sup>, M. Kallela<sup>4</sup>, A.E. Lehesjoki<sup>1,10</sup>, M. Wessman<sup>1,2</sup>.* 1) Institute of Genetics, Folkhälsan Research Center, Helsinki, Finland; 2) Institute for Molecular Medicine Finland FIMM, HiLIFE, University of Helsinki, Helsinki, Finland; 3) Outpatient Clinic for Persons with Intellectual Disabilities, Tampere University Hospital, Finland; 4) Department of Neurology, Helsinki University Central Hospital, Helsinki, Finland; 5) Psychiatric and Neurodevelopmental Genetics Unit, Massachusetts General Hospital, and Harvard Medical School, Boston, USA; 6) Department of Neurology, Massachusetts General Hospital, Boston, Massachusetts, USA; 7) Medical and Population Genetics Program, Broad Institute of MIT and Harvard, Cambridge, USA; 8) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, USA; 9) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, USA; 10) Neuroscience Center and Research Programs Unit, Molecular Neurology, University of Helsinki, Helsinki, Finland.

Migraine and epilepsy are both common disabling episodic disorders with a large number of similar triggers, medication and overlapping genetic contributions. Furthermore, the incidence of migraine in patients with epilepsy is almost twice of that in individuals without epilepsy (Ottman and Lipton 1994). We hypothesize that identifying predisposing variants to migraine and epilepsy will provide important insights into shared pathophysiology underlying the diseases. We have identified a migraine-epilepsy locus on chromosome 12q in a large Finnish migraine-epilepsy family (Polvi et al. 2012). Using SNP genotyping (48 individuals) we were able to restrict the 13.5 Mb large locus to a region of only 2 Mb. The region contains several potential candidate genes, such as transcriptional corepressor gene *NCOR2* (nuclear receptor corepressor 2) that has an important role in neuronal function. In order to identify susceptibility variants on 12q we have sequenced the 2 Mb region (GRCh37/hg19: chr12:123.750.000-126.250.000) in 48 individuals from the migraine-epilepsy family. So far, we have focused our analyses on *NCOR2* gene. Our preliminary analysis did not reveal any rare or low frequency and functionally interesting *NCOR2* variant shared by the affected family members. Next we will expand our variant analyses on other genes in the region and pay special attention to small deletions and insertions. In addition, we will utilize the genome-wide SNP data to perform copy-number variation analysis identifying possible larger deletions or duplications within the area.

**RNA-seq analysis after moderate blast exposure in peripheral blood samples.** H. Kim<sup>1</sup>, K. Edwards<sup>1</sup>, V. Motamedi<sup>1</sup>, S. Yun<sup>2</sup>, J. Gill<sup>1</sup>. 1) SML, NINR/NIH, Bethesda, MD; 2) Yotta Biomed, Bethesda, MD.

Blast induced traumatic brain injuries are a signature injury of recent war campaigns; yet little is known about the biological mechanisms underlying blast exposures. In a group of military personnel (N = 69), prior to, and on each day of a blast training program (10 days total), blood was collected; throughout training, blast exposure measures were detected by helmet sensors to determine the mean peak pressure in pounds per square inch (psi). On day 7, some participants (n = 29) sustained a moderate blast (mean peak pressure = 7.9 psi) and were matched to participants with no/low blast exposure during the training (n = 40). Headaches and concentration problems occurred on the day of the moderate blast exposure, and the headaches continue on the following day. Total RNA was isolated from blood samples and processed for Illumina's HiSeq 2500 sequencing system to measure expression of genes across the entire genome. Based on the dysregulation data from RNA-sequencing and top gene networks identified using Ingenuity Pathway Analysis, a subset of genes were chosen to validate with Nanos-tring's nCounter Digital Analyzer system. In this sample, day 10 samples from moderate blast cases (n = 29) were compared to each participant's own baseline, leading to the identification of 1,803 genes that were differentially expressed after moderate blast exposure (746 up-regulated genes and 1,058 down-regulated genes). IPA suggests dysregulation of networks for both cell death and survival as well as cellular development and function with the most altered network being related to amyloid precursor protein (APP).

**Very rare homozygous variants: A flashlight to possible involvement in ALS?** A. Orr-Urtreger<sup>1,2</sup>, O. Goldstein<sup>1</sup>, M. Gana-Weisz<sup>1</sup>, M. Kedmi<sup>1</sup>, S. Twito<sup>1</sup>, O. Nayshool<sup>1</sup>, B. Vainer<sup>3</sup>, B. Nefussy<sup>2</sup>, V.E. Drory<sup>2,3</sup>. 1) Gen Inst, Tel-Aviv Sourasky Med Ctr, Tel Aviv, Israel; 2) Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel; 3) Neuromuscular Service, Department of Neurology, Tel-Aviv Sourasky Medical Center, 6 Weizmann Street, Tel Aviv 64239, Israel.

North Africa Jews (NAJ) are considered a population with a genetic architecture that is relatively homogenous due to a history of religious and cultural restrictions. We previously showed that Amyotrophic Lateral Sclerosis (ALS) is observed in NAJ in a similar worldwide incidence but at an earlier age-of-onset, and that some ALS patients from this origin carry the homozygous *OPTN* 691\_692insAG founder mutation. We aimed to study the possibility that additional rare homozygous genetic variations may contribute to familial and sporadic ALS in NAJ patients. Methods: Whole Exome Sequencing (WES) of 43 NAJ individuals affected with ALS was carried out. Filtering was done to identify very rare recessive *in-silico* damaging variants, with allele frequencies of less than 0.002 in the gnomAD browser, annotated to ALS-associated cellular pathways. Two variants were subsequently genotyped in additional 70 unrelated NAJ ALS patients and 400 ethnically matched controls. Results: We identified 34 rare homozygous variants in genes associated with pathways that are known to be involved in ALS, including autophagy, mitochondria, RNA-binding and cytoskeleton. These included genes previously reported as upregulated (*SFXN4*) or downregulated (*ARMC4* and *MTHFSD*) in ALS patients, and genes previously associated with other neurodegenerative or neuromuscular diseases, such as *HTT* (Huntington's disease), *ATM* (Ataxia-Telangiectasia), *ZFYVE26* (Spastic Paraplegia 15) and *MFN2* (Charcot-Marie-Tooth disease type 2A). The homozygous variations that were detected in *MFN2* and *NEK1* (p.Arg663Cys and p.Arg261His) were further evaluated. Their allele frequencies in ALS patients were 11.2 and 1.9 times higher than in the ethnically matched controls, ( $p=0.031$  and not significant, respectively), with no homozygotes observed in controls for both. Overall, 10 ALS patients (23%) were homozygotes for more than one rare variant. In conclusion, we demonstrate that the unique homogenous population of North Africa Jews has the power to identify rare homozygous variants in ALS, suggesting that additional genes are involved in this disease. We report for the first time the association of *MFN2* with ALS, and suggest that the *NEK1* p.Arg261His is a risk factor for this disease. In addition, *MTHFSD*, which is involved in stress granules, might be a candidate for ALS. Our data also support oligogenic inheritance in ALS and highlight the importance of autophagy, mitochondria and RNA homeostasis in ALS pathogenesis.

**Whole-genome sequencing points to *SV2A*, *DENND4B*, *MIB2*, *SPTBN2*, and *APP* as new genes of interest in two individuals sporadically affected with childhood apraxia of speech.** B. Peter<sup>1,2</sup>, C. Vose<sup>1,2</sup>, E. Groff<sup>1,2</sup>, L. Eng<sup>1</sup>, M. Naymik<sup>3</sup>, I.B. Schrauwen<sup>3,4,5</sup>. 1) Speech & Hearing Sci, Arizona State University, Tempe, AZ; 2) Communication Sciences and Disorders, Saint Louis University, Saint Louis, MO; 3) Neurogenomics Division, Translational Genomics Research Institute, Phoenix, AZ; 4) Molecular & Human Genetics, Baylor College of Medicine, Houston, TX; 5) Division of Natural Sciences, Arizona State University, Tempe, AZ.

Childhood apraxia of speech (CAS) is a severe speech sound disorder that interferes with a child's ability to control the articulatory machinery towards intelligible speech. Since the discovery of the *FOXP2* gene in a family with syndromic CAS, additional evidence that CAS has a genetic etiology has been emerging. Aside from a few recurring genomic changes such as 6p11.2 deletions, the genetic etiology appears to be heterogeneous and includes inherited as well as sporadic changes, point mutations as well as copy-number variations (CNVs), and single as well as multiple hits. Many genes of interest are highly expressed in cerebellum, consistent with the phenotype. Here, we present two trios with affected offspring and unaffected parents. Patient 1, age 19 years, still exhibits residual signs of CAS in the form of monotone pitch and robotic-sounding speech rhythm. His identical twin has the same clinical history. Patient 2, age 6, shows active CAS signs including vowel errors and inconsistent word productions. In both cases, family history was negative for severe speech disorders except for Patient 1's twin brother. Whole-genome sequences obtained from blood samples were analyzed for *de novo* variants. Patients 1 and 2 carry 5 and 12 *de novo* CNVs, respectively, with no overlaps. None of the CNVs overlap with previously published regions of interest and all with but one gene-containing CNVs are reported in the Database of Genomic Variants. CNV causality is unlikely. The two patients share 22 variants, all rare, in 20 genes. One of the most damaging of these is a *SV2A* (synaptic vesicle glycoprotein 2A) E138G missense mutation. *SV2A* is highly expressed in brain, especially cortex and cerebellum, and influences motor regulation. Shared variants in *MIB2* (Mindbomb E3 Ubiquitin Protein Ligase 2) and *DENND4B* (DENN Domain Containing 4B) are also deleterious and expressed in cerebellum. The two patients carry nonidentical deleterious variants in several genes that are highly expressed in cerebellum, influence cell-cell adhesion, and/or are associated with motor discoordination. These include *PPFIA4*, *BSN*, *TNK2*, *PCDHA8*, *PCKCNH2*, *MAMDC4*, *CACNA1B*, *CCDC88B*, *SPTBN2*, *NCOR2*, and *KCNC3*. Both patients have inversions disrupting *APP*, which influences neurite growth, neuron adhesion, and axonogenesis. Results are consistent with the view that CAS is heterogeneous and may result from multiple hits. Future work includes investigating rare inherited variants in these trios.

**Mutation identification for epilepsy in the U.S. Latino population using whole exome sequencing.** C. Xu<sup>1</sup>, A. Garza<sup>1</sup>, Y. Ramirez<sup>1</sup>, J. Ordóñez<sup>2</sup>, C.X. Mao<sup>1</sup>, X.M. Gong<sup>2</sup>, R. Brower<sup>2</sup>. 1) University of Texas Rio Grande Valley, One West University Blvd, Brownsville, TX, 78520; 2) TTUHSC-El Paso.

Introduction: Epilepsy, characterized by recurrent unprovoked seizures, is a common neurological disorder related to a wide variety of genetic, developmental and acquired brain conditions. Genetically determined epilepsies are associated with a multiplicity of potential genetic variants identified in predominantly Caucasian populations. However, there has been limited research in the US Hispanics/Latino populations. Whole Exome Sequencing (WES) is a technique that is used to discover causative mutations for a variety of diseases and has enabled to identify pathogenic mutations in patients with well-characterized neurological disorders, including epilepsy reported from the non-Hispanic population. Moreover, *De Novo*- and transmitted mutations are emerging as important causes of neurological diseases, including epilepsy, and WES in case-parent trios design is a powerful method to detect them. Here, we report the findings of WES in two US Latino families with epilepsy. Methods: We performed WES in a total of 10 subjects who were recruited from the Department of Neurology at the Texas Tech University Health Sciences Center in El Paso, Texas. The genomic DNA was extracted from blood using standard methods, as in our previous study [20]. A total of 50 ng DNA from each patient was used for WES analysis using Illumina Nextera Rapid Capture Exome Enrichment kits (Illumina, FC-140-1001) on NextSeq 500 (Illumina) sequencer. Results: After the quality control and filtering, we identified three *de novo* mutations in these six affected subjects with epilepsy from two Hispanic families and they were non-synonymous rare mutations in *CACNA2D1*, *O4C3* and *WDR16* genes, including NM\_000722.2:c.1956-5\_1956-4dupTT in the *CACNA2D1* gene with potential splice-site alteration; NM\_001004702.1:c.169\_177delTTGCTGATC (9 base pair deletion in coding region, including p.Leu57\_Ile59) in the *OR4C3* gene and NM\_145054.4:c.1159delA (p.Ser388AlafsTer21) of the *WDR16* gene. In addition, we identified shared mutations between two families and homozygous mutations in affected subjects. These mutations are predicted to be pathogenic impact and may result in the in-frame deletion and frameshift respectively. Discussion: This WES led to the discovery of additional epilepsy genes in the U.S. Latino population; however, future validation and segregation analysis using a Sanger sequencing and more cases are needed to confirm the current findings.

Crino<sup>12</sup>, A. Poduri<sup>8</sup>, E.L. Heinzen<sup>1,13</sup>. 1) Institute for Genomic Medicine, Columbia University, New York, NY; 2) Department of Pediatrics, McGovern Medical School, University of Texas in Houston, Houston, TX; 3) Department of Neurosurgery, Stanford University School of Medicine, Stanford, CA; 4) Division of Pediatric Neurology, Duke University Medical Center, Durham, NC; 5) Department of Neurobiology, Duke University, Durham, NC; 6) Division of Medical Genetics, Department of Pediatrics, Duke University School of Medicine, Durham, NC; 7) Department of Neurosurgery, Duke University Medical Center, Durham, NC; 8) Epilepsy Genetics Program, Department of Neurology, Division of Epilepsy and Clinical Neurophysiology, Boston Children's Hospital, Boston, MA; 9) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 10) Harvard Medical School, Boston, MA; 11) Department of Radiology, Boston Children's Hospital, Boston, MA; 12) Department of Neurology, University of Maryland, School of Medicine, Baltimore, MD; 13) Department of Pathology and Cell Biology, Columbia University, New York, NY.*

Malformations of cortical development (MCD) comprise several phenotypes affecting the structure and organization of the cerebral cortex. MCD result from defects in neuronal migration and differentiation during development, leading to intractable epilepsy and intellectual disability. Because the majority of cases of MCD cannot be explained by an underlying genetic germline mutation, it has been hypothesized that *de novo* somatic mutations arising in neural progenitor cells lead to MCD. We and others have demonstrated that approximately 30% of cases of MCD can be explained by somatic mutations in the PI3K-AKT-mTOR pathway. To identify somatic mutations in MCD, we performed paired exome sequencing and/or targeted sequencing of surgically resected brain tissue and leukocytes from 30 individuals with MCD including hemimegalencephaly, focal cortical dysplasia and polymicrogyria. Sequencing libraries were prepared with either the Illumina TruSeq or Kapa library preparation kit; targeted capture of the exome was performed with either Illumina TruSeq or Roche SeqCap EZ Exome v3.0 exome enrichment kits, while targeted capture of the 192 genes in the PI3K-AKT-mTOR pathway was carried out with a custom Roche SeqCap EZ kit. Paired-end sequencing reads were generated on either an Illumina HiSeq 2000 or HiSeq 2500. The sequencing coverage was greater than 200-fold and 800-fold, on average, for the samples sequenced with exome sequencing and targeted sequencing, respectively. Somatic single nucleotide variants and indels were called with Mutect2 and Strelka; somatic loss of heterozygosity was evaluated with VarScan-2. Likely pathogenic variants, i.e., those that were predicted to have a deleterious effect on the final protein and that were absent from in-house controls and public databases, were confirmed with Sanger sequencing or digital droplet PCR. In our cohort, we have identified and confirmed five somatic point mutations in known genes. Two were confirmed in *MTOR* (NM\_004958.3:c.133C>A;p.Gln45Lys and NM\_004958.3:c.4447T>C;p.Cys1483Arg [MIM 601231]); two in *PIK3CA* (NM\_006218.2:c.1624G>A;p.Glu542Lys and NM\_006218.2:c.1633G>A;p.Glu545Lys [MIM 171834]); and one, in *TSC1* (NM\_000368.4:c.298C>T;p.Gln100\* [MIM 605284]). Additional candidates in novel genes are in the process of being confirmed. The confirmed mutations identified thus far further support the role for altered regulation of the mTOR pathway as a pivotal pathogenic mechanism for many MCD subtypes.

Wu<sup>1,2,3</sup>.* 1) Beijing Key Laboratory for Genetic Research of Skeletal Deformity, China; 2) Medical Research Center of Orthopedics, Chinese Academy of Medical Sciences, China; 3) Department of Orthopedic Surgery, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing, China; 4) Department of Interventional Neuroradiology, Beijing Neurosurgical Institute and Beijing Tiantan Hospital, Capital Medical University, Beijing, China; 5) Department of Internal Medicine, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing, China; 6) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, USA; 7) Department of Breast Surgical Oncology, National Cancer Center/Cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, China; 8) Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing, Beijing, China; 9) Department of Central Laboratory, Peking Union Medical College Hospital, Peking Union Medical College and Chinese Academy of Medical Sciences, Beijing 100730, China.

**INTRODUCTION:** Intracranial vertebra-basilar dissecting aneurysm (IVAD) can lead to life-threatening consequences if not diagnosed timely and susceptibility is linked to genetic risk factors. In this study, we aim to identify genetic variants contributing to the etiology of IVAD in sporadic patients. **METHODS:** We enrolled a cohort of cases with definite diagnoses of IVAD, and performed whole exome sequencing for all the participants (cases with some of the parents). Variant interpretation and prioritization and new disease gene discovery were performed. We identified variants contributing to IVAD in known and novel disease genes in sporadic trios and singletons. We performed phenotypic characterizations for the cases with a possible molecular diagnosis. **RESULTS:** Exome sequencing data were analyzed for the 44 participants consisting of 8 trios and 36 singletons. We identified five reported disease-causing variants (*COL3A1* and *FBN1*), two *de novo* variants (*VPS52* and *CDK18*) and two loss-of-function variants (*MYH9* and *LYL1*) as highly pathogenic changes. Subjects carrying these variants are considered possibly molecularly solved (7 of 44). In addition, eight novel variants in VAD-related genes and two biallelic variants in new disease genes for VAD were considered to be possibly contributing to the phenotype, but of unknown significance (8 of 44). An absence of hypertension and the symptom of headache were identified as distinctive phenotypic characteristics for patients carrying a genetic diagnosis of IVAD. **CONCLUSIONS:** The next generation genomic analysis approach enabled detection of disease associated variants in known and novel IVAD related genes. A mutational burden in IVAD sporadic cases revealed the complexity of the disease. Genetic screening is suggested for IVAD patients with the symptom of headache.

Cisplatin-induced peripheral neuropathy (CisIPN) is a debilitating, often irreversible outcome of platinum-based chemotherapy. No approved therapy exists and mechanisms remain elusive. We aimed to uncover the polygenic architecture of CisIPN using GTEx expression quantitative trait loci (eQTL)-based analyses from a GWAS of CisIPN in 680 genetically European testicular cancer survivors (TCS). **Methods:** TCS completed validated questionnaires to define a binary case-control CisIPN phenotype. Genotyping, quality control, and GWAS were performed. The enrichment of GTEx cis-eQTLs ( $p < 10^{-6}$  in any tissue) was assessed by permutation resampling. Briefly, GWAS was performed with randomized phenotype labels adjusting for covariates (age, 10 genotype principal components) 500 times. The number of GTEx eQTLs with  $p < 5 \times 10^{-3}$  in the shuffled-phenotype GWAS was computed for each permutation and the null empirical distribution of eQTL counts was used to approximate a normal distribution. A Z-score was computed from the observed overlap of GTEx eQTLs in the non-permuted GWAS to assess the significance. Protein-protein interactions (PPI) of protein-coding gene targets of enriched eQTLs and functional pathway enrichment were evaluated with KEGG using one-tailed Fisher's exact tests. **Results:** Out of 3485 genotyped SNPs with  $p < 0.005$  in the CisIPN GWAS, 725 were eQTLs for 498 gene targets, indicating significant eQTL enrichment ( $p = 0.0048$ ). We reassessed enrichment of eQTLs in each of the 44 tissues at the same threshold and another more stringent threshold (GWAS  $p < 0.005$  and  $0.001$  respectively) to ensure robustness. Seven of 44 tissues displayed eQTL enrichment ( $p < 0.05$  at both GWAS p-value thresholds): tibial nerve, tibial artery, subcutaneous adipose tissue, thyroid, pituitary, hypothalamus, and the nucleus accumbens. Protein-coding gene targets (349 of 498) provided the input for PPI, which displayed significant interaction ( $p = 2 \times 10^{-4}$ ), with 149/349 proteins forming a single network. KEGG pathway analysis implicated major immune functions, including autoimmunity pathways such as autoimmune thyroid disease (FDR  $q = 1 \times 10^{-4}$ ), type 1 diabetes ( $q = 2 \times 10^{-4}$ ) and rheumatoid arthritis ( $q = 4 \times 10^{-4}$ ). **Conclusion:** Our analysis implicates regulatory regions of a 149-protein network in CisIPN. This network involves proteins functioning in immune processes, e.g., TLR2, TLR4 and MHC. Deeper analysis and functional studies are needed to validate our findings.

## 2043F

**Hirschsprung's disease and the related genes in Taiwan.** W. Yang<sup>1,2</sup>, P.L. Chen<sup>2</sup>. 1) Chang Gung Memorial Hospital, Taoyuan, Taiwan; 2) National Taiwan University.

**Background** Hirschsprung's disease (HSCR) is a congenital disease when the enteric ganglion cells were absent in the variable lengths of gastrointestinal tract. Multiple genes have been found related to the disease, such as, *RET*, *GDNF*, *EDNRB*, *SOX10*, etc. Although *RET* is suspected to be the main gene related to HSCR, the phenotypic variability and incomplete penetrance observed in HSCR might suggest the involvement of modifier genes. Thus, a more precise correlation among these genes in HSCR should be studied. **Patients and Methods** Patients proved to be HSCR by pathology will were included after obtain their written consent under the ethical guidance of the Institutional Review Board of Chung Gang Memorial Hospital, so as their parents, siblings, and/or off springs. Total 30 families and 150 participants will be included. Patients with syndromic abnormal (such as Down syndrome) will be excluded. Peripheral blood is drawn for 20cc in all participants if possible, for children younger than 1-year-old, the amount is 10cc. After review previous articles thoroughly, there are 31 genes might be related to HSCR. A next-generation sequence (NGS) panel was designed accordingly. The DNA samples of all the patients will be sent to do NGS for detection of possible genetic mutations. Further Sanger's sequencing will be done for the mutations detected by NGS in both the patient and the family members to confirm the mutation to be de Novo or inherited. **Results** There are 15 families with 17 patients were included for NGS. Mutations were found in 13 patients among 7 different genes. The detection rate of a possibly pathogenic mutation is 76%, which was much higher than previous reported. Frameshift in *RET*, *L1CAM* and a stop codon in *NRG1* were only found in long segment HSCR patients, which may imply that an obvious loss of function in this 3 genes were related to more severe disease. Besides, a SNP in *RET* (rs1800860) was found in 100% of our patients. For most of the patient, the relation between phenotype and the genotype is unclear, and our case number is too small to made solid conclusion in penetrance. **Conclusion** NGS is a powerful tool to work up for a multigenic disease, such as HSCR. An obvious loss of function in *RET*, *L1CAM* and *NRG1* could result in long segment HSCR, and larger case number is needed to make more solid conclusions.

**Leveraging large-scale exome sequencing data from >5,000 individuals to elucidate the genetic influences of amyotrophic lateral sclerosis.** *S.M. Farhan<sup>1,2</sup>, M.J. Daly<sup>1,2</sup>, B.M. Neale<sup>1,2</sup>*. 1) Analytic and Translational Genetics Unit, Center for Genomic Medicine, Massachusetts General Hospital, Harvard Medical School. Boston, MA, USA; 2) Stanley Centre for Psychiatric Research, Broad Institute of MIT and Harvard. Boston, MA, USA.

Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disease characterized by degeneration of motor neurons, leading to progressive weakening of limb, bulbar, and respiratory muscles and is ultimately fatal, typically within 3-5 years of onset. Although ALS is classified as a rare disease, affecting 1-2 per 100,000 individuals, it is the most common motor neuron disease in adults and has a lifetime risk of 1 in 350/500 for men and women, respectively. There are two forms of ALS: familial (FALS) and sporadic (SALS), which differ in their etiology but are clinically indistinguishable. FALS accounts for only 5-10% of all cases however, the genes that have been identified through FALS pedigrees can explain up to 15% of SALS cases. Therefore, the application of genetic and genomic approaches in ALS has the potential to identify novel disease loci. The FALS and the ALSGEN Consortia are composed of international researchers who are willing to contribute sequencing data of ALS cases with the unifying goal of unveiling the complete ALS genetic landscape. We have aggregated sequencing data from >5000 cases and have integrated methods for quality control, statistical analysis, and variant discovery, while using >10,000 healthy individuals as controls. By processing the data jointly using Hail, a new open-source genetics pipeline developed in the Neale lab, we can improve the statistical power to potentially discover novel genetic risk factors as well as eliminate confounding biases. To the best of our knowledge, our study is the largest ALS exome case-control analysis pursued to date. In addition to our own statistical analyses, we plan to replicate the results of published reports to corroborate or refute previous associations. Upon novel genetic discoveries, we plan to study the defective gene product in stem cells from ALS patients included in our dataset. Our efforts in collecting the largest ALS exome data set will be valuable in identifying novel disease loci, which can potentially translate into clinically relevant targets.

**2045T**

**Whole genome sequencing and rare variant analysis in essential tremor families.** *Z. Odgerel<sup>1</sup>, N. Hernandez<sup>2</sup>, J. Park<sup>3</sup>, R. Ottman<sup>2,4,5,6</sup>, ED. Louis<sup>2</sup>, LN. Clark<sup>1,7</sup>*. 1) Department of Pathology and Cell Biology, College of Physicians and Surgeons, Columbia University, New York, NY 10032, USA; 2) Department of Neurology, Yale School of Medicine, Yale University, New Haven, CT 06510, USA; 3) G.H Sergievsky Center, Columbia University, New York, NY 10032, USA; 4) Department of Neurology, College of Physicians and Surgeons, Columbia University, New York, NY 10032, USA; 5) Department of Epidemiology, Mailman School of Public Health, Columbia University, New York, NY 10032, USA; 6) Division of Epidemiology, New York State Psychiatric Institute, New York, NY 10032, USA; 7) Taub Institute for Research on Alzheimer's Disease and the Aging Brain, College of Physicians and Surgeons, Columbia University, New York, NY 10032, USA.

Essential Tremor, one of the most common movement disorders, is genetically heterogeneous. The genetic etiology of ET remains largely unexplained. Whole genome sequencing (WGS) is likely to be of value in furthering our understanding of a large proportion of ET with complex disease inheritance patterns and enrichment of functional rare coding and non-coding variants may explain the heritability of ET. We performed WGS analysis of eight ET families (n=40 individuals) enrolled in the family study of Essential Tremor (FASET) at Columbia University. The analysis included filtering on WGS data based on allele frequency in population databases, rare variant burden analysis using the Mixed-Model Kernel Based Adaptive Cluster (KBAC) test and prioritization of candidate genes identified within families using gene set enrichment analysis, network analysis and phenolyzer. Genomic DNA was extracted from peripheral blood cells. Capturing was performed using the Illumina TruSeq DNA PCR-Free Library Preparation kit (Illumina, San Diego, CA.), paired end sequencing was performed at >30X coverage per sample on the Illumina HiSeq X ten instrument (Illumina, San Diego, CA). Sequence alignment to the human reference genome (UCSC hg19) was performed using the Burrows-Wheeler Aligner (BWA) algorithm, and variant calling was performed using the genome analysis toolkit (GATK; Broad Institute). QC was performed according to GATK best practices. Rare variants with MAF<0.01 and MAF<0.005 were included in the study. Burden analysis was performed using mixed model KBAC implemented in the Golden Helix SVS & Variation Suite. Variants were annotated using CADD, SIFT, Polyphen2, LRT, Mutation Taster, FATHMM, PROVEAN, MetaSVM and MetaLR. Overall, we identified a total of 167 genes with deleterious or damaging variants that co-segregated with ET within families. Gene set enrichment and network analyses of these genes identified significant enrichment of genes that encode proteins with a role in pathways or biological processes previously implicated in the pathophysiology of neurological and neurodegenerative disease. Phenolyzer prioritized candidate genes within families. This work has identified a number of candidate genes and pathways for ET in families that can now be prioritized for functional studies to further our understanding of the pathophysiology of ET using cellular and animal models.

**2046F**

**Novel loss-of-function mutation of  $\alpha$ -tocopherol transfer protein leads to vitamin E deficiency in a family.** E. Smith<sup>1</sup>, H.C. Yu<sup>1</sup>, J. Appis<sup>1</sup>, A. Kuusela<sup>1</sup>, R. Sainger<sup>1</sup>, S. Bureeva<sup>1</sup>, L. Guo<sup>2</sup>, T.J. Jönsson<sup>2</sup>, B.M. Whittman<sup>2</sup>, P. Brar<sup>1</sup>, R. Martin<sup>1</sup>, B. Perkins<sup>1</sup>, C.T. Caskey<sup>1,3</sup>. 1) Human Longevity, San Diego, CA; 2) Metabolon, Morrisville, NC; 3) Molecular and Human Genetics, Baylor College of Medicine, Houston, TX.

*TTPA* is a gene involved in the binding and transport of vitamin E ( $\alpha$ -tocopherol), which helps protect cells and tissues throughout the body from free radicals. Homozygous mutations in this gene have been reported to cause autosomal recessive ataxia with vitamin E deficiency. The condition has variable penetrance and expressivity. The pathophysiology of the condition is due to the accumulation of free radicals in neurons (Ulatowski L, et al. 2014). Currently, no data exists pertaining to a heterozygous clinical phenotype and individuals who are heterozygotes are assumed to be unaffected carriers. At the Health Nucleus (HN) In our studies, individuals have whole genome sequencing, microbiome sequencing, metabolomics, and clinical testing, such as echocardiogram, neuro-cognitive assessment, and full body MRI. The information collected from both genetics and clinical data is used to make health assessments for these individuals. Each person receives genetic counseling when receiving genetics results. A family consisting of a father, a mother, and two children visited our facility. One parent and both children were found to have a novel heterozygous nonsense variant in *TTPA*. Metabolomics data from this family was further analyzed after one of the sons had an abnormal vitamin E level which was surprising to the clinical team. The other family members were analyzed and were also found to have an abnormal of low vitamin E. The three family members demonstrated vitamin E levels ranging from -3.56 to -6.93 standard deviations from the mean. The other parent, who did not have the *TTPA* variant, had a normal vitamin E level. Family history review at the time of initial visit and then at the time of results disclosure, there was no family history of ataxia or balance problems reported. In the HN clinical testing, there was no gait or balance changes identified in exam. This novel variant leads to a premature stop codon at the N-terminus of *TTPA* protein, which is presumably associated with a more profound phenotype when found in the homozygous state. While initially counseled that they were unaffected carriers, a second discussion with the family members, we explained the value in increasing daily intake of vitamin E. This family demonstrates the value of using metabolomics and functional diagnostics in conjunction with genetics. In addition, it shows how there may be subclinical disease in the carriers of metabolic conditions previously believed to be unaffected.

**Exome sequence analysis identifies novel loci associated with carpal tunnel syndrome in DiscovEHR study cohort.** S. Krishna Murthy<sup>1</sup>, M. Malik<sup>2</sup>, D. Carey<sup>1</sup>, S. Friedenberg<sup>2</sup>, R. Metpally<sup>1</sup> on behalf of the DiscovEHR collaboration. 1) Department of Molecular and Functional Genomics, Geisinger Health System, Danville, PA; 2) Department of Neurology, Geisinger Health System, Danville, PA, USA.

Carpal tunnel syndrome (CTS) is one of the most common entrapment neuropathies of the hand due to compression of the median nerve at the wrist causing significant work related disability. The prevalence in the general adult population ranges from 3 to 6 percent [Atroshi et al 1999]. Symptoms include numbness, tingling, pain and weakness of hand muscles. The management includes conservative treatment with splints and pain medications but in severe cases requiring surgery. **Aim:** The aim of this retrospective study is to make use of available electronic health records (EHR) to understand the molecular genetic basis of CTS. This will help us to understand what genes/loci are associated with CTS, leading to the development of new treatments. **Method:** We analyzed both whole exome sequencing and corresponding imputed Human Omni Express Exome beadchip data from 51,289 individuals in the DiscovEHR cohort as described in Dewey et al 2016. Participants were phenotyped as cases by mining the EHR data with at least 3 independent calls of ICD9 codes for CTS, resulting in 3185 cases [6.2 % prevalence; 1072 are males, 2113 are females]. Mixed linear model based association analysis (MLMA) was performed on the whole exome sequences using GCTA-v12.6. Genome wide association study (GWAS) was also performed using PLINK-v1.9 on the imputed chip data. **Results:** We identified a common non-coding variant in *TPMTP1* [rs9959961: P =8e<sup>-6</sup>; 18q21 locus] with near genome wide significance from the GWAS analysis and MLMA revealed two near exome-wide significant variants in *TSTD2* [rs41274254: Pvalue:6e<sup>-7</sup>; 9q22.23 Locus], *MTMR11* [rs11205303: Pvalue:9.4e<sup>-7</sup>; 1q21.2 locus]. **Conclusion:** This is the first large scale, retrospective, association study of CTS using EHR; Understanding genes associated with CTS might elucidate the underlying causative mechanisms. Further study is warranted to understand the specific molecular determinants of CTS risk and links to environmental exposures.

**2048T**

**Genome-wide association study reveals candidate susceptibility loci for idiopathic hypersomnia.** K. Tanida<sup>1</sup>, T. Miyagawa<sup>1,2</sup>, M. Shimada<sup>1,2</sup>, H. Toyoda<sup>1</sup>, S.S. Khor<sup>1</sup>, K. Mishima<sup>3</sup>, Y. Honda<sup>4</sup>, M. Honda<sup>2,4</sup>, K. Tokunaga<sup>1</sup>. 1) Human genetics, Graduate school of Medicine, The University of Tokyo, Tokyo, Japan; 2) Sleep Disorders Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 3) Department of Psychophysiology, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan.

Idiopathic hypersomnia (IHS) is a rare sleep disorder characterized by excessive daytime sleepiness, great difficulty in awakening, and prolonged sleep time. The exact prevalence is unknown, but it has been estimated to be between 0.002 and 0.010%. Several familial studies have suggested that IHS is associated with genetic components. Narcolepsy is known to be strongly associated with a human leukocyte antigen (HLA) allele, specifically the *HLA-DQB1\*06:02*. However, there is no association between IHS and any particular HLA alleles. To identify susceptibility genes associated with IHS, we conducted a genome-wide association study (GWAS) in 120 Japanese patients with IHS and 1,791 healthy individuals. This study represents the first GWAS of IHS. Genome-wide SNP genotyping was performed with the Affymetrix Genome-Wide Human SNP Array 6.0. SNPs used in the case-control association analysis satisfied the following quality control criteria: (1) call rate  $\geq 97\%$ , (2) minor allele frequency  $\geq 5\%$  and (3) Hardy-Weinberg equilibrium  $P \geq 0.1\%$ . The genomic inflation factor ( $\lambda$ ) of the GWAS was 1.01, suggesting that population stratification has negligible impact on this analysis. Consequently, we found 80 SNPs which reached suggestive significance level ( $P < 10^{-4}$ ). After imputation of 1000 Genomes reference panels, 53 genotyped SNPs and 43 imputed SNPs were selected for a replication study (200 Japanese patients with IHS and 2,000 healthy individuals). We will conduct a multiple SNP genotyping assay using DigiTag2 for the candidate 93 SNPs selected in the GWAS stage. We are going to report the results of the replication study in this conference.

**2049F**

**Genome- and phenome-wide association analyses uncover MET as a susceptibility gene of cerebral palsy.** J.J. Connolly<sup>1</sup>, J. Li<sup>1</sup>, Y. Guo<sup>1</sup>, X. Chang<sup>1</sup>, D. Abrams<sup>1</sup>, F. Mentch<sup>1</sup>, H. Hakonarson<sup>1,2,3</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Dept. of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Pulmonary Medicine, Children's Hospital of Philadelphia, Philadelphia, PA.

Cerebral Palsy (CP) is a heterogeneous group of early-onset disorders that impair motor function, with severe adverse effects on movement and posture. Epidemiological studies suggest that genetic components make an important contribution to CP etiology, in addition to major environmental and maternal risk factors. We performed a genome-wide association study (GWAS) of CP and further meta-analyzed with two independent replication cohorts. In this first GWAS of CP, we identified a genome-wide significant locus at chr7q31.2 harboring the MET Proto-Oncogene, Receptor Tyrosine Kinase (*MET*) gene (rs714180,  $P=5.0 \times 10^{-16}$ ). The GWAS signal correlates with *MET* gene expression and promoter methylation. A phenome-wide association study of SNP rs714180 further confirms its phenome-wide significant association with infantile CP. Exome-sequencing of a subset of severe CP cases revealed an initiator codon variant enriched in CP cases emphasizing *MET* as a potentially important susceptibility gene for CP.

## 2050W

**RNAseq gene expression profiling of CD4+ and CD8+ T cells from multiple sclerosis patients and healthy controls.** S.D. Bos<sup>1,2</sup>, I.S. Brorson<sup>3</sup>, L. Barcellos<sup>3</sup>, T. Berge<sup>2,4</sup>, H.F. Harbo<sup>1,2</sup>. 1) Department of Neurology, University of Oslo, Oslo, OSLO, Norway; 2) Oslo University Hospital, Oslo, OSLO, Norway; 3) Division of Epidemiology, School of Public Health, California Institute for Quantitative Biosciences, University of California Berkeley, CA 94720-3220, USA; 4) Department of Mechanical, Electrical and Chemical Engineering, Oslo and Akershus University College of Applied Science, Oslo, OSLO, Norway.

**Introduction:** Multiple sclerosis (MS) is a complex disease characterized by an autoimmune attack against components of the central nervous system. Genetic variations, environmental factors and interaction between these contribute to an individuals' risk for MS. Close to 200 genetic associations have been identified in increasingly large genome-wide studies. More than one-third of these genetic associations can be linked to immune-regulatory genes, corroborating the clinical observations that the immune system plays a major role in disease etiology. Here we present the gene expression profiles of CD4+ T cells from untreated MS patients and age and gender matched healthy controls. **Materials and methods:** Blood was drawn from 20 MS patient and 20 controls, followed by peripheral blood mononuclear cell (PBMC) isolation by density gradient centrifugation. CD4+ T cells were purified from the PBMCs by negative selection. Flow cytometry was performed to confirm the purity of CD4+ T cells (>95%). RNA was extracted and submitted for sequencing using a 100-bp paired-end protocol. The resulting sequencing files were processed using the programs "kallisto" and "sleuth". Multiple Discriminant Analysis (MDA) analyses were used to identify potential outlier samples and these were excluded from further analyses. **Results:** 19 MS patient samples and 20 control samples were forwarded to analysis. Hierarchical clustering did not identify clear separation of MS patients and controls indicating there are no large-scale differences between CD4+ T cells from these groups. Individual gene differences were observed at a nominal significance level, however; when multiple testing was taking into consideration there was no significant difference between any genes. **Discussion and Conclusion:** At a global level we did not identify differences between MS patients and controls. Although the genes with most differential expression showed promising candidate genes with respect to the immune system, none reached a significant difference after correction for multiple testing. These patients were either newly diagnosed or have experienced a benign disease course. Global or individual gene expression differences may be more pronounced for severely affected patients. Using pathway analysis we may be able to identify pathways that exhibit several smaller changes in their gene expression, thereby providing insights in disease-related pathways.

## 2051T

**Gba1 haploinsufficiency in a Parkinson mouse impacts longevity and symptom severity independent of SNCA aggregate.** N. Tayebi<sup>1</sup>, L. Parisiadou<sup>2</sup>, B. Berhe<sup>1</sup>, A. Gonzalez<sup>1</sup>, R. Tamargo<sup>1</sup>, E. Maniwang<sup>1</sup>, H. Fujiwara<sup>3</sup>, R. Grey<sup>1</sup>, S. Hassan<sup>1</sup>, Y. Blech-Hermoni<sup>1</sup>, C. Makariou-Pikis<sup>2</sup>, M. Brooks<sup>2</sup>, E. Ginns<sup>4</sup>, D. Ory<sup>6</sup>, B. Giasson<sup>3</sup>, E. Sidransky<sup>1</sup>. 1) NIH/NHGRI, Bethesda MD; 2) Feinberg School of medicine, Northwestern Univ, Chicago, IL; 3) Dept. of Neuroscience, Univ of Florida, Gainesville, FL; 4) Lysosomal research program, Univ. of Massachusetts, Worcester, MA; 5) Dept. of Medicine, Washington Univ. St. Louis, MO.

Mutations in the glucocerebrosidase gene, *GBA1*, are a leading risk factor for Parkinson disease and associated Lewy body disorders. Many *GBA1* mutation carriers, especially those with severe or null *GBA1* alleles, have earlier and more progressive parkinsonism. To model the effect of partial glucocerebrosidase deficiency on neurological progression *in vivo*, mice with a human A53T  $\alpha$ -synuclein (*SNCA*<sup>A53T</sup>) transgene were crossed with heterozygous null *gba* mice (*gba*<sup>+/−</sup>). Survival analysis of 84 mice showed that in *gba*<sup>+/−</sup>/*SNCA*<sup>A53T</sup> hemizygotes and homozygotes, the symptom onset was significantly earlier than in *gba*<sup>+/+</sup>/*SNCA*<sup>A53T</sup> mice (p-values 0.023-0.0030), with exacerbated disease progression (p-value <0.0001). Over-expression of *SNCA*<sup>A53T</sup> resulted in reduced glucocerebrosidase levels, regardless of genotype or symptoms (p-value <0.05-0.001), recapitulating the relationship between *SNCA* and glucocerebrosidase in patients with parkinsonism. *gba* haploinsufficiency did not alter the abundance or distribution of *SNCA* pathology based on quantification of *SNCA* aggregates in 17 symptomatic mice, nor levels of monomeric *SNCA*. However, both *gba*<sup>+/−</sup>/*SNCA*<sup>A53T</sup> mice and patients with synucleinopathies carrying null *GBA1* mutations had lower levels of insoluble high molecular weight *SNCA* than those without mutant glucocerebrosidase. This model indicates that the effect of *gba* deficiency on symptoms is not directly related to *SNCA* aggregation, providing a valuable resource to identify modifiers, pathways and possible moonlighting roles of glucocerebrosidase in Parkinson pathogenesis.

**2052F****Effect of genetic variants associated with uric acid on multiple sclerosis: A Mendelian randomization study.**

*M.D. Montierth<sup>1</sup>, J.C. Denny<sup>2</sup>, M.F. Davis<sup>1</sup>.*  
 1) Department of Microbiology and Molecular Biology, Brigham Young University, Provo, UT; 2) Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, TN.

Multiple sclerosis (MS) is a severe disease of the central nervous system that affects approximately 400,000 Americans. Despite the prevalence and severity of MS, its cause and risk factors are still poorly understood. Over 100 genetic risk factors have been identified, including the *HLA-DRB1\*15:01* allele and other non-HLA loci. Studies have also indicated that oxidative stress plays a key role in the pathogenesis of MS. Uric acid, an antioxidant, has been suggested as having a protective affect against MS. However, previous studies of uric acid in MS are affected by many confounding factors, and as such it is still difficult to draw conclusions with regard to this association. In this study, we compared uric acid lab values between patients with MS and control patients in a large population of electronic medical records to better understand this difference. Additionally, Mendelian randomization studies can be used to lend power to epidemiological studies by using genetic variants as instrumental variables, and thus avoiding potential biases of observational studies. We performed a Mendelian randomization analysis to investigate the link between MS and uric acid. MS cases and controls were selected from the Vanderbilt University Medical Center's Synthetic Derivative (SD) database. The SD is composed of de-identified medical records set aside specifically for research purposes and includes more than 2 million individuals. Using lab values from 3803 individuals (500 cases, 3303 controls), we determined that uric acid levels were significantly lower in patients with MS than in the control population ( $p=1.64E-13$ ). From the SD database, 1,625 cases and 6,187 controls were genotyped. In these individuals, we identified 37 SNPs associated with uric acid, and used them to generate a weighted genetic risk score (WGRS) for each individual. We then regressed MS case status on the uric acid WGRS. We also created an MS WGRS using 110 SNPs associated with MS, and regressed uric acid lab values on the MS WGRS.

**2053W****A longitudinal metabolome-wide association study on beta amyloid in adults with increased risk for Alzheimer's disease.**

*B.F. Darst<sup>1,2</sup>, M.J.P. Rush<sup>1,3,4</sup>, P.D. Hutchins<sup>1,3,4</sup>, T. Reddy<sup>5</sup>, J.D. Russell<sup>1,4,5</sup>, R. Gangnon<sup>1,2,6</sup>, R.L. Kosciuk<sup>1,7</sup>, S. S. Middleton Memorial VA Hospital, Madison, WI; 9) Alzheimer's Disease Research Center, University of Wisconsin School of Medicine and Public Health, Madison, WI; 10) Department of Anesthesiology, University of Wisconsin School of Medicine and Public Health, Madison, WI; 11) Department of Biomolecular Chemistry, University of Wisconsin, Madison, WI.

Several cross sectional metabolomics studies of Alzheimer's disease (AD) have recently been reported, but a longitudinal examination of metabolomic profiles prior to AD diagnosis is crucial to establish early biomarker trajectories that influence the disease. Beta-amyloid ( $A\beta$ ) is one of the strongest predictors of AD and alterations to this protein are believed to predate the diagnosis of AD by decades. We investigated the longitudinal influence of metabolomics on  $A\beta$  using plasma samples from an ongoing longitudinal cohort of participants who were asymptomatic at enrollment and enriched with a parental history of AD. Metabolomic profiles were quantified with mass spectrometry on 152 individuals on up to four visits each. These individuals also had up to two visits with cerebral spinal fluid  $A\beta$  measures. Due to the fewer number of observations with  $A\beta$ ,  $A\beta$  measures were averaged across visits, while metabolomics were used longitudinally, and a total of 305 observations used in the current analysis. A metabolome-wide association study (MWAS) was performed using linear mixed effects regression models to assess the metabolites' main effects on outcomes  $A\beta_{42}$  and  $A\beta_{42}/A\beta_{40}$ . Due to the heterogeneity of AD mechanisms that can differ by an individual's *APOE* genotype, we also tested for interactions between the metabolites and an *APOE* genetic risk score for both outcomes. Of the 87 metabolites tested, preliminary analyses identified urea and sugar metabolites as some of the top main effects for both  $A\beta_{42}$  and  $A\beta_{42}/A\beta_{40}$ . The *APOE* risk score was found to interact with beta alanine and oxoproline for both  $A\beta$  outcomes. The implications of these initial longitudinal results could further explain the biological relevance of previously implicated pathways to AD. Ongoing analyses within this cohort and an independent replication cohort are being performed to investigate these relationships.

## 2054T

**Interplay of genetic risk at *SNCA* locus and dysbiosis of gut microbiome in Parkinson's disease.** Z.D. Wallen<sup>1</sup>, C.P. Zabetian<sup>2</sup>, R. Knight<sup>3,4,5</sup>, S.A. Factor<sup>6</sup>, E. Molho<sup>7</sup>, H. Payami<sup>1,8</sup>. 1) Departments of Neurology and Genetics, University of Alabama - Birmingham, Birmingham, AL; 2) Veterans Affairs Puget Sound Health Care System and Department of Neurology, University of Washington, Seattle, WA; 3) Department of Pediatrics, University of California San Diego, La Jolla, CA; 4) Department of Computer Science and Engineering, University of California San Diego, La Jolla, CA; 5) Center for Microbiome Innovation, University of California San Diego, La Jolla, CA; 6) Department of Neurology, Emory University School of Medicine, Atlanta, GA; 7) Department of Neurology, Albany Medical College, Albany, NY; 8) Center for Genomic Medicine, HudsonAlpha Institute for Biotechnology, Huntsville, AL.

Idiopathic Parkinson's disease (PD) is thought to result from gene-environment interaction. GWAS has identified 28 susceptibility variants, the strongest of which is rs356219 at 3' of *SNCA* (PMID:25064009). Recently, PD has been linked to the gut microbiome (PMID: 28195358). There is extensive evidence showing two-way interactions between the host genome and the microbiome, but the relationship between PD-associated genotypes and dysbiosis of the gut microbiome in PD has not been studied. Here, we studied the gut microbiome and *SNCA* rs356219 genotype in 214 PD cases and 122 healthy controls. *SNCA* was genotyped using DNA from whole blood. For the gut microbiome, DNA was extracted from stool, 16S rRNA amplicon sequencing was done using Illumina, and sequence variants were inferred using DADA2 R-package. First we tested the global composition of the microbiome as a function of PD, sex, age, *SNCA* genotype and *SNCA*xPD interaction (all included in the statistical model). Dissimilarities in the microbiomes were calculated using Canberra distances, and tested using permutational multivariate analysis of variance (PERMANOVA, with 10,000 permutations). PD ( $P < 0.0001$ ), sex ( $P = 0.0002$ ), age ( $P = 0.0004$ ), and *SNCA*xPD interaction ( $P = 0.006$ ) were significantly associated with the microbiome, *SNCA* genotype was marginal ( $P = 0.09$ ). Next, we sought to identify individual taxa whose abundance differed significantly as a function of the interaction, using the same statistical model (taxa~PD+sex+age+*SNCA*+*SNCA*xPD), and employing generalized linear model with negative binomial distributions and zero inflation, and FDR correction for multiple testing. A significant *SNCA*xPD interaction was detected for *Corynebacteriaceae\_Corynebacterium* (FDR  $Q = 0.001$ ). *Corynebacterium* occur naturally and are often innocuous, but some members can be opportunistic pathogens in immune compromised individuals. In conclusion, we confirmed the known associations of PD, sex and age with the gut microbiome, and found new evidence for interaction between *SNCA* genotype and disease on the microbiome that is independent of the disease effect. The taxon that is altered suggests the immune system may be involved in the interactive effect of *SNCA* and PD in the gut.

## 2055F

**Somatic copy number gains of alpha-synuclein (*SNCA*) in synucleinopathies (Parkinson's disease and multiple system atrophy).** C. Proukakis<sup>1</sup>, K. Mokretar<sup>1</sup>, D. Pease<sup>1</sup>, A. Soenmez<sup>1</sup>, A. Ejaz<sup>1</sup>, T. Lashley<sup>1</sup>, S. Gentleman<sup>2</sup>, H. Houlden<sup>1</sup>, J. Taanman<sup>1</sup>, J. Holton<sup>1</sup>, A. Schapira<sup>1</sup>, E. Nacheva<sup>2</sup>. 1) Institute of Neurology, University College London, London, England, United Kingdom; 2) Academic Haematology, University College London, London, England, United Kingdom; 3) Department of Medicine, Imperial College London, United Kingdom.

Parkinson's disease (PD), the second commonest neurodegenerative disorder, is usually sporadic, although rare inherited mutations, including CNVs, in *SNCA* and other genes can lead to it. The alpha-synuclein protein has a key role in pathogenesis. We have hypothesized a role of somatic *SNCA* mutations in sporadic synucleinopathies. The evidence for mosaicism in healthy and diseased brain is increasing rapidly. Somatic copy number (CN) gains of *APP* have been reported in Alzheimer's brain. We aimed to detect *SNCA* gains in post mortem brains from PD and multiple system atrophy (MSA), another synucleinopathy, and controls. We selected sporadic cases with relatively young onset and short disease duration, and obtained substantia nigra (SN) and other brain regions where possible. We analysed DNA by droplet digital PCR (ddPCR) for *SNCA* CN, and customized array CGH for all PD genes. We performed preliminary FISH using *SNCA* BAC probes. We then stained sections with Agilent SureFISH custom-designed probes for *SNCA* and multiple references, counting dopaminergic neurons (DN) in the SN with visible neuromelanin positivity and other cells separately in a blinded fashion, and identifying frontal neurons by NeuN staining. We excluded high level mosaicism by aCGH and / or ddPCR in at least the SN in 37 PD and two MSA cases, and 12 controls. BAC FISH probes showed occasional possible *SNCA* gains. We validated *SNCA* SureFISH probes on brain and fibroblasts with known CNVs, and analysed sections from 40 PD, 25 control, and 5 MSA cases, counting 142 DN and 306 other nuclei on average. PD cases were more likely than controls to have any DN *SNCA* gain (77.5% v 40%,  $p = 0.004$ ), or any cell with gain (95% v 68%,  $p = 0.005$ ). The % of DN gains was significantly higher in PD than controls (0.78% v 0.45%;  $p = 0.017$ ). There was a negative correlation of % DN gains with onset age ( $r = -0.39$ ,  $p = 0.013$ ), but not with disease duration, or age of death in PD or controls. All MSA cases had gains, and the highest levels of gains in DN were in two of these (2.76%, 2.48%). We performed selective validation with different control probes after dye-swapping. Control probes showed minimal gains (<0.1% in DN). We found occasional *SNCA* gains in frontal neurons of 4 PD cases studied. We present evidence of somatic gains of *SNCA* in brain, commoner in DN of the SN in PD than controls, negatively correlated with onset age, and possibly commonest in MSA. Somatic *SNCA* gains may be a novel risk factor for synucleinopathies.

**2056W****Protective effect of smoking and caffeine on Parkinson's disease:**

**A gene-environment study.** V. Altmann<sup>1</sup>, AF. Schumacher-Schuh<sup>2</sup>, M. Medeiros<sup>2</sup>, SM. Callegari-Jacques<sup>2</sup>, CRM. Rieder<sup>2</sup>, MH. Hutz<sup>1</sup>. 1) Genetics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Porto Alegre, Brazil; 2) Serviço de Neurologia, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; 3) Statistics, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil.

Parkinson's disease (PD) is the second most common neurodegenerative disease. Epidemiological studies have indicated several risk factors for PD. Among them, smoking and caffeine consumption have presented strong evidence of an inverse association with PD. Gene-environment interactions as risk modifiers might be important for PD susceptibility. Therefore, the objective of this study was to investigate the role of ABCB1, ADORA2A and NOS1 genes in interaction with smoking and caffeine consumption on PD risk. A total of 184 PD patients and 162 controls were recruited at Hospital de Clínicas de Porto Alegre, Brazil. Smoking was considered as never or ever (at least 100 cigarettes) used. Caffeine use included coffee and yerba mate (*Ilex paraguariensis*) and was evaluated as every day vs. occasionally or never used. ABCB1 haplotype (rs2032582, rs1128508 and rs1045642), ADORA2A diplotypes (rs2298383 and rs3761422) and NOS1 polymorphism (rs478597) were genotyped by allelic discrimination assays. Interaction results were assessed by binary logistic regression, controlling for age, gender and ancestry. Cigarette smoking and caffeine use were protective factors for PD (respectively, OR 0.42; 95% CI 0.27-0.65;  $P < 0.001$  and OR 0.57; 95%CI 0.36-0.88;  $P = 0.014$ ). ABCB1 haplotype T-non G-T was associated with PD in interaction with smoking ( $P_{\text{interaction}} = 0.016$ ). Smokers with T-non G-T haplotype had higher protection to this disease (OR 0.35; 95% CI 0.16-0.75) compared to those with C-G-C haplotype. NOS1 CC genotype in interaction with caffeine was associated with PD as protective factor (OR 0.20; 95% CI 0.09-0.44;  $P_{\text{interaction}} < 0.001$ ). ADORA2A diplotypes were not associated with PD in interaction with smoking. In conclusion, ABCB1 and NOS1 in interaction with smoking and caffeine seem to influence PD susceptibility in our population. PD risk seems to result of complex interplay and composite effects of both genetic and environment risk factors.

As the population ages, an ever-increasing prevalence of individuals suffers with neurodegenerative disease, with over 50 million people estimated to be affected worldwide in 2015. The Ontario Neurodegenerative Disease Research Initiative (ONDRI) is a provincial-wide, multi-year, observational cohort study characterizing five neurodegenerative diseases: 1) Alzheimer's disease and mild cognitive impairment (AD/MCI); 2) amyotrophic lateral sclerosis (ALS); 3) frontotemporal dementia (FTD); 4) Parkinson's disease (PD); and 5) vascular cognitive impairment (VCI). The ONDRI genomic subgroup's objective is to elucidate the often discounted, yet extremely important genetic landscape of these neurodegenerative disorders. For this investigation, a custom next-generation targeted resequencing panel, ONDRISeq, was designed to target 80 genes previously associated with familial forms of the five neurodegenerative diseases of interest. DNA samples from 520 unrelated ONDRI participants were sequenced with ONDRISeq and sequencing data were analyzed with a custom bioinformatics workflow to call and annotate variants. Manual curation of the variants is being performed based on their likelihood to be disease causing. Variants of interest are classified based on their pathogenicity using the 2015 American College of Medical Genetics Standards and Guidelines. To date, rare variant analysis has been completed for the 161 VCI participants, with 62.1% of individuals harbouring at least one rare candidate variant of probable clinical significance. Further, one variant of interest was identified in 37.9%, two variants in 18.6%, and three or more variants in 5.6% of participants. This rare variant burden is higher than to be expected from an unaffected population, which will be further confirmed by sequencing of control samples with the ONDRISeq panel. The rare variant burden will also be determined for the remaining 359 enrolled individuals. These pilot data suggest that our custom next-generation sequencing workflow is a robust tool for genetic evaluation of patients with neurodegenerative disease. This can be important for many individuals who are facing diagnostic odysseys, and can allow for the next stages of treatment or life-planning. Additionally, future multivariate regression analyses with the phenotypic data obtained from other ONDRI technological platforms will allow for the identification of new genetic markers correlated with disease progression and outcomes.

**2058F**

**Genome-wide CNV analysis identifies candidate causal genes for Parkinson's disease in the lysosomal pathway.** P.S. Eis<sup>1</sup>, B. Schüle<sup>2</sup>, S. Kim<sup>2</sup>, E. Hatchwell<sup>1</sup>. 1) Population Bio, Inc., Melville NY; 2) The Parkinson's Institute and Clinical Center, Sunnyvale, CA.

Parkinson's Disease (PD) is the second most common neurodegenerative disorder and affects ~1% of the population >60 years of age, but early-onset forms are also found. Genetics were not thought to play a role, but from 1997 to 2004 five genes (*SNCA*, *PARK2*, *PARK7/DJ-1*, *PINK1*, *LRRK2*) were found to harbor rare mutations that caused autosomal dominant (AD) or autosomal recessive (AR) PD. Additional PD genes have since been found but, to date, only 5-10% of patients are known to have causal mutations in one of these genes [PMID 28332488]. Interestingly, the gene *GBA* (glucocerebrosidase), which causes the AR lysosomal storage disorder (LSD) Gaucher disease (MIM 606463), was found to increase the risk of PD at least 5-fold in heterozygous carriers. A similar neuropathological presentation is found in PD patients carrying pathogenic variants in *SNCA*, *LRRK2*, and *GBA*, namely the presence of alpha-synuclein-positive Lewy bodies and neurites and neuronal cell loss in the substantia nigra. In <1% of patients, aberrant aggregation of alpha-synuclein protein is caused by pathogenic single nucleotide variants (SNVs) or copy number variants (CNVs), but in a majority of patients, alpha-synuclein pathology involves a variety of cellular and molecular mechanisms, such as mitochondrial dysfunction, oxidative stress, neuroinflammation, and lysosome/autophagy defects. With the aim of discovering additional genes that contribute to PD, we performed genome-wide CNV analysis using array-based comparative genomic hybridization (aCGH) on a PD cohort (n = 555, European ancestry, familial and sporadic cases). Interpretation of benign vs. potentially pathogenic CNVs was performed using our in-house CNV database and algorithms. Given the rapid advances on *GBA* as a drug target for development of disease-modifying PD therapies, we initially analyzed the aCGH data for CNVs impacting lysosomal pathway genes. Loss-of-function (LOF), exonic CNVs (size range 6-242 Kb) were found in 5 PD patients, which were absent in our control CNV data (1,000 subjects, European ancestry). These 5 LOF CNVs impact 5 different genes (*CERK*, *GALNS*, *PSAP*, *SUMF1*, *SCARB2*), 4 of which are known to cause an AR LSD: mucopolysaccharidosis IVA (MIM 612222), combined SAP deficiency (MIM 176801), multiple sulfatase deficiency (MIM 607939), and epilepsy, progressive myoclonic 4 (MIM 602257). Like *GBA*, we hypothesize that carriers of heterozygous pathogenic variants in these 5 lysosomal genes have an increased risk for PD.

**2059W**

**Genetic modifiers modulating the age of onset of amyotrophic lateral sclerosis caused by expanded GGGGCC repeats.** H. Kim<sup>1</sup>, J. Lim<sup>1</sup>, H. Bao<sup>1</sup>, B. Jiao<sup>1</sup>, J.D. Glass<sup>2</sup>, T. Wingo<sup>2</sup>, P. Jin<sup>1</sup>. 1) Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Department of Neurology, School of Medicine, Emory University, Atlanta, GA.

Amyotrophic lateral sclerosis (ALS) is a fatal neurological disorder characterized by progressive muscular atrophy and respiratory failure, leading to death within 2-5 years after the initiation of clinical symptoms. Unfortunately, no curable treatment has been developed yet except the management of symptoms. Through studies with familial and sporadic cases, genetic factors were proposed as the major contributor of ALS pathology; however, the frequency of mutations is very low among ALS patients, and all the known ALS associated mutations cannot account for phenotypic variability in terms of age of onset, type of motor neuron involvement, and disease duration. Given rapid progression of neurodegeneration once clinical presentation appears, the delay of age of onset would be a key therapeutic point. To identify novel genetic modifiers modulating the age of onset in ALS, we focused on the patients with the pathogenic expansion of GGGGCC (G<sub>4</sub>C<sub>2</sub>) repeats in the first intron of C9orf72, which is the most frequent mutation in both familial (~40%) and sporadic cases (~25%). We have performed whole-genome sequencing of both early-onset (younger than 40-year old) and late-onset (later than 70-year old) ALS patients with expanded G<sub>4</sub>C<sub>2</sub> repeat followed by functional testing using a previously developed fly model as well as target resequencing of additional cohort. Through these analyses, we have identified two genetic modifiers of the age of onset in ALS caused by the expanded G<sub>4</sub>C<sub>2</sub> repeats, *DLG2* (also known as PSD-93) and *CELF5*. Notably, the analysis of published RNA sequencing data showed that *DLG2* expression was inversely correlated with age of onset while *CELF5* was positively correlated, regardless the presence of expanded G<sub>4</sub>C<sub>2</sub> repeat. Taken together, our analyses demonstrated the effectiveness of sequencing-based genomics combined with functional genomics in identifying the genetic factors that could contribute to complex human diseases, such as ALS.

**2060T****CGG interruptions alter protein properties and increase disease**

**penetrance in SCA8.** B.A. Perez<sup>1,3</sup>, M. Banez-Coronel<sup>1,2</sup>, J. Estabrook<sup>1,2</sup>, H. Olafson<sup>1,4</sup>, S.H. Subramony<sup>1,3</sup>, T. Reid<sup>5</sup>, J. Richardson<sup>1,4</sup>, T. Ashizawa<sup>1,4</sup>, G. Xia<sup>6,7</sup>, K. Santostefano<sup>6,7</sup>, N. Terada<sup>5</sup>, A. Berglund<sup>1,2</sup>, E. Wang<sup>1,4</sup>, L.W. Rannum<sup>1,3</sup>. 1) Center for NeuroGenetics, University of Florida, Gainesville, FL; 2) Department of Molecular Genetics and Microbiology, University of Florida, Gainesville, FL; 3) Genetics Institute, University of Florida, Gainesville, FL; 4) Department of Neurology, University of Florida, Gainesville, FL; 5) Department of Biochemistry, University of Florida, Gainesville, FL; 6) Department of Pathology, Immunology and Laboratory Medicine, University of Florida, Gainesville, FL; 7) Center for Cellular Reprogramming, University of Florida, Gainesville, FL.

Spinocerebellar ataxia type 8 (SCA8) is a dominantly inherited neurodegenerative disorder caused by a bidirectionally transcribed CTG•CAG expansion mutation. Both RNA and protein gain-of-function (GOF) mechanisms are thought to contribute to disease. Expanded CUG transcripts sequester MBNL proteins within RNA foci (RNA GOF) and ATG-initiated polyGln and polyAla and polySer repeat associated non-ATG (RAN) proteins accumulate in SCA8 brains. Although the SCA8 mutation is dominantly inherited, the reduced penetrance of the disease often makes it appear as a sporadic disorder because there is no family history of the disease. Among the 75 SCA8 families we have collected, 77% presented as sporadic cases, 16% as recessive families and only 7% showed a dominant family history. Sequencing of the expansion mutations shows that CCG•CGG interruptions within the CTG•CAG repeat tract were found at a higher frequency in families with multiple affected members (8/11) versus families with a single affected member (3/29) ( $p=0.0003$ ). Transfection experiments show SCA8 expansions with CGG interruptions in the polyglutamine reading frame change their electrophoretic, aggregation and toxicity properties. To further investigate molecular differences that could alter SCA8 disease penetrance, we developed patient-derived induced pluripotent stem cell (iPSC) lines from affected and unaffected SCA8 expansion carriers. Since *ATXN8* mRNA was not detected in iPSCs and SCA8 primarily affects the CNS, we differentiated the iPSCs into neuronal precursor cells (NPCs). We found that the size of the expanded allele was stable in fibroblasts, iPSCs, and NPCs. Transcriptome analyses of control and affected NPCs detected 150 differentially expressed genes. Genes typically associated with SCA8 (e.g. *ATXN8OS*, *KLHL1*, and *MBNL1*, 2, and 3) showed no significant differences in expression. Asymptomatic expansion carrier NPCs are being analyzed, with initial data from one asymptomatic line showing a transcriptome profile more similar to control than affected samples. Ongoing studies aim to assess RNA-, and protein-GOF differences between symptomatic and asymptomatic groups and the molecular effects of CCG•CGG interruptions.

**2061F**

**The NINDS human genetics DNA and cell line repository: A publicly available biospecimen collection for neurological disease research.** A. Resch<sup>1</sup>, S. Heil<sup>1</sup>, A. Green<sup>1</sup>, J. Santana<sup>1</sup>, A. Amberson<sup>1</sup>, R. Zhang<sup>2</sup>. 1) Coriell Institute for Medical Research, Camden, NJ, USA; 2) National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD, USA.

The National Institute of Neurological Disorders and Stroke (NINDS) Human Genetics Resource Center, also known as the NINDS Human Genetics DNA and Cell Line Repository, is a public resource containing DNA and lymphoblastoid cell lines with corresponding de-identified clinical and phenotypic data. NINDS Repository samples cover a diverse population of neurological patients and neurologically normal controls. Since its establishment, specimens from over 44,000 individuals with cerebrovascular diseases, Parkinsonism, motor neuron diseases, epilepsy, Tourette syndrome, Dystonia, and neurologically-normal controls have been submitted to the repository and more than 34,500 unique samples have been successfully banked and can be accessed through an online catalog (<http://catalog.coriell.org/NINDS>). The burden of neurological disorders is a serious health concern and presents a massive challenge to healthcare systems. The causes of neurological disorders are often multifactorial, involving interactions of many genetic and environmental factors. In neurodegenerative disorders clear pathogenic mechanisms are not completely understood and the lack of reliable genetic markers for early diagnosis and intervention present great challenges for disease mitigation. Studies aimed at identifying pathogenic mechanisms will accelerate discovery of disease-specific genetic markers, the development of tools for monitoring disease onset and progression, and implementation of new therapies. Samples from the NINDS Repository have been used in GWAS, SNP, CNV, and sequencing studies and the results of these studies have been deposited in the Database of Genotypes and Phenotypes (dbGaP), a NIH/NLM-sponsored repository for restricted-access data from studies investigating the interaction of genotype and phenotype (<http://www.ncbi.nlm.nih.gov/gap>). The NINDS Repository regularly monitors new dbGaP studies to identify those that include genomic information about NINDS Repository samples. Cross-referencing of the NINDS repository and dbGaP databases allows NINDS Repository users to access additional clinical data for thousands of samples. By establishing a centralized, publicly accessible resource of biospecimens and associated clinical data, the NINDS Repository facilitates discovery of new genetic and molecular signatures related to neurological disorders.

## 2062W

**Burden analysis of ALS-gene variants in patients with and without C9orf72 expansion.** J.P. Ross<sup>1,2</sup>, C.S. Leblond<sup>1,2</sup>, D. Spiegelman<sup>2,3</sup>, A. Genge<sup>2,3</sup>, N. Dupré<sup>4</sup>, J.P. Bouchard<sup>4</sup>, P. Corcia<sup>5</sup>, W. Camu<sup>6</sup>, P.A. Dion<sup>2,3</sup>, G.A. Rouleau<sup>1,2,3</sup>. 1) Department of Human Genetics, McGill University, Montréal, QC, Canada; 2) Montreal Neurological Institute, McGill University, Montréal, QC, Canada; 3) Department of Neurology and Neurosurgery, McGill University, Montréal, QC, Canada; 4) Division of Neurology, CHU de Québec, and Faculty of Medicine, Université Laval, Québec, QC, Canada; 5) Centre SLA, CHRU de Tours, Tours, France; 6) Centre Hospitalier Universitaire Gui de Chauliac and Institut National de la Santé et de la Recherche Médicale U1051, Montpellier University 1, Montpellier, France.

**Background:** Over 30 genes are associated with ALS. While there exist several genes with penetrant variants, such as *SOD1*, *FUS*, *TARDBP*, and the *C9orf72* hexanucleotide repeat expansion, variants in most ALS genes typically have a low or unknown level of penetrance. One low penetrance variant may not directly cause the disease. However, the “Oligogenic Hypothesis,” that several concurrently inherited variants in certain genes are sufficient to cause ALS, could explain the disease in patients without a single known causal mutation. **Objectives:** We aimed to test whether patients without a known causal mutation carry significantly more variants in ALS-associated genes than patients with the *C9orf72* expansion. Further, we aimed to test whether types of patients will cluster by underlying genetic variance in these genes.

**Methods:** We included 119 ALS patients carrying the *C9orf72* repeat expansion, 120 ALS patients with no known causal mutation, and 143 unaffected controls. All individuals were recruited from clinics in Québec and France. The *C9orf72* repeat expansion was tested using Repeat-Primed PCR and genotyping assays. The protein-coding regions of 28 ALS-associated genes were targeted by a custom Molecular Inversion Probe Sequencing panel. Mutation burden was assessed using the ‘Burden’ method in the R package “SKAT.” Clustering was performed by Principal Component Analysis (PCA) using the smartpca module in EIGENSOFT 6.1.4. **Results:** None of the genes tested in the current study showed significantly increased burden between ALS patients with and without the *C9orf72* repeat expansion, nor between unknown-cause ALS patients and healthy controls. A significant difference in the total number of variants in ALS-associated genes was not observed. Further, PCA clustering analysis did not suggest a difference in genetic variance between *C9orf72*-positive patients and unknown cause patients. **Discussion:** The Oligogenic Hypothesis could help to explain why certain genes have been statistically associated with ALS, but that single mutations are often insufficient to cause the disease. However, because we did not observe a significantly increased burden of mutations within the ALS genes, it is unlikely that the disease is caused by carrying multiple mutations in these genes at once. It may be that there remain several undiscovered ALS genes that explain the disease in these unknown-cause patients. **Conclusion:** Our evidence does not support the Oligogenic Hypothesis in ALS.

## 2063T

**Identification of candidate amyotrophic lateral sclerosis risk loci using pedigree based analyses of next-generation sequencing data.** K.L. Russell<sup>1</sup>, J.M. Downie<sup>1</sup>, S.B. Gibson<sup>2</sup>, K.P. Figueroa<sup>2</sup>, M.B. Bromberg<sup>2</sup>, S.M. Pulst<sup>2</sup>, L.B. Jorde<sup>1</sup>. 1) Department of Human Genetics, University of Utah School of Medicine, 15 North 2030 East Rm 5100, Salt Lake City, UT 84112; 2) Department of Neurology, University of Utah School of Medicine, 175 North Medical Drive East, Salt Lake City, UT 84132.

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease that is characterized by the death of both upper and lower motor neurons. This neuronal degeneration leads to loss of voluntary muscle movement and eventual death 3-5 years after diagnosis. The molecular mechanisms that cause neuronal demise in ALS are not well understood. ALS can be classified into familial and sporadic forms. Familial ALS (FALS), which accounts for 10% of ALS cases, is defined by an index case that has a first- or second-degree relative that is also affected. Sporadic ALS (SALS) accounts for the remaining 90% of cases and has a heritability estimate of ~0.60. However, only 17% of SALS cases have a pathogenic variant in a known ALS-causing gene, suggesting that additional causal genes remain to be discovered. To investigate the potential role of *de novo* mutations in SALS causation, we used ALS family trios to detect potential ALS risk variants present in probands, but absent in both unaffected parents. Two trios were selected from a large cohort of ALS cases on whom whole-genome sequencing (WGS) was carried out at an average coverage of 60x. BWA and GATK (v3.3) were used to perform read alignment and variant calling. To identify candidate ALS risk genes, the pedigree-Variant Annotation Analysis and Search Tool (pVAAST) software was used. pVAAST first calculates logarithm of odds (LOD) scores to estimate linkage between the identified variants and disease. It then combines LOD scores with VAAST scores, which identify genes that are more burdened with deleterious, rare (MAF<0.01) variants in case genomes compared to 96 WGS healthy controls. After removal of false positives, the pVAAST analysis identified *ZNF587* as the top candidate risk gene. Next, Phenotype Driven Variant Ontological Re-ranking (Phevor) software was used to re-rank the pVAAST output by utilizing medical ontology databases. After removing variants that were common in control genomes, Phevor ranked *MTMR2*, a causative gene for Charcot-Marie-Tooth disease, and *ZNF587* as the top two candidate loci. The two probands had different, nonsynonymous variants in *ZNF587* (variants rs77577775 and rs144186084). *ZNF587* encodes zinc finger protein 587, thought to be involved in transcriptional regulation. Interestingly, knockdown of *ZNF587* in human glioblastoma cells was shown to decrease cell growth. These results indicate that ALS trio analysis can help to identify novel candidate ALS risk loci.

**2064F**

**Common variants at 5q33.1 predispose to migraine in African-American children.** X. Chang<sup>1</sup>, R. Pellegrino<sup>1</sup>, J. Garifallou<sup>1</sup>, M. March<sup>1</sup>, J. Li<sup>1</sup>, Y. Liu<sup>1</sup>, P. Sleiman<sup>1,2</sup>, H. Hakonarson<sup>1,2</sup>. 1) The Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania 19104, USA; 2) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania, 19104, USA.

Genome-wide association studies (GWAS) have identified multiple susceptibility loci for migraine in European adults. However, no large-scale genetic studies have been performed in children or African Americans with migraine. Here, we conducted a GWAS of 380 African-American children and 2,129 ancestry-matched controls to identify variants associated with migraine risk. We then attempted to replicate our primary analysis in an independent cohort of 233 patients and 4,038 non-migraine control subjects. We uncovered common variants at 5q33.1 associated with migraine risk in African-American children (rs1946225,  $P = 8.28 \times 10^{-8}$ ). The association was further validated in an independent study ( $P = 0.015$ ) for an overall meta-analysis  $P$ -value of  $9.55 \times 10^{-8}$ . Further, eQTL analysis of the GTEx data show the genotypes of rs1946225 were strongly correlated with the mRNA expression levels of *NMUR2* at 5q33.1. *NMUR2* encodes a G protein-coupled receptor of NMU. NMU, a highly conserved neuropeptide, participates in diverse physiological processes of the central nervous system (CNS). Our studies provide new insights into the genetic basis of childhood migraine and allow for precision therapeutic development strategies targeting migraine patients of AA ancestry.

**2065W**

**A novel mutation in *INF2* gene: Expanding the genetic spectrum of Charcot-Marie-Tooth disease and glomerulopathy.** P. Gupta, A. Gomez. Genetics, St. Josephs Regional Medical Cen, Paterson, NJ.

Introduction: Segmental glomerulosclerosis is a histological form of kidney injury characterized by focal and segmental areas of glomerular sclerosis and tubulointerstitial fibrosis (FSGS). Primary forms of FSGS usually occur as isolated proteinuria in children and adults, and may evolve to end-stage renal failure (ESRD). Charcot-Marie-Tooth neuropathy (CMT) is a heterogenous group of inherited disorders affecting peripheral neurons. Typical clinical features of CMT include progressive muscle weakness and distal limb atrophy, reduced tendon reflexes, and deformities in hands and feet. In CMT patients, an increased prevalence of glomerulopathies, mostly FSGS, has been documented. The estimated prevalence of FSGS in CMT is 1 in 400 CMT patients, compared to 1 in 1000,000 in the general population. However, it has been unclear whether these two processes represent in these individuals one disorder or if they are two separate diseases. Currently, mutations in several genes, highly expressed in podocytes, are known to cause familial FSGS. *INF2* mutations account for 12-17% of autosomal dominant (AD) cases of FSGS. Apart from podocytes, *INF2* is strongly expressed in Schwann cell cytoplasm. In recent years about 20 case reports have described a FSGS-CMT phenotype associated with *INF2* mutations. We present a 47 year old male with ESRD and CMT who has a novel mutation in *INF2*. Case Report: Our patient is a 47 year old male who presented to the genetics clinic for evaluation of CMT and possible recurrence risk in his children. He reports having an abnormal gait and foot drop when he was 11 years of age. CMT was confirmed through EMG studies and further neurological assessment. A routine urinalysis performed at 17 years of age revealed proteinuria and subsequent renal biopsy confirmed FSGS. He has received 3 renal transplants to date. Family history is significant for an 8 year old daughter who has frequent falls. Genetic testing revealed a variant of unknown significance (VOUS) in the *INF2* gene c.148T>G, which is a novel missense mutation with uncertain impact on protein function. Discussion: As we continue to learn more about the CMT-FSGS phenotype it is important to perform baseline urinalysis to assess renal function in order to make an early diagnosis especially in the event of a novel mutation in an affected family member.

Dupré<sup>6,7</sup>, C. Vilarinho-Güell<sup>8</sup>, A. Rajput<sup>9</sup>, S.L. Girard<sup>10</sup>, P.A. Dion<sup>1,2,3</sup>, G.A. Rouleau<sup>1,2,3</sup>. 1) Montreal Neurological Institute and Hospital, Montreal, QC, Canada; 2) Department of Human Genetics, McGill University, Montreal, QC, Canada; 3) Department of Neurology and Neurosurgery, McGill University, Montreal, QC, Canada; 4) Xenon® Pharmaceuticals Inc, 3650 Gilmore Way, Burnaby, BC V5G 4W8, Canada; 5) Centre Hospitalier Universitaire de Montréal (CHUM)-Notre-Dame, André Barbeau Movement Disorders Unit, Montreal, Quebec, Canada; 6) Department of Medicine, Faculty of Medicine, Laval University, Quebec City, QC, Canada; 7) Département des Sciences Neurologiques, CHU de Québec (Enfant-Jésus), Quebec City, QC, Canada; 8) Department of Medical Genetics, University of British Columbia, Vancouver, BC, Canada; 9) Division of Neurology, Saskatchewan Movement Disorders Program, University of Saskatchewan, Saskatoon Health Region, Saskatoon, SK, Canada; 10) Département des Sciences Fondamentales, Université du Québec à Chicoutimi, Saguenay, Canada.

**Introduction:** Essential tremor (ET) is a common neurological disorder characterized by postural, kinetic and intention tremors of a body part. ET is known to cluster in families and it is believed to be influenced by several genetic and environmental factors. Previous studies have suggested genetic variants and loci associated with the condition which provides valuable insights into the complexity of the genetic architecture of the disorder. Despite these recent advances, causative variants yet explain only a small proportion ET cases. Recently, a two-stage genome-wide association study (GWAS) that included 2,807 cases and 6,441 controls of European descent recently identified associations between essential tremor (ET) and specific intronic variants within three genes: a serine/threonine kinase (*STK32B*), a transcriptional coactivator (*PPARGC1A*) and a cell-adhesion molecule (*CTNNA3*). The present study aims to establish if coding variants from these genes might be associated with ET. **Methods and Results:** To further assess the role of *STK32B*, *PPARGC1A*, *CTNNA3* as ET predisposing factors, we first screened the coding regions of these genes for rare variants. Looking at exome and whole genome sequencing data, no rare deleterious variant were found to co-segregate with the disease in 14 autosomal dominant multiplex ET families. Next we used a targeted massive parallel sequencing approach to examine the protein-coding region of these genes in 269 ET cases and 287 control individuals. Thirty-four variants were identified but none had a significantly different allelic distribution between cases and controls. Finally, we performed a gene-based, variance-component test (SKAT-O) to assess the cumulative impact of rare variants. No difference in variant distribution for any of the genes was observed between the ET cases and the controls. **Conclusion:** No difference emerged regarding the distributions of individual variants (or gene) between cases and controls. Thus no rare mRNA altering variant further validated one of these genes as a risk factor for ET. The recent GWAS offers promising avenues but the genetic heterogeneity of ET is nonetheless challenging for the validation of risk factors, ultimately larger cohorts of cases should help to overcome this task.

**2067F**

**Whole-genome sequencing in primary progressive multiple sclerosis uncovers mutations in genes for inherited leukodystrophies and other MS phenocopies.** X. Jia<sup>1</sup>, L. Madireddy<sup>1</sup>, S.J. Caillier<sup>1</sup>, A. Santaniello<sup>1</sup>, F. Martinelli-Boneschi<sup>2</sup>, B.C. Cree<sup>1</sup>, S.L. Hauser<sup>1</sup>, J. Oksenberg<sup>1</sup>, S.E. Baranzini<sup>1</sup>. 1) Department of Neurology, University of California San Francisco, San Francisco, CA; 2) Department of Neurology, San Raffaele Scientific Institute, Milan, Italy.

Primary progressive multiple sclerosis (PPMS) is characterized by accumulation of neurological disability without relapses at disease onset and poor response to immunotherapies used for relapsing-remitting multiple sclerosis (RRMS). Population studies demonstrate a significant concordance in disease course (PPMS vs RRMS) between affected siblings, implicating genetics in PPMS pathogenesis. Furthermore, genetic mapping studies do not distinguish between RRMS and PPMS, suggesting a common susceptibility pattern. However, whether genetic modifiers influencing a primary neural susceptibility or the presence of relapses exists is still unclear. We performed whole-genome sequencing in 49 PPMS patients of European ancestry and obtained 81 publicly-available controls sequenced on the same platform. We identified 17 rare pathogenic variants in PPMS patients (but not in controls) in genes affecting Mendelian neurologic disorders, and attempted replication in 411 PPMS and 460 RRMS patients. Five top candidates were subjected to a second round of replication in an additional 335 PPMS, 2589 RRMS patients, and 1000 healthy controls. Four of the top 5 replicated variants were reported in diseases that share clinical features with MS, were found at a higher frequency in this PPMS cohort compared to large public cohorts, and had evidence of clinical impact in patients carrying the mutation. These included *KIF5A* p.Ala361Val in Spastic Paraplegia 10 ( $RR = 23$ ), *MFN2* p.Ala716Thr in Charcot-Marie-Tooth Type 2A ( $RR = 5.1$ ), *MLC1* p.Pro92Ser in Megalencephalic Leukodystrophy with Subcortical Cysts ( $RR = 1.8$ ), and *REEP1* c.606+43G>T in Spastic Paraplegia 31 ( $RR = 1.6$ ). Lastly, we tested the hypothesis that PPMS patients are enriched for mutations in genes affecting inherited leukodystrophies, and screened the discovery cohort for mutations in 48 genes that cause progressive demyelination in the central nervous system. Interrogation of 48 leukodystrophy genes revealed a 1.75-fold enrichment of rare potentially deleterious variants in 49 PPMS patients compared to 81 controls (T-test  $p = 0.012$ , simulation normal distribution  $p = 8.4 \times 10^{-6}$ ). This study found that mutations in genetic disorders that share some features with multiple sclerosis appear to contribute to disability in PPMS patients.

**2068W****Prioritizing Parkinson's disease genes using population-scale tran-**

**scriptomic data.** G. T. Wong<sup>1</sup>, Y.I. Li<sup>2</sup>, T. Raj<sup>1</sup>. 1) Ronald M. Loeb Center for Alzheimer's Disease, Departments of Neuroscience, Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; 2) Department of Genetics, Stanford University, Stanford, CA.

Genome-wide association studies have identified 26 genetic loci associated with late-onset Parkinson's Disease (PD) but identifying putative causal genes in PD remains particularly challenging. To address this, we leveraged large-scale transcriptomic data from 7,088 genotyped individuals across 61 tissues including 1,028 brains (461 prefrontal cortex from an aging cohort), peripheral blood, monocytes, T-cells, neutrophils, and 44 tissues from GTEx including 10 brain regions to study the genetic etiology of PD and to identify putative causal genes. Unlike Alzheimer's disease (AD), we found a strong enrichment of PD heritability near genes expressed in the brain, and to a lesser extent near genes with myeloid expression. Using a transcriptome-wide association study, we identified 86 significant gene-disease associations at FDR 5%, 58 of which are in novel PD loci with suggestive levels of GWAS association signal. We found 41 significant gene associations (e.g. *LRRK2*, *BST1*, etc.) in peripheral monocytes, of which two are shared genetic factors (*CD33* and *PILRA/B*) with AD. This points toward an overlap in the innate immune-mediated mechanisms that contribute to neurodegeneration. Interestingly, a large number of the associations were genes whose differential splicing in prefrontal cortex is associated with PD. These include known genes, e.g. the *MAPT* and *SNCA* loci which are explained by exon 3 inclusion and exon 5 exclusion, respectively. We also identified several novel genes (*MTOR*, *CLASP2*, *CAMLG*, *GALC*), whose splicing are associated with PD. A PD-associated variant (rs2076655) at the *MTOR* locus is associated with an increase in a minor *MTOR* isoform that extends the 5' end of an exon. Genes identified in our study are more likely to interact physically with PD genes and belong to the same or related pathways including lysosomal and autophagy function, which corroborates existing work on PD etiology. Overall, this study provides a strong foundation for further mechanistic studies that will elucidate the molecular drivers of PD. Thus, this work represents a significant step towards understanding the genetic basis of PD.

**2069T****Genetic analysis of SNCA gene polymorphisms in Parkinson's disease in an Iranian population.** M. Rahimi<sup>1</sup>, J. Jamshidi<sup>2</sup>, A. Tafakhori<sup>3</sup>, H. Darvish<sup>1</sup>.

1) Department of Medical Genetics, School of Medicine, Shahid Beheshti University of Medical Sciences, Tehran, CA; 2) Noncommunicable Diseases Research Center, Fasa University of Medical Sciences, Fasa, Iran; 3) Department of Neurology, School of Medicine, Imam Khomeini Hospital AND Iranian Center of Neurological Research, Tehran University of Medical Sciences, Tehran, Iran.

**Objectives:** Parkinson's disease (PD) is a complex disorder influenced by genetic and environmental factors. One of several genes indicated to be important in the etiology of PD is *SNCA*. Here we aimed to investigate the association of rs2301134, rs2301135, rs356221 and rs11931074 polymorphisms located in *SNCA* with PD. **Methods:** A case-control study was designed using 500 sporadic PD patients and 500 healthy controls. DNA was extracted from peripheral blood of all subjects and *SNCA* variations were genotyped using the PCR-RFLP method. **Results:** Significant associations were found for the two promoter polymorphisms of the *SNCA* gene, rs2301134 and rs2301135 (p-value=0.009, OR=0.79 95%CI: 0.66-0.94 and p-value=0.001, OR=1.33 95%CI: 1.12-1.59 respectively for differences in allele frequencies). Genotype frequencies were also significantly different in case and control groups for rs11931074 polymorphism located in 3'UTR region of the gene (p-value=0.036). **Discussion:** Our study indicates the possible effect of *SNCA* variations in the etiology of PD in the Iranian population. Further studies in different populations and also functional studies of the polymorphisms are suggested for more certainty in future studies.

**2070F**

**RNA-sequencing reveals novel immunological pathways in neuromyelitis optica.** I. Adrianto<sup>1</sup>, J.A. Ice<sup>1</sup>, G. Kumar<sup>1</sup>, J.L. Quinn<sup>1</sup>, A. Rasmussen<sup>1</sup>, R.H. Scofield<sup>1</sup>, G. Pardo<sup>1</sup>, K.L. Sivils<sup>1,2</sup>, R.C. Axtell<sup>1</sup>, C.J. Lessard<sup>1,2</sup>. 1) Arthritis and Clinical Immunology Research Program, Oklahoma Medical Research Foundation, Oklahoma City, OK; 2) Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK.

Neuromyelitis optica (NMO) is a rare devastating neuro-autoimmune disorder affecting primarily the optic nerve and spinal cord that has limited options for therapeutic intervention. NMO was initially characterized as a variant of relapsing-remitting multiple sclerosis (RRMS) but conventional RRMS therapies are not effective in NMO patients. There is now increasing evidence NMO shares auto-antibodies with Sjögren's syndrome (SS), an autoimmune disease of the exocrine glands. Currently, there are no studies that compare the molecular similarities and differences in patients with NMO, RRMS, progressive MS (PMS), and SS. In this study, we compared the transcriptional profiles of NMO, RRMS, PMS, and SS using RNA-sequencing. We obtained whole blood from treatment naïve patients (21 NMO, 24 RRMS, 23 PMS, and 27 SS anti-Ro-positive, 30 SS anti-Ro-negative) and 27 healthy controls. Whole blood RNA was isolated using the NuGEN Encore kit. Sequencing was performed using the Illumina HiSeq 2000 and 3000. Raw FASTQ files were aligned to the human genome using HISAT2. The read counts per transcript were generated using featureCounts. Differentially expressed (DE) transcripts were determined using DESeq2 with a false discovery rate q-value of less than 0.05 and fold change (FC) of >2 or <0.5. We found 1751 upregulated and 437 downregulated transcripts when comparing NMO to healthy controls. Although a large number of DE transcripts were protein-coding elements, ~40 of DE transcripts were non-coding RNAs. The majority of NMO and SS anti-Ro positive patients had elevated interferon-inducible genes and antibody isotype gene IGHA1 compared to SS anti-Ro negative, RRMS, PMS and healthy controls. In addition, pathway analyses of DE transcripts indicated the enrichment of those transcripts in synaptic transmission and nervous system development pathways, neurological disorders, and brain tissues. Our RNA profile analyses demonstrate that NMO and SS anti-Ro positive patients have many molecular similarities and both are significantly different than RRMS. Specifically, NMO and SS anti-Ro positive patients have elevated interferon signatures as well as humoral IgA responses. We are currently undertaking studies to further our understanding of the cellular and molecular similarities and differences between NMO, MS, and SS. These preliminary findings illuminate that potential treatment strategies that are under development for SS could be repurposed for use in NMO.

**Decoding GWAS discoveries of neurodegenerative diseases: Gene expression changes in single neurons.** L. Tagliafierro<sup>1,2</sup>, K. Bonawitz<sup>1,2</sup>, J. Barrera<sup>1,2</sup>, O.C. Glenn<sup>1,2</sup>, K. Dai<sup>1,2</sup>, O. Chiba-Falek<sup>1,2</sup>. 1) Neurology, Duke University Medical Center, Durham, NC; 2) Center for Genomic and Computational Biology, Duke University Medical Center, Durham, NC.

In the post genome-wide-association-studies (GWAS) era we are shifting gears toward translation of genetic disease loci to molecular mechanisms of pathogenesis. Large multi-center GWAS have found associations between extensive lists of genomic loci and dementia spectrum disorders, and candidate genes were inferred by the proximity to the associated-SNP. However, the precise target genes within the associated genomic regions and the causal variants effecting disease-risk are yet to be uncovered. Determining neuronal-specific alterations in gene expression profiles among different dementia-related neuropathologies and compared to cognitively healthy controls will advance the understanding of the target genes within the associated loci that contribute to the genetic etiologies of these diseases. Here we focused on late-onset Alzheimer's disease (LOAD), mild cognitive impairment (MCI) due to AD, and dementia with Lewy body (DLB). We developed a method to quantify cell-type specific gene expression levels. Archive human frozen brain tissues were used to prepare slides for rapid immunostaining, and single-neurons were isolated by Laser Capture Microdissection (LCM). Following RNA extraction, gene expression was determined digitally using nCounter Single Cell gene expression assay (NanoString). Using this method, we have analyzed the expression profiles of genes within LOAD and DLB-risk regions in neurons isolated from cortical brain tissues of LOAD, MCI, DLB and normal controls. We detected common and distinct trends of differential expression for several genes. In the neurons, *APOE*- and *TOMM40*-mRNAs were higher in all neurodegenerative pathologies compared to control. *SNCA*-mRNA levels were elevated in DLB neurons, and the levels of its alternative spliced variant (*SNCA112*) showed a further increase. Several other GWAS-genes also exhibited expression variations. We then evaluated the association between expression changes and disease associated variants. For example, *Rep1* genotypes were associated with *SNCA*-mRNA levels in the isolated neurons. In conclusion, we present a state-of-the-art method for detection of neuronal-specific gene expression changes using banked frozen human brain samples. Our results showed disease-associated changes in the expression of critical genes, also in early stages such as MCI. We suggest that the expression regulation of key genes possibly has a causative role in the etiology of dementia-related diseases in aging.

**2072T**

**The generation of iPSC-derived astrocytes from patients with Gaucher disease with and without Parkinsonism provide a model to study Parkinson pathogenesis.** *B. McMahon, E. Afaki, E. Sidransky.* National Institute of Health, Bethesda, MD., U.S.A.

Parkinson disease (PD) is caused by the disruption of dopaminergic neurotransmission in the basal ganglia, associated with a severe reduction in the number of dopaminergic neurons in the substantia nigra pars compacta and the formation of cytoplasmic inclusions called Lewy bodies. Currently, the role of glial cells such as astrocytes in PD pathogenesis is unknown. Astrocytes provide critical support for neuronal function by providing antioxidant protection, clearing glutamate, developing and/or maintaining the blood-brain barrier, and releasing gliotransmitters and cytokines. Mutations in GBA1, the gene encoding glucocerebrosidase (GCase) which is mutated in the lysosomal disorder Gaucher disease (GD), are the most common genetic risk factor for PD. We generated astrocytes from iPSCs derived from fibroblasts of five patients with type 1 GD (GD1), two with and three without parkinsonism (GD1-PD), including two siblings discordant for Parkinson disease. The patients were previously sequenced to establish their GBA1 genotype. The astrocytes exhibited decreased GCase activity and stored glycolipids when compared to astrocytes from a healthy control. Moreover, the astrocytes from patients with GD and PD had a decreased intracellular calcium response to ATP, an important molecule in glial-neuronal signaling. These cells therefore represent an excellent model for exploring the potential role of astrocytes in the pathogenesis of GBA1-associated PD.

**2073F**

**Selective activation of caspase family of genes in multiple sclerosis patients inducing neuronal apoptosis.** *Y. Kattimani, A. Veerappa.* Department of Studies in Genetics and Genomics, University of Mysore, Mysuru, India.

The risk of developing MS (Multiple Sclerosis) is strongly influenced by genetic predisposition. However, the exact mechanisms of MS initiation, its development, and progression are still elusive. It is imperative to understand the genetic complexity of multiple sclerosis by investigating the expression level of transcripts in MS cases with the age-matched controls. Whole transcriptome RNA-seq datasets from peripheral blood monocyte of 5 Multiple sclerosis cases and 3 age-matched controls were obtained from Binder et al (2016). whose original study did not report on the differential expression of genes between MS patients and controls. Therefore, we obtained the raw data files and these were aligned to a reference genome using STAR Align pipeline. Gene counts and transcripts counts were called and quantified using GSA and ANOVA pipelines. We identified 8948 genes to be up-regulated 2-34 fold, while 2727 genes were found down-regulated with fold change up to -9.3. Clustering of enriched Gene Ontology terms uncovered functional clusters relevant to neuron apoptotic pathway (positive regulation of neuron apoptotic process, Enrichment Score = 4.81 & P-value=0.00194; neuron apoptotic process= 5.51, P-value=0.038). Caspase family of genes *CASP2*, *CASP9*, *CASP6*, *CASP10*, and *CYCS* were found up-regulated 2-4 fold and were found activating intrinsic apoptotic signaling pathway, and endopeptidase activity pathways. *BCL2L1*, another pro-apoptotic regulator was found expressed across the cases, with P-value=0.000123, FDR =0.000996 with a fold change >2.17 indicating the constitutive activation of pro-apoptotic genes in cells undergoing death. The most prominent caveat in understanding MS is the primary cause that provokes autoimmunity against the CNS. The presence of not one but a number of different factors might trigger the demyelination leading to the activation of these caspase pathways. The initiation of autoimmunity might be the consequence of an efficient presentation of CNS antigens to T cells by DC in lymphoid organs. After initial activation, T cells migrate into the CNS, where they are reactivated. As a consequence the caspase dependent necrosis occurs. The implications of these findings will be presented.

**2074W****Common genetic variation contributes to cognitive performance in**

**Russian elderly population.** O. Makeeva<sup>1,2</sup>, A. Marusin<sup>1</sup>, A. Bocharova<sup>1</sup>, K. Vagaitseva<sup>1</sup>, V. Markova<sup>2</sup>, L. Minaycheva<sup>1,2</sup>, I. Zhukova<sup>3</sup>, N. Zhukova<sup>3</sup>, V. Stepanov<sup>1</sup>. 1) Institute of Medical Genetics, Tomsk, Russian Federation; 2) Nebbiolo Centre for Clinical Trials, Tomsk, Russian Federation; 3) Siberian State Medical University, Tomsk, Russian Federation.

**Background:** Maintenance of cognitive abilities in older ages as well as the late onset Alzheimer's disease are to the big extent genetically determined. A set of 62 single nucleotide variants previously reported to be linked to cognitive endophenotypes, psychiatric conditions, or late onset Alzheimer's disease was tested in respect to Montreal Cognitive Assessment (MoCA) total score and timed executive function test (Trials B) in 710 older subjects from a population-based registry from Tomsk, Russia. **Methods:** Volunteers (n=2032) were identified through a local centralized medical care system and were invited for neurocognitive assessment as a part of Alzheimer's disease prevention program. Self-reported information on individual's medical and family history, demographic information, level of education, and profession was collected. Genetic variants in 45 genes previously reported to be associated with cognitive phenotypes, psychiatric disorders and Alzheimer's disease in multiple GWAS or meta-analysis studies were genotyped using MALDI-TOF mass spectrometry. **Results:** Mean age in the study group was 72±5 years (from 56 to 91), 77.1% of the sample were female. Age ( $r=-0.338, p<0.001$ ) and education ( $r=+0.422, p<0.001$ ) significantly influenced MoCA total score; male and female subjects performed similarly on the test. MoCA scores corrected for covariates were subjected to the analysis of variance in order to estimate the contribution of studied SNPs to individual variability. Nine variants were associated with the variance of MoCA score. The largest contribution that cumulatively accounted for 8.6% of the MoCA total score variance was found for *APOE-TOMM40-PVRL2* gene cluster on chromosome 19q13.32. The effect of single SNPs in this cluster varied from 0.7% to 1.8%. Other significant signals were detected for variants at *CSMD1*, *SNX29*, *FBXO40*, and *TENM4* loci. Executive function was measured as the time for the Trials B execution in subjects who succeed to complete the test (n=665). Association was found with *TOMM40*, *PVRL*, *NKAPL*, *STK24* variants. **Conclusions:** The study confirms the role of structural variability in *APOE-TOMM40-PVRL2* locus and points several other loci associated with the cognitive performance in Russian elderly population. (The work was supported by the Russian Science Foundation grant #16-14-00020).

**2075T****Identifying the genetic underpinnings of social withdrawal.**

N. Roth Mota<sup>1,2</sup>, J. Bralten<sup>1</sup>, K. Klemann<sup>1</sup>, T.E. Galesloot<sup>2</sup>, L.A.L.M. Kiemeneij<sup>3</sup>, G. Poelmans<sup>1</sup>, B. Franke<sup>1,2</sup>. 1) Department of Human Genetics, Radboud University Medical Center, Nijmegen, Netherlands; 2) Department of Psychiatry, Radboud University Medical Center, Nijmegen, Netherlands; 3) Department of Health Evidence, Radboud University Medical Center, Nijmegen, Netherlands.

Social withdrawal is characterized by a tendency to avoid social contacts and activities, and to prefer being alone rather than with others. While it is a continuously distributed trait in the population, high levels of social withdrawal represent a common early manifestation of multiple psychiatric disorders - such as Schizophrenia (SCZ) and Major Depressive Disorder (MDD) - and neurological diseases, such as Alzheimer's disease (AD). Given the complex nature of this trait, multiple risk factors - e.g. genetic, environmental, and psychological factors - are expected to influence it. However, the underlying biological basis of social withdrawal is still to be identified. Here, we aim to investigate the genetic underpinnings of social withdrawal trait in the general population. In this respect, based on questionnaire data from a Dutch population cohort (the Nijmegen Biomedical Study) of 2988 adults (46.5% male; mean age=59), we constructed a proxy measure of social withdrawal. This measure is based on 4 items from the Extraversion subscale of the Eysenck's Personality Questionnaire (EPQ) regarding social interaction avoidance, and on 3 items from the Autism Spectrum Quotient (AQ) scale about (lack of) social skills. For the EPQ items, respondents indicated if the statement applied to them or not; for AQ items, they indicated how much it applied to them on a 4-point Likert scale and answers were then dichotomized; for each respondent, a total score of social withdrawal was calculated by adding the scores of the 7 items (range 0-7). Genome-wide association analysis was performed to test the effect of individual genetic variants on the total score for our social withdrawal measure. This was followed by gene-based analyses to determine the joint effect of variants in each gene. Although no single variant reached genome-wide significance, gene-based analyses revealed the association of one gene - *GIT1* -with social withdrawal ( $P=2.30E-06$ ), which survived correction for the 17.876 genes tested. The implication of *GIT1* gene, located on chromosome 17, on social withdrawal is an interesting and promising finding since *GIT1* is known to play an important role in neurite outgrowth and synapse formation. Additional analyses are being conducted in order to further investigate the implication of *GIT1* on social withdrawal and also to test the potential of genetic factors previously associated to SCZ, MDD and AD to predict social withdrawal measure in the general population.

**2076F****Genetic investigation of restricted and repetitive traits in autism. M.L.**

*Cuccaro*<sup>1,2</sup>, *S. Luzzi*<sup>1,2</sup>, *E.R. Martin*<sup>1,2</sup>, *H.N. Cukier*<sup>1,2,3</sup>, *A.J. Griswold*<sup>1,2,4</sup>, *D.D. Dykxhoorn*<sup>1,2</sup>, *M.A. Pericak-Vance*<sup>1,2</sup>. 1) University of Miami School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics; 3) Department of Neurology; 4) Department of Pathology.

Restricted and repetitive behaviors (RRBs) are a defining feature of Autism Spectrum Disorder (ASD). Two RRB subdomains, repetitive sensory motor behaviors (RSMB) and insistence on sameness (IS), have yielded suggestive association in stratified analyses in prior genetic studies of ASD. We hypothesize that genetic variants modify the expression of RRBs in individuals with ASD and that this genetic variation will be associated with RSMB and IS scores. Using the Autism Diagnostic Interview-Revised (ADI-R), a semi-structured interview for ASD administered to a knowledgeable informant, we calculated RSMB and IS scores for 1118 ASD participants from the Hussman Institute for Human Genomics and the Simons Simplex Collection. All individuals had DNA sequence data available from a 17Mb custom capture covering 681 genes within regions identified by GWAS of ASD. Gene-based and single-variant tests for association with IS and RSMB as quantitative traits were conducted using SKAT-O. Combinations of synonymous, non-synonymous, missense, stop, loss-of-function and splice variants were investigated in different hypothesis tests. A Bonferroni correction for the number of genes tested was used as a significance threshold for each hypothesis with an experiment-wise significance level of 0.05. Gene-based tests revealed different genes in association for the respective traits although none passed our Bonferroni corrected significance level. For the IS trait, two zinc finger genes were most significant when all exonic variants were included (*ZNF397*,  $p=2.24E-03$ , *ZSCAN30*,  $p=2.63E-03$ ) and when only missense variants were examined (*ZNF397*,  $p=2.73E-03$ , *ZSCAN30*,  $p=3.16E-03$ ). For the RSMB trait, we observed a convergence on the gene *PTPRT* for analyses of both damaging ( $p=1.49E-04$ ) and missense ( $p=1.63E-04$ ) variants. *PTPRT* (*protein tyrosine phosphatase, receptor type, T*) is a gene that is highly expressed in the developing and adult CNS and is involved in both CNS signal transduction and cellular adhesion. These results are in line with prior studies showing IS and RSMB as distinct type of RRBs. Our work shows that these different RRBs are potentially mediated by different genes. Our results suggest the value of identifying genes associated with phenotypic traits that are a part of ASD as an alternative to using the broad ASD diagnostic phenotype.

**2077W****MAPK3 identified as candidate gene influencing schizophrenia and BMI in the 16p11.2 CNV region. L. Davis<sup>1</sup>, Y. Ji<sup>1</sup>, J. Sutcliffe<sup>1</sup>, E. Cook<sup>2</sup>, H. Im<sup>3</sup>, A. Barbeira<sup>3</sup>, B. Li<sup>1</sup>.** 1) Division of Genetic Medicine, Vanderbilt University Medical Center, Nashville, TN; 2) Department of Psychiatry, University of Illinois, Chicago, IL; 3) Section of Genetic Medicine, Department of Medicine, University of Chicago.

Deletions of the 16p11.2 chromosomal region have been reproducibly associated with autism spectrum disorders (ASDs), intellectual disability, and obesity, while duplications are associated with ASDs, ID, microcephaly, schizophrenia, and low body mass index. The 600 kb region between break points 4 and 5 has been most consistently associated with neurodevelopmental phenotypes, however, recent studies have shown the transcriptional consequences of copy number variants (CNVs) in this region extend beyond the boundaries of the CNV itself (Blumenthal et al., 2014). Thus, we sought to narrow the list of contributory candidate genes in the 16p11.2 chromosomal region. We hypothesize that altered expression of risk genes in the region contributes to disease predisposition and used MetaXcan (Barbeira et al., 2017), a method which utilizes genetic and gene expression data from GTEx and the Depression Genes Network to develop prediction models of gene expression levels in 45 human tissues. The genetically regulated component of gene expression is then "imputed" in an independent sample of cases and controls ascertained for genome-wide association studies (GWAS). MetaXcan allows the use of summary statistics for model testing bypassing the need for individual level genetic data and facilitating the use of very large sample sizes collected through consortium efforts. We tested the association between the predicted expression of 179 RefSeq genes (annotated to the 16p11.2 chromosomal region) across 45 tissues, and 101 publicly available GWAS phenotypes. A total of 32 genes demonstrated expression-phenotype associations that exceeded a Bonferroni correction for the total number of tests conducted ( $p=3.2E-06$ ). Consistent with expectation, predicted increased expression of MAPK3 demonstrated a significant association with schizophrenia based on a GTEx whole blood model ( $Z = 6.51$ ,  $p = 7.48E-11$ ), a DGN whole blood model ( $Z = 4.68$ ,  $p = 2.75E-06$ ), and a EBV transformed lymphocyte model ( $Z = 4.91$ ,  $p = 8.97E-07$ ), while predicted expression demonstrated significant associations with decreased hip circumference based on a GTEx whole blood model ( $Z = -5.27$ ,  $p = 1.36E-7$ ) and a DGN whole blood model ( $Z = -5.08$ ,  $p = 3.59E-07$ ), and with waist circumference based on a GTEx whole blood model ( $Z = -4.78$ ,  $p = 1.73E-06$ ). Our findings suggest that MAPK3 plays a role in both obesity and schizophrenia phenotypes and highlight this gene as a potential risk gene influencing the 16p11.2 phenotypes.

**Inherited mutations in Human Accelerated Regions (HARs) are associated abnormal social and cognitive behavior.** *R.N. Doan<sup>1</sup>, T. Shin<sup>2</sup>, B.I. Bae<sup>1</sup>, M. Nieto<sup>3</sup>, B. Cubelos<sup>3</sup>, S. Al-Saad<sup>4</sup>, N.M. Mukaddes<sup>5</sup>, C.A. Walsh<sup>1,6,7</sup>, The Homozygosity Mapping Consortium for Autism.* 1) Genetics and Genomics, Boston Children's Hospital, Boston, MA; 2) Departamento de Biología Molecular, Centro de Biología Molecular 'Severo Ochoa', Universidad Autónoma de Madrid, UAM-CSIC, Nicolas Cabrera, 1, Madrid 28049, Spain; 3) Department of Molecular and Cellular Biology, Centro Nacional de Biotecnología, CNB-CSIC, Darwin 3, Campus de Cantoblanco, Madrid, 28049 Spain; 4) Kuwait Center for Autism, Kuwait City 73455, Kuwait; 5) Istanbul Faculty of Medicine, Department of Child Psychiatry, Istanbul University, Istanbul 34452, Turkey; 6) Howard Hughes Medical Institute, Boston Children's Hospital, Boston, MA; 7) Departments of Pediatrics and Neurology, Harvard Medical School, Boston, MA.

Comparative analyses have identified genomic regions potentially involved in human evolution, but do not directly assess function. Human accelerated regions (HARs) represent conserved genomic loci with elevated divergence in humans compared to other primate and non-primate species. At least some HARs are thought to contribute to neurodevelopmental functions underlying the unique social and behavioral traits of humans. If some HARs regulate human-specific social and behavioral traits, then mutations would likely impact cognitive and social disorders. Recent studies support the role of HARs in complex neurodevelopmental functions and associated disorders, but the contribution of individual rare HAR mutations has yet to be fully characterized. Strikingly, we find an important contribution for inherited HAR mutations in disease manifestation through large-scale whole genome and targeted "HAR-ome" sequencing in individuals with abnormal social and cognitive development. Through a combined approach of chromatin interaction sequencing, massively parallel reporter assays (MPRA), and transgenic mice, we identified disease-linked, inherited HAR mutations in active regulatory elements for *CUX1*, *PTBP2*, *GPC4*, *CDKL5*, and other genes implicated in neural function, autism spectrum disorder, or both. Our data provide genetic evidence that specific HARs are essential for normal development, consistent with suggestions that their evolutionary changes may have altered social and/or cognitive behavior.

**CNV meta-analysis of major neurodevelopmental and neuropsychiatric disorders.** *J.T. Glessner, J. Li, M. March, C. Kim, K. Thomas, C. Kao, P.M.A. Sleiman, H. Hakonarson.* Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia PA.

Neurodevelopmental and neuropsychiatric disorders represent a wide spectrum of heterogeneous yet inter-related disease conditions. The overlapping clinical presentations of these diseases suggest a shared genetic etiology. In a meta-analysis of copy number variation (CNV) analysis in five cohorts of neuropsychiatric disorders, 14 genes containing CNVs with exonic overlap reached genome-wide significance threshold of meta P-value  $< 2 \times 10^{-6}$ ; and another 41 genes had meta P-value  $< 5 \times 10^{-4}$ . Twenty of these genes demonstrated abundant brain expression during infancy and among them and their direct interactors we observed significant enrichment in CNV burden involving ErbB, neurotrophin and MAPK signaling pathway genes. We observed significant associations of genes in several loci previously reported to be associated with neuropsychiatric disorders. In addition, we identified and validated novel significant associations of *DOCK8/KANK1* duplications (Meta P-value =  $7.5 \times 10^{-7}$ ) across all cohorts. Taken together, in our large scale meta-analysis of CNVs across multiple neurodevelopmental/psychiatric diseases, we uncovered significant associations of structural variants in multiple genes shared by five major neurodevelopmental/psychiatric diseases suggesting common etiology of these clinically distinct neurodevelopmental conditions.

**Identification of novel variants in autism spectrum disorder using whole-exome trio sequencing.** R.S. Harripaul<sup>1,2</sup>, N. Vasli<sup>3</sup>, A. Rodrigues<sup>4</sup>, A. Rabia<sup>5</sup>, S. Mahmood<sup>6</sup>, A. Heidari<sup>6</sup>, L.A. Ayadhi<sup>7</sup>, B. Bozorgmehr<sup>8</sup>, R. Sasanfar<sup>9</sup>, M. Ayub<sup>9</sup>, J.B. Vincent<sup>1,2,3</sup>. 1) Centre for Addiction and Mental Health, Toronto, Ontario, Canada; 2) Institute of Medical Sciences, Toronto, Ontario, Canada; 3) Department of Psychiatry, Toronto, Ontario, Canada; 4) SickKids Research Institute, Toronto, Ontario, Canada; 5) University of Health Sciences, Lahore, Punjab, Pakistan; 6) Qazvin University, Qazvin, Qazvin Province, Iran; 7) King Saud University, Riyadh, Saudi Arabia; 8) University of Massachusetts Memorial Hospital, Worcester, MA, USA; 9) Department of Psychiatry, Queen's University, Kingston, Ontario, Canada.

Autism Spectrum Disorder (ASD) affects 1% of the population and signs of ASD occur before the age of three years and are often comorbid with other psychiatric disorders such as Epilepsy and Intellectual Disability (ID). ASD is believed to have a high degree of genetic heterogeneity with many rare variants contributing to the disorder. Thus far, most ASD research has focused on *de novo* and dominant variants because the emphasis has been placed on small Western families where recessive variants are hard to identify. This has led to a substantial knowledge gap about the effects of recessive variants on diseases such as ASD. The aim of this study is to assess the role recessive variants play in ASD and neurodevelopmental disorders. We used Whole Exome Sequencing (WES) for 43 trios so far. In addition, we have DNA from 257 Iranian, 115 Pakistani, and 20 Saudi ASD trios that will be analyzed over the next few months. The analysis pipeline consists of genome alignment using SNAP and the Genome Analysis Toolkit GlobalHaplotyper (GATK) implemented on a high-performance Hadoop infrastructure. Variant calls are annotated using recently released databases and pathogenicity scores including M-CAP, Intervar, Sift, Polyphen2, MutationTaster and comparing against 123 000 exomes in gnoMAD and 2497 exomes in the GME Server. We have identified *de novo* variants in known ID or ASD genes *ZNF292*, *MYT1L*, *CHD8*, *DYRK1A*, and novel genes such as *ANXA4*; also an X-linked variant in known ID gene *THOC2*. Biallelic mutations have been found in the known ID/ASD gene *CC2D1A*, and new candidate gene *FAXDC2*. The *FAXDC2* is a homozygous truncating mutation that has not been associated with ASD or ID previously. *FAXDC2* is a fatty acid hydroxylase domain containing protein with no known function or previous associations with disease. *ANXA4* is part of the annexin family of genes previously associated with ID/ASD. It is a calcium dependent phospholipid binding protein and is expressed in the brain. Mouse models of *ANX4* indicate behavioral and neurological impairments when knocked out. We are in the process of analyzing 300 trios the results of which will be available in next few months. Once the function of these mutations and the associated clinical features is characterized, these genes can be utilized for molecular diagnosis, better clinical management and in the long-term may act as potential targets for personalized therapeutics.

**2081T**

**Discovery of multifaceted genomic features as a promising approach to novel autism risk gene identification.** Y. Ji, Q. Wang, R. Chen, B. Li. Vanderbilt Genetics Institute, Light Hall, 2215 Garland Ave. Nashville, TN.

Autism spectrum disorders (ASD) is a common and highly heritable neuro-developmental disease. Understanding the underlying risk genes of ASD will deepen our knowledge of brain function and fuel therapeutic development for more appropriate treatment. GWAS studies only identified 5 GWS loci so far. *De novo* mutations (DNM) in ASD cases have been used effectively to identify risk genes due to their larger effect size and pathway convergence. However relying on recurrence of loss of function DNMs in the same gene only helped us find 10s of the estimated ~1000 ASD risk genes due to the rarity of DNMs. A big challenge is how to sift true risk genes from the massive amount of DNMs discovered in cohorts of ASD probands. We hypothesize that ASD risk genes have distinct genomics characteristics, and in this study we aim to systematically discover such genomic features and leverage these multi-dimensional predictive features in an integrative framework to identify ASD risk genes from DNMs not simply rely on recurrence. Specifically, we considered 3 categories of features: function based (e.g. disease-related pathway), sequence based (e.g. loss of function intolerant, conservation) and tissue-specificity based (e.g. genes of brain development). Using the 65 curated high-confident ASD genes (Sanders SJ, et al. Neuron 87-6), we identified a handful of genomic features that are characteristic of ASD risk genes compared to the genome background. In particular, features like target genes of RNA-binding protein FMRP ( $p=2.2e-16$ , OR=17.22, fisher-exact one-sided test) are highly enriched for ASD genes, pLi (loss of function intolerant) scores ( $p=6.9e-12$ , t-test) distinguish clearly ASD genes from the rest. In total we have found 14 features that reflect the characteristics of ASD genes. We reasoned that integrating the collection of distinguishing genomic features as a comprehensive source of evidence provides greater power to identify ASD risk genes. To test that, we used an independent set of ASD genes from SFARI database and found significant difference between ASD genes and random selected genes from genome background in the "integration score" of 14 features ( $p=5.67e-20$ ). We have developed a Bayesian framework that enables the integration of the discovered predictive features as well as the *de novo* discovery of ASD relevant pathways, and are employing this new approach to systematically identify ASD risk genes from public DNMs generated by large ASD consortia. .

**Gene expression profiling predicts clinical outcome in autism spectrum disorder: Confirmation of potential biomarkers and initial characterization of clinically homogeneous subgroups.** *F. Macciardi<sup>1,3</sup>, G. Guffanti<sup>2</sup>, R. Miramontes<sup>3</sup>, R. Padilla<sup>3</sup>, D. Babek<sup>4</sup>, H. Bennett<sup>5</sup>, C. Eckman<sup>6</sup>, E. Eckman<sup>6</sup>, K. Selvaggi Fadden<sup>5</sup>, T. Gleeson<sup>5</sup>, M. Rabin<sup>4</sup>, C. Sabatino<sup>4</sup>, C. Gergati<sup>1</sup>, M. Mapstone<sup>3</sup>, G. Cossu<sup>7</sup>, H. Federoff<sup>8</sup>, M. Fiandaca<sup>3</sup>, R. Kurlan<sup>8</sup>.* 1) Dept of Psychiatry, University of California, Irvine, CA; 2) McLean Hospital, Department of Psychiatry, Harvard Medical School; 3) Dept of Neurology, University of California, Irvine, CA; 4) Atlantic Neuroscience Institute, Summit, NJ; 5) Department of Child Neurology and Developmental Pediatrics, Goryeb Children Hospital, Morristown, NJ; 6) Biomedical Research Institute of New Jersey (BRINJ), Cedar Knolls, NJ; 7) Centro di Foniatria, Padova, Italy; 8) Center for Neurodevelopmental and Neurological Health, Voorhees, NJ.

We present the initial results from the first reported blood whole transcriptome expression profiling (RNA sequencing) in 20 patients with Autism Spectrum Disorder (ASD) and 19 age- and gender-matched normally developing children, as part of a larger exploratory study of gene expression in childhood ASD. We first identified 152 differentially expressed transcripts that are significant at a nominal p-value < 0.05, of which one third overlap with genes already found associated with ASD from the SFARI (Simon Foundation Autism Research Initiative) database, while the remaining two thirds present potentially new findings. We also confirmed the differential expression of a subset of transcripts (N=10), originally reported by Glatt and colleagues (2012) using RNA microarrays from peripheral blood. Using these 10 transcripts in a disease-predictive model, we can distinguish between our cases and controls with high sensitivity and specificity. This finding in an independent sample represents the first confirmation of potential peripheral biomarkers indicative of an increased risk of developing ASD. Since the current diagnosis of ASD is still based on a clinical phenotype that only becomes discernable when an affected child is age 3 years or older, the availability of early actionable biomarkers indicative of ASD provides clinical relevance in avoiding delay in possible therapeutic interventions. Additionally, an exploratory analysis of co-expressed gene networks allowed us to untangle the heterogeneity of the ASD phenotype into at least two homogeneous subgroups characterized by contrasting clinical features, including the presence or absence of severe language impairment, IQ scores, and certain motor traits. .

**Using the DGRP to identify gene networks associated with autism-like behaviors.** *L.T. Reiter<sup>1</sup>, P. Cavich<sup>1</sup>, B. May<sup>1</sup>, D. Johnson<sup>2</sup>, K.A. Hope<sup>1,3</sup>.* 1) Dept Neurology, Univ Tennessee HSC, Memphis, TN; 2) Molecular Bioinformatics Core, Univ Tennessee HSC, Memphis, TN; 3) IPBS Program, Univ Tennessee HSC, Memphis, TN.

Appropriate social behaviors are essential for reproduction and survival. Defects in social interaction and communication in humans can cause autism spectrum disorder (ASD). The basic neurogenetics controlling complex ASD-like behaviors in humans is still largely unknown. Here we used an unbiased quantitative trait locus (QTL) approach in *Drosophila melanogaster* to identify gene interactions that influence communication during mating (receptive and expressive), repetitive behaviors and social interactions in flies. The *Drosophila* Genetic Reference Panel (DGRP) has been used to analyze a range of naturally occurring behaviors including sleep, appetite, olfaction, and aggression. The DGRP represent >4.8M single nucleotide polymorphisms (SNPs) and >2.9M non-SNP variants mirroring the variation for each of 205 flies in a wild type population. Genetic variation within each line is fixed, while variation across lines represents the naturally occurring variation in the original population. This is the most powerful system available for behavioral genetics among model organisms. Using genome wide association tools designed for the DGRP, we identified genes associated with ASD-like behaviors across 40 DGRP lines. Social communication during mating was used as a proxy for expressive and receptive communication, grooming behavior as a proxy for repetitive behavior and physical spacing as a measure of social interaction among flies. Measures used for genome wide association were time to latency (expressive/receptive communication), average time grooming and average distance between flies (social space). We identified at least one gene, *sfl* (*sulfateless*), associated with all three ASD-like behaviors. *sfl* encodes a heparan sulfate N-deacetylase known to be essential for synaptic vesicle endocytosis. We show that knock down for *sfl* levels in neurons causes both decreased grooming and increased social spacing defects. We have also identified QTLs in 130 genes affecting ASD-like behaviors including homologous of *NLGN2* and *CNTNAP2*, but have only tested ~20% of the fully sequenced DGRP lines. Optimizing resolution and statistical power of these associations will require assessment of all 205 lines for all ASD-like behaviors. Our end goal is to identify new gene-gene relationships or even variants in known ASD genes that are associated with these behaviors in humans.

**2084T**

**Epigenetic dysregulation of *DYRK1A* may have a role in ASD development in a discordant monozygotic twin pair.** C. Sjaarda<sup>1,2</sup>, L. Santavy<sup>1,2</sup>, A. McNaughton<sup>1,2</sup>, M. Hudson<sup>1,2</sup>, A. Guerin<sup>3</sup>, M. Ayub<sup>3</sup>, X. Liu<sup>1,2</sup>. 1) Queen's Genomics Laboratory at Ongwanada, Ongwanada Resource Center, Kingston, Ontario, Canada; 2) Department of Psychiatry, Queen's University, Kingston, Ontario, Canada; 3) Department of Pediatrics, Queen's University, Kingston, Ontario, Canada.

Autism spectrum disorder (ASD) is a complex and highly heritable neurodevelopmental condition with a poorly understood etiology. Genetic sequence variation, aberrant gene expression, and dysregulation of gene expression have all been implicated in ASD, though few studies have examined the combined effect of all three genetic factors. Using an integrative genomics approach, we investigate potential genetic and epigenetic mechanisms underlying the ASD phenotype in a family with a discordant monozygotic twin pair and a non-twin sibling with ASD. Whole exome sequencing of both subjects with ASD identified potentially significant variants. Transcriptome sequencing identified differentially expressed genes between monozygotic twins that are enriched for pathways relevant to ASD including MAPK signaling. Most importantly, expression of *DYRK1A*, a kinase involved in neurodevelopment and previously implicated in ASD, was significantly reduced in both individuals with ASD relative to unaffected family members. MicroRNA sequencing identified 46 differentially expressed microRNA between monozygotic twins including two microRNAs, miR-150-3p and miR-369-3p, that are significantly overexpressed in the twin with ASD and predicted to target the *DYRK1A* gene transcript. These results may indicate a role for aberrant *DYRK1A* expression in development of ASD in the affected twin and sibling and suggests that one possible mechanism of *DYRK1A* dysregulation is by differential microRNA expression.

**2085F**

**Epigenetic factors and gene-environment interactions in autism: Prenatal maternal stress and the SERT gene.** Z. Talebizadeh<sup>1</sup>, A. Shah<sup>1</sup>, J. No-el-MacDonnell<sup>1</sup>, P. Hecht<sup>2</sup>, D. Beversdorf<sup>2</sup>. 1) Children's Mercy and University of Missouri-Kansas City School of Medicine, Kansas City, MO; 2) University of Missouri, Columbia, MO.

There is insufficient knowledge of the potential environmental factors or gene X environment interactions (GxE) in autism. Maternal stress exposure may be important in autism. By surveying for history/timing of prenatal psychosocial stressors, we found autism mothers to have a higher incidence of stressors compared to controls, which was subsequently confirmed by larger epidemiological studies. To explain why prenatal stressors might result in autism in some cases but not others, we began to explore GxE. The serotonin transporter (SERT) gene is well studied for its role in stress reactivity. The most widely studied variation is an insertion/deletion within the promoter region, resulting in long (L) or short (S) alleles. The S-allele has been linked to autism in some but not all studies. These contradictory findings could, in part, be explained by the presence of a gene/stress interaction or epigenetic factors. There is also emerging evidence that microRNAs may play a regulatory role in the serotonergic pathway and prenatal stress, particularly, in response to chronic stress through interaction with serotonergic genes. In the present study, we examined microRNAs in blood samples (n=34) from mothers of children with autism, with known pregnancy stress history. The samples were divided into 5 groups based on SERT genotypes (LL, LS, and SS) and prenatal stress level (High and Low). Five-way ANOVA showed differential expression (DE) of 119 microRNAs (P<0.05), 90 (76%) of which showed a similar pattern of expression in High vs Low stress groups (stress-dependent microRNAs). Intriguingly, two of them, miR-1224-5p and miR-331-3p, were recently reported by our group to exhibit stress-dependent expression in rodent brain samples from embryos exposed to prenatal stress. Another stress-dependent microRNA, miR-145-5p, has been reported in association with maternal stress. To assess the role of SERT genotype, we conducted a 3-way ANOVA on groups exposed to a high level of prenatal stress. This analysis showed a smaller number of DE microRNAs (n=20), 5 (25%) of which were among the stress-dependent microRNAs. These 5 microRNAs may be candidates for stress X SERT genotype interactions. One of them, miR-663a, has been previously reported to be DE in response to Fluoxetine (SSRI drug). We have also performed exome analysis and will correlate the microRNA expression with exome data to detect other potential serotonergic genes that may play a role in this GxE model.

**2086W****Assembling the effects of genetic and environment risk factors in autism spectrum disorder using patient-derived neurons.** *K. Tammimies<sup>1</sup>, M. Becker<sup>1</sup>, M. Arora<sup>2</sup>, S. Stamouli<sup>1</sup>, M. Kele<sup>3</sup>, S. Bölte<sup>1</sup>, A. Falk<sup>3</sup>.*

1) Women's and Children's Health, Center of Neurodevelopmental Disorders (KIND), Karolinska Institutet, Stockholm, Sweden; 2) Department of Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York, USA; 3) Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden.

Autism spectrum disorder (ASD) is a common neurodevelopmental disorder affecting 1-2% of the population. Hundreds of genes and multiple environmental risk factors have been linked to ASD susceptibility. Using a highly informative twin cohort of more than 150 twin pairs, enriched for monozygotic (MZ) pairs discordant for ASD, we are studying genetic and environmental risk factors underlying the disorder. No discordant genetic variants have been identified in the discordant MZ twins in saliva- or blood-derived genomic DNA. However, we have identified shared rare copy number and sequence level variants in genes and loci earlier implicated in ASD. Additionally, we have demonstrated a dysregulation of essential and toxic metals, including zinc and lead, during the prenatal and early postnatal periods (Arora *et al.* Nat Commun. 2017 Jun 1;8:15493). We are generating induced pluripotent stem cells (iPSCs) from the same twins to simultaneously model the identified genetic and environmental risks during neuronal development. The iPSCs are derived based on earlier reported protocol (Uhlir *et al.* Stem Cell Res. 2017 Jan;18:22-25) and the cells are further reprogrammed into neuroepithelial stem cells (NES) before the neuronal differentiation. We have selected twin pairs for further characterization based on the identified genetic risk factors. These include ASD-discordant MZ twin pairs with 0.95 Mb duplication of chr16q14.1 and another pair with a splice site mutation affecting an X-linked synaptic protein *CASK*. We will mimic the environmental risk conditions such as the prenatal zinc deficiency using modified cell culture media which we have optimized using chelating agents or by the addition of toxic metals. The effect of the risk conditions is measured using single cell transcriptomics during different time points of neuronal differentiation. Furthermore, we are testing different chelating drugs such as Clioquinol in our system. We will validate the molecular pathways affected by both the genetic variants and environmental exposures using additional cellular assays, i.e. measuring cellular energy levels and synaptogenesis. With our approach, we aim to understand better the mechanisms underlying ASD, identify novel drug targets and putative therapeutic strategies for subgroups with ASD.

Autism spectrum disorder (ASD) exhibits complex genetic architecture with well demonstrated contributions of both common and rare, especially *de novo*, variants. Biallelic mutations provide another powerful, but comparatively underexplored, avenue for illuminating disease-relevant biological processes. We report the largest analysis to date of biallelic mutation in ASD using whole exome sequencing data from >8,000 individuals in the ASC. We confirm an excess of biallelic, autosomal loss-of-function (LOF) mutations in ASD, and extend these observations to biallelic damaging missense variation as well. The observed excess is especially striking in females (10% of affected females), with patterns consistent with a female protective (or male susceptibility) effect. We also find that ~60% of genes subject to biallelic LOF in the ASC are also knocked out in ExAC. From this observation we develop gene and allele filters based on ExAC and demonstrate that their application cuts observed rates of biallelic mutation by half, but leaves the ascertainment differential between cases and controls intact, thus indicating that the excess of biallelic mutation in ASD is driven by genes under recessive constraint. We identify several patients diagnosed with ASD due to biallelic knockout of known and/or emerging recessive neurodevelopmental genes (*CA2*, *DDHD1*, *NSUN2*, *PAH*, *RARB*, *ROGDI*, *SLC1A1*, *USH2A*). We also identify ASD-specific, biallelic gene knockouts in genes that affect neurobiological mechanisms not previously implicated by *de novo* mutations, including *FEV*, a transcription factor required for development and function of serotonergic circuitry, a system long suspected to be dysregulated in ASD. Our data refine the contributions of recessive mutation to ASD and suggest paths for using rare recessive mutations to illuminate novel biological pathways underlying ASD.

**Chronic psychosocial stress in mice alters brain myelination in a genetic background-dependent manner.** I. Hovatta<sup>1</sup>, M. Laine<sup>1</sup>, K. Trontti<sup>1</sup>, Z. Misiewicz<sup>1</sup>, N. Kuleskaya<sup>1</sup>, S. Saarnio<sup>1</sup>, E. Jokitalo<sup>2</sup>, D. Greco<sup>2</sup>, I. Balcells<sup>1</sup>, E. Sokolowska<sup>1</sup>. 1) Department of Biosciences, University of Helsinki, Helsinki, Finland; 2) Institute of Biotechnology, University of Helsinki, Helsinki, Finland.

Chronic psychosocial stress is a well-established risk factor for anxiety disorders and major depression. Mechanisms by which chronic stress impacts susceptibility and resilience to psychiatric disorders are largely unknown. Animal models allow administration of specific stressors in a controlled manner in inbred genetic backgrounds to reveal gene-environment interactions. To identify brain gene expression changes taking place after chronic psychosocial stress, we used 10-day chronic social defeat model in mice, and carried out RNA-seq from medial prefrontal cortex (mPFC) and ventral hippocampus (vHPC) of C57BL/6 (B6; a non-anxious inbred strain) and DBA/2 (D2; an anxious inbred strain) mice. The two mouse strains showed a distinct behavioral response to stress, as measured by the social avoidance test carried out after social defeat. Sixty % of the B6 mice but only 10% of D2 mice were resilient to stress, the remainder being susceptible. We discovered that the expression levels of several myelination-related genes differed substantially due to chronic stress in both brain regions, and 'myelination' pathway was over-represented in gene-set enrichment analysis. To establish whether and how myelin thickness and structure are altered after stress, we carried out transmission electron microscopy. We found that the B6 stress resilient mice had significantly thicker myelin of small diameter mPFC axons compared to the B6 control mice. In the vHPC, susceptible B6 mice had thinner myelin compared to B6 control mice. In the D2 strain, susceptible mice had thicker myelin than resilient mice within the mPFC and resilient mice had thinner myelin of small diameter axons compared to the controls in the vHPC. Our findings suggest significant white matter plasticity in response to chronic psychosocial stress in mice. Such differences have previously been observed in response to early-life stress or social isolation in adult mice. Our results extend these previous findings to psychosocial stress, and demonstrate that the pattern of myelination differences is dependent on the genetic background and varies across brain regions.

**2089W**

**Analysis of the genetics and heritability of a shared endophenotype in ADHD and FASD.** J. Kaplanga<sup>1,2,5</sup>, T. Trudeau<sup>3</sup>, B. Laufer<sup>4</sup>. 1) Pediatrics, Western University, London, ON, Canada; 2) Pediatrics/Genetics, Grey Bruce Health Services, Owen Sound, ON, Canada; 3) Biology, Western University, London, ON, Canada; 4) Schulich School of Medicine, Western University, London, ON, Canada; 5) Summerside Medical Center, Summerside, PEI, Canada.

ADHD and FASD share an behavioral endophenotype characterized by impaired executive function, emotional regulation, cognition, learning and social adaptation. Genetic factors play a significant role in both FASD and ADHD, and in ADHD families the shared endophenotype is heritable. While FASD is causally associated with prenatal alcohol exposure (PAE) and includes severe forms known as fetal alcohol syndrome (FAS) characterized by distinctive physical features, PAE and distinctive physical features are not associated with ADHD. However, individuals with undiagnosed ADHD are at risk for substance and alcohol abuse during the reproductive years. Children with ADHD often have mothers who have ADHD and children with FASD often have mothers with undiagnosed ADHD. This raises the question of whether inheritance of genetic factors and not PAE is the cause of the shared endophenotype in FASD. It also raises the question of whether or not FAS is in fact a separate PAE – induced disorder that does not share etiology with FASD and ADHD. We hypothesize that ADHD and FASD share a heritable endophenotype that is associated with specific etiologic factors. This study is i) to determine whether or not ADHD and FASD share an endophenotype, ii) to determine whether the endophenotype is heritable, and iii) to determine if mothers of FASD patients have undiagnosed ADHD. **Methods:** Children aged 3 to 17, with FASD and/or ADHD and their consenting mothers were recruited after ethics approval. Patient interviews and chart analysis were conducted to extract clinical information focused on behavioral features, and maternal childhood history of ADHD and alcohol consumption. **Results:** Data analysis identified 184 ADHD and 166 FASD children, and 84 ADHD and 74 FASD mothers. Of these 91% ADHD and 93% FASD children had mothers with the endophenotype; and 85% of ADHD and 88% of FASD mothers had children with the endophenotype, respectively. Further, for the ADHD and FASD children 80% and 77% of the mothers with the endophenotype, respectively had at least 2 affected children. **Conclusion:** Children with ADHD and FASD share a certain heritable behavioral endophenotype that is also observed in their corresponding mothers. Genetics and not PAE is the explanation for the shared endophenotype in children diagnosed as FASD. This implies that ADHD and FASD are the same disorder and are caused by the same etiologic factors. FAS is a separate disorder.

**2090T**

**Genetic polymorphism and gene-environment interactions of dopamine receptor genes and nicotine dependence in the population of the Northwest Indian region.** J. Kaur, R. Kaur. Department of Human Genetics, Punjabi University, Patiala, Punjab, India.

**Purpose:** Nicotine Dependence (ND) like many other addictive behaviors has a genetic component. Furthermore, D1 and D2 like dopamine receptor genes involved in dopaminergic reward pathways of the brain are considered excellent candidates for contributing to the genetic components of these addictive behaviors. In the present study we aimed to ascertain the association, if any, between DRD1, ANKK1 *TaqIA*, DRD2 *TaqIB*, DRD2 *TaqID* and DRD3 gene SNPs with nicotine dependence by case-control. **Methods:** Genomic DNA was extracted using standard salting out method and genotyped using PCR-RFLP method in ND cases (n=173) and healthy controls (n=188) inhabiting North-West region of India. The degree of nicotine dependence was ascertained by FTND, HSI and HWRSS (six reasons for smoking). Data were analyzed using MedCalc and SPSS 16.0, Haploview program, version 4.2, SHEsis and Multifactor Dimensionality Reduction (MDR) Analysis. **Results:** A total of 361 subjects (173 nicotine dependent cases with a mean age 35.37±14.29 years and 188 healthy age/ethnicity matched controls with a mean age of 35.79±13.37 years) participated in the study. Both the groups were found to be in Hardy-Weinberg equilibrium. On applying contingent chi-square test, DRD2 *TaqID* showed significant differences between cases and controls at the allelic level ( $\chi^2=20.2$ , d.f=1, 0.000<p<0.05) and DRD3 showed significant differences both at the genotypic ( $\chi^2=5.84$ , d.f=2, 0.054<p<0.05) and allelic level ( $\chi^2=5.63$ , d.f=1, 0.018<p<0.05). However, after applying the stringent Bonferroni correction the differences remained significant only at the allelic level for DRD3 and DRD2 *TaqID*. DRD3 gene showed a 2 fold risk of ND (OR 2.11, 95% CI 1.118-3.985, 0.021<p<0.05) with rare genotype (*Gly/Gly*) compared to predominant (*Ser/Ser*) genotypes. D' value suggested a strong linkage between the three sites ANKK1 *TaqIA*, DRD2 *TaqIB* and DRD2 *TaqID*. Gene-environment interplay unveiled synergistic interactions between DRD1-ANKK1 *TaqIA* (gene-gene), DRD3-Pack years smoked (Gene-environment), NAR-DRD1 (Gene-environment), DRD2 *TaqID*-NAR (Gene-environment), DRD2 *TaqIB*-NAR (Gene-environment) and DRD1-Pleasure (Gene-environment) for nicotine dependence risk prediction in ND cases and controls. **Conclusion:** Our results suggest a higher risk of nicotine dependence in individuals carrying minor T allele of DRD3 and D1D1 genotype of DRD2 *TaqID* in their lifetime than others.

**2091F**

**Whole-genome sequencing to identify risk loci for nighttime eating in American Indians.** C. Koroglu<sup>1</sup>, M.E. Gluck<sup>2</sup>, S. Vortuba<sup>2</sup>, J. Krakoff<sup>2</sup>, M. Traurig<sup>1</sup>, P. Piaggi<sup>1</sup>, P. Chen<sup>1</sup>, L.J. Baier<sup>1</sup>. 1) Diabetes Molecular Genetics Section, Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ; 2) Obesity and Diabetes Clinical Research Section, Phoenix Epidemiology and Clinical Research Branch, NIDDK, NIH, Phoenix, AZ.

Night eating syndrome (NES) is characterized by increased food intake in the evening and night time, with or without nocturnal awakenings to eat. Familial aggregation has been shown for NES, suggesting that this syndrome has genetic determinants. Individuals with NES are prone to weight gain and the disorder can complicate diabetes management; therefore, our study focused on identifying genetic determinants of nighttime eating (NE) behavior in American Indians who are at high risk for obesity and type 2 diabetes. We performed whole-genome sequencing on 23 individuals with NE and 27 controls, where all individuals were >50% American Indian. These individuals had been clinically characterized over a 3-day period as inpatients in our Clinical Research Center, and NE status was determined based on the occurrence of food intake on any of the 3 nights between 11 pm and 5 am, recorded by a computerized vending machine. Among sequence data from these individuals, 6.2 million variants of high quality were detected. As expected with this small sample size, no variant achieved genome-wide significance for NE in a case/control analysis. Therefore, the top signals for NE (396 variants with a  $P < 1 \times 10^{-4}$ ) were further analysed in 6,789 American Indians with longitudinal data on BMI. Among these top signals for NE, only rs2268953 in *AKAP6* also associated with maximum lifetime BMI ( $P = 5.1 \times 10^{-6}$ , adjusted for age, sex, birth year, admixture and the principal components 1-5), where the risk allele for NE (G allele) associated with a higher BMI. *AKAP6* is most highly expressed in the brain, but it is also expressed in cardiac and skeletal muscle. Its protein product is involved in anchoring PKA to the nuclear membrane or sarcoplasmic reticulum. Interestingly, *AKAP6* has previously been reported as a risk locus for anorexia nervosa in a genome-wide association, which supports a potential role of *AKAP6* in determining eating behaviour. We are currently pursuing functional studies of *AKAP6*, but are also looking at variation in other candidate loci (e.g. genes that have a role in regulation of leptin, ghrelin, melatonin, and cortisol levels) which may have only achieved nominal statistical evidence for association with NE in this small sample size.

**2092W****RNAseq transcriptome study of schizophrenia in the MGS African**

**American sample.** A. Sanders<sup>1,2</sup>, J. Duan<sup>1,2</sup>, E. Drigalenko<sup>3</sup>, H. Göring<sup>4</sup>, P. Gejman<sup>1,2</sup>, *Molecular Genetics of Schizophrenia (MGS) Collaboration.* 1) Res Inst, NorthShore Univ HealthSystem, Evanston, IL; 2) Dept of Psychiatry and Behavioral Neuroscience, Univ of Chicago, Chicago, IL; 3) Dept of Genetics, Texas Biomedical Res Inst, San Antonio, TX; 4) South Texas Diabetes and Obesity Inst, Univ of Texas Rio Grande Valley Sch of Med, San Antonio, TX.

GWAS on predominantly European ancestry (EA) samples have implicated over 100 loci as being associated at genome-wide significant levels with risk for schizophrenia (SZ). Some of these risk loci are shared across ancestral groups, including within variably admixed African American (AA) samples. Regulation of mRNA expression may be involved in the etiology for some of these loci, thus suggesting utility of a transcriptomic profiling approach. In both of two previous large transcriptomic profiling studies on lymphoblastoid cell lines (LCLs) from non-overlapping EA SZ case-control samples, using arrays (N=714; Sanders et al., 2013) and RNAseq (N=1,189; Sanders et al., 2017), we found genes differentially expressed by affection status to be enriched for immune-related genes, consistent with hypothesized immune contributions to SZ risk. The single largest reported SZ GWAS on an AA sample is on the Molecular Genetics of SZ (MGS) dataset (Shi et al., 2009), from which we derived the current transcriptomic (RNAseq) sample. After various sample quality control steps including identity verification ensuring concordance between known sex (i.e., dosages of X and Y chromosomes) and RNAseq expression levels of sex-dimorphic expressed genes on chromosomes X and Y, and RNAseq-derived genotype concordance versus previous GWAS genotypes, we moved samples with at least 8M read depth from 378 SZ cases and 386 controls to analyses. To adjust for known or potentially confounding effects, we collected data on measured (EBV load, growth rate, and energy status), RNAseq batch, ancestry (top two genotypic principal components from GWAS), and other demographic (sex, age) covariates to include in the regression analysis to identify genes differentially expressed by affection status. We will present and discuss results in several main areas: (1) degree of replication of AA transcriptomic results for previous EA findings, (2) pathway and network analyses of differentially expressed genes, (3) gene set enrichment analyses, especially for immune related genes, (4) differences compared to findings for previous EA transcriptomic work, and (5) combined analyses of the current AA and previous EA transcriptomic datasets. This work was supported NIH grant R01MH098059 using samples from the MGS collaboration.

**Minds, genes, and machines: Performance on online cognitive assessments is correlated with individual characteristics in 23andMe customers.** O.V. Sazonova<sup>1</sup>, L. Germine<sup>2</sup>, C. Wilson<sup>1</sup>, P. Fontanillas<sup>1</sup>, C.E. Carey<sup>3</sup>, *23andMe Research Team.* 1) 23andMe, Mountain View, CA; 2) Center for Human Genetic Research, Massachusetts General Hospital, Boston, MA; 3) Department of Psychological and Brain Sciences, Washington University, St. Louis, MO.

Personality and cognitive traits can have a profound impact on individual quality of life. Together with environmental factors, a significant body of literature points to a genetic component of individual variation in human behavior. Specifically, cognitive traits such as risk-taking tendency, impulsivity, and processing speed have shown heritability in twin studies. Uncovering novel causal relationships between cognition and the combination of genetics, lifestyle, and demographics can deepen our understanding of the mechanisms by which cognitive processes manifest. 23andMe is a consumer genetics company with a database of over 2 million genotyped customers, the majority of whom consent to participate in 23andMe research. 23andMe has recently deployed a series of online cognitive assessments designed to capture phenotypic variation in cognitive traits. In the present study, we mined our database for associations with performance on the Balloon Analog Risk Task ("BART") and the Digit Symbol Substitution Test ("DSST"). Higher BART scores have been associated with neuropsychiatric disorders that involve risk-seeking behavior. The DSST is a test of processing speed, attention and cognitive efficiency and is broadly sensitive to brain dysfunction. Ongoing data collection has resulted in over 10,000 consented research participants for each of the BART and the DSST. We modeled scores as continuous and discrete phenotypes (adjusting for extreme outliers) and explored genetic and phenotypic associations in our database. Preliminary results suggest a genetic component to performance on both tasks, as well as associations between BART scores and phenotypes pertaining to education and "Big Five" personality traits. As independent validation, we also compared performance on the BART with a survey of risk-taking, where 23andMe research participants rated themselves as "adventurous" on a 5 point scale. This study represents an ongoing effort to combine genetics and self-reported phenotypic data with online cognitive assessments. A better understanding of the mechanisms that influence cognitive traits may guide the development of more effective treatments for neuropathic conditions such as impulse control disorder or bipolar disorder. As a novel paradigm in crowdsourcing biomedical discoveries, our research model holds great promise for uncovering causal factors that contribute to the continuum of human cognition.

## 2094F

**Network analysis of gene polymorphisms in GABA, dopamine, cannabinoid, mu-opioid and alcohol metabolism pathways with alcohol dependence in scheduled class (SC) population of Punjab (Northwest India).**

R. Sharma, A.J.S. Bhanwer. Human Genetics, Guru Nanak Dev University, Amritsar, Punjab, India.

The role of GABA, dopamine, cannabinoid, mu-Opioid and alcohol metabolism pathways in alcohol dependence (AD) are evident from animal models and human studies. Aim of this study was to investigate association between genes in the different pathways of AD. This case-control study was designed to investigate the association of SNPs in *ADH2* (rs1229984), *ALDH2* (rs671), *CNR1* (rs806368), *DRD2* (rs1800497, rs1079597, rs1799732), *DRD4* (rs916455), *GABRA2* (rs567926, rs279858) and *OPRM1* (rs1799971) genes with AD in the SC population. Male subjects comprising of 300 AD cases and 300 age, ethnicity matched normal controls were enrolled in this study. The G allele of *CNR1* (rs806368) variant conferred 1.5 fold risk towards AD [p=0.001, OR=1.58 (1.2-2.08)]. Of the three polymorphisms analyzed in *DRD2* gene, significant risk to AD was posed by minor alleles of rs1800497 (T allele) [p=1.5×10<sup>-5</sup>, OR=1.8 (1.38-2.35)] and rs1799732 (D allele) [p=0.0003, OR=1.67 (1.26-2.22)]. The minor alleles (C allele) of both variants of *GABRA2* (rs567926, rs279858) posed 1.4 fold risk for alcohol abuse. The G allele of *OPRM1* rs1799971 was associated with increased risk for AD [p=1.96×10<sup>-4</sup>, OR=1.82 (1.33-2.51)]. Both *ADH2* (rs1229984) and *ALDH2* (rs671) were observed to be monomorphic for G allele. Haplotype analysis of *DRD2* gene created two novel combinations: TGC providing risk for AD [p=7.9×10<sup>-4</sup>, OR=2.12 (1.35-3.31)] while CAA playing protective role against AD [p=5.1×10<sup>-4</sup>, OR=0.51 (0.35-0.75)]. TT combination of *GABRA2* provided protection from AD [p=2.8×10<sup>-4</sup>, OR=0.6 (0.46-0.79)]. MDR analysis detected 3 loci genetic model comprising of *CNR1* (rs806368), *DRD2* (rs1800497) and *GABRA2* (rs567926) variants to increase the susceptibility of AD by 5 fold [p<0.0001, OR=5.77 (3.82-8.72)]. Prediction of RNA secondary structure from the base sequence using minimum free energy (MFE) based on thermodynamic approach was also outlined which revealed that ancestral type alleles to be structurally more stable. This analysis further evaluated the impact of studied variants on the RNA structure. Further, network analysis was conducted to unravel the remaining interrelating genes among the studied pathways. In conclusion, combinatorial effect of genes in different studied pathways conferred the major genetic risk for AD and can serve as potential biomarkers for determining the genetic predisposition towards AD in the SC population of Punjab.

## 2095W

**Understanding remission on venlafaxine in late-life depression: A genome-wide approach.**

V.S. Marshe<sup>1,2</sup>, M. Maciukiewicz<sup>2</sup>, S. Rej<sup>3,4</sup>, A.K. Tiwari<sup>2,4</sup>, E. Sibille<sup>2,5</sup>, D. Blumberg<sup>6</sup>, J.F. Karp<sup>6,7</sup>, E.J. Lenze<sup>8</sup>, C.F. Reynolds III<sup>6</sup>, J.L. Kennedy<sup>1,2,4</sup>, B.H. Mulsant<sup>1,2,4</sup>, D.J. Mueller<sup>1,2,4</sup>. 1) Institute of Medical Science, University of Toronto, Toronto, ON, Canada; 2) Campbell Family Mental Health Research Institute, Centre for Addiction and Mental Health, Toronto, ON, Canada; 3) Department of Psychiatry, McGill University, Montreal, QC, Canada; 4) Department of Psychiatry, University of Toronto, Toronto, ON, Canada; 5) Department of Pharmacology, University of Toronto, Toronto, ON, Canada; 6) Department of Psychiatry, University of Pittsburgh, Pittsburgh, PA, USA; 7) VA Pittsburgh Health System, Geriatric Research Education and Clinical Center, Pittsburgh, PA, USA; 8) Healthy Mind Lab, Department of Psychiatry, Washington University, St. Louis, MO, USA.

**Background:** In geriatric depression, antidepressant treatment response is often slow and incomplete; new biomarkers for antidepressant response could lead to precision medicine and uncover new mechanisms of illness. Therefore, we conducted a genome-wide association study (GWAS) in older adults treated with venlafaxine. **Methods:** Three-hundred and fifty participants (>60 years) of mixed ethnic ancestry, diagnosed with major depression (MADRS > 15), were treated with venlafaxine (~12 weeks). Individuals were genotyped using the Illumina PsychArray, and genetic data was imputed to 7.5 million variants per individual. Associations with remission status (MADRS < 10) and change in MADRS score were conducted using logistic/linear regressions, adjusted for ancestry, sex, recruitment site, length in treatment, depressive episode duration, and baseline depressive severity. We also conducted pathway enrichment analysis using DEPICT. **Results:** No variants were significant at the genome-wide level. Our top hit variant, in a schizophrenia susceptibility gene, showed an association with MADRS score change. This gene has been implicated in post-ketamine treatment down regulation of GABA and glutamate levels in the rat prefrontal cortex and hippocampus, resulting in an antidepressant effect. We also observed a suggestive association between remission status and a genetic variant upstream of neuro-specific gene expressed in the hypothalamus and amygdala, suggesting a role in synaptic neurotransmitter signalling. Our top hit pathways included processes in the metabolic pathway of amyloid precursor protein. **Conclusions:** Our findings suggest novel gene variant associations with measures of venlafaxine remission in older adults, as well as, interesting neuro-relevant genetic pathways. A new, larger study of geriatric depression treatment will confirm these novel findings.

**2096T**

**Abnormal expression of sonic hedgehog as a biomarker and therapeutic target for depression and suicide in bipolar disorder.** *M. Galdzicka<sup>1</sup>, J. Karlgren<sup>2</sup>, E.I. Ginns<sup>2</sup>.* 1) Pathology, UMass Memorial Medical Center, Worcester, MA; 2) Psychiatry, UMass Memorial Medical Center, Worcester, MA.

**Purpose:** Bipolar affective disorder (BPAD) is a global public health problem. Compelling clinical-epidemiologic evidence supports a significant genetic predisposition. Our GWAS for BPAD protective genes in the Old Order Amish (OOA) identified genomic loci containing Shh antagonists (EVC and Hhip). No Amish individual with Ellis-van Creveld (EVC) dwarfism in these bipolar families has had bipolar disorder. The molecular change causing EVC disrupts Shh signaling. There is no cure, and many patients with depression and risk for suicide find that their bipolar symptoms are only partially managed with available treatments. More effective treatment for BPAD thus remains an enormous unmet need. A critical barrier to uncovering causes of BPAD is lack of biological markers for BPAD. The goal of this study is to determine the extent that sonic hedgehog expression is a biomarker and potential therapeutic target for depression and suicide in bipolar disorder. **Methods:** RNA was extracted from fibroblasts of three normal and three BP1 affected related OOA family members using Qiagen RNeasy Mini Kit. Residual genomic contamination in samples was removed by the on-column DNase digestion step. Integrity of each RNA sample was verified on the Agilent® Bioanalyzer. The cDNA synthesis was performed from two micrograms of total RNA using the RT2 First Strand Kit. Real Time PCR was performed using ABI7500 Fast instrument according to the RT2 RNA QC PCR Array protocol using Human Hedgehog Signaling Pathway array (Qiagen). The array contains primers for 84 key genes in this pathway. **Summary of Results:** Quantitative PCR using the Qiagen human Shh signaling pathway array (PAHS-078Z) indicated a greater than 600 fold elevated expression of Shh mRNA in fibroblasts from Amish BP1 compared to Amish controls. **Conclusion:** Our research has benefited from a rare, informative “experiment of nature” of families where EVC individuals at high risk for BPAD do not get BP1. Ketamine, lithium and SSRIs act as antagonists of Wnt and Shh signaling, mimicking the EVC mutation BPAD protective effect. We expect that results from this study will increase our understanding of altered brain signaling in bipolar disorder, and lead to more personalized molecular diagnosis. Our discovery suggests that sonic hedgehog signaling can be modulated to help manage bipolar symptoms in adolescents and adults by repurposing FDA approved drugs or those already in clinical trials for other medical conditions.

**2097F**

**A multi-omics analysis towards understanding of the polygenicity in schizophrenia.** *P. Jia<sup>1</sup>, X. Chen<sup>2,3</sup>, W. Xie<sup>4</sup>, Z. Zhao<sup>1,5</sup>.* 1) School of Biomedical Informatics, The University of Texas Health Science Center at Houston, Houston, TX; 2) Department of Psychology, University of Nevada Las Vegas, Las Vegas, NV; 3) Nevada Institute of Personalized Medicine, University of Nevada Las Vegas, Las Vegas, NV; 4) Department of Electrical Engineering & Computer Science, Vanderbilt University, Nashville, TN; 5) Human Genetics Center, School of Public Health, The University of Texas Health Science Center at Houston, Houston, TX.

Numerous high throughput omics studies have been conducted in schizophrenia, providing an accumulated catalogue of susceptible variants and genes. The results from these studies, however, are highly heterogeneous and complex. The variants and genes nominated by genetic studies often have limited overlap with those from transcriptomic and epigenetic studies, and vice versa. There is thus a pressing need for integrative analysis to unify the different types of data and provide a convergent view of candidate genes in schizophrenia. In this study, we collected a comprehensive, multidimensional dataset, including 7475 brain-expressed genes. The data hosted genome-wide association evidence in genetics (e.g., genome-wide association studies, linkage studies, copy number variations, *de novo* mutations), epigenetics (methylation), transcriptomes, and literature mining. We developed a method named Mega-analysis of Odds Ratio (MegaOR) to prioritize candidate genes. Application of MegaOR in the multidimensional data resulted in consensus sets of candidate genes associated with schizophrenia (SZgenes), which were enriched with condensed evidence from multi-dimensions. We proved that our SZgenes had highly tissue-specific expression in brain and nerve and had intensive interactions significantly higher than randomly expected. Furthermore, we found that our SZgenes were involved in the human brain development by showing strong spatiotemporal expression patterns, which were replicated in independent brain expression data sets. Finally, we found the SZgenes were enriched in critical functional gene sets involved in neuronal activities, ligand gated ion signaling, and Fragile X mental retardation protein targets. In summary, these results assessed rich association evidence to demonstrate a converged set of schizophrenia candidate genes, whose characteristics provided insights into the pathophysiology underlying schizophrenia.

**Genetics of schizophrenia in Cooperative Studies Program #572.** N. Sun<sup>1,2</sup>, Q. Lu<sup>2</sup>, Y. Hu<sup>2</sup>, B. Li<sup>2</sup>, Q. Chen<sup>1,2</sup>, M. Aslan<sup>1,2</sup>, K. Radhakrishnan<sup>1</sup>, K.H. Cheung<sup>1,4</sup>, Y. Li<sup>1,5</sup>, N. Rajeevan<sup>1,5</sup>, F. Sayward<sup>1,5</sup>, S. Pyarajan<sup>6,7</sup>, J.M. Gaziano<sup>6,7</sup>, J. Concato<sup>1,3</sup>, H. Zhao<sup>1,2</sup>, P. Harvey<sup>8,9</sup> on behalf of the Cooperative Studies Program (CSP) #572 and VA Million Veteran Program (MVP). 1) VA Clinical Epidemiology Research Center (CERC), VA Connecticut Healthcare System, West Haven, CT; 2) Department of Biostatistics, Yale School of Public Health, New Haven, Connecticut; 3) Department of Medicine, Yale University School of Medicine, New Haven, Connecticut; 4) Department of Emergency Medicine, Yale University School of Medicine, New Haven, CT; 5) Yale Center for Medical Informatics, Yale University School of Medicine, New Haven, CT; 6) Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC), VA Boston Healthcare System, Boston, MA; 7) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 8) Research Service, Miami VA Healthcare System; 9) Department of Psychiatry, University of Miami School of Medicine.

**Background:** Given cognitive impairments and disability associated with schizophrenia (SZ) and bipolar disorder (BP), considerable interest has arisen in identifying determinants of the diseases and their features. These psychiatric conditions are known to have a substantial hereditary component to their etiology, including possible overlap in genetic contributions. Various loci have been implicated to date, based on results from large international efforts focusing on genetic determinants of SZ. **Design and Methods:** Veterans Affairs (VA) Cooperative Studies Program (CSP) Study #572 recruited and evaluated cognitive and functional capacity (FC) measures among BP and SZ patients. In conjunction with the VA Million Veteran Program (MVP), and using a customized Affymetrix Axiom genotyping array for samples from 3,388 SZ #572 patients and 195,843 MVP controls, we conducted genomewide association analyses for European Americans (1,133 cases and 146,842 controls) and African Americans (1,647 cases and 29,502 controls), separately. **Results:** One SNP in the CHD gene region ( $2.9E-08$ ) had genome-wide statistical significance in the EA samples; no statistically significant results were found for the AA samples. We applied the summary statistics-based version of PrediXcan to calculate gene-level test statistics across 44 tissues and did not identify any associated genes. Using LD score regression and tissue and cell type-specific annotations (GenoSkyline-Plus), 12 out of 66 tissues/cell types showed significant enrichments in functionally annotated regions at the 0.05 significance level, with brain\_inferior\_temporal\_lobe being most significant (0.005). Based on the comparison between summary statistics from this study and those from published GWAS of 55 diseases or traits, statistical significance was determined for genetic correlation between this current SZ GWAS and published GWASs on SZ ( $7.8E-55$ ), BP ( $1.5E-14$ ), and major depression ( $6.0E-07$ ). In addition, statistically significant correlations were identified between CSP#572 SZ GWAS and CSP#572 BP GWAS results ( $1.0E-4$ ). **Conclusion:** Although only one region showed statistically significant results in this GWAS, a strong genetic correlation was found between the current results and previously published GWASs on SZ, BP, and major depression. The lack of statistical signals is likely due to a relatively small sample size. Meta-analysis of our results with other studies may lead to novel genes associated with SZ. .

**A genome-wide association study reveals a novel locus significantly associated with ADHD in African Americans and replicating in ADHD cases of European ancestry.** B. Almqoguera<sup>1</sup>, L. Vazquez<sup>1</sup>, J. Connolly<sup>1</sup>, T. Lingren<sup>2</sup>, B. Namjou-Khales<sup>2</sup>, B.C. Cobb<sup>2</sup>, J.B. Harley<sup>2,3</sup>, F. Mentch<sup>1</sup>, M. March<sup>1</sup>, P. Sleiman<sup>1</sup>, H. Hakonarson<sup>1</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 2) Center for Autoimmune Genomics and Etiology, Department of Pediatrics, University of Cincinnati, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio, USA; 3) US Department of Veterans Affairs Medical Center, Cincinnati, Ohio USA.

**Introduction:** Attention-deficit/hyperactivity disorder (ADHD) is the most prevalent neurobiological disorder among children, with an incidence of 6-7% that has remained stable for decades. ADHD is highly heritable, and genetic factors may account for 75%-90% of etiology. Although several genome-wide association studies (GWASs) have been performed, no single locus has yet been reported surpassing the genome-wide level of significance. **Methods:** We performed a GWAS study where ADHD cases and controls were identified with a phenotyping algorithm that mines electronic health record (EHR) data for pertinent diagnostic (ICD9 codes) and medication information. The EHR-algorithm was validated by manual chart review of 50 predicted cases and 50 controls at the Center for Applied Genomics (CAG) and Cincinnati Children's Hospital Medical Center (CCHMC). Positive predictive values (PPVs) were calculated. Imputation was performed on the Michigan Imputation Server against release 1.1 of the Haplotype Research Consortium (HRC) reference panel. Samples were separated by ancestry into African American (AA) and European American (EA) based on the principal component analysis, which was performed with Eigenstrat 3.0. SNPTEST was used for the GWAS of the EA and AA samples, and meta-analysis was performed using METAL. **Results:** The algorithm was validated by manual chart review internally at CAG and yielded positive predictive values (PPVs) of 96% and 86% for cases and controls, respectively. Secondary validation was performed at CCHMC and the PPVs were 89% and 91%, for cases and controls. A total of 11,322 ADHD cases (N=1,652) and controls (N=9,670) were included in the analysis: 4,369 AA (N=714 cases) and 6,953 EA (N=938 cases). A GWAS of the AA sample yielded a significant association of rs2105158 in the intronic region of *SMYD3* ( $p=9.63 \times 10^{-9}$ ), which replicated in the EA sample ( $p=0.018$ ). Two ethnic-specific associations, including rs114359002 at chr 12 in the region between the genes *ANO6* and *PLEKHA8P1* ( $p=5.88 \times 10^{-9}$ ) and rs189771980, downstream of *EFEMP1* ( $p=4.27 \times 10^{-8}$ ) at chr 2 were also identified in the AA cases. No significant results were uncovered in the EA sample. **Conclusions:** We have identified a novel locus at *SMYD3* that is significantly associated with ADHD in AA children and replicating in cases of EA ancestry. While further characterization of the locus is underway, the present study provides the first report of GWAS variants significantly associated with ADHD.

**2100F**

**Using genetic diversity from East Asia to improve the biological insight into schizophrenia.** H. Huang<sup>1,2</sup>, M. Lam<sup>3</sup>, C. Chen<sup>1,2</sup>, A. Martin<sup>1,2</sup>, Z. Li<sup>4</sup>, S. Ripke<sup>1,2,5</sup>, M. O'Donovan<sup>6</sup>, M. Daly<sup>1,2</sup>, PGC Schizophrenia Asia Initiative. 1) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston MA, USA; 2) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge MA, USA; 3) Institute of Mental Health, Singapore; 4) Bio-X Institutes, Shanghai Jiaotong University, China; 5) Department of Psychiatry and Psychotherapy, Campus Charité Mitte, Germany; 6) Division of Psychological Medicine and Clinical Neurosciences, Cardiff University, UK.

Schizophrenia is a disabling psychiatric disorder affecting about 1% of the world population. While the biological mechanisms of schizophrenia remain largely elusive, over 100 genomic loci have been associated with schizophrenia through genome-wide association studies (GWAS). However, to date, the majority of schizophrenia genetic studies are derived from the European population, severely limiting our understanding of the schizophrenia biology. Here we present a large-scale schizophrenia genetic study in the Asian population, comprising of 13 cohorts from Singapore, Hong Kong, Taiwan, mainland China, Japan, and Indonesia. After quality control, there are 13,760 cases and 16,883 controls. We found 12 loci significantly ( $p < 5e-8$ ) associated with schizophrenia, including four previously unreported loci. One of the new loci implicates *CACNA2D2*, a calcium channel auxiliary subunit associated with early infantile epileptic encephalopathy. European studies, with 3 times more samples, failed to find this association because it is extremely rare (0.7% minor allele frequency, vs. 45% in Asians). We found that genetic effects derived from the Asians are consistent with those derived from the Caucasians, indicating that schizophrenia etiology is shared across major world populations. More specifically, across the two populations, all known schizophrenia associations have the same direction of effect, and effect sizes show no significant heterogeneity. Given this observation we conducted a fixed-effect meta-analysis across the Asian and Caucasian populations, which identified over 40 new loci associated with schizophrenia. While the genetic effects of causal variants are consistent across populations, effects of non-causal variants in linkage disequilibrium with them can vary across populations owing to differences in recombination history and drift. A novel fine-mapping algorithm leveraging this observation significantly improved the association resolution. Using a published fine-mapping method (Huang et al., Nature 2017) and a Caucasian-only dataset (Ripke et al. Nature 2014), we mapped 11 schizophrenia associations to credible sets each has  $\leq 5$  variants. The number increased to 18 associations when we used the novel fine-mapping algorithm on a combined European and Asian dataset. This improved resolution allows us to better isolate the causal alleles and facilitate the functional interpretation of schizophrenia associations.

**A missense variant in *PER2* is associated with delayed sleep phase disorder.** T. Miyagawa<sup>1,2</sup>, M. Shimada<sup>1,2</sup>, A. Hida<sup>3</sup>, Y. Honda<sup>4</sup>, K. Mishima<sup>3</sup>, K. Tokunaga<sup>2</sup>, M. Honda<sup>1</sup>. 1) Sleep Disorders Project, Department of Psychiatry and Behavioral Sciences, Tokyo Metropolitan Institute of Medical Science, Tokyo, Japan; 2) Department of Human Genetics, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan; 3) Department of Psychophysiology, National Institute of Mental Health, National Center of Neurology and Psychiatry, Tokyo, Japan; 4) Japan Somnology Center, Neuropsychiatric Research Institute, Tokyo, Japan.

Delayed sleep phase disorder (DSPD) is a circadian rhythm sleep disorder, and is characterized by an inability to fall asleep until very late at night and awaken at a socially acceptable morning time. The pathogenesis and genetic background of DSPD are poorly understood. Recently, several large scale GWASs of chronotype have reported genetic variants associated with variation in chronotype. The associated variants were located in or near genes with a known role in circadian rhythms. Therefore, this study was performed to identify variants associated with DSPD from known circadian genes. Genes related to circadian rhythms were selected as candidates using previous studies and pathway databases such as KEGG. We focused on infrequent and rare missense variants, which are expected to have larger effects on the phenotype. We utilized data obtained from whole-exome and whole-genome sequencing databases, such as ExAC and Integrative Japanese Genome Variation Database. Candidate variants were extracted by integrating these sequencing data and in silico assessment. DNA samples from 236 patients with DSPD and 1,436 healthy controls were genotyped to examine whether the candidate variants are associated with DSPD. As a result, a missense variant (p.Val1205Met) in *PER2* showed a significant association with DSPD (minor allele frequency (MAF) of 2.5% in cases and 1.1% in controls,  $P = 0.026$ , odds ratio = 2.32). In addition, MAF of the variant in 569 patients with central disorders of hypersomnolence other than narcolepsy was also significantly higher than in 1,079 healthy controls (MAF of 1.9% in cases and 1.0% in controls,  $P = 0.037$ , odds ratio = 1.91). MAFs of the variant in European and African were less than 0.1%. *PER2* is noted for its major role in circadian rhythms. *PER2* forms a heterodimer with *CRY*, and the heterodimer plays an important role in the regulation of the circadian rhythm. The p.Val1205Met substitution was located in the *PER2* *CRY*-binding domain. The substitution in *PER2* could be a potential genetic marker for circadian rhythms and sleep phenotypes.

**Schizophrenia and adult height show an inverse polygenic correlation within specific functional domains of the genome.** *A.P.S. Ori<sup>1</sup>, L.M. Olde Loohuis<sup>1</sup>, R.A. Ophoff<sup>1,2,3</sup>*. 1) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California, Los Angeles, California, USA; 2) Department of Human Genetics, David Geffen School of Medicine, University of California, Los Angeles, California, USA; 3) Brain Center Rudolf Magnus, Department of Psychiatry, University Medical Center Utrecht, Utrecht, The Netherlands.

Many epidemiological studies have reported on an inverse relationship between schizophrenia (SCZ) and adult human height (H), two highly heritable traits. Genome-wide analysis has not provided evidence of a genetic correlation between the traits, however. To address the shared genetic architecture more systematically, we performed a genetic covariance analysis using advanced statistical methods and annotation-stratified domains across the genome. We applied GNOVA (GeNetic cOVariance Analyzer), a novel statistical framework that estimates annotation-stratified genetic covariance using GWAS summary statistics (Qiongshi et al., Biorxiv 2017). Annotation-stratified analyses can identify genetic overlap that would otherwise be missed across the whole genome. We used the most recent published GWAS summary statistics for both SCZ and H and estimated LD from 1000 Genome reference panel. We analyzed their genetic covariance ( $\rho$ ) stratified by minor allele frequency (MAF) bins, the predicted functional genome, and transcriptomic and epigenomic annotations from a broad range of tissues and cell types from the GTEx and Roadmap Epigenomics consortia. Across the whole genome, we identified a significant inverse genetic relationship ( $\rho = -0.0036$ ,  $r = -0.03$ ,  $P = 0.03$ ), which was not detectable using the LD score regression method (LDSC;  $r = 0.00$ ,  $P = 0.91$ ). We found that the covariance is concentrated in variants of lower allele frequencies (MAF bin1: 5-18%,  $\rho = -0.0044$ ,  $P = 0.003$ ) that are predicted to be functional ( $\rho = -0.0043$ ,  $P = 0.001$ ). Across 53 tissues of GTEx, using the subset of lower frequency variants, we observe the SCZ and H covariance in 13 tissues ( $P < 9.4e-4$ ). These include 6 brain tissues, but also spleen, whole blood, and lung. Across 220 chromatin profiles, we find significant covariance in 11 profiles ( $P < 2.3e-4$ ) that are mainly brain- and blood-specific cell types and tissues. In summary, we are the first to report a significant inverse genetic relationship between SCZ and H. We show that this genetic overlap is small, but concentrated in variants of lower allele frequencies and specific functional domains of the genome. Current work involves Mendelian randomization analysis in a large SCZ cohort with anthropometric data available to further dissect their pleiotropic relationship. Our work confirms observations of decades of epidemiological studies and provides an integrative framework to investigate the shared genetic architecture between two complex traits.

**Copy number variation analysis of psychiatric traits in a large population-based sample of youth.** *M. Zarrei<sup>1,2</sup>, D. Merico<sup>1,3</sup>, W. Engchuan<sup>1,2</sup>, J. MacDonald<sup>1</sup>, J. Wei<sup>1</sup>, E. Higginbotham<sup>1,2</sup>, G. Pellecchia<sup>1</sup>, M. Faheem<sup>1,2</sup>, A. Chan<sup>1,2</sup>, B. Xiao<sup>2</sup>, L. Strug<sup>1,2,4</sup>, C. Marshall<sup>1</sup>, C. Burton<sup>5</sup>, J. Crosbie<sup>6</sup>, P. Arnold<sup>6,7</sup>, R. Schachar<sup>6</sup>, S. Scherer<sup>1,2,8</sup>*. 1) The Centre for Applied Genomics (TCAG), The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Program in Genetics and Genome Biology, the Hospital for Sick Children, Toronto, Canada; 3) Deep Genomics Inc., Toronto, Ontario, Canada; 4) Division of Biostatistics, Dalla Lana School of Public Health, University of Toronto, Toronto, Canada; 5) Neurosciences and Mental Health, Psychiatry, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Mathison Centre for Mental Health Research and Education, Hotchkiss Brain Institute, University of Calgary, Alberta, Canada; 7) Departments of Psychiatry and Medical Genetics, Cumming school of Medicine, University of Calgary, Alberta, Canada; 8) Department of Molecular Genetics and McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

'Spit for Science' is a sample of over 17,000 youth (6-17 years of age) seen at a local science museum with psychiatric phenotypes collected and DNA from saliva. Quantitative data on Attention Deficit Hyperactivity Disorder (ADHD) traits using the Strengths and Weaknesses of ADHD and Normal Behavior (SWAN) scale, Obsessive Compulsive Disorder (OCD) traits using the Toronto Obsessive-Compulsive scale and response inhibition using the Stop-Signal task (an endophenotype for ADHD) was collected. We genotyped unrelated Caucasians ( $n = 5,636$ ) using Illumina HumanCoreExome beadchips. Here, copy number variations (CNVs) were called from 4,815 Caucasian samples using three algorithms (PennCNV, QuantiSNP, iPattern). We defined a 'stringent' set of rare CNV ( $< 1\%$  population frequency) being  $> 10\text{kb}$  in size and detected by a minimum of two algorithms, and performed global burden and functional gene-set burden analysis, modelled using linear regression against different traits. Overall, we identified 9,490 rare CNVs across the dataset (1.97/individual). From this, we identified sex-chromosome and autosomal aneuploidies (e.g. 45,XO, 47,XXY, 47,XXX, 47,XYY, 48,XXXY, and 47,XX,+21) in 12 (0.25%) of individuals. In 59 (1.2%) different participants, we identified CNVs affecting 23 genomic loci previously implicated in neurodevelopmental conditions (e.g. 1q21.1, 15q11.2, 16p12.1, 17p12, 22q11.2). Large CNVs affecting known psychiatric genes such *ASTN2*, *CNTN4*, *MACROD2*, *NRXN1*, and others, were also identified. ADHD traits were associated with increased CNV deletions ( $p = 0.015$ ). Although response inhibition was also associated with deletions with a borderline significance ( $p = 0.072$ ), there was an increased burden of duplication for this trait ( $p = 0.004$ ). We found no global burden of duplications or deletions for OCD traits. ADHD traits showed significant enrichment for deletions in genes associated with mouse neurophenotypes ( $p = 0.01$ ) and with gene ( $p = 0.003$ ) and protein expression ( $p = 0.007$ ) specifically in the human brain. OCD traits showed enrichment for duplications in genes specifically expressed in the brain ( $p = 0.003$ ) while response inhibition was enriched for duplications or deletions in genes specifically expressed in the brain ( $p = 0.007$ ).

**Genome-wide association study of cognitive flexibility assessed by Wisconsin Card Sorting Tests.** H. Zhang<sup>1,2</sup>, H. Zhou<sup>3,6</sup>, T. Lencz<sup>1</sup>, L. Farre<sup>1</sup>, H.R. Kranzler<sup>4</sup>, J. Gelernter<sup>3,4,5,6</sup>. 1) Department of Psychiatry, Boston University School of Medicine, Boston, MA; 2) Department of Medicine (Biomedical Genetics), Boston University School of Medicine, Boston, MA; 3) Department of Psychiatry, Yale University School of Medicine, New Haven, CT; 4) Department of Genetics, Yale University School of Medicine, New Haven, CT; 5) Department of Neurobiology, Yale University School of Medicine, New Haven, CT; 6) VA Connecticut Healthcare System, West Haven, CT; 7) Department of Psychiatry, Hofstra Northwell School of Medicine, Hempstead, NY; 8) Department of Psychiatry, University of Pennsylvania Perelman School of Medicine and VISN4 MIRECC, Crescenz VAMC, Philadelphia, PA.

Cognitive flexibility is a critical component of executive function strongly influenced by genetic factors. We conducted a genome-wide association study of cognitive flexibility (as measured by perseverative errors on the Wisconsin Card Sorting Test) in two sets of African American (AA) and European American (EA) samples (Yale-Penn 1: 1,411 AAs and 949 EAs, genotyped by Illumina's HumanOmni1-Quad v1.0 microarray; Yale-Penn 2: 1,178 AAs and 1,335 EAs, genotyped by Illumina's HumanCore Exome BeadChip). The R package GWAF was used to test the association of both genotyped and imputed SNPs with cognitive flexibility. In AAs, two close and linked common SNPs (rs7165213 and rs35633795) in the downstream region of noncoding gene *LOC101927286* on chromosome 15 showed genome-wide significant associations ( $P < 5 \times 10^{-8}$ ) with cognitive flexibility. In EAs, no GWAS associations were observed. Enriched gene sets by DEPICT analysis of top SNPs ( $P_{\text{met-analy- sis}} < 10^{-5}$ ) included signalosome and ubiquitin specific peptidase 9, X-linked (USP9X) subnetwork in AAs as well as abnormal frontal and occipital bone morphology in EAs. We also performed polygenic risk score (PRS) analysis to examine the genetic correlation of cognition-proxy phenotypes (general cognitive function, education attainment, childhood intelligence, and infant head circumference) and cognitive flexibility in EAs. The PRS derived from general cognitive function-associated SNPs was significantly associated with cognitive flexibility. Non-genetic factors (age, education, sex, and tobacco recency) exerted significant effects on cognitive flexibility. Our study demonstrated that both genetic and non-genetic factors impact cognitive flexibility, and variants in genes involved in protein degradation and brain development may contribute to cognitive decline.

**Integrating multi-omics data to boost the translation of GWAS to biology and therapeutics for schizophrenia.** Q. Wang, R. Chen, Q. Wei, H. Yang, Y. Ji, B.S. Li. Vanderbilt University, NASHVILLE, TN.

Genome-wide association studies (GWAS) have identified numerous variants associated with schizophrenia (SCZ). However, how to translate GWAS findings to biological mechanism, especially clinical applicability, for example the development of new therapeutics, remains challenging. Few drugs are now available for SCZ, and the drug development for SCZ, or generally psychiatric disorders, is largely stalled. The therapeutic impasse is largely due to the lack of the understanding of the biology of the diseases and therefore the lack of novel, accurate drug targets. One reason is that GWAS hits, in most cases, refer to genomic loci, not specific genes. It is thus difficult to identify the risk genes driving the significant associations without further scrutiny. It is increasingly clear that drugs that target genes with genetics evidence for a particular disease are more effective, making it extremely important to systematically identify risk genes for SCZ and other psychiatric disorders. Here we proposed a Gibbs sampling algorithm in a Bayesian framework which is capable of integrating multi-omics data, to accurately infer risk genes through which GWAS SNPs exert their functions by a sampling strategy. The proposed method is very flexible to leverage data from different relevant sources, and cumulatively orchestrate them to calculate the sampling probability for risk gene prediction. By applying the framework to the 108 SCZ loci, we predicted a set of high-confident risk genes (HRGs) that are supported by multiple lines of evidence: 1) the predicted HRGs are consistent with the leading pathophysiological hypotheses of SCZ; 2) HRGs are enriched in the *de novo* mutations (DNMs) identified in SCZ and other diseases like autism and intellectual disability, confirming the functional convergence between regulatory and coding variants, and the genetic sharing across neurodevelopmental disorders; 3) HRGs are highly expressed in brain tissues; 4) knockout of HRGs shows central nervous system (CNS) relevant phenotypes in mouse; 5) HRGs are more druggable, suggesting the potential of repositioning drugs of other diseases for the treatment of SCZ. Collectively, these results strongly demonstrated the utility of multi-omics data in interpreting GWAS and our framework is a powerful tool to translate GWAS into biology and therapeutics.

**2106F**

**Neurodevelopmental copy number variants and clinical risk: A pediatric record population study.** *K. Ahn<sup>1</sup>, F. Mentch<sup>2</sup>, S. An<sup>3</sup>, C. Kao<sup>2</sup>, H. Hakonnarson<sup>2</sup>, J. Rapoport<sup>1</sup>.* 1) Child Psychiatry Branch, National Inst Mental Health, NIH, Bethesda, MD; 2) Center for Applied Genomics, Children's Hospital at Philadelphia, Philadelphia, PA; 3) Department of Environmental Health and Engineering, Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

**Background:** Chromosomal copy number variants (CNVs) associated with schizophrenia also carry etiological risk for neurodevelopmental disorders, including autism and intellectual deficiency. It is not known however what is their risk for any disorders. Here we applied well-replicated 'neurodevelopmental' CNVs (NRXN1 del, MYT1L dup, 15q13.3 del/dup, 16p11.2 del/dup, and 22q11.2 del/dup) and interrogated their frequency and overall clinical penetrance for broad categories of disorder in a general pediatric population. **Methods:** Eight selected CNVs were screened within a population sample of 60,644 pediatric patients. CNV carriers were examined with respect to pre-scored digitized pediatric records and compared to records for a 5:1 non-carrier control group matched for each individual CNV. Prevalence for 12 clinical categories were estimated. **Results:** Seven of these CNVs (NRXN1 del, MYT1L dup, 22q11 dup, 16p11 del/dup, and 15q11.3 del/dup) were detected in the pediatric population at expected rates based on large control population studies. Having any CNV predicted an increase for two of the 12 disease categories after Bonferroni correction: Nervous system ( $p=1.43 \times 10^{-5}$ ) and mental/neurodevelopmental disorder ( $p=2.9 \times 10^{-10}$ ), and were associated with greater cost of medical care. Individual CNVs were examined in relation to their matched non-carriers for previously described associated disorders. As anticipated, 15q13.3 del was associated with mental/neurodevelopmental disorders, and 16p11 del was associated with congenital deficits, CNS disorders and mental/neurodevelopmental disorders. 16p11 del carriers showed more circulatory disorders than their non-carriers. Finally, in addition to association with mental/neurodevelopmental and congenital defects, a significant association was found between 22q11 dup and pediatric gastrointestinal reflux disorder (GERD) ( $p=0.0037$ ) which was more likely to be present in the presence of developmental delay. **Conclusions:** These findings extend previous clinically based studies providing a high prediction of risk for 16p11.2 del, 15q13.3 del and 22q11.2 dup. A broader concept of overall clinical penetrance is important for understanding the pathophysiology of these disorders and may inform genetic counseling. To our knowledge, this is the first report of a CNV association (22q11 dup) for pediatric GERD, which may represent a delay in vagal nerve maturation, and first report of a 16p11 del associated with circulatory disorders.

**2107W**

**Potential role of rare variants in the genetics of tardive dyskinesia.** *A. Alkelai<sup>1</sup>, L. Greenbaum<sup>2,3</sup>, D. Goldstein<sup>1</sup>, B. Lerer<sup>4</sup>.* 1) Institute for Genomic Medicine, Columbia University Medical School, Columbia University Medical Center, New York, NY, USA; 2) The Danek Gertner institute of Human Genetics, Chaim Sheba medical center, Tel Hashomer, Ramat Gan, Israel; 3) The Joseph Sagol Neuroscience Center (JSNC), Chaim Sheba medical center, Tel Hashomer, Ramat Gan, Israel; 4) Biological Psychiatry Laboratory, Department of Psychiatry, Hadassah-Hebrew University Medical Center, Jerusalem, Israel.

Tardive dyskinesia (TD) is a chronic, irreversible side effect of antipsychotic treatment. TD occurrence is influenced by both clinical and demographic variables, as well as genetic factors. Contribution of common variants to TD susceptibility has been investigated in recent years, including by the genome-wide association study approach, but results are inconsistent. In order to discover the involvement of rare variants in this phenotype, we implemented the whole exome sequencing method. We performed whole exome sequencing in 20 Ashkenazi and 20 Non-Ashkenazi Jewish schizophrenia patients with severe TD, and 18 Ashkenazi and 27 Non-Ashkenazi patients without any manifestation of TD (total AIMS score of zero) despite more than 10 years of exposure to antipsychotics. We performed a case-control, exome-wide collapsing analysis including 40 patients with severe TD and 45 patients without any manifestation of TD. We also performed an additional analysis including 40 patients with severe TD and 880 unrelated healthy Jewish controls. Comparing genetic variation across 18,668 protein-coding genes we found a suggestive case-enrichment of rare loss of function and deleterious non-synonymous variants in genes that seem to be relevant to this disorder. Follow-up case-control study in a larger Jewish TD sample is needed to confirm these initial results.

**2108T**

**Exome sequencing study of bipolar disorder in a genetically isolated population.** L. Hou<sup>1</sup>, L. Kassem<sup>1</sup>, T.G. Schulze<sup>2</sup>, F. Lopes<sup>1</sup>, L. Willie<sup>1</sup>, N. Akula<sup>1</sup>, D. Chen<sup>1</sup>, M. Crawford<sup>3</sup>, A.R. Shuldiner<sup>4</sup>, F.J. McMahon<sup>1</sup>. 1) Human Genetics Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, MD, USA; 2) Ludwig Maximillians University, Munich, Germany; 3) University of Kansas, Lawrence, Kansas, USA; 4) Regeneron Genetics Center, Regeneron Pharmaceuticals, Tarrytown, New York, USA.

Bipolar disorder is a highly heritable, mental illness that affects about 2% of the US population. Genome-wide association studies (GWAS) have found many common, low-risk variants, but genetic heterogeneity has hindered the identification of high-risk alleles. We are pursuing an exome sequencing study of 1000 cases and 2500 unaffected relatives ascertained from Amish and Mennonite (Anabaptist) communities, where genetic isolation, large families, and low rates of drug and alcohol abuse may facilitate the identification of high-risk alleles. Here we present a preliminary analysis of the first 460 exomes in order to sample the genetic architecture and plan future analyses. Capture was performed with the IDT xGen Exome Research Panel v1.0, followed by sequencing by Illumina Hi-Seq. Raw reads were mapped to reference genome build 38 using BWA followed by variant calling with GATK. After sample and variant level QC, 227K single nucleotide and 8.8K indel variants were identified, of which 64K (27%) were novel. Variants that met the following criteria qualified for further analysis: shared by at least 2 cases; functional annotation as stopgain, stoploss, frameshift, or nonsynonymous in an ENSEMBL gene; <10% missing calls in cases and unaffected relatives; maximum frequency <1% (or missing) in 1000Genomes, ExAC, and esp6500 reference populations; called in at least one of two Anabaptist reference samples, with frequency <1% (or missing) in 1000 Anabaptists sequenced by the TopMED Consortium. After filtering, there were 3,789 variants in 3,100 unique genes. No variant was shared by more than 6% of cases, and there was no evidence of excess homozygosity. 110 genes carried three or more qualifying variants each, including *ANK3*, *SYNE1*, and *TENM4 (ODZ4)*. Of these genes, 29 had a >90% probability of intolerance to loss of function (lof) mutations by LoFtool. As a set, these 29 genes were enriched for ion channels and transporters by GeneMANIA. The results suggest 3 interim conclusions: 1) there is considerable genetic heterogeneity among people with bipolar disorder, even in Anabaptist communities; 2) genes with multiple otherwise rare, functional variants shared by cases include some genes previously implicated in bipolar disorder by GWAS; 3) the most lof-intolerant of these genes comprise a non-random set enriched for biological processes thought to contribute to mental illness. Future work will focus on family-based burden tests in the full sample.

**2109F**

**Maternal antenatal depression and child socio-emotional outcomes: Investigating intervening child genetic risk for ADHD and biological pathways.** L.M. Chen<sup>1,2,3</sup>, A-A. Bouvette-Turcot<sup>1,2,3</sup>, E. Garg<sup>2,3</sup>, T.T.T. Nguyen<sup>2,3</sup>, P.P. Silveira<sup>1,2,3</sup>, J. Diorio<sup>2,3</sup>, M.S. Kobor<sup>4</sup>, K.J. O'Donnell<sup>1,2,3</sup>, M.J. Meaney<sup>1,2,3,5</sup>, MAVAN Team. 1) McGill University, Montreal, Quebec, Canada; 2) Douglas Mental Health University Institute, Montreal, Quebec, Canada; 3) Ludmer Centre for Neuroinformatics and Mental Health, Montreal, Quebec, Canada; 4) University of British Columbia, Vancouver, British Columbia, Canada; 5) Singapore Institute for Clinical Sciences, Singapore.

**Background** Maternal antenatal depression is associated with offspring socio-emotional problems. Yet, individual differences are observed, which are likely due to genetic factors. **Aim** We sought to identify genes and biological pathways that moderate the relation between maternal antenatal depressive symptoms (MADS) and child socio-emotional outcomes. **Methods** Our sample included 190 mother-child dyads. MADS was measured with the Center for Epidemiologic Studies – Depression Scale. Child socio-emotional outcomes were mother-reported at 5 years with the Child Behavior Checklist. We constructed genomic profile risk scores from the children's SNPs genome-wide that account for polygenic risk for attention deficit/hyperactivity disorder (GPRS<sub>ADHD</sub>) based on risk information from the genome-wide associations with ADHD by the Psychiatric Genomics Consortium and applied them in our gene-environment interaction (GxE) model. SNPs constituting the best-fit GPRS<sub>ADHD</sub> in the GxE model were used in a genome-wide by environment association analysis follow-up. We used MetaCore to examine the enriched gene ontology in a subset of SNPs in the GxE model with p-values < .01. **Results** GPRS<sub>ADHD</sub> moderated the relation between MADS and child internalizing problems ( $t(186)=3.22$ ,  $p<.05$ ). A positive association between MADS and internalizing trait was found only in children with high GPRS<sub>ADHD</sub>. The top significant genes underlying this moderating effect of the GPRS<sub>ADHD</sub> were enriched in processes such as "neuron development" ( $p=1.56e-7$ ) and "synapse organization" ( $p=5.58e-7$ ), in molecular functions such as "inositol 1,4,5-trisphosphate-sensitive calcium-release channel activity" ( $p=3.66e-4$ ) and "retinoic acid receptor binding" ( $p=4.49e-4$ ), and in pathway networks such as "synaptic contact" ( $p=1.12e-4$ ), "synaptogenesis" ( $p=2.90e-4$ ), "axonal guidance" ( $p=1.11e-3$ ), "attractive and repulsive receptors" ( $p=3.80e-3$ ), and "transmission of nerve impulse" ( $p=1.60e-3$ ). **Conclusion** The enriched biological pathways are implicated in axon development and synaptic functions, vital in fetal brain development. Some genome-wide significant genes include *TNFRSF19*, which is essential in fetal neurodevelopment, and *CACNA1C*, which is a shared risk factor in major psychiatric disorders and is important in hippocampal neurogenesis. These findings suggest that specific genes involved in the biological framework for antenatal neurodevelopment can confer sensitivity or resilience to the influences of MADS on mental health.

**2110W**

**Genome-editing of the *RERE* super-enhancer alters expression of genes in independent schizophrenia GWAS regions.** C. Barr<sup>1,2</sup>, Y. Feng<sup>1,2</sup>, A. Dineen<sup>1,2</sup>, K. Wigg<sup>1,2</sup>, A. Sarkar<sup>1,2</sup>. 1) Genetics & Development, Krembil Research Institute, UHN, Toronto, ON, Canada; 2) Program in Neurosciences and Mental Health, Hospital for Sick Children, Toronto, ON, Canada.

**Background:** The majority of associated markers for complex genetic traits reside in gene regulatory regions, particularly enhancers and super-enhancers. Enhancers can reside megabases from the gene they regulate (target gene) and their targets are often not the nearest gene. Thus, the assumption that the gene nearest a GWAS-significant marker will be the risk gene will in many cases be incorrect. **Methods:** To identify the target genes of enhancers with GWAS significant markers, we analyzed Capture-HiC data selecting enhancers for functional studies using CRISPR/Cas9 in human neural precursor cells (hNPCs). The impact on expression was measured by RT-qPCR and RNA-seq in the edited versus the mock-transfected cells. **Results:** We selected the super-enhancer spanning the 3' end of the *RERE* gene for study, the site of 12 GWAS significant SNPs for schizophrenia. Capture-HiC data indicate interactions of the super-enhancer with *RERE* (co-repressor/co-activator involved in retinoic acid signaling), *PARK7* (Parkinsons 7, protects neurons from oxidative stress) and *PER3* (Period 3). These 3 genes are transcription co-regulators or transcription factors. Using CRISPR/Cas9, we deleted a 2kb region of the super-enhancer in hNPCs and analyzed the transcriptome by RNA-seq. We identified 107 genes that were differentially expressed, including 14 regulated by retinoic acid. Importantly, 3 of these are located in independent GWAS regions for schizophrenia. **Conclusions:** Capture-HiC provides important new leads in pinpointing the target genes of enhancer-mediated regulation emanating from the GWAS findings and functional studies confirm altered expression of interacting genes. We are currently differentiating the CRISPR/Cas9 edited NPCs to neurons to examine the impact of the edits on differentiation and neuronal phenotypes. The finding of altered expression of genes in independent GWAS regions is an important new lead in understanding the regulation of schizophrenia risk genes.

Attention-Deficit/Hyperactivity Disorder (ADHD) is a common neurodevelopmental disorder with a complex genetic background, hampering identification of underlying genetic risk factors. We hypothesized that combining linkage analysis and whole exome sequencing (WES) in multi-generation pedigrees with multiple affected individuals can point towards novel ADHD genes.

Three families with multiple ADHD-affected members ( $N_{\text{total}}=70$ ) and apparent dominant inheritance pattern were included in this study. Genotyping was performed in 37 family members, and WES was additionally carried out in 10 of those. Linkage analysis was performed using multi-point analysis in Superlink Online SNP 1.1. From prioritized linkage regions with a LOD score  $\geq 2$ , a total of 24 genes harboring rare variants were selected. Those genes were taken forward and were jointly analyzed in gene-set analyses of exome-chip

data using the MAGMA software in an independent sample of patients with persistent ADHD and healthy controls (N=9 365). All 24 genes together, and particularly the gene-set from one of the three families (12 genes), were significantly associated with persistent ADHD in this sample. Among the latter, gene-wide analysis for the *AAED1* gene reached significance. A rare variant (rs151326868) within *AAED1* segregated with ADHD in one of the families. The analytic strategy followed here is an effective approach for identifying novel ADHD risk genes. Additionally, this study suggests that both rare and more frequent variants in multiple genes act together in contributing to ADHD risk, even in individual multi-case families.

## 2112F

### Limited contribution of rare, noncoding variation to autism spectrum disorder from sequencing of 2,076 genomes in quartet families. D.M.

**Introduction:** Genomic studies in autism spectrum disorder (ASD) have largely focused on *de novo* mutations that disrupt protein-coding sequence. Given the size of the noncoding genome and its regulatory role in gene function, it is likely that rare, noncoding variation represents an important component of the genetic architecture of ASD. Characterization of noncoding mutations may also highlight the cell types and critical developmental stages involved in ASD. However, there is no obvious noncoding equivalent to protein-truncating variants, thus necessitating an unbiased and statistically rigorous association strategy for noncoding variation that parallels standards set by common variant analyses. **Methods:** Using whole genome sequencing (WGS) of 2,076 individuals from 519 quartets, we evaluated the contribution of genomic variation across the spectrum of variant size and frequency. The results of 12 variant discovery algorithms were integrated to identify *de novo* SNVs, indels, and structural variants (SVs); cross-site validation exceeded 93% for all variant classes. Variants were annotated using an extensive series of noncoding functional annotations and gene sets of plausible relevance to ASD, resulting in 51,801 combinations of annotation categories. ASD association within each category was assessed using a binomial test to compare variant counts in cases and controls in a Category-Wide Association Study (CWAS). To account for multiple testing, correlations of p-values were assessed between the 51,801 categories from 20,000 sets of simulated variants. Eigenvalue decomposition estimated that 4,211 effective tests explained 99% of the variation. **Results:** A small excess of *de novo* noncoding variants was observed in cases (1.02-fold), which was not significant after correcting for paternal age. While we identified several variants that were likely causal for an individual, no annotation category was significant after correcting for 4,211 tests in the CWAS and the lowest p-values were observed in coding regions, including missense variation and SVs. Similarly, no category of rare inherited variants demonstrated parental transmission bias or ASD association. **Conclusion:** There is no clear category of rare noncoding variation with equivalent impact on ASD risk as large SVs or protein-disrupting mutations in evolutionarily constrained genes. We estimate substantially larger sample sizes will be required to quantify this risk, likely in excess of 5,000 cases.

**2113W****Genetics of bipolar disorder in Cooperative Studies Program #572.**

Harvey<sup>8,9</sup> on behalf of Dept of Veterans Affairs Cooperative Studies Program (#572) & Million Veteran Program.* 1) Cooperative Studies Program, VA Clinical Epidemiology Research Center (CERC), VA Connecticut Hlthcare System, West Haven, CT; 2) Department of Medicine, Yale University School of Medicine, New Haven, CT; 3) Department of Biostatistics, Yale University School of Public Health, New Haven CT; 4) Department of Emergency Medicine, Yale University School of Medicine, New Haven, CT; 5) Yale Center for Medical Informatics, Yale University School of Medicine, New Haven, CT; 6) Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC), VA Boston Healthcare System, Boston, MA; 7) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 8) Research Service, Miami VA Healthcare System; 9) Department of Psychiatry, University of Miami School of Medicine.

**Background:** Given the prominence of cognitive impairments and disability associated with schizophrenia (SZ) and bipolar disorder (BP), substantial interest has arisen in identifying determinants of the diseases and their features. Both of these psychiatric conditions have long been shown to have a substantial genetic component to their etiology, including possible overlap in genetic contributions. From large international efforts to identify genomic associations for the etiology of BP, various loci have been implicated to date. **Design and Methods:** Veterans Affairs (VA) Cooperative Studies Program (CSP) Study #572 recruited and evaluated cognitive and functional capacity (FC) measures among BP and SZ patients. In conjunction with the VA Million Veteran Program (MVP), and using a customized Affymetrix Axiom genotyping array for samples from 4,663 BP #572 patients and 195,843 MVP controls, we conducted genomewide association analyses (GWASs) for European Americans (2,908 cases and 146,842 controls) and African Americans (1,030 cases and 29,502 controls), separately. **Results:** No SNPs were identified meeting genome-wide statistical significance in either the EA or AA samples. We applied the summary statistics-based version of PrediXcan to calculate gene-level test statistics across 44 tissues and did not identify any associated genes. Based on the comparison between summary statistics from this study, and those from published GWAS of 55 diseases and traits, a statistically significant genetic correlation was found between this current BP GWAS and published GWASs, including SZ (3.8E-35), BP (4.5E-20), smoking (7.1E-09), and depression (1.1E-08). In addition, a statistically significant correlation (0.4554) was observed between CSP#572 SZ GWAS and CSP#572 BP GWAS results (p-value=1.02E-04). **Conclusion:** Although no region was detected showing statistically significant results from the CSP#572 BP GWAS, a strong genetic correlation was evident between the current results and previously published GWASs on SZ, BP, and depression, suggesting many shared factors with weak to moderate effects on disease risk. The lack of statistical signals is likely due to the relatively small number of case patients with the disorder. Meta-analysis of our results with other studies may lead to novel genes associated with BP.

**Genome-wide associations with generalised anxiety disorder symptoms and self-reported anxiety disorder: An investigation of unique and shared genomic contributions.** *K.L. Purves, J.R.I. Coleman, G. Breen, E.C. Eley.* SGDP, King's College London, London, United Kingdom.

Generalised Anxiety Disorder (GAD) is a pervasive condition characterised by states of consistently high anxiety across multiple situations. GAD is highly comorbid with other Anxiety Disorders (AD's) with approximately 60% of GAD patients being additionally diagnosed with one of these disorders (Wittchen et al. 2011). In addition to phenotypic overlap, GAD shows significant genetic overlap with other AD's (Waszczuk et al. 2014). There is evidence that traits central to GAD (such as heightened anxiety sensitivity) are associated with specific genetic variants (Davies et al. 2015). A meta-analysis of genome-wide association studies of AD's identified loci associated with anxiety case status, and with a common anxiety factor score (Otowa et al. 2016). Thus, there is evidence that core components of GAD symptom spectrum are associated with variation in specific genetic loci, and that AD's share common genetic factors. To date, no studies have investigated GAD-specific genome-wide associations, nor the overlap between these and other AD's. The current study aims to analyse the association between GAD and genome-wide single nucleotide polymorphisms (SNP's), and investigate the extent to which these associations are unique to GAD, or are shared across AD's. Analyses were undertaken in approximately 138,811 individuals from the UK Biobank. Three approaches to defining anxiety phenotypes were adopted. (1) Adjusted raw scores on the Generalised Anxiety Disorder-7 (GAD-7) were used for all participants, resulting in a continuous quantitative GAD-7 phenotype, (2) GAD case status was established using responses to items from the Composite International Diagnostic Interview – short form (CIDI - SF), and (3) AD case status was established through self-report of any life time diagnosis of any AD. Associations between adjusted GAD-7 total scores and genome wide SNP's were analysed using linear regression. Associations between GAD and AD case status and genome-wide SNP's were analysed using logistic regression. SNP heritability was estimated for all phenotypes. The correlation between SNP heritability of GAD and non-specific AD diagnoses is investigated.

**Parent-of-origin and maternal effects in attention deficit hyperactivity disorder.** *D. Smajlagic<sup>1,6,8</sup>, S. Connolly<sup>2</sup>, H. Hakonarson<sup>3,4</sup>, I. Waldman<sup>5</sup>, J. Elia<sup>2</sup>, E. Heron<sup>2</sup>, J. Haavik<sup>6</sup>, S. Johansson<sup>1,6,8</sup>, T. Zayats<sup>8</sup>.* 1) KG Jebsen Center for Neuropsychiatric Disorders, Department of Clinical Science, University of Bergen, Bergen, Norway; 2) Neuropsychiatric Genetics Research Group, Department of Psychiatry, Trinity College Dublin, Trinity Centre for Health Sciences, Dublin, Ireland; 3) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA, USA; 4) Department of Pediatrics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, USA; 5) Emory University, Atlanta, GA, USA; 6) Center for Medical Genetics and Molecular Medicine, Haukeland University Hospital, Bergen, Norway; 7) Department of Child and Adolescent Psychiatry, The Children's Hospital of Philadelphia, Philadelphia, PA, USA; 8) KG Jebsen Center for Neuropsychiatric Disorders, Department of Biomedicine, University of Bergen, Bergen, Norway.

Attention Deficit Hyperactivity Disorder (ADHD) is one of the most common and most heritable childhood-onset neuropsychiatric disorders, characterized by multifaceted genetics. To date, genetic studies of ADHD focused on additive effects only, explaining just a fraction of its heritability. Thus, we aimed at examining parent of origin effects (POE) together with maternal and additive effects, providing novel insight into the complex genetic architecture of ADHD. We compiled parent-offspring data collected through the Psychiatric Genomics Consortium and the Norwegian Mother and Child Cohort, consisting of 2060 trios and 328 duos. Additional parent-offspring data is being added. ADHD was diagnosed based on DSM-IV, ICD-10 and child behavior checklist. POE, maternal and additive genetic effects are being evaluated using multinomial modelling implemented in EMIM software. We explored our signals in the light of known imprinted genes (POE) and the largest ADHD genome-wide association study (GWAS) in children (N=17666). Gene based analyses are being performed using MAGMA software. Heritability estimates and genetic correlations of the examined effects are being calculated using LD score regression. Our preliminary results indicate the presence of non-additive genetic effects in the development of ADHD. Our preliminary strongest imprinting signal is located in *CALD1* locus (rs11980823, effect=0.77, SE=0.14, P=1.21E-07). This gene also revealed strong association signal in the previously reported large-scale childhood ADHD GWAS (rs79846815, P=2.03E-06). *CALD1* plays essential role in nerve regeneration, a function previously implicated in a number of neuropsychiatric disorders. Our preliminary gene-based analyses of the known imprinted genes revealed strong association with *TP73* locus (P=0.0034), encoding a transcription factor implicated in disorders of nervous system (e.g. neuroblastoma). Additional hits were noted in the non-coding RNA genes, adding to the recent observations in neuropsychiatric genetics of gene regulation playing a pivotal role in the development of disorders of mental health. In conclusion, this is the first and the largest genome-wide parent-offspring study in ADHD, exploring its non-additive genetic effects by detecting and distinguishing between POE (imprinting), maternal and child effects. As we increase our sample size, we will provide estimates of such effects as well as those of their heritability and genetic correlations.

**2116W**

**GWAS to drug: PTPRD as a drug target for addictions, RLS and neurofibrillary neurodegenerations.** G.R. Uhl<sup>1,2,3</sup>, M.J. Martinez<sup>1,2</sup>, J. Drgonova<sup>4</sup>, A. Suliman<sup>5</sup>, K.C. Rice<sup>5</sup>. 1) New Mexico VA Healthcare System, Albuquerque NM; 2) Biomedical Research Institute of New Mexico, Albuquerque NM; 3) University of New Mexico, Albuquerque NM; 4) Center for Scientific Review, Rockville MD; 5) Chemical Biology Research Branch, NIDA, Rockville MD.

We and others have identified PTPRD in GWAS studies of addiction/quit success phenotypes, RLS and neurofibrillary neuropathologies. We have reported a) 70% differences in brain PTPRD mRNA levels in individuals with common PTPRD haplotypes; b) lack of baseline behavioral abnormalities in heterozygous PTPRD knockouts that nearly mimic these common human differences; c) striking reductions in cocaine reward in heterozygous knockout mice (assessed by conditioned place preference); d) sleep onset difficulties in PTPRD knockouts that resemble those in RLS. There are no reported PTPRD ligands. We now report synthesis of a 7-butoxy illudalic acid analog (7-BIA) based on its reported ability to inhibit activity of phosphatases from related rPTPs, PTPRS and PTPRS. 7-BIA inhibits phosphatase activity of recombinant PTPRD and PTPRS fusion proteins with 3 and 30  $\mu\text{M}$   $\text{EC}_{50}$  values, respectively. The time course of action suggests pseudoirreversible inhibition, as postulated for activities at PTPRF. Acute and repeated intraperitoneal (ip) administration to C57Bl mice resulted in no apparent compound related toxicity by behavioral, gross pathologic or histopathologic criteria. In initial results, 7-BIA pretreatments prior to cocaine conditioning sessions resulted in significant decreases in subsequent preference for places previously paired with effects of 10 mg/kg cocaine doses, supporting reduced cocaine reward from 7-BIA. These results support progress from GWAS to animal model to compounds that provide paths to lead compounds for pharmaceutical development for common, disabling disorders that lack effective pharmacotherapeutics.

**Genome-wide association study of comorbid alcohol dependence and major depression.** H. Zhou<sup>1</sup>, R. Polimanti<sup>1</sup>, B.Z. Yang<sup>1,2</sup>, Q. Wang<sup>3</sup>, S. Han<sup>4,5</sup>, R. Sherva<sup>6</sup>, Y.Z. Nunez<sup>1,2</sup>, H. Zhao<sup>3,7,8,9</sup>, L. Farrer<sup>6,10,11,12,13</sup>, H. Kranzler<sup>4,15</sup>, J. Gelernter<sup>1,2,8,16</sup>. 1) Dept of Psychiatry, Yale University, New Haven, CT; 2) VA CT Healthcare Center, West Haven, CT; 3) Program in CBB, Yale University, New Haven, CT; 4) Dept of Psychiatry, University of Iowa, Iowa City, IA; 5) Interdisciplinary Graduate Program in Genetics, University of Iowa, Iowa City, IA; 6) Dept of Medicine (Biomedical Genetics), Boston University, Boston, MA; 7) Dept of Biostatistics, Yale University, New Haven, CT; 8) Dept of Genetics, Yale University, New Haven, CT; 9) VA Cooperative Studies Program Coordinating Center, West Haven, CT; 10) Dept of Neurology, Boston University, Boston, MA; 11) Dept of Ophthalmology, Boston University, Boston, MA; 12) Dept of Genetics and Genomics, Boston University, Boston, MA; 13) Dept of Epidemiology and Biostatistics, Boston University, Boston, MA; 14) Dept of Psychiatry, University of Pennsylvania, Philadelphia, PA; 15) VISN 4 MIRECC, Crescenzo VA Medical Center, Philadelphia, PA; 16) Dept of Neurobiology, Yale University, New Haven, CT.

**Importance** Alcohol dependence (AD) and major depression (MD) are leading causes of disability, and they often co-occur. Genetic epidemiologic data have shown that they share, at least to some extent, a common genetic etiology. The molecular nature of this shared genetic basis is poorly understood. **Objective** To detect genetic risk variants for comorbid AD and MD and to determine whether polygenic risk alleles are shared with neuropsychiatric traits or subcortical brain volumes. **Design, setting and participants** This genome-wide association study (GWAS) analyzed criterion counts of comorbid AD and MD in the Yale-Penn sample of subjects recruited for drug or alcohol dependence studies including African Americans (AA) and European Americans (EA). After excluding subjects who were never exposed to alcohol or had missing information for any diagnostic criterion, we performed GWAS on two samples ("Yale-Penn-1" and "Yale-Penn-2") totaling 4,653 AAs and 3,169 EAs. AAs and EAs were analyzed separately. We then tested whether polygenic risk scores (PRS) derived from potentially related traits (using data from SS-GAC, PGC and ENIGMA consortia) in EAs could be used to predict comorbid AD and MD. **Main Outcome(s) and Measure(s)** Comorbid criterion counts (ranging from 0-14) comprised of *DSM-IV* AD (7 criteria) and MD (9 criteria, scaled to 7). **Results** Under a linear regression model adjusted for age, sex and 10 PCs, rs139438618 at the *SEMA3A* locus was significantly associated with AD-MD comorbidity in AAs in the Yale-Penn-1 sample ( $P=2.76 \times 10^{-8}$ ). In the Yale-Penn-2 sample, the association was also significant ( $P=2.06 \times 10^{-4}$ ). Meta-analysis of the two samples yielded  $P=2.41 \times 10^{-11}$ . There was no significant association identified in EAs. PRS analyses showed that individuals with a higher level of neuroticism ( $P=1.03 \times 10^{-4}$ ) or depressive symptoms ( $P=1.80 \times 10^{-3}$ ) and a lower level of subjective well-being ( $P=4.19 \times 10^{-4}$ ) and educational attainment ( $P=5.13 \times 10^{-4}$ ) were at higher risk of AD+MD; while larger intracranial ( $P=2.18 \times 10^{-4}$ ) and smaller putamen volumes ( $P=1.22 \times 10^{-3}$ ) predicted higher risks of AD+MD. **Conclusions and Relevance** *SEMA3A* variation is significantly associated with comorbid AD and MD in AAs. Using PRS analyses, we identified pleiotropy with neuropsychiatric traits and brain volumes. Further studies are warranted to understand the biological and genetic mechanisms of this comorbidity, which could facilitate medications development and other treatments for comorbid AD and MD.

**Expanding the neurological and skeletal phenotypes of individuals with *de novo* *KMT2A* mutations.** A.J.S. Chan<sup>1,2</sup>, R.K.C. Yuen<sup>1,2,3</sup>, M. Uddin<sup>1,4</sup>, M. Zarrei<sup>1</sup>, S. Walker<sup>1</sup>, N. Hoang<sup>5</sup>, I. Drmic<sup>5</sup>, C. Cytrynbaum<sup>2,3,6</sup>, K. Drew<sup>1</sup>, T. Higginbotham<sup>1,2</sup>, R. Schachar<sup>7</sup>, M. Woodbury-Smith<sup>8</sup>, R. Weksberg<sup>3,6,9,10</sup>, S.W. Scherer<sup>1,2,3,11</sup>. 1) University of Toronto, Toronto, Ontario, Canada; The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 3) Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 4) Mohammed Bin Rashid University of Medicine and Health Sciences, College of Medicine, Dubai, United Arab Emirates; 5) Autism Research Unit, The Hospital for Sick Children, Toronto, Ontario, Canada; 6) Division of Clinical & Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Department of Psychiatry and Research Institute, The Hospital for Sick Children, University of Toronto, Toronto, Canada; 8) Department of Psychiatry and Behavioural Neurosciences, McMaster University, Hamilton, Canada; 9) Institute of Medical Science, University of Toronto, Toronto, Ontario, Canada; 10) Department of Pediatrics, University of Toronto, Toronto, Ontario, Canada; 11) McLaughlin Centre, University of Toronto, Toronto, Ontario, Canada.

*De novo* loss of function (LoF) mutations in *KMT2A* have been associated with Wiedemann-Steiner Syndrome (WSS), which is characterized by hypertrichosis cubiti, dysmorphic facial features, short stature, developmental delay, and intellectual disability. Also, *de novo* LoFs in *KMT2A* have been identified in some individuals with neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD). *KMT2A* encodes a histone methyltransferase that is required for neurogenesis, early development and hematopoiesis. Here, we present the clinical and genomic characterization of four unrelated individuals with ASD, attention-deficit and hyperactivity disorder (ADHD) or WSS. By combining our four cases with a meta-analysis of *KMT2A* mutations, we found that *de novo* LoF mutations in *KMT2A* were significantly enriched in NDD individuals compared to controls (43/13,431 vs. 0/2,299,  $p=0.0011$ ), suggesting *de novo* LoF mutations are highly penetrant for NDDs. By examining the phenotypes of WSS or NDD individuals with *de novo* LoF or missense variants in *KMT2A*, seizures/epilepsy, speech and language delay/difficulties, anxiety, ADHD, obsessive compulsive symptoms, tics, oppositional defiant disorder, and Klippel-Feil Syndrome are neurodevelopmental and skeletal phenotypes that were not previously reported in WSS patients. These findings expand the neurological and skeletal phenotypes associated with *KMT2A* and suggest that these features and other NDDs are under-diagnosed in individuals with *KMT2A* mutations.

**Polygenic burden analysis of longitudinal clusters of psychopathological features in a cross-diagnostic group of individuals with severe mental illness.** E.C. Schulte<sup>1,2</sup>, I. Kondofersky<sup>3</sup>, M. Budde<sup>2</sup>, K. Adorjan<sup>1,2</sup>, F. Aldinger<sup>1,2</sup>, H. Anderson-Schmidt<sup>4</sup>, T. Andlauer<sup>5</sup>, K. Gade<sup>4</sup>, U. Heilbronner<sup>2</sup>, J. Kalman<sup>1,2</sup>, S. Papiol<sup>6</sup>, F.J. Theis<sup>3</sup>, P. Falkai<sup>1</sup>, N.S. Mueller<sup>7</sup>, T.G. Schulze<sup>2</sup>. 1) Department of Psychiatry and Psychotherapy, Medical Center of the University of Munich, Munich, Germany; 2) Institute for Psychiatric Phenomics and Genomics (IPPG), Medical Center of the University of Munich, Munich, Germany; 3) Institute of Computational Biology, Helmholtz Zentrum München, Munich, Germany; 4) Department of Psychiatry and Psychotherapy, Medical Center Georg August University, Göttingen, Germany; 5) Department of Translational Research in Psychiatry, Max Planck Institute of Psychiatry, Munich, Germany.

Bipolar disorder (BD), schizophrenia (SZ) and schizoaffective disorder (SZA) are complex genetic disorders with largely polygenic architecture and severe and overlapping psychiatric symptoms. Stratification of cases into homogeneous subgroups across diagnoses using both psychometric and genetic information could identify individuals with higher risk for severe illness. Examined at four time points over 18-months, a subset of 198 participants (46.9±12.4 yrs; 46% female) with DSM-IV diagnoses of SZ, SZA or BD from an ongoing longitudinal cohort study ([www.kfo241.de](http://www.kfo241.de)) were genotyped on Illumina's Infinium PsychArray and imputed using the 1000genomes. 67 variables from the Positive and Negative Syndrome Scale (PANSS), the Inventory of Depressive Symptoms (IDS) and the Young Mania Rating Scale (YMRS) entered cluster analyses. Longitudinal trajectories derived from abstract data dimensions computed by factor analysis for mixed data (FAMD) were used for clustering. SZ-polygenic risk scores (PRS) based on the Psychiatric Genetics Consortium 2 SZ results were tested for cluster association at 11 thresholds. Two clusters were identified in the first two dimensions: (A) individuals with continuously low scores on PANSS and IDS (70.7%) and (B) individuals with consistently high scores on PANSS and IDS (29.3%). Clusters differed significantly with regard to Global Assessment of Functioning (higher in (A); FDR-adjusted  $p$ -value=2.23x10<sup>-10</sup>), while there were no significant differences regarding sex, age, diagnosis, center, age at onset, family history, duration of illness, or association with the SZ-PRS. In this preliminary data set, longitudinal clustering identified cross-diagnostic homogeneous subgroups. Surprisingly, more severe psychopathological features were not associated with increased genetic risk burden.

**The regulatory landscape of genetic variants associated with psychiatric disorders and neurodegenerative diseases.** A. Amlie-Wolf<sup>1,2</sup>, L. Qu<sup>2</sup>, E.E. Mlynarski<sup>2</sup>, C.D. Brown<sup>1,2,3</sup>, G.D. Schellenberg<sup>1,2,3</sup>, L.S. Wang<sup>1,2,3</sup>. 1) Genomics and Computational Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Penn Neurodegeneration Genomics Center, Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Genome-wide association studies (GWAS) have identified thousands of mostly noncoding genetic variants associated with phenotypes, but due to linkage disequilibrium (LD), these variants tag many potentially causal variants. To identify the causal variants and tissue-specific regulatory mechanisms underlying GWAS signals, we propose the INFERNO (INFERring the molecular mechanisms of Noncoding genetic variants) pipeline. INFERNO builds LD blocks from GWAS variants using 1,000 Genomes Project data. Each linked variant is then overlapped with transcription factor binding sites (TFBSs) for 332 TFs and active enhancer annotations across 239 tissues and cell types from FANTOM5 and Roadmap Epigenomics. GWAS summary statistics are used in a Bayesian model to identify colocalized GWAS and eQTL signals across 44 GTEx tissues. Tissues and cell types are grouped into 32 tissue categories to allow data integration and provide unbiased identification of the affected tissue contexts. Background sampling is performed to quantify the enrichment of enhancer overlaps in each tissue category. To characterize the landscape of regulatory genetic variation across brain-related traits, we applied INFERNO to variants associated with neurodegenerative diseases (Alzheimer's disease (AD), amyotrophic lateral sclerosis (ALS), frontotemporal dementia, corticobasal degeneration (CBD)) and psychiatric disorders (schizophrenia (SCZ), bipolar disorder, attention deficit hyperactivity disorder, major depressive disorder, and autism). We identified significant enrichments of enhancer overlaps in the brain category in CBD, the brain and nervous categories in ALS, 18 categories including the blood and brain categories in AD, and 11 categories including blood, brain, and stem cell categories in SCZ. The blood category includes immune-related cell types, providing evidence of an immune system role in AD and SCZ etiology. INFERNO identified 1,266 strongly colocalized GWAS-eQTL signals across these phenotypes, including 403 supported by variants overlapping concordant tissue enhancers with TFBS overlap and/or a high probability of underlying the colocalization signal. One AD signal has been validated by luciferase assays, with more experiments underway, and we continue to analyze the strongly colocalized signals. In summary, INFERNO provides a comprehensive and principled tool for integrating hundreds of diverse functional genomics datasets to characterize the regulatory effects of noncoding variants.

**2121F**

**Common genetic variation contributes to risk of severe developmental disorders.** M. Niemi, H. Martin, J. Barrett, *The Deciphering Developmental Disorders Study*. Wellcome Trust Sanger Institute, Hinxton, United Kingdom.

Recent studies have conclusively implicated both rare and common genetic variation in common neurodevelopmental conditions, such as autism and schizophrenia. For rare developmental disorders, rare variants are presumed to account for the disease phenotype, and thus the contribution of common genetic variation to disease risk has not been widely studied. The Deciphering Developmental Disorders (DDD) study has recruited 13,500 children with severe developmental disorders without a previous genetic diagnosis from around the UK and Ireland. We exome sequenced the children and their parents to search for rare or *de novo* variants of strong effect, because these individuals are presumed to have Mendelian genetic disorders. To investigate the contribution of common genetic variants (MAF>0.05) to developmental disorders, we genotyped the subset of DDD patients of European ancestry whose disorder included an abnormality of nervous system physiology or morphology. Our genome-wide association analysis of 7,274 DDD patients and 13,087 population-matched controls and 728 trios found no SNPs with genome-wide significance ( $p < 5 \times 10^{-8}$ ). This is unsurprising given the diversity of the phenotypes in the DDD cohort. However, using LD score regression, we estimated the observed-scale SNP heritability to be 0.07 (SE=0.03), which implies there are subtle polygenic effects contributing to risk of being in the neurodevelopmental DDD cohort ('neuro-DD risk'). We further found that this neuro-DD risk is significantly negatively genetically correlated with years of schooling, which is a proxy for cognitive performance ( $r_g = -0.62$ ,  $p = 6.6 \times 10^{-9}$ ). We also found evidence for a positive genetic correlation with schizophrenia ( $rg = 0.30$ ,  $p = 0.003$ ) and obesity ( $rg = 0.29$ ,  $p = 0.009$ ). We constructed a polygenic risk score (PRS) of neuro-DD risk, and found that DDD patients with a diagnostic exome mutation do not differ in their PRS from as yet undiagnosed patients, which suggests that polygenic effects act additively with Mendelian variants. We also find that DDD patients with autism spectrum disorder (ASD) have a higher polygenic risk for ASD ( $p = 0.001$ ) and educational attainment ( $p = 0.0005$ ) than other patients. Altogether these data suggest there is a polygenic component to developmental disorders in at least a subset of patients, and that there may be shared common genetic architecture among a range of neurodevelopmental disorders.

**2122W**

**Link genetic variation to schizophrenia through cognitive and brain anatomical phenotypes.** Z. Liu<sup>1,2</sup>, P.C. Sham<sup>1,2</sup>, M. Li<sup>1,2,3</sup>. 1) Centre for Genomic Sciences, The University of Hong Kong; 2) Department of Psychiatry, The University of Hong Kong; 3) Precision Medical Genetics Lab, Zhongshan School of Medicine, Sun Yat-sen University.

**Background:** Schizophrenia (SCZ) is an important cause of mental disability. Although several studies have suggested associations between SCZ and its possible endo-phenotypes, the power to discover the causality is limited. It has been predicted that deficits of cognitive phenotypes may lie upstream of the liability for SCZ and brain volume changes may lie downstream of SCZ liability (Toulopoulou, T *et al. Mol Psychiatry*. 2015). Thus, we hypothesize that the causation of different phenotypes to SCZ show different directions in this pathway. **Methods:** In this study, we collected GWAS summary data for cognitive, brain anatomical phenotypes and SCZ. Then, we used Mendelian randomization (MR) to detect the causal effects between cognitive/anatomical traits and SCZ in a gene-centered method. For each gene region, we selected LD-pruned single nucleotide polymorphisms (SNPs) with a P-value of less than  $1e-6$  as instrumental variables (IVs) for each exposure trait. We further filtered these SNPs by integrating eQTL data from brain tissues. Then the corresponding effects of selected SNPs in the outcome trait were included to perform MR analysis. Next, we ran sensitivity tests (including heterogeneity test, pleiotropy test and directionality test *etc*) to keep the valid MR results. For the remaining causal relations, we investigated whether the genes, which was used for IVs selection in the MR analysis, were also responsible for the exposure/outcome traits by performing transcriptome-wide association study using summary data from GWAS and eQTL studies. **Results:** We found that causality exists between cognitive/anatomical traits and SCZ. For example, using SNPs from *ALDH2* gene whose mutation was reported to confer susceptibility to SCZ (Zheng F *et al. Cereb Cortex*. 2017), one cognitive trait (reaction time) showed significant causation on SCZ ( $P = 0.0004$ ); using SNPs from *SRR* gene which was reported as the age-related oxidative stress selectively target within the hippocampus (Billard JM. *Eur J Neurosci*. 2013), SCZ showed significant causation on anatomical traits (Hippocampus,  $P=0.0007$ ). **Conclusions:** Although the association of cognitive/anatomical phenotypes with SCZ has been observed in recent GWASs, our preliminary study shows that some of them are causes and some are consequences. More efforts are required to validate these causal relations between SCZ and cognitive/anatomical traits and investigate the underlying molecular basis.

**DNA banking and genetic analysis of adverse drug reactions in the New Zealand healthcare setting.** M.A. Kennedy<sup>1</sup>, S.D.S. Maggo<sup>1</sup>, J. Foulds<sup>2</sup>, S. Luty<sup>2</sup>, E.W. Chua<sup>3</sup>, S. Cree<sup>1</sup>, K. Ton<sup>1</sup>, Y. Liau<sup>1</sup>, A.L. Miller<sup>1</sup>, P. Chin<sup>4</sup>, K. Lehnert<sup>5</sup>, M. Doogue<sup>1</sup>. 1) Dept Pathology, University of Otago, Christchurch, Christchurch, New Zealand; 2) Department of Psychological Medicine University of Otago, Christchurch, New Zealand; 3) Universiti Kebangsaan Malaysia, Kuala Lumpur, Malaysia; 4) Department of Clinical Pharmacology, University of Otago Christchurch and Christchurch Hospital, New Zealand; 5) Biological Sciences, Faculty of Science, University of Auckland, New Zealand.

Adverse drug reactions (ADRs) cause considerable morbidity and mortality, consume substantial healthcare resources and compromise therapeutic relationships. It is now recognised that many ADRs have significant underlying genetic factors which may be useful for risk prediction and prevention. Understanding the range of genetic variants that contribute to ADR risk is important as clinical genome sequencing becomes affordable and more widely used. One of the limiting factors in defining genetic contributors to ADRs is the availability of consented DNA samples from clinically well-defined cases. We have established a programme called UDRUGS (Understanding Drug Reactions Using Genomic Sequencing) to allow informed consent, DNA collection, storage and analysis for various adverse drug reactions in the New Zealand healthcare setting. In the pilot stages of this study we recruited ~80 participants with ADRs from 12 general drug classes, through clinician referrals and specific clinical studies. We have carried out candidate gene analyses (for relevant pharmacogenes such as *CYP2D6* and *CYP2C19*) in 25 cases, particularly those with ADRs to antidepressants, and applied whole exome sequencing to 20 cases. We consent participants for return of findings, and report these back via the referring physicians. Our hospital (Christchurch, New Zealand) recently implemented electronic prescribing and administration software (MedChart®) such that every drug prescription and every drug administration is recorded electronically and patients' ADRs are recorded. These data facilitate efficient identification of potential cases, and this software is being progressively implemented throughout New Zealand hospitals. We are now aiming to expand the UDRUGS DNA Bank and research studies on genetic factors contributing to ADRs using these electronic tools. Initial target ADRs include severe hyponatraemia due to a range of commonly used drugs, severe ADRs due to proton pump inhibitors (PPIs), and ADRs to antidepressant drugs. As appropriate, we will carry out candidate gene or whole exome/genome sequencing to identify variants that may be relevant to each ADR, and contribute samples to genome-wide association studies. The establishment of this ADR biobank provides a resource to support pharmacogenomic research specific to the New Zealand population, and will enable contribution to international collaborative research in this area.

**Association of *HTR3C*, *HTR3D*, *HTR5A*, and *HTR6* gene polymorphisms with treatment response to risperidone in Chinese schizophrenia patients.** S. Qin, W. Zhou, L. He. Bio-X Institutes, Shanghai Jiaotong University, Shanghai, Shanghai, China.

Previous assessments of the pharmacological profile of antipsychotics have shown that the serotonin receptor family is involved in their pharmacodynamics. The current study was designed to evaluate the effect of serotonin receptor polymorphisms on risperidone response in Han Chinese patients with schizophrenia. Two independent sets of Han Chinese in-patients with schizophrenia (N = 201) were followed for a 4-week risperidone monotherapy treatment. Psychopathological symptoms were assessed using the Positive and Negative Syndrome Scale (PANSS) and response was defined as a reduction of 50% or more of PANSS scores. Fourteen single nucleotide polymorphisms (SNPs) selected from the *HTR3C*, *HTR3D*, *HTR5A*, and *HTR6* genes were genotyped. A significant association between rs1467257 and the rs939334–rs1467257–rs6792482 haplotype in the *HTR3D* gene and risperidone efficacy was detected (for rs1467257, allele: odds ratio [OR] = 2.51, 95% confidence interval [CI] = 1.26–5.02,  $P=0.008$ ; genotype:  $P=0.03$ ; for the haplotype,  $P=0.035$ , OR = 2.299, 95% CI = 1.046–5.056). Furthermore, the rs6801865 polymorphism in the *HTR3C* gene significantly influenced total ( $P=0.018$ ) and negative ( $P=0.032$ ) PANSS score improvement during risperidone treatment. These findings suggests that variants in *HTR3C* and *HTR3D* may act as biomarkers to predict risperidone response in Han Chinese populations. The current study has clinical significance in evaluating the response to risperidone.

**Risperidone-induced multi-dimensional phenotypic alteration in first-episode drug-naïve schizophrenia patients: A longitudinal study of DNA methylation and neurophysiological phenotyping.** C. Chen<sup>1</sup>, Y. Xia<sup>1</sup>, M. Hu<sup>2</sup>, X. Zong<sup>2</sup>, S. Jiang<sup>3</sup>, Z. Li<sup>1</sup>, Y. He<sup>2</sup>, J. Bishop<sup>3</sup>, C. Liu<sup>2</sup>, X. Chen<sup>2</sup>. 1) State key lab of medical genetics, Central South University, Changsha, China; 2) Department of Psychiatry, Second Xiangya Hospital, Central South University, Changsha, China; 3) Department of Psychiatry, University of Illinois at Chicago, Chicago, IL.

Schizophrenia (SCZ) is a complex neuropsychiatric disorder and whether the biological alterations are due to chronic illness or to antipsychotic treatment effects remains to be elucidated. In this study, we performed intensive phenome-wide assessments for 38 Han Chinese drug-naïve, first-episode SCZ patients (FESPs) at baseline and after eight weeks of risperidone monotherapy and for 38 matched healthy controls. DNA methylation (DNAm) of peripheral blood was measured using Illumina 450K BeadChip. We calculated brain anatomical network using diffusion tensor imaging and spontaneous brain activity using functional magnetic resonance imaging. Cognitive function and FESPs' clinical states were also evaluated. We first conducted the epigenome-wide association study for FESPs and controls, next combined differential DNAm and co-methylation connectivity to explore significant connectivity and DNAm changes during treatment. Finally, we linked DNAm changes with all other phenotypes and constructed phenome networks. Three independent studies were used as validation. We found 8326 CpGs were differentially methylated between FESPs and controls, 9428 CpGs between post-treatment patients and controls, and 5904 CpGs in pre- versus post-treatment patients ( $P<0.05$ ). Based on 5904 CpGs we detected 200 differentially methylated regions mapped to 134 Genes. These genes enriched for calcium signaling pathway and long-term depression (adjusted  $P<0.05$ ). We found 586 CpGs showed differential DNAm between FESP and controls also showed differential between pre- and post-treatment, 583 of them were normalized, and 392 of these changes correlated with PANSS-positive symptoms and cognitive function as well as the anatomical brain network and spontaneous brain activity alterations. In the co-methylation networks, we extracted the CpGs with significant connectivity changes, which mapped to 831 unique Genes enriched for negative regulation of GTPase activity. Finally, using CpG and brain phenotypes network, we observed the most connected CpG site, cg00478599, correlated with the white matter connectivity in amygdala, ACG and PCG, and the white matter connectivity in these regions have correlated with spontaneous brain activity in different brain regions. Overall, we found risperidone not only normalized DNAm but also linked to network connectivity changes in patient blood. Our complex web analysis depicts relationships among multi-dimensional variables induced by treatment.

**Genetic and functional analysis of the GRIN2C gene as a candidate gene of schizophrenia.** *M. Cheng, S. Tsai, H. Tsai, S. Hsu.* Department of Psychiatry, Yuli Branch, Taipei Veterans General Hospital, Hualien County, Taiwan.

Schizophrenia is a chronic debilitating mental disorder with a high genetic component in its etiology. Hypofunction of the *N*-methyl-*D*-aspartate (NMDA) receptor-mediated signal transduction has been implicated in the pathophysiology of schizophrenia. The *GRIN2C* gene encodes a subunit of the NMDA receptor, which is a subtype of ionotropic glutamate receptor involves synaptic function, learning, memory, and neurodevelopmental disease. The study aimed to investigate the involvement of the *GRIN2C* gene in the genetic susceptibility to schizophrenia. We resequenced the exon regions of the *GRIN2C* gene in 1000 subjects, including schizophrenic patients and normal control, both being Han Chinese from Taiwan. We identified 11 missense mutations, including seven schizophrenia-specific mutations. Bioinformatic analysis showed some of these mutations were damaging or pathological to the protein function. Also, we detected one schizophrenia-specific nonsense mutation (c.3355C>T), which results in a premature stop codon, and in a truncated nonfunctional the *GRIN2C* protein. Taken together, multiple rare missense and nonsense mutations in the *GRIN2C* gene contribute to the pathophysiology of schizophrenia in some patients, but functional gene assays are needed to verify their relevance to the pathogenesis of schizophrenia. Our study supports common disease and rare variants hypothesis for schizophrenia.

**2127F**

**Major depressive disorder and nausea and vomiting during pregnancy.**

**Shared genetic factors?** *L. Colodro Conde<sup>1</sup>, B. Couvy-Duchesne<sup>2</sup>, P. Lind<sup>1</sup>, J. Painter<sup>1</sup>, M. Wright<sup>2</sup>, G. Montgomery<sup>2</sup>, D. Nyholt<sup>3</sup>, S.E. Medland<sup>1</sup>.* 1) QIMR Berghofer Medical Research Institute, Brisbane, QLD, Australia; 2) University of Queensland, Brisbane, QLD, Australia; 3) Queensland University of Technology, Brisbane, QLD, Australia.

Nausea and vomiting in pregnancy (NVP) affects ~70% of pregnant women to different degrees. Around 14% of pregnant women experience severe NVP and this progresses to hyperemesis gravidarum (HG) in around 1-3%. Women who experience severe NVP and HG have higher rates of major depressive disorder (MDD) prior to the index pregnancy. We therefore hypothesize that there is a genetic correlation between NVP/HG and depression. To test this hypothesis, we examined the extent to which individual differences in the occurrence of NVP, HG and the severity of NVP can be predicted by a polygenic risk score (PRS) derived from the most recent Psychiatry Genomics Consortium MDD analyses (PGC-MDD2, leave QIMR out). Our preliminary analyses using data on NVP were obtained from two studies undertaken at the QIMR Berghofer (Australia), (N= 1,440 unrelated women). The phenotypes were: 1) presence of NVP for 7 days or more, 1) degree of severity of NVP (5 point scale), and 3) presence of severe NVP, characterized by disruption of daily routine, prescription of medication, loss of weight, and intravenous feeding (proxy for HG). Polygenic risk scores were calculated using the PLINK profile score method for clumped SNPs (thresholds of  $p \leq 0.5 \times 10^{-8}$ ,  $0.1 \times 10^{-5}$ , 0.001, 0.01, 0.05, 0.1, 0.5 or 1). Logistic and linear regressions on the profile scores were performed, controlling for ancestry, age and age<sup>2</sup> at survey time, cohort, and if it was a twin pregnancy. Among the women from our sample, in at least one of their pregnancies, 53.1% had symptoms of NVP for 7 or more days and 18.7% had severe symptoms. After fitting covariates, the MDD PRSs (independent of the time at which any depressive symptoms manifest) predicted the probability of presenting with NVP, the degree of severity (all PRS under threshold <0.001), and very severe NVP or HG (all PRS under threshold 0.05) at a nominally significant level. However, only MDD-PRS < 0.1 predicting the degree of severity of NVP survived multiple correction testing. Further genotyping of an HG case-control cohort is currently underway and we expect the increase in power will increase the support for these findings and allow the calculation of genetic correlations using LD score regression. We will also present an update to the GWAS meta analysis for NVP.

Genome-wide array-based analyses of tobacco use have identified many associated common variants, but the vast majority of the heritability remains unexplained. Rare variants likely contribute to risk for smoking and other addictive behaviors, and cost-effective whole genome sequencing is now making genome-wide analyses of rare variants possible. The present study reports rare variant association results for tobacco use from TOPMed, which has at present called genotypes from 9,536 30x whole genome sequences in 8 distinct studies with smoking phenotypes. We conducted a genome-wide association study (GWAS) of all discovered variants with minor allele count > 10 for four phenotypes: regular vs never smoker (n=9,536;n variants=34,115,958), current vs former smoker (n=4,601;n variants=27,243,212), age of initiation of regular smoking (n=4,467;n variants=27,141,662) and cigarettes smoked per day (n=4,590;n variants=27,547,744). The GWAS yielded no significant results after Bonferroni correction per phenotype, although there was a signal suggested for the known variant rs16969968 in *CHRNA5* (p=7.718e-05). Rare variant burden tests of highly deleterious variants also yielded no significant results. Finally, we used the TOPMed sequences to fine map 182 recently discovered smoking-related loci—defined as 1MB regions around top associated variants—from array-based GWAS meta-analyses across all four smoking phenotypes (N ranging from 256,658 to 991,257 depending on the phenotype). Of the 182 most significantly associated common variants within these 182 loci, two were significant after Bonferroni correction for 182 tests (rs56113850 in *CYP2A6*, p=7.3e-5 and rs112878080 in *CHRNA3*, p=2.6e-5), and 121 of the 182 variants showed the same direction of effect in TOPMed and GSCAN (p=5.1e-6). Forward selection fine mapping tests in TOPMed within the 182 loci discovered one additional conditionally independent variant in an intron of *ASXL1* (rs148986225, MAF=0.003, p=1.7e-7) associated with cigarettes smoked per day after Bonferroni correction per phenotype. We expect to present updated results on a much larger data freeze approaching 50,000 total individuals, greatly increasing power and precision of all analyses.

**Genetics of cognitive function in schizophrenia and bipolar disorder.** P.D. Harvey<sup>1,2</sup>, N. Sun<sup>3,4</sup>, Q. Lu<sup>4</sup>, B. Li<sup>4</sup>, Q. Chen<sup>3,4</sup>, M. Aslan<sup>3,5</sup>, K. Radhakrishnan<sup>2</sup>, K.H. Cheung<sup>6,6</sup>, Y. Li<sup>3,7</sup>, N. Rajeevan<sup>3,7</sup>, F. Sayward<sup>3,7</sup>, S. Pyarajan<sup>8,9</sup>, J.M. Gaziano<sup>8,9</sup>, J. Concato<sup>3,5</sup>, H. Zhao<sup>3,4</sup>, U.S. Department of Veterans Affairs Cooperative Studies Program (#572) and Million Veteran Program. 1) Miami VA Healthcare System, Miami, FL; 2) University of Miami, Miami, FL; 3) VA Clinical Epidemiology Research Center (CERC), VA Connecticut Healthcare System, West Haven, CT; 4) Department of Biostatistics, Yale University School of Public Health, New Haven CT; 5) Department of Medicine, Yale University School of Medicine, New Haven, CT; 6) Department of Emergency Medicine, Yale University School of Medicine, New Haven, CT; 7) Yale Center for Medical Informatics, Yale University School of Medicine, New Haven, CT; 8) Massachusetts Veterans Epidemiology Research and Information Center (MAVERIC), VA Boston Healthcare System, Boston, MA; 9) Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA.

**Background:** Cognitive impairment is a frequent and serious problem in patients with various forms of severe mental illnesses, including schizophrenia (SZ) and bipolar disorder (BP). Cognitive performance in patients with bipolar disorder or schizophrenia has been found to be very similar in underlying structure, and recent research has suggested genomic linkage to several different cognitive phenotypes. In addition, recent evidence from the Cognitive Genomics Consortium (COGENT) study, focusing on a pooled population of more than 35,000 healthy European ancestry patients from 24 studies, reported an estimated SNP heritability of 21.5%. The current study examined the genomic correlates of cognitive and functional skills performance in 8,051 U.S. veterans with either SZ or BP. **Design and Methods:** Veterans Affairs (VA) Cooperative Studies Program (CSP) Study #572 evaluated cognitive and functional capacity (FC) measures among BPI and SZ patients, using a subset of tests from the MATRICS Consensus cognitive battery (MCCB) and the UCSD Performance-based skills assessment-brief version (UPSA-B). In conjunction with the VA Million Veteran Program, and using a customized Affymetrix Axiom genotyping array for samples from 3,388 SZ and 4,663 BP CSP #572 patients (N=8,051 total), we conducted genome-wide association analyses for European Americans (3,952) and African Americans (2,598) separately. **Results:** There are no SNPs with genome-wide statistically significant results for either EA or AA samples. We also applied MetaXcan to calculate gene-level test statistics across 44 tissues and did not identify any associated genes. However, based on the comparison between summary statistics from this study and those from published GWAS of 55 diseases/traits, there is statistically significant evidence of genetic correlation between cognitive function and schizophrenia (1.7E-09), but not bipolar illness. **Conclusion:** No SNPs with strong evidence of association with cognitive performance were identified in this study, but genetic correlation analysis between this study and published GWAS on schizophrenia from other studies suggests shared factors between cognitive functions and schizophrenia. Later analyses will perform targeted examination of the linkage of previously identified genes and SNPs to overall performance and specific cognitive phenotypes.

**Transcriptional signatures of childhood onset schizophrenia in hiPSC-derived NPCs and neurons are concordant with signatures from post mortem adult brains.** G.E. Hoffman<sup>1,4</sup>, B.J. Hartley<sup>2,5</sup>, E. Flaherty<sup>2,5</sup>, I. Ladrán<sup>3,5</sup>, P. Gochman<sup>6</sup>, D. Ruderfer<sup>1,4</sup>, J. Rapoport<sup>6</sup>, P. Sklar<sup>1,3,4,5</sup>, K.J. Brennan<sup>1,2,3,4</sup>. 1) Department of Genetics and Genomics, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 3) Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 4) Institute of Genomics and Multiscale Biology, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 5) Friedman Brain Institute, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 6) Childhood Psychiatry Branch, National Institute of Mental Health, National Institutes of Health, Bethesda, MD 20892, USA.

Large-scale genome wide association studies (GWAS) revealed that schizophrenia (SZ) risk reflects both rare and common variants. Whereas highly penetrant rare variants have proven well-suited to human induced pluripotent stem cell (hiPSC)-based models, the power of hiPSC-based studies to resolve the much smaller effects of common variants within the size of cohorts that can be realistically assembled remains uncertain. Childhood-onset-SZ (COS) patients have both a higher rate of rare SZ-associated copy number variations (CNVs), and also stronger common SZ polygenic risk scores. We developed a case/control hiPSC cohort (12 individuals with COS and 10 controls) with which to conduct a comprehensive evaluation of global gene expression in hiPSC-derived neural progenitor cells (NPCs) and neurons. Although we identified many sources of variation across our 94 RNAseq samples, this was partially addressed by establishing a rigorous series of bioinformatic practices to reduce and assess the variance inherent in this approach. We report that the donor-specific signal is enriched for post-mortem brain expression quantitative trait loci (eQTLs), but also that there is a significant correlation between the case/control differential expression observed in our hiPSC-derived COS neurons and the CommonMind Consortium post-mortem study. While the issue of small sample size is shared between post-mortem and hiPSC-based studies, and may be exacerbated in hiPSC-based experiments through the variability that arises as a result of the reprogramming and neural differentiation processes, we find that the common variation effects predicted in GWAS and detected in much larger post-mortem analyses are reflected in hiPSC-neurons. We predict a growing convergence of common variation findings between hiPSC and post-mortem studies as both approaches expand to larger cohort sizes.

**Copy number variation in Thai individuals with schizophrenia and schizoaffective disorder.** N. Jinawath<sup>1,2</sup>, W. Thammachote<sup>1</sup>, S. Promsri<sup>1</sup>, N. Jantaratnotai<sup>3</sup>, D. Wattanasirichaigoon<sup>4</sup>, R. Kongsakon<sup>5</sup>. 1) Program in Translational Medicine, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Bangkok, Thailand; 2) Integrative Computational Bioscience Center, Mahidol University Salaya Campus, Nakhon Pathom, Thailand; 3) Department of Pharmacology, Faculty of Science, Mahidol University, Thailand; 4) Division of Medical Genetics, Department of Pediatrics, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand; 5) Department of Psychiatry, Faculty of Medicine Ramathibodi Hospital, Mahidol University, Bangkok, Thailand.

Schizophrenia is a chronic and severe neuropsychiatric disorder presented in approximately 1% of the general population. Patients with schizophrenia may lose touch with reality, exhibit emotional and behavioral disruptions, and impaired thinking and memory. Schizoaffective disorder is a rarer entity with more pronounced mood disorder symptoms. These mental disorders are multifactorial illnesses and share some genetic etiologies including copy number variations (CNVs) with other neuropsychiatric and neurodevelopmental disorders such as bipolar disorder, intellectual disability, and autism spectrum disorder (ASD). The aims of this study were to identify novel schizophrenia and schizoaffective disorder-associated CNVs and to evaluate the diagnostic yield of chromosomal microarray (CMA) in Thai patients with these disorders. Illumina CytoSNP-850K BeadChip was used to identify CNVs in the 67 patients who met the DSM-IV-TR criteria for schizophrenia (46 patients) and schizoaffective disorder (21 patients). Multiple large curated CNV databases including Thai CNV database were utilized for interpretation of clinical significance. We detected pathogenic CNVs and variants of uncertain significance (VOUS)-likely pathogenic CNVs in 5 of 67 patients (7.5%). Of the five cases, four had known schizophrenia-associated alterations including 15q13.3 microduplication, *NRXN1* exon deletion, 16p13.11 microdeletion, and triple X syndrome. Another case had 10q26 microdeletion syndrome, a syndrome with no previous link to schizophrenia. Interestingly, we observed a significantly high frequency of 15q13.3 duplications involving *CHRNA7* in Thai schizoaffective patients (2 of 21 patients, 9.5%), while none was seen in the 46 schizophrenia patients and 114 ASD patients previously studied. This duplication is known to exhibit incomplete penetrance and variable expressivity. Its frequency in the 3,017 general Thai individuals is 0.36%. In conclusion, this is the first SNP-based microarray study in a cohort of Thai patients with schizophrenia and schizoaffective disorder. Our findings provide supportive evidence that CMA should be considered as a first tier genetic analysis for patients with schizophrenia. Additionally, CNV analysis using ancestry-matched controls in underrepresented population is a valuable tool for identification of novel disease-associated alterations and phenotypes, thus expanding both the genetic and phenotypic spectrum of the disorders.

**2132T**

**Sex-stratified analysis of obsessive-compulsive disorder reveals minor differences in genetic architecture.** E.A. Khramtsova<sup>1,2</sup>, L.K. Davis<sup>3</sup>, B.E. Stranger<sup>2,4</sup>, P.G.C. OCD Workgroup<sup>5</sup>. 1) Department of Medicine, Section of Genetic Medicine, The University of Chicago, Chicago, IL; 2) Institute for Genomics and Systems Biology, The University of Chicago, Chicago, IL; 3) Vanderbilt Genetics Institute, Vanderbilt University, Nashville, TN; 4) Center for Data Intensive Science, The University of Chicago, Chicago, IL; 5) Psychiatric Genomics Consortium Obsessive-Compulsive Disorder Workgroup.

Obsessive-compulsive disorder (OCD), demonstrates sexual dimorphism in age of onset and clinical presentation, suggesting a possible sex difference in genetic architecture. We present the first genome-wide assessment of sex-specific genetic architecture of OCD on currently the largest OCD cohort available from the Psychiatric Genomics Consortium (N=9870 after QC, 1:1.4 male/female ratio). First, we used heritability ( $h^2$ ) analysis to test for evidence of variable liability threshold for OCD between sexes and to assess the proportion of overall OCD  $h^2$  explained by the X chromosome. There were no significant differences between sexes in OCD  $h^2$ . The X chromosome contributed 6.7% to total  $h^2$  which is not statistically different from expectation. The genetic correlation between sexes is high: GCTA GREML (1.0,  $se=0.27$ ) and LDSC (1.04,  $se=0.51$ ,  $p=0.0405$ ). Second, we performed a sex-stratified meta-GWAS to identify specific autosomal and sex chromosome risk factors with different effects in sexes. There were no genome-wide significant associations in either sex. Third, we assessed whether heterogeneous OCD risk alleles and top ( $p<10^{-3}$ ) sex-specific genome-wide associations are involved in gene regulation to elucidate the biological mechanisms by which those variants may impact dimorphism. On a genome-wide level, heterogeneous SNPs (including and excluding SNPs in the HLA region) were strongly enriched for immune expression quantitative trait loci ( $p<0.001$ ); top female associations were significantly enriched for brain eQTLs ( $p=0.003$ ), while top male associations were significantly enriched for immune eQTLs ( $p=0.003$ ). Using Disease Association Protein-Protein Link Evaluator we identified 10 genes implicated by heterogeneous OCD risk brain eQTLs (FDR<0.05) that showed significantly more network connectivity than expected by chance. Among them are two solute carrier family transporters: SLC8A2 (sodium/calcium exchanger) which is differentially expressed between males and females in the cerebellum ( $q=0.027$ ), and SLC25A1 (calcium-binding mitochondrial protein carrier), a polymorphism in which has been associated with autism and global cerebral hypomyelination. In conclusion, we identified minor sex differences in genetic architecture of OCD, and although the sex-stratified sample size is likely too small to identify variants with small effect, we have developed a pipeline for sex-stratified genetic analysis which will be applied when a larger OCD cohort is available.

**The transcriptional consequences of bipolar disorder polygenic risk and medication use.** C.E. Krebs<sup>1</sup>, A.P.S. Ori<sup>2</sup>, L.M. Olde Loohuis<sup>3</sup>, M.P. Boks<sup>3</sup>, R.S. Kahn<sup>3</sup>, R.A. Ophoff<sup>1,2,3,4</sup>. 1) Department of Human Genetics, UCLA, Los Angeles, CA; 2) Center for Neurobehavioral Genetics, UCLA, Los Angeles, CA; 3) Department of Psychiatry, Brain Center Rudolf Magnus, University Medical Center Utrecht, Utrecht, The Netherlands; 4) Department of Psychiatry and Biobehavioral Sciences, UCLA, CA.

Bipolar disorder (BPD) is a debilitating psychiatric disorder that is highly heritable and polygenic. Genome-wide association studies of BPD have yielded a number of associated loci, yet little is known about the disorder's etiology. We sought to characterize the functional transcriptomic impact of BPD polygenic risk and disease state in a large cohort from The Netherlands. We collected genotyping and RNA sequencing data from peripheral whole blood as well as extensive phenotypic information, including medication use, from 240 BPD cases and 240 controls. We aligned the RNA-seq reads with TopHat2, quantified gene counts using HTSeq, and normalized, voom transformed, and corrected for known contributing technical and biological covariates using limma. Of note, medication use and specifically the current use of lithium, which is the most commonly prescribed mood stabilizer for BPD patients, contributed significantly to variation in gene expression. With these corrected gene counts we performed several analyses to assess the transcriptional consequences of BPD genetic risk and disease state in our cohort. Using limma we identified five differentially expressed genes (DEGs) at FDR < 0.05 between cases and controls, 641 DEGs between cases currently taking lithium and cases not currently taking lithium, and 2,631 DEGs between cases currently taking lithium and controls. Altogether these DEGs had small effect sizes ( $\log_2$  fold change mean = 0.13, max = 1.33) in line with the complex nature of BPD. Interestingly, among the five case-control DEGs is *DOCK3*, which exhibits reduced expression in cases and is well characterized as inducing axonal outgrowth in the central nervous system. The lithium DEGs were enriched for biological terms related to apoptosis and cell death, which are known cellular consequences of lithium treatment. Gene-set analysis using MAGMA showed no enrichment of BPD-associated genetic risk in the DEGs we identified. We discovered BPD-specific eQTLs using Matrix-eQTL after additionally correcting for hidden covariates using PEER, but none remained significant after FDR correction. Overall our analyses point to a lack of transcriptomic consequences of BPD polygenic risk in blood but they do reveal a strong effect of medication use.

**Rare heterozygous mutation in glutamate receptor gene segregating in a schizophrenia family.** P. Kukshal<sup>1</sup>, J. John<sup>1</sup>, U. Bhattacharya<sup>1</sup>, T. Bhatia<sup>2</sup>, V.L. Nimgaonkar<sup>3</sup>, S.N. Deshpande<sup>3</sup>, B.K. Thelma<sup>3</sup>. 1) Department of Genetics, University of Delhi, South Campus, New Delhi, Delhi, India; 2) Department of Psychiatry, Dr. RML Hospital, New Delhi, India; 3) Departments of Psychiatry and Human Genetics, Western Psychiatric Institute and Clinic, University of Pittsburgh, Pittsburgh, USA.

**Objectives:** Schizophrenia (SZ) is a common complex disorder affecting 1% of the population worldwide and gene-environment interactions are known to be the etiological factors. With the advent of Next Generation Sequencing (NGS) tools, and the discovery of rare variants and *de novo* mutations, the paradigm has shifted to common disease rare variant. Recently a large number of *de novo* mutations have been identified in pathways of brain development. It is hypothesised that many neural circuits are important in schizophrenia and subject to spontaneous genetic mutations. Employing NGS tools on familial cases of schizophrenia would facilitate identification of rare putative causal variants in known or novel candidate genes. In this study we analysed a schizophrenia family with multiple member affected SZ family by Whole Exome Sequencing (WES) approaches. **Methods:** An extended family with three affected members and a probable autosomal dominant mode of inheritance was recruited from Dr R.M.L Hospital, New Delhi, following institutional ethical committee clearance and informed consent. Diagnosis for SZ was confirmed using Hindi version of Diagnostic Interview for Genetic Studies and Family Interview for Genetic Studies. WES of three affected and one unaffected member were captured using Agilent V5+UTR capture kit and sequenced on an Illumina HiSeq 2000 platform. WES processing, variant calling and variant annotations were performed using bioinformatic tools and software. The variants were prioritised based on the likely mode of inheritance, functional significance and rarity. **Results:** Of the several variants found most promising was a rare heterozygous missense variant in exon 3 (rs528711346) in *GRIN3B* (Glutamate Ionotropic Receptor NMDA Type Subunit 3B). *In silico* analysis predicted the variant to be damaging. **Conclusion:** Common SNPs in this gene has been previously reported to be associated with SZ. However, rare putative causal variants identified in this gene and segregating with SZ phenotype in the family reiterates the role of this gene in disease etiology.

Hans, Institute for Biological Psychiatry, Capital Region of Denmark, Roskilde, Denmark; 11) Department of Clinical Medicine, University of Copenhagen, Copenhagen, Denmark; 12) Department of Medicine, Harvard Medical School, Boston, MA, USA.

The current data indicated that the allelic architecture of complex traits is caused by many common and rare variants. Large GWAS meta-analyses have been successfully applied in the search for common variants affecting the risk of developing psychiatric disorders, in particular schizophrenia and major depressive disorder. However, these studies are designed to examine only the common variant proportion of the genomic landscape whereas high-throughput sequencing allows direct examination of both common and rare alleles. Schizophrenia is one of the most disabling mental disorders; it has a lifetime prevalence of around 1% and a heritability estimated as high as 80%. Although around one third of the heritability can be attributed to common variants, prior studies indicate that rare variants also contribute to its etiology. A collaboration between iPSYCH (The Lundbeck Initiative for Integrative Psychiatric Research, Denmark) and the Broad Institute (in Cambridge, MA, USA) is conducting large scale exome sequencing of major psychiatric disorders, including schizophrenia. DNA is extracted from dried blood spots (DBS) stored at the Danish Neonatal Screening Biobank. The samples can be matched to a wide range of phenotypic information available in Danish registries. We present here the analysis of a large collection of schizophrenia individuals recruited in clinical centers (1,866) and from DBS samples (3,710): a total of 5,576 cases and 7,468 controls from Denmark. We follow up in a similarly sized sample from Sweden with 4,969 cases and 6,245 controls. The combined analysis represents the largest exome sequencing study in schizophrenia to date. We have found evidence showing a higher per-person rate of disruptive ultra-rare loss-of-function variants located in constrained genes among schizophrenia cases compared to controls (combined p-value 1.6e-07). Meta-analysis SKAT of rare and ultra-rare variants at gene level has been performed. The results from burden and enrichment analysis, as well as ranking of mutational load, will be discussed in the larger perspective of findings from both GWAS and other exome analyses in schizophrenia.

## 2136F

**Increased predicted C4A expression is associated with cognitive deficit in both schizophrenia and Alzheimer's disease.** N.S. McCarthy<sup>1,2,3</sup>, S.M. Laws<sup>3,4,5</sup>, T. Porter<sup>3,4</sup>, S.C. Burnham<sup>6</sup>, E.K. Moses<sup>1</sup>, A. Jablensky<sup>6</sup>. 1) The Centre for the Genetic Origins of Health the Disease, School of Biomedical Sciences, University of Western Australia and Curtin University, MRF Building, 50 Murray St, Perth, WA 6000, Australia; 2) The Centre for Clinical Research in Neuropsychiatry, School of Psychiatry and Clinical Neurosciences, University of Western Australia, MRF Building, 50 Murray St, Perth, WA 6000, Australia; 3) Cooperative Research Centre for Mental Health, Carlton, South, Victoria, Australia; 4) Collaborative Genomics Group, Centre of Excellence for Alzheimer's Disease Research & Care, School of Medical and Health Sciences, Edith Cowan University, 270 Joondalup Dr, Joondalup WA 6027; 5) School of Biomedical Sciences, Faculty of Health Sciences, Curtin Health Innovation Research Institute, Curtin University; 6) CSIRO Health and Biosecurity, Parkville, Victoria.

Recently, Sekar *et al.* (Nature, 2016) reported that the top GWAS hit for schizophrenia in the major histocompatibility complex (MHC) locus implicated structural variants in the C4 gene which are associated with C4A expression and may affect synaptic pruning. Synapse loss is associated with cognitive decline in a number of disorders, including Alzheimer's disease and schizophrenia. We hypothesised that C4A expression predicted from C4 structural alleles is associated with cognition. We tested this in the Western Australian Family Study of Schizophrenia (WAFSS) (n=770, including 402 schizophrenia cases and 368 controls), and the Australian Imaging, Biomarkers and Lifestyle Study (AIBL) (n=1,112, including 211 Alzheimer's disease cases, 133 with mild cognitive impairment and 768 controls). Sekar *et al.* showed that C4 structural alleles could be imputed from GWAS data with an accuracy of ~70%. We used 222 reference haplotypes with C4 structural alleles measured by Sekar *et al.* to impute C4 alleles in all individuals using Beagle. C4A expression was predicted for each individual using the regression coefficients calculated by Sekar *et al.* Composite measures of cognition were available for both WAFSS and AIBL (Hallmeyer *et al.*, Am J Hum Genet. 2005; Burnham *et al.*, J Alzheimers Dis. 2015). Linear regression was used to assess their relationship with predicted C4A expression. P values for these relationships were calculated using linear mixed models to account for the relatedness between some WAFSS participants, and repeated measurements in the AIBL dataset. All analyses were adjusted for case status, age, sex, and education. Although mean C4A expression was not significantly different between schizophrenia cases and controls in the WAFSS (P=0.7), cases were overrepresented in those with the highest C4A expression levels. There was a small but consistent association between increased cognitive deficit and increased levels of C4A in both the WAFSS and the AIBL samples (P<0.05) which was particularly pronounced in cases. These data suggest that C4 structural variants previously shown to be associated with schizophrenia may specifically implicate the cognitive deficit which is a core feature of schizophrenia. Further, our finding that a similar relationship between C4A levels and cognition exists in patients with schizophrenia and Alzheimer's disease suggests that the locus may be pleiotropic and have implications for a range of neuropsychiatric disorders.

## 2137W

**BBS1 M390R/M390R mice have impaired anxiety-like behavior.** T. Pak<sup>1,2</sup>, C. Carter<sup>1</sup>, S. Gupta<sup>3</sup>, J. Wemmie<sup>3</sup>, S. Huang<sup>1,2</sup>, N. Nuangchamngong<sup>1</sup>, C. Searby<sup>1</sup>, P. Abbott<sup>1</sup>, H. Stevens<sup>3</sup>, V. Sheffield<sup>1</sup>. 1) Pediatrics, University of Iowa, Iowa City, IA; 2) Medical Scientist Training Program, University of Iowa, Iowa City, IA; 3) Psychiatry, University of Iowa, Iowa City, IA; 4) Obstetrics and Gynecology, University of Iowa, Iowa City, IA.

Bardet Biedl Syndrome (BBS) is a clinically and genetically heterogeneous autosomal recessive ciliopathy with core features that include polydactyly, obesity, retinopathy, and nephropathy. There is also increased prevalence of psychiatric illness in BBS patients. The connection between BBS and psychiatric illness is not well understood. We studied the behavioral phenotypes in mice with the most common human BBS mutation, BBS1<sup>M390R/M390R</sup>. Open field testing, carbon dioxide evoked freezing, elevated plus maze evaluation, and marble burying testing examine anxiety-like behavior. Anxiety-like behavior is expressed by set patterns of defensive behavior such as apprehensions, sustained arousal, and vigilance. For the open field testing and carbon dioxide evoked freezing, there was no difference between BBS1<sup>M390R/M390R</sup> and wild type mice. For elevated plus maze evaluation, BBS1<sup>M390R/M390R</sup> mice showed less inhibitive anxiety than wild type mice. This was seen by the increased duration the BBS mutant mice stayed in the open arm (p=0.027). For the marble burying test, we found that BBS1<sup>M390R/M390R</sup> mice show an increased obsessive anxiety phenotype. This was accounted for by the increased number of marbles buried by the BBS mutant mice (p=0.015). To understand the impaired anxiety-like behavior in our BBS mutant mice, we studied the lateral amygdala (LA). The LA receives sensory inputs about potential threats. We assessed neuronal processing of the LA by testing its synaptic plasticity and strength using electrophysiology. The synaptic plasticity is impaired in the LA of BBS mutant mice as seen by the increased paired pulse ratio of the lateral amygdala (p=0.030). In addition, the synaptic strength of the LA is lower in the BBS mutant mice as seen by the decreased frequency and amplitude of the miniature excitatory postsynaptic currents (p=0.003, p<0.001). Impaired neuronal processing of potential threats by the lateral amygdala aligns with the impaired anxiety-like behavior in our BBS1<sup>M390R/M390R</sup> mice.

**Initial results from the meta-analysis of the whole-exomes of 20,000 schizophrenia cases and 45,000 controls.** *T. Singh*<sup>1,2,3</sup>, *B. Neale*<sup>1,2,3</sup>, *M.J. Daly*<sup>1,2,3</sup> on behalf of *Schizophrenia Exome Sequencing Meta-Analysis Consortium*. 1) Analytic and Translational Genetics Unit (ATGU), Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 2) Program in Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, Massachusetts, USA; 3) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA.

Schizophrenia is a debilitating psychiatric disorder that affects nearly 1% of the general population. Schizophrenia has been demonstrated to have a substantial genetic component, with common and rare variants contributing to individual risk. While over a hundred common risk loci have been implicated for schizophrenia, rare variant analyses from sequencing studies have yet to reliably implicate individual genes, presumably owing to power limitations. Here, we present the Schizophrenia Sequencing Meta-Analysis Consortium (SEMACE), a large multi-site collaboration to aggregate, generate, and analyze high-throughput sequencing data of schizophrenia to advance gene discovery. To date, we have sequenced and processed the whole exomes of over 20,000 schizophrenia cases and 45,000 matched controls using a standardized variant-calling and QC pipeline based on GATK and Hail, yielding one of the largest sequencing data sets of a complex trait to date. The included studies actively recruited from diverse global populations, and sampled individuals of European, Latin American, East Asian, Ashkenazi Jewish, and African American ancestry. Because our exomes were sequenced with various capture technologies over a span of seven years, we developed a novel pipeline to estimate exon-by-exon coverage of all sequencing batches in our data set, and incorporated this information during the quality control and analysis steps. After adjusting for local differences in coverage, we observed comparable quality metrics between different cohorts and sequencing waves, which we then took forward for analysis. We successfully replicated findings from earlier sequencing studies of schizophrenia, including a substantial enrichment of ultra-rare damaging variants in genes with a near-complete depletion of protein-truncating variants. We also recapitulated a significant burden of disruptive variants in genes and gene sets previously associated with other neurodevelopmental disorders. We present the first gene-based burden results from our exome meta-analysis, and extend the sample using an independent set of 4,000 whole-genome sequenced cases and 7,000 controls. Finally, we present a new browser for exome association results that allows for easy viewing of identified variants and gene-based results. In summary, we introduce the largest multi-center effort to aggregate sequencing data of a psychiatric trait, and the initial results from the harmonization and analysis of over 65,000 exomes.

**2139F**

**Enrichment of treatable metabolic disease gene variants in a large cohort of schizophrenia, bipolar and major depressive disorder patients.** *V. Sriretnakumar*<sup>1,2</sup>, *R. Harripaul*<sup>4,5</sup>, *K. Mittal*<sup>1</sup>, *J. Vincent*<sup>4,5</sup>, *J. Kennedy*<sup>1,3,4</sup>, *J. SO*<sup>1,2,3,4,6</sup>. 1) Neurogenetics Lab, Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada; 2) Laboratory Medicine and Pathobiology (LMP), University of Toronto, Toronto, Ontario, Canada; 3) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 4) Institute of Medical Sciences, University of Toronto, Toronto, Ontario, Canada; 5) Molecular Neuropsychiatry and Development Laboratory, Centre for Addiction and Mental Health (CAMH), Toronto, Ontario, Canada; 6) The Fred A. Litwin Family Centre in Genetic Medicine, University Health Network and Mount Sinai Hospital, Toronto, Ontario, Canada.

Genetic diseases are individually rare but collectively common. Many genetic conditions can mimic mental health disorders, with psychiatric symptoms that are difficult to treat with regular medications. Treatment of the underlying genetic disease can cure the associated psychiatric symptoms or help regular medications work better. Discovery of rare genetic diseases in psychiatric patients would reveal specific treatment options, and give information about the chances of other family members being affected. In this study, we test the hypothesis that psychiatric populations are enriched for pathogenic variants associated with selected treatable genetic disorders. Using targeted exome sequencing, we screened 2,046 schizophrenia, bipolar and major depressive disorder patients for variants in genes associated with Niemann-Pick disease type C (NPC), Wilson disease (WD), homocystinuria (HOM), and acute intermittent porphyria (AIP). Our study is the first to explore the prevalence of NPC, WD, HOM and AIP gene variants in well-defined psychiatric populations. We found carrier rates of 0.88%, 0.88% and 0.20% for NPC, WD and HOM, respectively. Furthermore, an AIP affected rate of 0.20% was observed across the entire psychiatric cohort, a 200X enrichment in comparison to what is expected in the general population. Discovering genetic diseases in psychiatric patients will shift how health care is delivered to these vulnerable patients by addressing underlying conditions rather than masking symptoms with medications and will especially help patients who don't respond to regular medications. This will lead to significant cost savings to the health care system.

**2140W**

**Integrated analysis supports *ATXN1* as a schizophrenia risk gene.** *B. Su, J.W. Liu.* Kunming Inst Zoology, Chinese Academy Sci, Kunming, Yunnan, China.

Protein-protein interaction (PPI) is informative in identifying hidden disease risk genes that tend to interact with known risk genes usually working together in the same disease module. With the use of an integrated approach combining PPI information with pathway and expression analysis as well as genome-wide association study (GWAS), we intended to find new risk genes for schizophrenia (SCZ). We showed that *ATXN1* was the only direct PPI partner of the known SCZ risk gene *ZNF804A*, and it also had direct PPIs with other 18 known SCZ risk genes. *ATXN1* serves as one of the hub genes in the PPI network containing many known SCZ risk genes, and this network is significantly enriched for the MAPK signaling pathway. Further gene expression analysis indicated that *ATXN1* is highly expressed in prefrontal cortex, and SCZ patients had significantly decreased expression compared with healthy controls. Finally, the published GWAS data supports an association of *ATXN1* with SCZ as well as other psychiatric disorders though not reaching genome-wide significance. These convergent evidences support *ATXN1* as a promising risk gene for SCZ, and the integrated approach serves as a useful tool for dissecting the genetic basis of psychiatric disorders.

**2141T**

**The role of miRNAs in 22q11.2 deletion syndrome.** *A.K. Victor<sup>1,2</sup>, M.E. Fuller<sup>2</sup>, S. Zakharenko<sup>2</sup>, L.T. Reiter<sup>2,3,4</sup>.* 1) IPBS Program, University of Tennessee Health Science Center, Memphis, TN; 2) Neurology, University of Tennessee Health Science Center, Memphis, TN; 3) Pediatrics, University of Tennessee Health Science Center, Memphis, TN; 4) Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN; 5) Department of Developmental Neurobiology, St. Jude's Children's Research Hospital, Memphis, TN.

22q11.2 deletion syndrome (22q11DS) has a variable clinical phenotype, which includes mild dysmorphic features, learning difficulties, hypernasal speech, congenital abnormalities and an increased risk for developing psychiatric disorders. Affected individuals have an ~30 times higher risk of developing schizophrenia than the general population. Using neuronal cultures derived from dental pulp stem cells of affected individuals and neurotypical controls we performed both miRNA and mRNA expression studies to look for gene dysregulation associated with schizophrenia (SCZ). We identified several mRNAs and miRNAs that may be involved in the 22q11DS. We identified 16 miRNAs significantly differentially expressed between 22qDS and control which putatively target three known SCZ associated genes: *DISC1*, *SYN2* and *HTR2A*. We hypothesize that when these miRNAs are overexpressed in 22q11DS neurons, transcript levels decrease for these SCZ associated genes. Here we overexpressed three *DISC1* targeting miRNAs into HEK293T cells to validate the interactions of the suspect miRNAs with the *DISC1* transcript. Pilot qRT-PCR experiments have shown that at least one of the predicted miRNAs decreases expression of *DISC1*. These experiments are the first steps in identifying gene expression and regulatory miRNA changes in 22qDS neurons that may contribute to the SCZ phenotype in 22qDS.

**2142F****Identifying a shared regulatory background for neurodevelopmental disorders through meta-analysis of genome-wide association studies.**

Z. Yang<sup>1</sup>, T. Tsetsos<sup>1,2</sup>, P. Paschou<sup>1</sup>. 1) Dept of Biological Sciences, Purdue University, West Lafayette, IN, US; 2) Dept of Molecular Biology and Genetics, Democritus University of Thrace, Xanthi, Greece.

Gilles de la Tourette Syndrome (TS) is a neuropsychiatric disorder characterized by motor and vocal tics and high comorbidity rate with other neurodevelopmental disorders including Attention Deficit/Hyperactivity Disorder (ADHD), Obsessive-Compulsive Disorder (OCD), and Autism Spectrum Disorder (ASD). The high level of comorbidity rates among these disorders indicates a possible shared genetic basis, which has not yet been fully established. We set out to perform a cross-disorder meta-analysis across all four phenotypes based on published Genome-wide Association Studies (GWAS) on a total of 11394 cases across all disorders and 13,897 controls (ASD: 5,305 cases, ADHD: 2,787 cases, OCD: 1,889 cases, TS: 1,413 cases). We analysed 1,492 single-nucleotide polymorphism (SNPs) which we found as overlap among these datasets. We undertook a meta-analysis as implemented via the software METAL under a fixed-effects analysis model. According to the inverse variance based analytical strategy, the effect size estimates of each input dataset was weighed by the inverse of their corresponding standard errors. For heterogeneity analysis, we used Cochran's Q-test and I<sup>2</sup> test. As a result, two SNPs, rs4575830 ( $p = 3.05e-08$ ) and rs4306813 ( $p = 4.03e-08$ ), reached the genome-wide significant threshold. Both SNPs belong to a piece of intron variant on chromosome 3 and they are in linkage disequilibrium with each other. They reside on a non-coding RNA gene LOC101928135, which is associated with a set of enhancers including brain-enriched protein coding gene ARPP21, and other non-coding RNA genes including MIR128-2. Besides these, 16 additional SNPs were proven significant over Bonferroni correction. To our knowledge this is the first study trying to reveal the common genetic foundation for TS, ADHD, OCD and ASD. The regulation effect of the implicated gene sheds light into a possible shared underlying neurobiology for the studied disorders.

**2143W****A study of subthreshold hallucinatory experiences and thier relationship to genetic liability for schizophrenia.**

H. Young<sup>1</sup>, M. Liu<sup>1</sup>, R. Wedow<sup>1</sup>, A. Pandit<sup>2</sup>, E.M. Schmidt<sup>2</sup>, G.J.M. Zajac<sup>2</sup>, W. Li<sup>2</sup>, K. Brieger<sup>2</sup>, G.R. Abecasis<sup>2</sup>, S. Vrieze<sup>1</sup>. 1) Institute for Behavioral Genetics, University of Colorado, Boulder, CO, USA; 2) Department of Biostatistics and Center for Statistical Genetics, University of Michigan School of Public Health, Ann Arbor, MI., USA.

One hallmark symptom of schizophrenia is the presence of hallucinations. Consistent with the liability threshold model of schizophrenia, clinically subthreshold hallucinatory symptoms also occur in non-psychotic healthy individuals in the general population. Over 100 common variants have been associated with schizophrenia to date, but symptom specificity of these associations and associated neurobehavioral mechanisms are unknown and require study. The aim of the present work is to assess if subthreshold hallucinatory experiences and schizophrenia share genetic liability, and whether any known schizophrenia-associated locus influences hallucinations. In Genes for Good, an online study of health and behavior, 28,221 participants were administered the Launay-Slade Hallucination Scale (LSHS), a measure of predisposition to hallucinations. Of these individuals, 3,028 were genotyped on a genome-wide array and imputed to the Haplotype Reference Consortium panel. In addition to a genome-wide association study, we conducted a targeted genetic association study of 124 known risk variants associated with schizophrenia were tested for association with subthreshold hallucinatory experiences. Genetic correlations between schizophrenia and subthreshold hallucinations were tested with polygenic risk scores and LD score regression. In the dataset of 3,028 genotyped individuals, no reliable associations with hallucinatory experiences were found that reached genome-wide significance. None of the 124 previously established significantly associated schizophrenia risk variants were found to be significant after correcting for 124 tests. A polygenic risk score based on genetic vulnerability to schizophrenia with 80% power to detect a correlation of 0.05 was unable to successfully predict hallucinatory experiences using scores from the LSHS ( $p > 0.05$ ). LD score regression results will also be presented. All results will be presented on the current full dataset of 28,221 individuals, of whom ~8,000 will be genotyped. No substantial evidence was found to support the association between genetic liability for subclinical hallucinatory experiences and schizophrenia. However, more data from Genes for Good participants has become available and the above analyses are currently underway for a sample of 5,655 and growing, providing much greater power to rule out the existence of genetic correlations and shared associations between schizophrenia and subthreshold hallucinations.

**2144T****Genetics of attention deficit hyperactivity disorder dimensions.**

*T. Zayats<sup>1</sup>, C. Burton<sup>2</sup>, S. Medland<sup>3</sup>, B. Xiao<sup>2</sup>, J. Crosbie<sup>2</sup>, P. Arnold<sup>2,7</sup>, R. Schachar<sup>2</sup>, S. Johansson<sup>4</sup>, B. Neale<sup>5,6</sup>, J. Haavik<sup>1</sup>.* 1) K.G.Jebsen Center for Neuropsychiatric Disorders, Department of Biomedicine, University of Bergen, Bergen, Norway; 2) SickKids Research Institute, University of Toronto, Toronto, Canada; 3) Queensland Institute of Medical Research, Brisbane, Australia; 4) K.G.Jebsen Center for Neuropsychiatric Disorders, Department of Clinical Science, University of Bergen, Bergen, Norway; 5) Analytical and Translational Genetics Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, Massachusetts, USA; 6) Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 7) Mathison Centre for Mental Health Research & Education, University of Calgary.

Attention-deficit/hyperactivity disorder (ADHD) is one of the most common and heritable childhood onset psychiatric conditions. The clinical phenotype is multidimensional with main symptoms being inattention and/or hyperactivity/impulsivity. As ADHD persists into adulthood (in up to ~80% of cases), some symptoms become more pronounced than others. Furthermore, the various aggregates of dimensions are associated with different clinical features (e.g. co-morbidities) and treatment outcomes of ADHD. So far, the biology behind such symptomatology of ADHD is far from understood. In this study, we aimed to explore the genetics of ADHD dimensions in children and their correlation with neuropsychiatric phenotypes in adulthood. The childhood sample consisted of 11,784 children from (1) Australia (N=4,000), (2) Canada (N=4,339) and (3) Norway (The Norwegian Mother Child Cohort (MoBa), N=3,445). ADHD dimensions were measured by the Strengths and Weaknesses of ADHD and Normal Behavior (SWAN) rating scale in Australia and Canada, and by Swanson, Nolan and Pelham, Teacher and Parent Rating Scale (SNAP) in Norway. The genetic similarity of SWAN and SNAP measures was assessed by LD regression. We also examined how genetic risk for ADHD symptoms correlated with neuropsychiatric phenotypes in adulthood, including schizophrenia, major depression disorder, bipolar disorder, Alzheimer's disorder, subjective well-being, neuroticism and educational attainment. Overall, our preliminary results (N=3,445, SNAP data) suggest that the genetics of hyperactivity/impulsivity dimension in childhood show higher correlation with genetics of neuropsychiatric phenotypes in adulthood than that of childhood inattention, with strong contrasts between genetic correlations of hyperactivity/impulsivity and inattention with schizophrenia ( $h^2=-0.115$  and  $0.0037$ ), depressive symptoms ( $h^2=0.483$  and  $0.278$ ), subjective well-being ( $h^2=-0.564$  and  $-0.369$ ), anxiety ( $h^2=0.307$  and  $0.188$ ) and Alzheimer's disease ( $h^2=0.280$  and  $0.076$ ). We will present the results from the full sample (N=11,784). Further exploration of how ADHD dimensions in childhood relate/lead to neuropsychiatric pathology in adulthood will aid our understanding of biological processes underlying ADHD symptomatology and, potentially, lead to better diagnosis, treatment and prevention options for ADHD.

**2145F****Gene-based meta-analysis of GWAS in African American and European ancestry populations implicates novel genes for PTSD.** *H. Zhang, J. Jung, S.P. Chou.* NIH/NIAAA, Rockville, MD.

Post-traumatic stress disorder (PTSD) is a prevalent, serious mental health condition. Genetic factors account for up to 30-40% of the risk for PTSD. Previous genome-wide association studies (GWAS) mainly focus on individual genetic variant. This approach limits the statistical power to detect the aggregated effects of a set of SNPs within truly susceptibility genes. By using publicly available summary data, gene-based tests for association were performed on the largest GWAS of PTSD (summary results downloaded from Psychiatric Genomics Consortium), including 2,479 cases and 6,744 controls in the seven African American (AA) cohorts and 2,424 cases and 7,113 controls in the nine European ancestry (EA) cohorts. The GCTA-fastBAT (a fast and flexible set-Based Association Test) program was employed to conduct gene-based association analysis using GWAS summary data in each ethnic group separately, followed by meta-analysis on gene-based association results across ethnic groups using Fisher's method. A total of 17 PTSD-associated genes ( $P < 10^{-3}$ ) were identified by gene-based association method in the AA discovery cohort. Among them, 2 genes (SPPL2C and RHCG) passed a marginally significant threshold ( $P \leq 0.06$ ) in the EA replication cohort and produced significant outcomes ( $P < 10^{-3}$ ) in meta-analysis. Furthermore, 7 additional genes (ISOC1, MIR4633, VAMP5, MIR4320, P2RY2, RNF181, TMEM150A) passed the significant threshold in both AA and EA cohorts (discovery  $P \leq 0.01$ , replication  $P \leq 0.05$ , meta-analysis  $P \leq 0.001$ ) and were suggested to be related to PTSD susceptibility. For example, MIR4320 gene (microRNA 4320) on 18q21.1 was associated with PTSD (discovery  $P = 7.7 \times 10^{-3}$ , replication  $P = 5.7 \times 10^{-3}$ , meta-analysis  $P = 4.9 \times 10^{-4}$ ). Our gene-based meta-analysis of GWAS identified several novel genes underlying susceptibility to PTSD. Our results demonstrated the importance and power of the gene-based GWAS methods in identifying and further prioritizing loci of interest for complex traits or common diseases.

**Centrality pattern of susceptibility genes to complex disorders in functional specific protein-protein interaction sub-networks.** *T. Zhang<sup>1</sup>, N.L. Saccone<sup>2</sup>, J.P. Rice<sup>2</sup>.* 1) Dept. of Epidemiology and Biostatistics, School of Public Health, Xi'an Jiaotong University, Xi'an, Shaanxi, China; 2) Department of Psychiatry, Washington University in Saint Louis, Saint Louis, MO, USA; 3) Department of Genetics, Washington University in Saint Louis, Saint Louis, MO, USA.

The biological process of human beings is regulated through complex molecular networks. One of the most important features of network is that the effect that is caused by blocking one pathway within a network can be bypassed through some other "back door pathways". This indicates that, if a gene loses its function because of a mutation occurs within it, and if it does not locate at the central position of a gene network, it may have little impact to the biological process due to the bypassing effects. On the other hand, if this gene has a relatively high centrality in the gene network, the loss of its function may block several pathways simultaneously and therefore no bypassing pathway can be used to supplement its loss of function. In this study, we will present that what the centrality distribution pattern would be in function specific sub-networks for several sets of susceptibility genes contributing to complex disorders. Gene expression data of human brain tissue recorded in the Human Protein Atlas were extracted and utilized to construct a series of brain function specific sub-networks. Susceptible genes from three categories of complex disorders, including neurodegenerative disorder, psychiatric disorder and non-brain related disorder, were extracted from the GWAS catalogue. We identified a significant enrichment pattern of high centrality of susceptibility genes contributing to neurodegenerative and psychiatric disorders in these sub-networks. Our findings indicate that susceptibility genes of complex disorder might have higher centralities in functional specific sub-networks. Our study provide a primary evaluation of the significance of centrality measures calculated from function specific sub-networks as indicators of the biological functions of relevant genes.

**2147T**

**Rare human knockouts in consanguineous pedigrees aggregated with schizophrenia and bipolar disorder compared to matched healthy population controls.** *Q. He<sup>1</sup>, A. Dionne-Laporte<sup>2</sup>, D. Spiegelman<sup>2</sup>, R. Joob<sup>2</sup>, G.A. Rouleau<sup>2</sup>, L. Xiong<sup>1,4</sup>.* 1) Centre de recherche, Institut universitaire en santé mentale de Montréal, Université de Montréal, Canada; 2) Montreal Neurological Institute and Hospital, McGill University, Montreal, Canada; 3) Douglas Mental Health University Institute, McGill University, Montreal, Canada; 4) Département de psychiatrie, Faculté de médecine, Université de Montréal, Montréal, Canada.

**Introduction:** Recent publications reported that highly consanguineous populations like Pakistan would result in offspring carrying certain homozygous loss-of-function (homLOF) variants without major disease phenotypes. Isolated populations, such as Icelandic and Finnish population with recent bottlenecks, could also carry such rare complete human knockouts without severe outcomes. However, study of unrelated Swedish schizophrenia cases and controls reported an elevated burden of gene-disruptive and protein-damaging ultra-rare variants (variants unique to individuals) in affected individuals. **Samples and methods:** 123 schizophrenia and bipolar disorder affected individuals and 107 unaffected family members from 10 large consanguineous pedigrees underwent whole-exome sequencing (WES). WES data of 3222 healthy British Pakistani-heritage adults and 96 Punjabi Pakistanis samples from 1000 Genomes Project were used as external matched population controls. Unified variant-calling algorithms, consistent variant quality control and aligned gene annotation pipeline were applied to these datasets. **Results:** 1) In total, 3225 high-quality LOFs were identified from the 230 exomes of 10 pedigrees (20.5% as singletons), each individual carries on average  $5.5 \pm 2.6$  rare homozygotes (rhomLOFs) and  $53.2 \pm 13.0$  rare LoF heterozygotes; however, the affected individuals tend to have slightly more rare homozygotes ( $5.9 \pm 2.6$ ) compared to unaffected individuals ( $5.1 \pm 2.4$ ); 2) No perfect segregation of the rhomLOFs (shared by all affected but not any unaffected) are running in each pedigree; 3) 104 selected genes with rhomLOFs have only 0-23 overlaps with reported rhomLoF genes from the ExAC samples, the healthy British Pakistanis, and the Pakistanis in Myocardial Infarction Study, the Icelandic and Finnish populations (total of 44 overlapped genes collectively); 4) Only 6.7% of 104 genes are intolerant to LOFs, similar to the proportion of constraint genes in other human knockout reports from isolated and inbred populations. **Conclusion:** The rare homozygous knockout variants seem to be mainly population specific and the ones found in our consanguineous pedigrees with psychiatric disease show a complicated profile, without satisfying the classical recessive model. More comprehensive and in-depth comparisons with the unaffected family members and matched population controls are under way, as well as comparing to the LOF genes from other cohorts.

**Catalogue of 1 billion candidate ultra rare variants across 11670 Han Chinese individuals.** *S. Mangul, E. Eskin, J. Flint.* University of California, Los Angeles, Los Angeles, CA, 90025, USA.

Currently, we have relatively complete catalogs of common genetic variants and assessments of their contribution to complex traits. However, we lack similar knowledge for ultra-rare variants (URVs). Next-generation sequencing has the potential to generate the required information, but the cost currently is too high to collect data from sufficiently large sample sizes. Here we describe the use of a new method (RAREV) to capture URVs from low-coverage sequencing data. Standard methods of variant calling typically discard singleton variants supported by a single read, since the error rates are assumed to be too high for this information to be useful. We show that it is possible to obtain reliable information about sequence variants even from a single read. To test RAREV, we applied the method to 500 individuals from the 1000 Genomes Project who were subject to both whole exome (WES) and whole genome (WGS) sequencing. To obtain a gold standard and evaluate the performance of RAREV on low coverage WGS data, we used alleles with a coverage of greater than 10 reads per allele from WES. Direct detection of variants based on pileup data, including URVs supported by a single read, resulted in a false positive rate of 1%. We then applied RAREV, which includes a multi-step filtering procedure to exclude spurious signals due to error introduced by sequencing machine or mismapping. RAREV was able to reduce the false positive rate down to 0.0001%. We applied RAREV, to 11670 samples from the CONVERGE Consortium, which were sequenced at a median coverage of 1.7X. RAREV was able to detect 1 billion variants, including 30 million tri-allelic variants (i.e., sites with two different alternative alleles). We identified 480 million singletons variants, including variants supported by a single read. The vast majority of variants fall into intronic and intergenic regions. Intronic includes 47% of the variant and intergenic 32% of the variant. While the positions of URVs across the genome are in line with current views, the distribution of alleles is non-random, with a higher than expected proportion lying within gene intronic regions. We identify 2540 genes with low rates of variants (LRV) and compare those genes to LRV genes reported in ExAC. We then explore the use of our variants to understand the contribution of URVs to common complex diseases, such as major depression disorder, and we identify specific sets of genes that are enriched in deleterious mutations (LOF).

**Association between TNF- $\alpha$  G-308A polymorphism and depression: A meta-analysis.** *T. Kim<sup>1</sup>, H.C. Jeong<sup>2</sup>, S.N. Kim<sup>3</sup>, K. Shin<sup>2</sup>.* 1) Department of Clinical Pharmacology, Konkuk University Medical Center, Seoul, Republic of Korea; 2) College of Pharmacy, Research Institute of Pharmaceutical Sciences, Kyungpook National University, Daegu, Republic of Korea; 3) Department of Psychiatry, Seoul National University College of Medicine, Seoul, Republic of Korea.

Although a number of studies have investigated the association between a single nucleotide polymorphism (SNP) TNF- $\alpha$  G-308A and depression, the relationship between TNF- $\alpha$  G-308A and depression remains controversial. To clarify the role of TNF- $\alpha$  G-308A polymorphism on the risk of depression, we performed a meta-analysis. Related studies were searched from PubMed, Medline, Embase and Scopus (up to April 18, 2017). The odds ratios (ORs) and 95% confidence intervals (CIs) were estimated in the models of allele comparison (G vs. A), homozygote comparison (GG vs. AA), dominant (GG + GA vs. AA), and recessive (GG vs. GA+AA) to estimate the strength of the associations. A total of 10 case-control studies were included in this meta-analysis. Overall, no significant association between TNF- $\alpha$  G-308A and depression was found (G vs. A: OR [95% CI]=1.09 [0.92, 1.29]; GG vs. AA: 1.24 [0.71, 2.15]; GG+GA vs. AA: 1.22 [0.70, 2.13]; GG vs. GA+AA: 1.01 [0.76, 1.35]). However, in Asian subgroup analyses, there was a trend that the frequency of depression was higher in genotype AA than in other genotypes (GG vs. AA: 2.34 [0.98, 5.57],  $P=0.06$ ; GG+GA vs. AA: 2.29 [0.96, 5.49],  $P=0.06$ ). In conclusion, we found that the TNF- $\alpha$  G-308A polymorphism is not associated with susceptibility to depression. However, the result of Asian subgroup analysis suggested potential ethnic difference in the effect of TNF- $\alpha$  G-308A polymorphism on the susceptibility of depression.

**Antidepressant effectiveness study in major depressive disorder in STAR\*D patients.** *W. Guo<sup>1</sup>, L. Hou<sup>1</sup>, A.J. Rush<sup>2</sup>, F. McMahon<sup>1</sup>, Y.Y. Shugart<sup>1</sup>.*  
1) National Institutes of Health, Bethesda, MD; 2) Duke – National University of Singapore, Singapore.

Sequenced treatment alternatives to relieve depression (STAR\*D) Study aimed to assess the effectiveness of depression treatments in 4,041 outpatients with major depression. In the STAR\*D data, four levels of the study were designed to assess the effectiveness of depression medication in patients with major depressive disorder. Our GWAS study will focus on the level 1, in which participants were given the All participants began at Level 1, and were treated with the antidepressant citalopram (Celexa), a selective serotonin reuptake inhibitor (SSRI) from 2 to 14 weeks. In this study, QIDS-SR<sub>16</sub> was used as the primary measure to report Celexa's efficacy. To check the imputation quality, the imputed genotypes of STAR\*D data were compared with the original genotyped genotypes or imputed genotypes of STARD-Omni1S data to evaluate the quality of imputation. About 80% of the genotyped genotypes showed Pearson correlation between the imputed genotypes of STAR\*D data and the original genotyped genotypes of STARD-Omni1S data. The genome-wide significant SNP was rs17071498 ( $P = 1.49 \times 10^{-8}$ ) which was obtained in GWAS of QIDS-SR<sub>16</sub> on exit week and linked to ARF4P4 gene ( $r^2 = 0.9$  and distance=28kb). The ARF4P4 gene has an association with Nerve tissue in GTEX samples. .

1) Morphology and Genetics, Universidade Federal de São Paulo, São Paulo, São Paulo - SP, Brazil; 2) Interdisciplinary Laboratory of Clinical Neurosciences, Universidade Federal de São Paulo, São Paulo - SP, Brazil; 3) Department of Psychiatry, Universidade Federal de São Paulo, São Paulo, São Paulo - SP, Brazil; 4) Department of Psychobiology, Universidade Federal de São Paulo, São Paulo, São Paulo - SP, Brazil; 5) Department of Psychiatry - Faculty of Medicine, Universidade de São Paulo, São Paulo, São Paulo - SP, Brazil; 6) Department of Psychiatry, Universidade Federal do Rio Grande do Sul, Porto Alegre - RS, Brazil; 7) Center of Mathematics, Computation and Cognition, Universidade Federal do ABC, São Paulo, São Paulo - SP, Brazil; 8) Laboratory Center for Applied Genomics of Children's Hospital of Philadelphia, United States; 9) Amity Institute of Biotechnology - Amity University, Noida - India.

Psychiatric disorders are one of the main causes of youth disability. Maltreatment suffered during childhood might be an important risk factor for the development of these disorders. Furthermore, there are studies showing a strong relationship between telomere length (TL) and child maltreatment (CM). We investigated whether there is a relationship between TL and psychiatric diagnoses, psychopathology and CM in childhood and adolescence. We accessed biological data of 559 children from a large prospective community school-based study in Brazil, the High Risk Cohort (HRC) Study for Psychiatric Disorders in Childhood, from 6 to 14 years old, wherein 165 were children and adolescents with a psychiatric disorder (according to DSM-IV) and 394 controls (children with no psychiatric disorder). We also had access to the children psychopathology scales (CBCL) and to CM data. TL was accessed from blood and measured by a multiplex quantitative polymerase chain reaction (q-PCR). The technique consists in determining the relative ratio (T/S) between the telomere region copy number (T) and a single copy gene (S), using a relative standard curve. We used the albumin gene (*ALB*) as the single copy gene. After using TL as dependent variable in generalized linear models, we found no significant association was observed between TL measurement and psychiatric disorder, comparing cases and controls. There was also no correlation between TL and CM (i.e. physical neglect, physical, sexual or emotional abuse) or psychiatric symptoms. On the other hand, considering the interaction effect between gender and CM and correlation with TL, boys who experienced more early life traumas seem to have a shorter TL. Other studies have shown a diminished telomere in adults who reported experiencing early life stress, as CM and related trauma. Although our result is in agreement with literature, we expected to find a shorter TL also among girls. The maintenance of TL in girls might be influenced by hormonal processes. Estrogen is thought to induce telomerase activity, providing a possible protection of telomeres from oxidative stress from early life adversity. The telomere shortening mechanism seems to biologically reflect the damages early life stress as CM may cause.

**2152W**

**Preliminary analysis of whole genome sequences of simplex autism spectrum disorder.** M.B. Neu<sup>1,2</sup>, D. Gray<sup>1</sup>, M. Thompson<sup>1</sup>, J. Lawlor<sup>1</sup>, B. Weaver<sup>1</sup>, S. Hiatt<sup>1</sup>, J. Whittle<sup>1</sup>, K. Bowling<sup>1</sup>, C. Finnila<sup>1</sup>, G. Cooper<sup>1</sup>. 1) HudsonAlpha Institute for Biotechnology, Huntsville, AL; 2) University of Alabama at Birmingham, Birmingham, AL.

While large-scale DNA sequencing has led to the discovery of many genes and genetic variants underlying Autism Spectrum Disorder (ASD) risk, many cases remain in which genetic causes have not been identified. To this end, we exploit whole genome sequencing (WGS) data of simplex ASD families from the Simons Simplex Collection (SSC) to identify novel genetic variation in ASD-affected individuals, who previously underwent exome sequencing, but no causal variation was detected. WGS from ~540 simplex ASD families from the SSC, each of which includes an affected proband, unaffected sibling, and both biological parents, are undergoing variant analysis to identify candidate diagnostic variants. In parallel, computational methods are being used to logically group variants according to biological pathway, known ASD genes/pathways, and mutation type, with an emphasis on annotations of non-coding functionality. Differences between affected probands and unaffected siblings are being assessed using CADD, a quantitative method for scoring variant impacts. Due to ASD's higher prevalence in males, we are also examining variants in sexually dimorphic pathways and assessing variant subsets transmitted from mothers to affected sons to explore a possible "female protective" mechanism for otherwise pathogenic single variants. Preliminary comparisons between ASD probands and their unaffected siblings reveal no statistically significant difference in burden or CADD score of de novo variants. Furthermore, maternally inherited variants grouped by gene do not have a statistically significant CADD score distribution difference between probands and their unaffected siblings. A more clear understanding of genetic variant contributions to ASD risk may serve to both increase clinical diagnostic effectiveness and identify ASD-associated genes, pathways, and molecular mechanisms. This data may also be useful for identifying potential future therapeutic targets.

**2153T**

**Autism spectrum disorder in the Amish: Exome sequencing in a founder population unveils novel coding variants.** C.G. Tise<sup>1</sup>, J.W. Kleinberger<sup>1</sup>, M.A. Pavlovich<sup>1</sup>, M.L. Daue<sup>1</sup>, J.A. Perry<sup>1</sup>, J.R. O'Connell<sup>1</sup>, J.G. Reid<sup>2</sup>, J.D. Overton<sup>2</sup>, L.M. Yerges-Armstrong<sup>1</sup>, A.R. Shuldiner<sup>2</sup>, N.A. Zaghoul<sup>1</sup>. 1) Program in Personalized and Genomic Medicine, University of Maryland School of Medicine, Baltimore, MD; 2) Regeneron Genetics Center LLC, Regeneron Pharmaceuticals Inc., Tarrytown, NY.

**Background:** Autism spectrum disorder (ASD) is a heterogeneous disorder that affects 1 in 68 children in the U.S., occurring in all racial, ethnic, and socioeconomic groups, with males affected almost five-times more often than females. The heritability of ASD is estimated to be 50%, suggesting both genetic and environmental factors contribute significantly to the etiology of the disorder. To date, sequencing efforts to identify genetic determinants of ASD have focused largely on *de novo* copy number variants and loss-of-function variants in severely affected children. In this study, we evaluated exonic variants for association with quantitative measures of social impairment within the autism spectrum among adult subjects. **Methods:** The Social Responsiveness Scale™, Second Edition (SRS-2), Adult Self-Report Form by Western Psychological Services was administered to 203 generally healthy Amish adults (110 women, 93 men) who were participants in ongoing studies at the University of Maryland Amish Research Clinic. The SRS-2 is a 65-item, Likert-scale, objective measure of symptoms associated with ASD used to identify the presence and severity of social impairment within the autism spectrum, with higher scores correlating with increased severity (normal ≤59, mild 60-65, moderate 66-75, severe ≥76). Using exome sequencing data, an exome-wide association analysis (ExWAS) of SRS-2 score as a continuous trait was performed using Mixed Models for Analysis of Pedigree/Populations (MMAP), adjusting for age, sex, and relatedness. Results were limited to exonic variants in Hardy-Weinberg equilibrium ( $P \geq 0.05$ ) with at least five heterozygotes. **Results:** SRS-2 scores ranged from 37-75 with a mean of  $49.3 \pm 6.1$  (SD). Two variants, each associated with increased SRS-2 score, reached exome-wide significance ( $P < 1 \times 10^{-6}$ ): rs368577988 in *SR-related CTD associated factor 1* (*SCAF1* p.A262V;  $\beta = 9.5$ ,  $P = 4.6 \times 10^{-7}$ ) and rs752371351 in *Spermatogenesis associated 13* (*SPATA13* p.V540M;  $\beta = 14.7$ ,  $P = 8.8 \times 10^{-7}$ ). Both genes are highly expressed in brain tissue according to data from the Genotype-Tissue Expression (GTEx) project. **Conclusion:** We evaluated adults across the full spectrum of ASD-related behavioral traits, and through ExWAS, identified germ-line variants in several genes that may provide insight into disease mechanisms and identify potential drug targets. Extension and replication of these findings will be required to confirm and further refine these novel genetic signals.

**2154F**

**Mid-childhood adaptive function in individuals with 22q11.2 deletion syndrome is associated with immune-deficiency, but not oral/palatal or cardiac phenotypes.** *J.G. Baskin<sup>1</sup>, O.Y. Ousley<sup>2,3</sup>, K. Coleman<sup>1,3</sup>, J.F. Cubells<sup>1,2</sup>.* 1) Dept. of Human Genetics, Emory University School of Medicine, Atlanta, GA; 2) Emory Autism Center, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, GA; 3) Marcus Autism Center, Department of Pediatrics, Emory University School of Medicine, Atlanta, GA.

Common features of 22q11.2 deletion syndrome (22q11.2DS) include heart malformations, oral/palatal anomalies, and immune deficiency. These and other clinical features of 22q11.2DS vary widely among patients. We tested the hypothesis that the presence of at least one of these features would associate with poorer adaptive function in patients with the syndrome. While most studies suggest no association between cardiac malformations and adaptive function, no studies to date have examined oral/palatal or immune phenotypes with regard to adaptive function. This retrospective medical chart review used the Adaptive Behavior Assessment System, Second edition (ABAS-II) to evaluate adaptive function in 54 children, 6-12 years old, with 22q11.2DS ( $M = 9.0$ ,  $SD = 2.2$ ). The ABAS-II is a parental report questionnaire from which a general adaptive composite (GAC) score can be derived. Children were assessed for heart malformations, oral/palatal anomalies, and immune deficiency as well as other clinical features during visits to a specialty clinic for 22q11.2DS. During those visits, parents filled out the ABAS-II. We compared ABAS-II GAC scores among children with and without each 22q11.2DS-associated clinical feature. GAC scores followed a normal distribution that was shifted downward from the general population norms ( $M = 72.5$ ,  $SD = 17.1$ ). Based on the results of t-test analysis, we found that presence of oral/palatal anomalies or cardiac defects did not associate with GAC scores. However, children without immune deficits had significantly higher mean GAC scores ( $M = 86.2$ ,  $SD = 17.7$ ), compared to children with immune deficits ( $M = 71.1$ ,  $SD = 16.6$ );  $t(52) = 1.93$ ,  $p < .05$ , one-tailed, suggesting that less immune impairment associates with higher adaptive function in children with 22q11.2DS. In conclusion, children with 22q11.2DS exhibit lower mean adaptive function compared to normative data, but the presence of cardiac or oral/palatal anomalies does not further impair functioning. However, children with more immune impairment show lower GAC scores than those without immune deficiencies. Our results suggest that all children with 22q11.2DS should receive periodic assessment of adaptive function to guide specific interventions. Those with documented immune deficits should receive even closer attention. These observations may be useful to parents receiving genetic counseling for children with 22q11.2DS.

**PYROXD1 is responsible for cellular functions in myoblasts and homozygous missense mutation in PYROXD1 causes limb-girdle muscular dystrophy among patients from Saudi Arabian cohort.** *M. Saha<sup>1</sup>, H.M. Reddy<sup>1</sup>, M. Salih<sup>2</sup>, M. Jones<sup>1</sup>, S. Mitsuhashi<sup>3</sup>, K. Cho<sup>1</sup>, E. Estrella<sup>4</sup>, M. Lek<sup>5,6</sup>, B.B. Cummings<sup>5,6</sup>, E. Valkanas<sup>5,6</sup>, D.G. MacArthur<sup>5,6</sup>, L.M. Kunke<sup>4</sup>, C. Pacak<sup>7</sup>, P.B. Kang<sup>1,7,8</sup>.* 1) Department of Pediatrics, University of Florida, GAINESVILLE, FL; 2) Department of Pediatrics, Division of Neurology, King Saud University, Riyadh, Saudi Arabia; 3) Department of Neurology, Boston Children's Hospital & Harvard Medical School, Boston, MA; 4) Division of Genetics & Genomics, Boston Children's Hospital and Harvard Medical School, Boston, MA; 5) Analytic and Translational Genetics Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA; 6) Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge, MA; 7) Department of Neurology and Department of Molecular Genetics and Microbiology, University of Florida College of Medicine, Gainesville, FL; 8) Genetics Institute and Myology Institute, University of Florida, Gainesville, FL.

**Statement of purpose:** Limb-girdle muscular dystrophy (LGMD) is a neuromuscular disorder characterized by progressive proximal muscle weakness, accompanied by classic histological findings on muscle biopsy. *PYROXD1*, a gene that was recently associated with myofibrillar myopathy, is located at chromosome 12p12.1 in humans and encodes a pyridine nucleotide-disulfide oxidoreductase domain-containing protein. The missense mutation p.Asn155Ser in *PYROXD1* causes reduced expression of the encoded protein in muscles. Not much is known about the influence of *PYROXD1* in the cellular functions for muscular development. **Methods used:** Subcellular fractionation was confirmed by western blotting of subcellular fractions with respective antibodies. We used Dharmafect reagent to successfully transfect C2C12 myoblasts with *Pyroxd1* siRNA. RT-PCR was performed using Taqman probes. Proliferation assays, MTT assays, and Seahorse analysis were used to measure developmental and metabolic function. Desmin staining and measurement of myoblast fusion indices were performed as previously published.

**Summary of results:** We recruited and analyzed 16 families with LGMD from Saudi Arabia using traditional approaches and whole exome sequencing. One family was found to have a mutation in *PYROXD1*, demonstrating that mutations in this gene may also cause LGMD. Subcellular fractionation and immunofluorescence analysis indicated that the localization of endogenous *Pyroxd1* to be nucleocytoplasmic in myoblasts. *Pyroxd1* siRNA was transiently transfected into C2C12 myoblasts and successful knockdown was confirmed via RT-PCR and western blot analysis. *Pyroxd1* knockdown myoblasts demonstrated significant proliferation defects compared to control scrambled siRNA treated myoblasts, as shown in NF CyQuant assays. Impaired desmin staining and reduced myoblast fusion indices indicate that the process of differentiation is also impaired in *Pyroxd1* knockdown myoblasts. MTT assays suggested reduced metabolic activity in *Pyroxd1* knockdown myoblasts. More specifically, *Pyroxd1* knockdown myoblasts exhibited decreased oxygen consumption rates (OCRs), basal respiration, and spare respiratory capacity on Seahorse assays. **Conclusion:** These analyses reveal that *PYROXD1* mutations may cause LGMD as well as myofibrillar myopathy, and that *Pyroxd1* deficiency leads to developmental and metabolic defects in mouse myoblasts.

**Using electronic health records for the identification of novel genes associated with adverse drug reactions.** L. Milani<sup>1</sup>, K. Krebs<sup>1</sup>, T. Tasa<sup>1,2</sup>, M. Kals<sup>1</sup>, R. Mägi<sup>1</sup>, T. Esko<sup>1</sup>, J. Vilo<sup>2</sup>, A. Metspalu<sup>1</sup>. 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Computer Science, University of Tartu, Tartu, Estonia.

Combining genomic information with electronic health records (EHRs) provides new opportunities for the interpretation of the role of genetic variation in different diseases and traits. Despite recent advances in pharmacogenomic research, interindividual variability in drug metabolism and sensitivity for drug toxicity persists as a major problem for drug development and treatment. To address this, we designed a study of adverse drug reactions using specific ICD-10 codes extracted from the EHRs of biobank participants, and tested for their association with rare and common genetic variants among individuals who had purchased prescription drugs according to records from the Estonian Health Insurance Fund. We sequenced the whole genomes of 2,240 participants of the Estonian biobank using PCR-free sample preparation and 30x coverage at the Broad Institute, and further included all variants imputed for 14,219 genotyped subjects in the biobank. In the Estonian population, we found 4.1 million previously undetected single nucleotide variants (SNVs). When focusing on 64 genes highly involved in drug response (pharmacogenes) and genetic variants predicted to have high impact on protein function in this large dataset, we detected 46 loss-of-function (LoF) and 656 non-synonymous SNVs of which more than 22% were novel and more than 80% were rare with minor allele frequencies (MAF) <0.5%. Each individual carried an average of 1 LoF and 34 non-synonymous variants in these genes, which all require further studies to confirm their effects on drug response phenotypes. When focusing on 64 genes important in drug response and by linking genetic data with the EHRs we were able to validate several previously documented genetic variants associated drug induced ADRs. By genome wide analysis we identified a novel gene, *CTNNA3*, to associate with ADRs among individuals treated with oxycams. As drug prescription and EHRs were available for the entire cohort of 52,000 biobank participants, we were able to replicate this finding in an extended cohort of the biobank. In conclusion, EHRs can serve as a reliable tool for explorative pharmacogenomic studies. Very rare variants, however, will require deeper phenotyping and further studies to confirm their effects on drug response.

**2157F**

**The intersection of type 2 diabetes and cognitive impairment in Mexican Americans: Insights from the mitochondria.** T. Silzer<sup>1,6</sup>, N. Phillips<sup>1,3,4</sup>, J. Sun<sup>1,3</sup>, R. Barber<sup>1,3,4</sup>, L. Johnson<sup>2,5</sup>, S. O'Bryant<sup>2,4</sup>. 1) Institute for Molecular Medicine, University of North Texas Health Science Center, Fort Worth, TX; 2) Institute for Healthy Aging, University of North Texas Health Science Center, Fort Worth, TX; 3) Center for Medical Genetics, University of North Texas Health Science Center, Fort Worth, TX; 4) Center for Aging and Neurodegenerative Disease Research, University of North Texas Health Science Center, Fort Worth, TX; 5) Center for Neuroscience Discovery, University of North Texas Health Science Center, Fort Worth, TX; 6) Graduate School of Biomedical Sciences, Genetics Program, University of North Texas Health Science Center, Fort Worth, TX.

Mitochondrial dysfunction and systemic stress response is common in many complex age-related diseases. Multiple environmental and genetic factors, including variants in both nuclear and mitochondrial DNA (mtDNA), may contribute to the cycle. The role of mitochondrial function in cognitive decline has not been studied in Mexican American populations. This group is of interest because of their rapidly growing population within the United States and because of the high prevalence of type 2 diabetes (T2D). T2D is strongly associated with accelerated cognitive decline, and Mexican American populations may be at higher risk for developing Alzheimer's disease (AD) due to the high prevalence of this comorbid condition. **Hypothesis.** Mitochondrial dysfunction and resulting systemic stress may provide a mechanistic link between T2D and cognitive decline. We investigate the intersection of cognitive impairment and T2D with respect to indicators of mitochondrial function (expression of key genes) and mitochondrially-sourced proinflammatory stressors (cell-free mtDNA, CFmtDNA). **Methods.** Peripheral blood samples (buffy coat and plasma fractions) were obtained from subjects of the Healthy Aging Brain among Latino Elders (HABLE) cohort. Individuals were partitioned into groups based on T2D diagnosis, and were matched across groups based on age, gender and cognitive status. Expression of key mitochondrial function genes was quantified from buffy coat RNA isolates (TRIzol™ Plus RNA Kit, ThermoFisher) using the Mitochondria RT2 Profiler qPCR array (Qiagen). Circulating cell-free mtDNA (CFmtDNA) was quantified within plasma using TaqMan®-based absolute quantification (Kavlick *et al.*, 2011) via real-time PCR performed on the 7500 Real-Time PCR system (Applied Biosystems); additional assays were conducted to further characterize CFmtDNA. **Results.** Preliminary analysis indicate group differences in CFmtDNA both with respect to T2D status and cognition; notably, a significant interaction was observed as individuals with T2D and cognitive impairment was responsible for the bulk of the effect between T2D+ and T2D- groups. Differential expression of mitochondrial related genes between T2D+ and T2D-individuals is anticipated as a result. **Conclusion.** CFmtDNA and mitochondrial dysfunction may be particularly important in key populations where inflammatory comorbidities (e.g., T2D) can exacerbate age-related cognitive decline and predispose individuals to earlier onset of dementia.

Neurological disorders with isolated symptoms or complex syndromes are relatively frequent among inherited mitochondrial diseases. Recently, we have shown that recessive pathogenic variants in *RTN4IP1* cause isolated and syndromic optic neuropathies (Angelbault et al. *Am. J. Hum. Genet.* 2015 <https://www.ncbi.nlm.nih.gov/pubmed/26593267>). We have used targeted and whole exome sequencing to delineate the spectrum of clinical phenotypes associated with pathogenic variants in *RTN4IP1/OPA10*, encoding a mitochondrial quinone oxidoreductase. Here we present the clinical and molecular investigations performed on 12 individuals from 11 families with CNS presentations ranging from isolated optic atrophy to severe encephalopathy, thereby clarifying the molecular diagnosis for patients with severe CNS diseases. Recessive, pathogenic *RTN4IP1* variants were identified in all patients. Six families, among them 5 consanguineous, presented with isolated optic atrophy in whom we identified previously-reported p.(Arg103His) or the novel p.(Ile362Phe), p.(Met43Ile) and p.(Tyr51Cys) amino acid substitutions (*RTN4IP1* Genbank accession number: NM\_032730.5). Five other families presented severe neurological syndromes with a common core of symptoms consisting of optic atrophy, seizures, intellectual disability, growth retardation and elevated lactates. Additional features were deafness, stridor, brain MRI abnormalities, and abnormal EEG patterns, eventually leading to death before the age of 3 years. In these patients, we identified rare homozygous and compound heterozygous pathogenic variants, associated with a loss of steady-state *RTN4IP1* protein levels, a defect in mitochondrial complex I assembly and mild fragmentation of the mitochondrial network. Our results confirm that a broad clinical spectrum of neurological features ranging from isolated optic atrophy to severe early-onset epileptic encephalopathies is associated with bi-allelic *RTN4IP1* variants, and should prompt screening of this gene in both syndromic neurological presentations and non-syndromic recessive optic neuropathies.

**Novel mutation in the *MT-ND4* gene at low heteroplasmy level likely associated with a mild phenotype: A case report. A. Gonzalez Garcia<sup>1</sup>, A. Rajadhyaksha<sup>2</sup>, P. Jayakar<sup>2</sup>.** 1) Medical Education, Nicklaus Children's Hospital, Miami, FL; 2) Genetics and Metabolism, Nicklaus Children's Hospital, Miami, FL.

The patient is an 8-year-old female with normal development who presented with seizures, headaches, tremors and exercise intolerance since age 3. Her symptoms have been stable and not progressive. MRI brain was normal and genetic testing including metabolic workup, CMA and WES were negative. Family history is significant for mother having migraines with aura. A muscle biopsy done showed mild degree of ultrastructural mitochondrial cytopathy with small fibers being affected; however mitochondrial enzymes in muscle were negative for respiratory chain enzyme deficiency. NGS on muscle showed the following: Heteroplasmic (4%) novel variant m.12054 G>A, on the *MT-ND4* gene causing an amino acid change from Arginine to Glycine at position 432 (p.R432G) and homoplasmic variant on *MT-ND2* m.4917 A>G (p.N150D). Mitochondrial sequencing in blood showed the same findings. Maternal testing for the variant in *MT-ND4* was negative in blood. The variant in the *MT-ND4* has not been described in literature. It is a semi-conservative amino acid substitution that may impact secondary protein structure as these residues differ in some properties. This position is conserved across species and In silico analysis predicts this is probably damaging to the protein. Based on these results, the variant was interpreted as a strong candidate for a disease causing mutation. Mutations in the *MT-ND4* have been reported to cause a variety of signs and symptoms including ataxia and seizures. Limited understanding of the phenomenon of heteroplasmy continues to make counseling on mitochondrial diseases challenging. The threshold for mutation load to produce a clinical phenotype or affect the mitochondrial respiratory chain is unknown. This novel heteroplasmic variant has not been identified as benign in the general population nor has it been described in literature as disease causing. Furthermore, this variant has not been noted in the mother probably due to lower than detection level in blood. However, it maybe present in tissues not tested. Although functional testing is required to further define the phenotype caused by this mutation we predict the p. R432G mutation in the *MT-ND4* gene to be pathogenic, likely disease causing.

**2160F**

**A hypertension-associated mtDNA mutation alters the tertiary interaction and function of tRNA<sup>Leu</sup>(UUR).** *M. Guan, M. Zhou, M. Wang.* Genetics, Zhejiang University, Hangzhou, Zhejiang, China.

Several mitochondrial tRNA mutations have been associated with hypertension. However, the pathophysiology of these tRNA mutations remains poorly understood. In this report, we identified the novel homoplasmic 3253T>C mutation in the mitochondrial tRNA<sup>Leu</sup>(UUR) gene in one Han Chinese pedigree with maternally inherited hypertension. The m.3253T>C mutation affected a highly conserved uridine at position 22 at D-stem of tRNA<sup>Leu</sup>(UUR). The m.3253T>C mutation introduced the G-C base-pairing (13G-22C) at the D-stem and formed a tertiary base pairing (22C-G46) with the G46 in the variable loop of tRNA<sup>Leu</sup>(UUR). It was anticipated that the m.3253T>C mutation may alter the structure and function of tRNA<sup>Leu</sup>(UUR). Using cybrid cell lines derived from the Chinese family, we demonstrated that the m.3253T>C mutation perturbed the conformation of tRNA<sup>Leu</sup>(UUR), as suggested by faster electrophoretic mobility of mutated tRNA with respect to the wild-type molecule. Northern analysis revealed ~45% decrease in the steady-state level of tRNA<sup>Leu</sup>(UUR) in the mutant cell lines carrying the 3253T>C mutation. Furthermore, ~35% reduction in aminoacylated efficiency of tRNA<sup>Leu</sup>(UUR) was observed in mutant cells derived from this Chinese JBC C o n f i d e n t i a l hypertension linked mitochondrial tRNA<sup>Leu</sup>(UUR) mutation 2 family. A failure in tRNA<sup>Leu</sup>(UUR) metabolism impaired mitochondrial translation, especially for polypeptides with a high proportion of Leu(UUR) such as ND6. Altered mitochondrial translation caused the decreasing activities of complexes I and V. Furthermore, marked decreases in the levels of mitochondrial ATP and membrane potential were observed in mutant cells. These mitochondrial dysfunctions caused an increasing production of reactive oxygen species in the mutant cells. Our findings may provide new insights into the pathophysiology of maternally inherited hypertension.

**2161W**

**Identification of genetic causes for age-related hearing loss.** *S.H. Blanton<sup>1,2,3</sup>, B.A. Schulte<sup>4</sup>, J.R. Dubno<sup>5</sup>, L.J. Matthews<sup>5</sup>, S. Guo<sup>2</sup>, X.Z. Liu<sup>1,2,3</sup>.* 1) Department of Human Genetics, University of Miami School of Medicine, Miami, FL; 2) John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 3) Department of Otolaryngology, University of Miami School of Medicine, Miami, FL; 4) Department of Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC; 5) Department of Otolaryngology-Head and Neck Surgery Medical University of South Carolina, Charleston, SC.

Age-related hearing loss (ARHL), also known as presbycusis, affects more than 28 million Americans, 75% of whom are over age 55. ARHL is a consequence of accumulated environmental stresses and part of the intrinsic genetically controlled aging process with heritability estimates of ~35-55%. Although several studies have attempted to identify the genetic underpinnings of ARHL, little is known about the underlying genes involved in its development and progression. Studies of animal models, human temporal bones, and human subjects have suggested several subtypes of ARHL recognizable by different pathological alterations and auditory phenotypes. To understand the development and progression of ARHL, we are analyzing results from the Medical University of South Carolina (MUSC) longitudinal database of >1,500 individuals who have been followed for up to 28 years. To investigate the contribution of specific genetic variants, a cohort of 501 adults >55 years of age and of European ancestry was assembled (mean age 72.3 years; 53% female). Whole exome sequencing was performed using the Agilent SureSelect XT Human All Exon V5-UTRs library capture kit. Study participants were classified using Quadratic Discriminant Analysis of pure-tone thresholds into one of four audiometric phenotypes: Older-Normal, Metabolic, Sensory, and mixed Metabolic+Sensory. We took a candidate gene approach and examined the data for association between audiometric phenotypes and variants in 203 known/possible deafness genes. Gene based associations were tested using SKAT-O with sex and age as covariates. In the analysis of Sensory vs. Older-Normal, one gene, *TBX4*, was significant ( $p=0.000166$ ), assuming a Bonferroni correction ( $p<0.00025$ ); 11 genes had a nominal  $p<0.05$ . None of the genes were significant in the Metabolic vs Older-Normal analysis; the top gene, *CLPP*, had a  $p=0.0073$  and an additional 5 genes had  $p<0.05$ . *KCNQ1* was the only gene with a  $p<0.05$  in both groups (0.034 and 0.023). *KCNQ1* encodes a voltage-gated potassium channel protein and mutations in this gene cause Jervell and Lange-Nielsen syndrome, which is characterized by congenital deafness, prolongation of the QT interval, syncopal attacks due to ventricular arrhythmias, and a high risk of sudden death. These results suggest that variation in deafness genes, while not a primary cause of ARHL, may contribute to the genetic etiology as well as to specific subtypes.

**2162T**

**Cochlear nerve deficiency presenting as auditory neuropathy spectrum disorder.** A. Pandya<sup>1</sup>, A. O'Brien<sup>1</sup>, P. Roush<sup>2</sup>. 1) Pediatric Genetics and Metabolism, University of North Carolina, Chapel Hill, NC; 2) Department of Otolaryngology, Head neck and Surgery, University of North Carolina, Chapel Hill, NC.

Cochlear nerve deficiency (CND) is a condition with an absent or hypoplastic cochlear nerve which may present with an auditory brainstem response (ABR) pattern consistent with Auditory Neuropathy Spectrum Disorder (ANSD). ANSD is clinically heterogeneous, with both, congenital and acquired causes. It accounts for more than 10% of all children with congenital hearing loss. Infants with ANSD have an abnormal auditory nerve response, as indicated by absent or abnormal ABR and, evidence of normal outer hair cell function as measured by either presence of a cochlear microphonic in the ABR or present otoacoustic emissions. Multiple etiologies including prematurity, hyperbilirubinemia, viral infections, hypoxia, and single gene sequence variants in the OTOF, and pejvakin genes can result in ANSD. Buchman et al. (2006) first reported the association of CND in nine of 51 children with ANSD, demonstrating unilateral or bilateral CND. To date, we know very little about the prevalence or etiology of CND in children. We present one of the largest series of patients with CND in the USA, ascertained through the Otolaryngology and Audiology clinic at UNC-Chapel Hill, and describe the demographic and clinical characteristics including their hearing loss profile, auditory neuropathy pattern, MRI findings, and existing co-morbidities. After IRB approval, we reviewed records on 267 patients diagnosed with ANSD from 1999-2016. Of the 254 probands in our cohort who had information on the laterality of ANSD, the majority (67.7%) had a bilateral and 32.3% had a unilateral auditory neuropathy. Overall, 15% (n=40) children had CND identified, and of those with a unilateral auditory neuropathy, 34% had cochlear nerve hypoplasia/aplasia identified by temporal bone imaging studies. All of them had a "refer" on their newborn audiologic screen however the age of diagnosis of CND ranged from birth to six years. In contrast to bilateral ANSD, only a minority of children with CND were born preterm and/or had hyperbilirubinemia, which are risk factors for ANSD. Response to cochlear implantation is also suboptimal in children with CND. Elucidating the clinical presentation and etiology for CND is critical to provide families with an accurate and timely diagnosis and to offer optimal rehabilitation. Children with CND represent a unique and homogenous group amongst the extreme heterogeneity noted with ANSD, and therefore offer an opportunity to determine a unifying genetic etiology. .

**Association of PMEL missense variants with ocular pigment dispersion and pigmentary glaucoma.** M.A. Walter<sup>1</sup>, A.A Lohola-Chomiak<sup>1</sup>, T. Footz<sup>1</sup>, T-K. Nguyen-Phuoc<sup>1</sup>, G.J. Neil<sup>2</sup>, W.T. Allison<sup>1,2</sup>, O.J. Lehmann<sup>1,3</sup>. 1) Dept Med Gen, Univ Alberta, Edmonton, AB, Canada; 2) Dept Biol Sci, Univ. Alberta, Edmonton, AB, Canada; 3) Dept Ophthalmol, Univ Alberta, Edmonton, AB, Canada.

Pigmentary glaucoma (PG) is the most common secondary glaucoma making it a major cause blindness worldwide. Previous research into PG demonstrated a substantial heritable component, but to date no candidate genes have been identified. We here report that variants in the melanosome structural protein premelanosome protein (PMEL) are associated with pigment dispersion syndrome (PDS) and PG. Whole exome sequencing of members in two Mennonite kindreds affected by PDS/PG identified several candidate genes of which *PMEL* was selected for further functional characterization based on its well established role in ocular pigmentation and the ocular phenotypes observed in several *Pmel* animal models. Targeted sequencing of *PMEL* in 114 additional sporadic cases revealed three additional missense variants. Functional analysis of these four (p.N111S, p.A340V, p.G370D, and p.L389P) variants using an *in vitro* cell culture system revealed defects in proteolytic cleavage (1 of 4), glycosyl group maturation (2 of 4), and melanosome fibril formation (4 of 4). Together these structural deficits provide evidence that the PG-associated variants in *PMEL* cause functional defects impacting *PMEL*'s normal ability to form amyloid fibrils. Intriguingly, these data may indicate these *PMEL* variants are gain-of function mutations that switch *PMEL* from a functional to a pathological amyloid. Disruption of the homolog *pmela* in zebrafish caused profound pigmentation defects in the eye further supporting *PMEL*'s role in ocular pigmentation. While *PMEL* mutations have previously been associated with pigmentation and ocular defects in animal models this research represents the first report of human disease-causing coding variants in *PMEL*.

**2164W**

**Gene-set enrichment analysis identifies pathways involved in tinnitus.** *E. Franssen<sup>1</sup>, A. Gilles<sup>2</sup>, P. Van de Heyning<sup>2</sup>, G. Van Camp<sup>1</sup>.* 1) Center for Medical Genetics, University of Antwerp, Antwerp, Belgium; 2) Department of Otorhinolaryngology, Head and Neck surgery, Antwerp University Hospital, Edegem, Belgium.

Tinnitus, the perception of an auditory phantom sound in the form of ringing, buzzing, roaring or hissing in the absence of an external sound source, is perceived by approximately 15% of the population and 2.5% experiences a severely bothersome tinnitus. Previous studies suggested only a minor contribution of genes to this condition, with a heritability estimate of 14% in a Norwegian study and a small GWAS in which the variance explained by all SNPs in the GWAS was estimated to be only 3.2%. None of the SNPs in this latter GWAS reached the threshold for genome-wide significance ( $p < 5.0 \times 10^{-8}$ ), with the most significant SNPs, situated outside coding genes, reaching a p-value of  $3.4 \times 10^{-7}$ . Here we report the results of gene set enrichment analysis on the results of this GWAS using the program MAGENTA. This highlighted several statistically significant metabolic pathways, including pathways involved in oxidative stress, endoplasmic reticulum (ER) stress and serotonin reception mediated signalling. These results are a promising basis for further research into the genetic basis of tinnitus, including GWAS with larger sample sizes and considering tinnitus subtypes for which a greater genetic contribution is likely.

**2165T**

**New risk loci for primary open-angle glaucoma.** *P. Gharahkhani<sup>1</sup>, A.W. Hewitt<sup>2</sup>, K.P. Burdon<sup>2</sup>, J.N. Cooke Bailey<sup>2</sup>, D.A. Mackey<sup>2,4</sup>, J.L. Wiggs<sup>5</sup>, J.E. Craig<sup>6</sup>, S. MacGregor<sup>1</sup>.* 1) Statistical Genetics, QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 2) University of Tasmania, Hobart, Tasmania, Australia; 3) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, OH; 4) Centre for Ophthalmology and Visual Science, Lions Eye Institute, University of Western Australia, Perth, Australia; 5) Department of Ophthalmology, Harvard Medical School, Massachusetts Eye and Ear Infirmary, Boston, MA; 6) Department of Ophthalmology, Flinders University, Adelaide, South Australia, Australia.

Primary open-angle glaucoma (POAG), characterised by irreversible optic nerve degeneration, is a major cause of blindness worldwide. Optic nerve parameters including cup area (the central area without nerve fibers), disc area (the total area of optic disc including cup area and the surrounding area containing axons of the retinal ganglion cells), and Vertical cup-disc ratio (the ratio of the cup area to the total diameter of the optic disc) are key measurements used to assess POAG progression. Raised intraocular pressure (IOP) is a known risk factor for POAG. Genome-wide association studies (GWASs) have identified several genetic risk loci associated with POAG, however, these risk loci together explain only a small proportion of the heritability. To identify additional risk loci, we performed a GWAS in 3,071 POAG cases and 6,750 unselected controls. To increase our statistical power to identify new risk loci for POAG, we performed a meta-analysis of the GWAS summary results for POAG with publicly available GWAS data for IOP and optic disc parameters. We identified and validated four novel genome-wide significant associations within or near *MYOF/CYP26A1*, *LINC02052/CRYGS*, *LMX1B*, and *LMO7*. We also used gene-based and pathway-based approaches to identify further genes and relevant cellular mechanisms involved in the development of POAG. We identified two additional new risk loci (*MIR3125* and *C9*) using gene-based tests, and two genetic pathways - "response to fluid shear stress" and "abnormal retina morphology" - in pathway-based tests. Interestingly, some of these new risk loci contribute to risk of other genetically-correlated eye diseases including myopia and age-related macular degeneration. Of further note, *LMX1B* is mutated in Nail-Patella Syndrome, characterised by nail, patella and elbow dysplasia, in which some patients develop POAG. Bioinformatics functional analyses suggested that these loci have functional relevance in the development of POAG. This study highlighted the potential of combining genetic data from genetically-correlated eye traits for the purpose of gene discovery and mapping. The novel risk loci, in addition to the previously known risk loci, will improve risk profiling for glaucoma, providing better opportunities to identify high-risk individuals. Fine-mapping and functional studies of the new risk loci will help better understand the aetiology of POAG, which may lead to improved prevention and intervention strategies.

**2166F**

**Identifying genes that underlie eye disorders and vision loss using predicted gene expression.** J.B. Hirbo<sup>1</sup>, E.R. Gamazon<sup>1</sup>, P. Evans<sup>1</sup>, R. Tao<sup>2</sup>, M. Brantley<sup>3</sup>, N.J. Cox<sup>1</sup>. 1) Genetic Medicine, Vanderbilt University School of Medicine, Nashville, TN; 2) Biostatistics, Vanderbilt University School of Medicine, Nashville, TN; 3) Vanderbilt Eye Institute, Vanderbilt University School of Medicine, Nashville, TN.

Eye disorders and vision loss pose a large public health and economic burden that is estimated at nearly 140 billion annually. One of the main limiting factors in developing effective therapies for eye disorders is lack of clear understanding of the molecular mechanism in disease etiologies. Genome-Wide Association Studies (GWAS) have successfully identified numerous variants associated with some common eye diseases like glaucoma, age dependent macular degeneration, cataract etc., but the biological mechanism underlying these associations are yet to be elucidated. Over 95% of these variants are noncoding that might be part of instructions that determine when, where, and how much of a gene is expressed. Thus, gene expression and how it correlates with disease can provide a powerful method to prioritize genes involved in the etiology of the eye phenotypes. We used two recently developed gene based method that provide framework for directly correlating imputed gene expression data with individual's genetic profile, PrediXcan and MetaXcan. The imputed gene expression is generated using a transcriptome reference panel. We used both genome wide data generated from biobank samples at Vanderbilt University Medical Center (BioVU) and publicly available data on eye diseases to determine which genes exhibit pattern of altered gene expressions in 5,100 eye disease cases relative to 6,000 unaffected controls using PrediXcan. We also analyzed summary statistics of published GWAS studies of eye diseases using MetaXcan. We identified novel genes that fall in regions with sub-genome wide significant SNPs in GWAS results. We also confirmed genes that were previously suggested to be causal in eye phenotypes because of being in vicinity to loci identified in GWAS. Most of the genes identified are also associated with complex neurological, vascular and metabolic disorders. Our results points to potential pathophysiology that underlie eye diseases.

**Exome sequencing identifies susceptibility genes for chronic central serous chorioretinopathy.** R.L. Schellevis<sup>1</sup>, M. Pauper<sup>1,2</sup>, D. Zafeiropoulou<sup>2</sup>, M.B. Breukink<sup>1</sup>, C.B. Hoyng<sup>1</sup>, C. Gilissen<sup>2</sup>, C.J.F. Boon<sup>3</sup>, A.I. den Hollander<sup>1,2</sup>, E.K. de Jong<sup>1</sup>. 1) Dept. of Ophthalmology, Donders Institute of Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen, the Netherlands; 2) Dept. of Genetics, Donders Institute of Brain, Cognition and Behaviour, Radboud University Medical Center, Nijmegen., the Netherlands; 3) Dept. of Ophthalmology, Leiden University Medical Center, Leiden, the Netherlands.

Chronic central serous chorioretinopathy (cCSC) is a rare multifactorial eye disease characterized by subretinal fluid accumulation that leads to vision loss. Clinically, cCSC is associated with stress and corticosteroid use, although it is unclear how this contributes to disease etiology. Strikingly, cCSC is more frequent in males (80%, prevalence 9.9:100,000). Only a limited number of genetic studies have thus far been performed for cCSC, identifying associations with both Single Nucleotide Polymorphisms (SNPs) and common Copy Number Variants (CNVs). However, familial occurrence of cCSC suggests a role for (rare) genetic variants in the disease susceptibility. We therefore performed gene association analysis on exome sequencing data of cCSC patients to elucidate the role of (rare) protein-altering variants in the disease. Exome sequencing was performed using the SureSelect all exon V4 capture library on 269 cCSC patients and 1,586 controls. Data was processed according to the Genome-Analysis-Toolkit (GATK) best practices (v3.4) and batch effects were minimized by filtering according to the recommendations of Carson, AR et al. 2014 prior to variant recalibration in GATK. Population stratification was assessed with a principal component analysis in PLINK (v1.90b4.1), and only subjects of European descent were retained. Cryptically related individuals were removed after identification with KING (v2.0). Variants were annotated with Anno(tation) (v. Sep2011), and protein altering variants were used for downstream analyses. Using the SKAT R-package (v1.2.1), Burden, SKAT and SKAT-O tests were performed. Variants were weighted based on minor allele frequency. Bonferroni correction was applied for 20,000 genes and  $P \leq 2.5 \times 10^{-6}$  were deemed statistically significant. After filtering, the dataset contained 261 cCSC patients, 1325 controls and 189,346 protein-altering variants. Analyses corrected for gender and 2 principal components identified 1 significantly associated gene involved in DNA repair and actin dynamics ( $P_{\text{burden}} = 1.72 \times 10^{-6}$ ;  $P_{\text{SKAT}} = 1.33 \times 10^{-7}$ ;  $P_{\text{SKAT-O}} = 4.24 \times 10^{-7}$ ) and 3 suggestive associations with  $P < 1 \times 10^{-5}$  in at least one of the tests. With these results, we have confirmed that (rare) protein-altering variants play a role in the etiology of cCSC. We are currently performing additional functional studies to determine the effect of these variants on protein function and to elucidate the exact role of the identified genes in the biological mechanism of cCSC.

Age-related macular degeneration (AMD), a complex oligogenic disease, leads to vision loss and blindness. To foster identification of new genes and validate existing loci for complex diseases, the Million Veteran Program (MVP) was initiated in 2011. To date, >500,000 participants have been enrolled and genotyped with a custom Affymetrix Axiom Biobank array. To classify participants as definite/probable cases, controls or unknown for AMD, we developed algorithms utilizing structured [International Classification of Diseases, 9th and 10th Revisions, Clinical Modification (ICD-9-CM and ICD-10-CM) and Current Procedural Terminology (CPT) codes] and unstructured data (clinical free text) in the electronic health records (EHRs). Imaging data is not yet available in MVP, so our algorithms do not include fundus photography, optical coherence tomography, or other gold-standard tools that clearly define AMD. We developed test sets of N>50 cases and controls across each of three VA medical centers (Cleveland, Providence, Buffalo) and refined the algorithm via detailed chart and imaging reviews by retinal specialists. Of 123,606 participants, cases were ≥50 and controls ≥65 years old with comprehensive eye exams (CPT codes 92004 and 92014). Definite cases (N=26,255) were identified via two separate clinic visits with ICD-9-CM (36.43, 362.50, 362.51, 362.52 or 362.57) or ICD-10-CM (H35.30, H35.31, H35.32) codes for AMD; probable cases (N=12,598) with a single code mention are poised for further evaluation with >50 text mining terms to detect AMD in clinical notes. Individuals with no AMD codes but with recent eye exams were designated as controls (N=84,753). Recently, the Cleveland VA validated 79 cases and 69 controls representing European Americans (85.9% and 75.0%), African Americans (AA; 11.5% and 25.0%), and Pacific Islanders (2.6% and 0.0%). Review of their EHRs showed ~14% and ~1% of cases vs. controls were misclassified by sole use of ICD-9-CM and ICD-10-CM codes; sample positive predictive value 86.08%, confidence interval 78.1-91.5%. Three of 11 misclassifications were AA, disproportionate to the number of AA cases observed herein. Additional cases and controls will be examined at Providence and Buffalo to improve the algorithm. In summary, our algorithm led to high misclassification rates for cases. Text mining will be used to improve the algorithm prior to finalizing case and control identity for downstream genome-wide association and rare variant studies.

**Identification of rare sequence variants in genes involved in focal adhesion and Wnt signaling pathways in keratoconus human corneas.** J.A. Karolak<sup>1,2</sup>, T. Gambin<sup>3,4</sup>, M. Rydzanicz<sup>5</sup>, P. Stawinski<sup>6</sup>, P. Polakowski<sup>6</sup>, R. Ploski<sup>6</sup>, J.P. Szaflik<sup>6</sup>, M. Gajecka<sup>1,2</sup>. 1) Department of Genetics and Pharmaceutical Microbiology, Poznan University of Medical Sciences, Poznan, Poland; 2) Institute of Human Genetics, Polish Academy of Sciences, Poznan, Poland; 3) Institute of Computer Science, Warsaw University of Technology, Warsaw, Poland; 4) Department of Molecular & Human Genetics, Baylor College of Medicine, Houston, TX, USA; 5) Department of Medical Genetics, Medical University of Warsaw, Warsaw, Poland; 6) Department of Ophthalmology, Medical University of Warsaw, Warsaw, Poland.

Keratoconus (KTCN, OMIM 148300) is a protrusion and thinning of the cornea, resulting in loss of visual acuity. The etiology of KTCN condition remains unclear. To assess a potential genetic contribution to KTCN, corneal tissues derived from five Polish unrelated individuals with KTCN were examined using whole exome sequencing (WES). Variants were filtered in a step-wise manner to exclude variants with minor allele frequency greater than 0.001 in the public and our internal database, and to exclude variants predicted as neutral by prediction tools. Genes with potential causative variants were enriched in 14 pathways, including focal adhesion and Wnt signaling (c.1066C>A in *PTK6*, c.1063G>T in *WNT1*, c.4204A>C in *COL5A3*, and c.4822C>T in *LRP6*). All patients have rare variant in at least one gene from focal adhesion and/or Wnt signaling pathways. These pathways play a role in corneal organization and were previously recognized as involved in KTCN. This first WES profiling of human KTCN corneas indicates that the accumulation of sequence variants in several genes from focal adhesion and Wnt signaling pathways might cause the phenotypic effect and supports the importance of previously described molecular pathways in KTCN etiology. Supported by National Science Centre in Poland, Grant 2013/10/M/NZ2/00283.

**Updated carrier rates for deafness-inducing mutation c.35delG (*GJB2*) in Russia and common haplotypes associated with c.35delG in Siberia.** O. Posukh<sup>1,2</sup>, M. Zytar<sup>1,2</sup>, N. Barashkov<sup>3,4</sup>, O. Shubina-Olejnik<sup>5</sup>, N. Danilenko<sup>5</sup>, V. Danilchenko<sup>1,2</sup>, A. Solovyev<sup>3,4</sup>, I. Morozov<sup>2,6</sup>, A. Bondar<sup>6</sup>. 1) Federal Research Center Institute of Cytology and Genetics, SB RAS, Novosibirsk, Russian Federation; 2) Novosibirsk State University, Novosibirsk, Russian Federation; 3) Yakut Scientific Center of Complex Medical Problems, Yakutsk, Sakha Republic, Russian Federation; 4) M.K. Ammosov North-Eastern Federal University, Yakutsk, Sakha Republic, Russian Federation; 5) Institute of Genetics and Cytology, National Academy of Sciences, Minsk, Belarus; 6) Institute of Chemical Biology and Fundamental Medicine, SB RAS, Novosibirsk, Russian Federation.

Mutations in gene *GJB2* (13q11-q12) are the major causes of deafness and their spectrum and prevalence are specific for various populations. Mutation c.35delG is more frequent in patients of European origin and absent or found with very low frequencies in Asian populations. There is generally accepted hypothesis that c.35delG is an "old" mutation that arose ~ 10000-14000 years ago from a common ancestor in Middle East or the Mediterranean and spread throughout Europe with Neolithic migrations. This hypothesis is supported by the presence of common STR- and SNP-haplotypes for c.35delG in individuals of European descent. Recently, we evaluated mutational spectrum and *GJB2*-contribution to deafness in patients of different ethnicities living in Altai, Tuva (Southern Siberia) and Yakutia (North-Eastern Siberia) and found predominance of c.35delG among Russian patients in contrast to indigenous Siberian peoples. Carrier frequency of c.35delG was found to be 4.1% in Russian residents of Novosibirsk city (Western Siberia). Our data supplement scarce information on the c.35delG prevalence in Siberia and generally among ethnically heterogeneous populations of Russia. Carrier frequency of c.35delG in Russians varies from 7.5% in north-western part of Russia to 2.5% in Yakutia averaging as 4-5% in central part of Russia. Therefore, Siberia can be considered as eastern "endpoint" of the c.35delG prevalence in Eurasia. Genotyping of intragenic rs3751385 and the STRs flanking *GJB2* (D13S141, D13S175, D13S1853) in homozygotes for c.35delG and in control individuals living in Siberia revealed two common specific haplotypes strongly associated with c.35delG: 126-T-105-202 (37.5%) and 124-T-105-202 (25.0%) (~ 316 kb). Moreover, comparative analysis revealed common conservative region between D13S141 and D13S175 (~ 125 kb) among the most frequent c.35delG-haplotypes in deaf patients living far from each other (Belarus, Volga-Ural region of Russia and Siberia). We roughly estimated the age of c.35delG in Siberia as ~ 8800-6800 years ago. The settlement of Siberia by the Russians began only in the late 16th century and contemporary Siberian population of Caucasian descent was formed as a result of multiple migrations from European part of Russia. Thus, roughly estimated age of the c.35delG in Siberia can rather reflect complex processes of early formation of population of Europe. Study was supported by Project #0324-2015-0004 and the RFBR grants #14-04-90010 Bel\_a, #15-04-04860a.

**Forty novel genetic loci associated with intraocular pressure in a large multi-ethnic genome-wide association study.** H. Choquet<sup>1</sup>, K.K. Thai<sup>1</sup>, J. Yin<sup>1</sup>, T.J. Hoffmann<sup>2,3</sup>, M.N. Kvale<sup>2</sup>, Y. Banda<sup>2</sup>, C. Schaefer<sup>1</sup>, N. Risch<sup>1,2,3</sup>, R. Melle<sup>4</sup>, E. Jorgenson<sup>1</sup>. 1) Kaiser Permanente Northern California (KPNC), Division of Research, Oakland, CA; 2) Institute for Human Genetics, University of California San Francisco (UCSF), San Francisco, CA; 3) Department of Epidemiology and Biostatistics, UCSF, San Francisco, CA; 4) KPNC, Department of Ophthalmology, Redwood City, CA.

**Purpose:** Intraocular pressure (IOP) is associated with glaucoma, a common eye condition which can lead to vision loss. Family studies indicate that IOP has a moderate genetic component, with heritability estimates ranging from 0.29 to 0.67. Previously published genetic association studies have reported 11 loci associated with IOP, suggesting that additional loci remain to be discovered. **Methods:** We first conducted a trans-ethnic genome-wide association study (GWAS) linking 373,967 IOP measurements to 73,107 individuals from four race/ethnicity groups (non-Hispanic white, Latino, East Asian, and African American) in the Genetic Epidemiology Research in Adult Health and Aging (GERA) cohort. Confirmation of our findings was then conducted in an external sample consisting of 37,930 individuals of European and Asian descent. We also conducted genome-wide conditional analysis by including all lead single nucleotide polymorphisms (SNPs) identified in the GWAS analyses of IOP as covariates. Epistasis analysis of all pairs of lead SNPs was also performed. We also investigated a total of 13 SNPs associated with IOP at a genome-wide significance level ( $P < 5 \times 10^{-8}$ ) in previous studies. Array heritability was estimated in the non-Hispanic white sample using GCTA v1.26.0, and the proportion of IOP variation explained by our newly-identified SNPs was estimated using a genetic risk score. **Results:** We identified 47 genome-wide significant IOP-associated loci, of which 40 were novel, that is, not previously-reported to be associated with IOP. Thirty novel IOP-associated loci (75%) replicated in an external sample. Conditional analysis did not identify any additional genome-wide significant signals for IOP, and epistasis analysis did not detect any significant epistatic interactions between IOP SNPs after Bonferroni correction. Our results also confirmed 92% of previously identified IOP-associated loci. Array-based heritability of IOP explained by all autosomal variants was estimated to be 24%, and our newly-identified SNPs increased the proportion of variance explained from 1.1% to 3.7%. **Conclusions:** The large number of new and replicated IOP-associated loci represents a major step forward to understanding the role of genetic variation in this important risk factor for glaucoma.

## 2172F

**A transethnic genome-wide association study identifies five novel genetic loci associated with primary open angle glaucoma.** *E. Jorgenson<sup>1</sup>, K.K. Thai<sup>1</sup>, J. Yin<sup>1</sup>, T.J. Hoffmann<sup>2,3</sup>, M.N. Kvale<sup>2</sup>, Y. Banda<sup>2</sup>, C. Schaefer<sup>1</sup>, N. Risch<sup>1,2,3</sup>, R. Melle<sup>4</sup>, H. Choquet<sup>1</sup>.* 1) Division of Research, Kaiser Permanente, Oakland, CA; 2) Institute for Human Genetics, University of California San Francisco, San Francisco; 3) Department of Epidemiology and Biostatistics, UCSF; 4) KPNC, Department of Ophthalmology, Redwood City, CA, USA.

**Purpose:** Glaucoma is the second leading cause of blindness worldwide. Genome-wide association studies have reported a number of loci associated with primary open angle glaucoma (POAG), the most common type of glaucoma, but the discovery of additional risk loci has been limited by available sample size. **Methods:** We conducted a transethnic meta-analysis of primary open angle glaucoma (POAG) in 5,235 cases and 65,213 controls, all adults from four race/ethnicity groups (non-Hispanic white, Latino, East Asian, and African American) in the Kaiser Permanente Northern California (KPNC) Genetic Epidemiology Research in Adult Health and Aging (GERA) cohort. We identified POAG cases using KPNC longitudinal electronic health records as those GERA participants who had at least two diagnoses of primary open angle or normal tension glaucoma by a KPNC ophthalmologist on separate days and no diagnoses of any other type of glaucoma. Controls had a history of at least one vision examination at which an intraocular pressure measurement was taken and no diagnoses of any type of glaucoma, nor any diagnosis of ocular hypertension. We conducted a genome-wide association study of POAG, using genome-wide genotype data generated on Affymetrix Axiom arrays and imputed to the 1000 Genomes reference panel. Genetic association analyses with POAG were performed using logistic regression adjusted for age, sex, and ancestry principal components. **Results:** We identified 14 loci with at least one associated variant reaching genome-wide significance ( $P < 5.0 \times 10^{-8}$ ), of which 5 were novel. We confirmed 9 POAG-loci previously reported, including *TMCO1*, *AFAP1*, *GMDS*, *CDKN2B-AS1*, *ABCA1*, *TMTC2*, *SIX1-SIX6*, *GAS7*, *TXNRD2*. We conducted replication analysis of the lead SNP in the novel loci using summary statistics from published GWAS studies. **Conclusions:** The identification of 5 new loci underlying primary open angle glaucoma represents an important step toward understanding glaucoma genetic etiology.

## 2173W

**Trial to make the combined genotyping to detect high-risk individuals for cold medicine related Stevens-Johnson syndrome (CM-SJS) with severe ocular complications (SOC).** *M. Ueta<sup>1</sup>, K. Tokunaga<sup>2</sup>, C. Inoue<sup>1</sup>, H. Sawai<sup>2</sup>, C. Sotozono<sup>3</sup>, S. Kinoshita<sup>1</sup>.* 1) Department of Frontier Medical Science and Technol, Kyoto Prefectural University of Medicine, Kyoto, Japan; 2) Department of Human Genetics, Graduate School of Medicine, University of Tokyo; 3) Department of Ophthalmology, Kyoto Prefectural University of Medicine.

In future, it is possible that combined genotyping for the associated variants may help to predict the risk for CM-SJS/TEN in Japanese individuals. We previously reported that in Japanese individuals, *HLA-A\*02:06* was strongly associated with CM-SJS/TEN. We also documented that *HLA-A\*02:06* and *TLR3* polymorphisms exerted more than additive effects, and that *HLA-A\*02:06* and *PTGER3* polymorphisms exhibited additive effects in CM-SJS/TEN with SOC. We recently reported that *HLA-A\*02:06* and *Rec114 rs16957893* CG also exerts more than additive effects in CM-SJS/TEN with SOC ( $OR = 110$ ,  $p = 4.45 \times 10^{-8}$ ). These findings might suggest that there are many interactions between polymorphisms associated with CM-SJS/TEN with SOC, and these interactions might show high odds ratio. In this study, we tried to make a prediction system to detect high-risk individual for cold medicine related Stevens-Johnson syndrome. We selected the 81 SNPs which showed associations with  $p < 10^{-5}$  with CM-SJS/TEN with SOC in Japonica array. We also selected 19 HLA-A, B, C alleles which tended to be associated with CM-SJS/TEN with SOC. Using the 19 HLA class I alleles and the 81 SNPs of 117 cases and 628 controls, we made pairs of HLA-SNP, SNP-SNP, HLA-HLA, and calculate p values and odds ratio, respectively. We found about 70 pairs which showed  $p < 10^{-5}$  and  $OR > 15$ , although maximum OR was 6.4 for *HLA-A\*02:06* in separate analysis. Thus, we could find many interaction between the polymorphisms, although our sample numbers were small. In future, it is possible that combined genotyping for the associated variants may help to predict the risk for CM-SJS/TEN with SOC in Japanese individuals.

**2174T**

**Loss of ELOVL6, a fatty acid elongase, rescues ER stress-induced apoptosis in model of retinitis pigmentosa.** R.A.S. Palu, C.Y. Chow. Human Genetics, University of Utah, Salt Lake City, UT.

An important goal of the Precision Medicine Initiative is to address the phenotypic heterogeneity that impedes diagnosis and treatment in both Mendelian and complex genetic diseases. Individuals with the same causative mutation may display vast differences in disease penetrance and expressivity. Cryptic genetic variation is a key contributor to this heterogeneity, but the underlying genetic architecture and modifiers are largely unknown. Understanding the roles of genetic modifiers in disease processes will enable the development of individualized therapeutic approaches. Recently developed model organism tools allow researchers to study the effects of natural genetic variation on disease phenotypes. One of these, the *Drosophila* Genetic Reference Panel (DGRP), is a collection of ~200 inbred strains, each representing a unique and fully sequenced wild-derived genome. In a previous study, we utilized the DGRP to study the effects of natural genetic variation on a model of ER stress-associated retinal degeneration. Overexpression of a mutant, misfolded rhodopsin protein (*Rh1<sup>G69D</sup>*) induces ER stress in the developing eye, ultimately resulting in apoptosis and a small, degenerate eye in the adults. Degenerate eye phenotypes were incredibly variable among the 200 DGRP strains. Using genome-wide association methods, we identified 84 conserved candidate modifiers, many of which are associated with ER stress and apoptosis. One of these, *balddspot*, is the *Drosophila* orthologue of *ELOVL6*, an ER-associated fatty acid elongase. *ELOVL6* activity has been linked to ER stress, insulin sensitivity, and obesity in mammals. We demonstrate that RNAi-mediated knockdown of *ELOVL6* alleviates degeneration in the *Rh1<sup>G69D</sup>* model of retinal degeneration. This is associated with a reduction in ER stress and apoptosis and appears to be linked to the fatty acid elongase activity of *ELOVL6*. Furthermore, loss of *ELOVL6* in other tissues also reduces degenerative phenotypes induced by ER stress, suggesting that *ELOVL6* is not retinal-specific, but a general modifier of ER stress. We hypothesize that *ELOVL6* acts by altering the fatty acid composition of the ER and the activity of IRE1. We will present evidence from cell culture experiments for this. Our findings suggest that *ELOVL6* is a general modifier of ER stress that functions in a variety of disease contexts. *ELOVL6* may be a possible therapeutic target not only in retinal degeneration, but also in many ER stress-associated diseases.

**2175F**

**Evaluation of genetic polymorphisms in the determination of optic disc parameters and circumpapillary retinal nerve fiber layer thickness in normal individuals in a sample of the Brazilian population.** M. Atique-Tacla, C. Zangalli, B.B. Souza, D. Stancato, G. Ananina, V.P. Costa, M.B. Melo, J.P.C. Cabral. Unicamp, Campinas, Campinas, Brazil.

**Background:** Glaucoma is a degenerative disease of the optic nerve considered the leading cause of irreversible blindness worldwide. Primary open angle glaucoma (POAG[MIM137760]) is the most common subtype in African and European descendants and is a complex heterogeneous disease with molecular mechanisms poorly understood. The study of endophenotypes in glaucoma offers the possibility of reducing its genetic complexity and includes optic nerve head (ONH) parameters, such as optic disc area (ODA) and neuroretinal rim area, and circumpapillary retinal nerve fiber layer thickness (RNFLT), among others. *SALL1* [602218], *ATOH7* [609875], *CDC7/TGFRB3* [603311] and *CARD10* [607209] polymorphisms have already been associated to ODA. Anatomic differences in the ONH between normal individuals, specially when they belong to different ethnic groups, as well as a non standardized evaluation of ONH parameters might have led to less precise genetic associations in previous studies. **Objectives:** to evaluate the association of *SALL1*, *CDC7/TGFRB3*, *CARD10* and *ATOH7* polymorphisms with ODA, global neuroretinal rim, circumpapillary RNFL and axial length, in a cohort of 195 normal individuals (without glaucoma). **Methods:** The project was approved by the Research Ethics Committee of the Faculty of Medical Sciences of the State University of Campinas Genomic. DNA was amplified by polymerase chain reaction and the polymorphisms were analyzed by Sanger sequencing. ONH images were acquired by spectral domain optic coherence tomography - SD-OCT- Spectralis (Heidelberg Engineering, GmbH, Heidelberg, Germany). **Results:** To evaluate if each of the dependant variables could be associated to any of the four polymorphisms, a multiple linear regression analysis with a stepwise backward elimination was performed. *SALL1 rs1362756* genotypes G/C and G/G were significantly associated with ODA ( $p = 0.035$  and  $p = 0.01$ , respectively) and with global neuroretinal rim area ( $p = 0.016$  and  $p = 0.032$ , respectively). There were no significant associations with this SNP to other parameters analyzed (axial length and RNFL thickness). Other SNPs included in our study (*ATOH7 rs 1900004*, *CDC7/TGFRB3 rs1192415* and *CARD10 rs9607469*) did not present association with any of the parameters evaluated. **Conclusions:** *SALL1 rs1362756* SNP presented a significant association with optic disc area and with global rim area in a cohort of normal individuals.

**2176W**

**Lineage-specific linkage analysis localizes novel rare variant-driven genomic loci for the glaucoma endophenotype of cup to disc ratio in a large extended pedigree from Nepal: The Jiri Eye Study.** M.P. Johnson<sup>1</sup>, S.S. Thapa<sup>2</sup>, T.D. Dyer<sup>1</sup>, S. Laston<sup>1</sup>, K.L. Anderson<sup>2</sup>, B. Towne<sup>1</sup>, J. Subedi<sup>3</sup>, H.H.H. Göring<sup>1</sup>, J. Blangero<sup>1</sup>, S. Williams-Blangero<sup>1</sup>. 1) South Texas Diabetes and Obesity Institute, School of Medicine, University of Texas Rio Grande Valley, Brownsville, TX, USA; 2) Tilganga Institute of Ophthalmology, Kathmandu, Nepal; 3) Department of Ophthalmology, School of Medicine, UT Health San Antonio, San Antonio, TX, USA; 4) Department of Community Health, Boonshoft School of Medicine, Wright State University, Kettering, OH, USA; 5) Department of Sociology and Gerontology, College of Arts and Science, Miami University, Oxford, OH, USA.

The leading cause of irreversible blindness worldwide is glaucoma, a heterogeneous group of eye diseases that results in progressive damage to the optic nerve, loss of retinal ganglion cells, and specific visual field deficit. Glaucoma development and progression is governed by a complex interplay of genetic and environmental risk factors. Identifying genetic risk factors for a heterogeneous disease such as glaucoma is best achieved by dissecting the genetic architecture of its biological constituents (endophenotypes) that contribute to the disease process. Intraocular pressure (IOP), central corneal thickness (CCT), and optic nerve cupping as measured by cup to disc ratio (CDR) are well established endophenotypes for glaucoma. The Jiri Eye Study is an ongoing, family-based study (target sample size: 2,000) with the objective of identifying rare functional variants that influence ocular health and disease in the Jirel population of eastern Nepal. In pursuit of genomic loci (QTLs) that harbor rare functional variants influencing glaucoma endophenotype trait variation in the Jirels, we adopt a novel analytical strategy that is based on founder-specific lineages and is able to identify founders who segregate rare functional variants. The model employed is a variance component mixed model with a fixed effect for a given founder's identity-by-descent (IBD) probability vector that is extracted from the usual IBD matrix. In our current sample size ( $n = 1,047$ ), IOP ( $h^2 = 0.29$ ,  $p = 4.0E-07$ ), CCT ( $h^2 = 0.65$ ,  $p = 4.9E-28$ ), and CDR ( $h^2 = 0.48$ ,  $p = 3.9E-16$ ) are all significantly heritable. Using existing genome-wide markers, we identify five suggestive ( $p$ -values from 0.001 to 0.004) CDR QTLs likely due to rare variation on chromosomes 1 (2 QTLs), 7, 9 and 12. The chromosome 1 loci harbor genes (*TMCO1*; ~0.28 Mb from our maximum signal) previously identified in glaucoma and IOP GWAS, and genes (*NENF*; ~0.70 Mb from our maximum signal) that encode proteins with known/hypothesized roles in the glaucomatous process; the chromosome 7 locus harbors genes (*TMEM248*; ~1.18 Mb from our maximum signal) previously identified in CCT GWAS; the chromosome 9 locus has been previously implicated in juvenile-onset primary open angle glaucoma (GLC1J locus); and the chromosome 12 locus shares some overlap with a previously detected CDR QTL. To our knowledge, the loci on chromosomes 1, 7, and 9 have not been implicated in CDR trait variation.

Pasutto<sup>8</sup>, J.L. Wiggs<sup>9</sup>, NEIGHBORHOOD Consortium. 1) Department of Epidemiology and Biostatistics, Case Western Reserve University, Cleveland, OH, USA; 2) QIMR Berghofer Medical Research Institute, Brisbane, Queensland, Australia; 3) Ophthalmology and Visual Sciences, University of Wisconsin-Madison, Madison, Wisconsin, USA; 4) Feinberg Cardiovascular Research Institute, Northwestern University, Chicago, Illinois, USA; 5) Division of Nephrology/Hypertension, Northwestern University, Chicago, Illinois, USA; 6) Department of Ophthalmology, Flinders University, Adelaide, South Australia, Australia; 7) Department of Ophthalmology, Northwestern University Feinberg School of Medicine, Chicago, Illinois, USA; 8) Institute of Human Genetics, Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany; 9) Department of Ophthalmology, Massachusetts Eye and Ear Infirmary, Boston, Massachusetts, USA.

Primary open-angle glaucoma (POAG), a major worldwide cause of blindness, is a genetically and clinically heterogeneous disease. POAG has a significant genetic component; however, the 15 genomic regions associated with POAG risk account for only a fraction of disease heritability, suggesting the existence of additional disease-related genes. Recently, *TIE2* (*TEK*) loss-of-function mutations have been identified in congenital glaucoma families with age of disease onset varying from birth to adulthood. The purpose of this study is to examine POAG association for SNPs located in the genomic regions that include *TIE2* and its ligand *ANGPT1* as well as a related receptor ligand pair *ANGPT2* and *TIE1*. We first accessed results from two previously reported POAG imputed genome-wide association study (GWAS) datasets: the NEIGHBORHOOD consortium (3,853 POAG cases, 33,480 controls) and the Australian ANZRAG consortium (1,155 POAG cases, 1,992 controls). We assessed 2,302 SNPs located within the genomic regions corresponding to *TIE1*, *TIE2*, *ANGPT1*, and *ANGPT2* in the NEIGHBORHOOD; SNPs with  $P < 1 \times 10^{-5}$  were carried forward to ANZRAG. We additionally accessed results from Illumina HumanExome chip data in the NEIGHBORHOOD (2836 cases, 3207 controls) as well as sequence data from 528 German POAG cases. We detected significant association ( $P < 2.17 \times 10^{-5}$ , correcting for multiple testing of 2,302 SNPs) at 19 SNPs located in the genomic region around *ANGPT1* (top SNP rs34597339[T],  $P = 3.24 \times 10^{-6}$ , OR = 0.81). Thirteen of these SNPs are located in a 15-kb promoter region (ENCODE) that includes an alternative transcription start site used by various cell types, including human umbilical vein endothelial cells (HUVEC). We did not observe significant association with POAG at SNPs located in the *TIE1*, *TIE2*, and *ANGPT2* genomic regions ( $P > 2.17 \times 10^{-5}$ ) in the NEIGHBORHOOD GWAS. Further evidence of replication was detected in three nonsynonymous variants in *ANGPT1* in three individuals with POAG with onset >60 years and high intraocular pressure. Prior studies have shown that *ANGPT1* and *TIE2* are necessary for development of Schlemm's canal and that loss-of-function mutations in *TIE2* cause glaucoma with variable age of onset. The results from our study highlight SNPs located in the *ANGPT1* genomic region that are associated with POAG, which suggests that modulation of *ANGPT1-TIE2* signaling may also contribute to the development of adult-onset glaucoma.

**anti-VEGF treatment response in age-related macular degeneration.** O. Garcia Rodriguez<sup>1</sup>, S.S. Pan<sup>1</sup>, P. Whitehead-Gay<sup>1</sup>, L.D. Adams<sup>1</sup>, J.K. Welch<sup>1</sup>, R.A. Laux<sup>2</sup>, J.A. Fortun<sup>3</sup>, M.A. Brantley, Jr.<sup>4</sup>, J.L. Kovach<sup>5</sup>, S.G. Schwartz<sup>5</sup>, A. Agarwal<sup>6</sup>, J.L. Haines<sup>7</sup>, M.A. Pericak-Vance<sup>8</sup>, W.K. Scott<sup>1</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami, FL; 2) Population & Quantitative Health Sciences, Case Western Reserve University, Cleveland, OH; 3) Bascom Palmer Eye Institute, University of Miami, Miami, FL; 4) Ophthalmology & Visual Sciences, Vanderbilt University Medical Center, Nashville TN; 5) West Coast Retina, San Francisco, CA.

Age related macular degeneration (AMD), a leading cause of vision loss in older adults, has a complex etiology comprising genetic and environmental risk factors. In advanced stages, vision loss results from geographic atrophy or choroidal neovascularization (CNV). Response to anti-vascular endothelial growth factor (anti-VEGF) treatment for CNV is variable, with 10-30% of patients continuing to lose visual acuity (VA) after 6 months' treatment. Although a replicated association with the rs4910623 variant in *OR52B4* was recently reported in a genome wide association study (GWAS), there are few genetic factors reproducibly associated with treatment response. Therefore, we conducted a second GWAS in 90 individuals (107 eyes) with CNV followed for at least one year. Samples were genotyped using the Illumina CoreExome Array and imputed against the 1000Genomes reference panel; after quality control, 6.3 million SNPs with minor allele frequency > 0.05 were retained for analysis. Association of one-year change in visual acuity (VA, analyzed as logMAR) with SNP dosage was analyzed using linear mixed models, adjusting for age at exam, antibody type (ranibizumab, bevacizumab, or aflibercept), and sex, and allowing for correlations between eyes for individuals with bilateral CNV. Two regions on chromosome 4 were identified as significantly associated ( $p < 5 \times 10^{-8}$ ) with change in VA: 2 intronic variants in *KLHL2* and 2 variants in the 3'UTR of *C4orf50*. In both regions, the two SNPs were in complete linkage disequilibrium and the minor allele was associated with reduced VA after 1 year. Imputation quality at all 4 SNPs was good ( $R^2 > 0.75$ ) and validation with TaqMan genotyping showed strong correlation with imputed dosages. Association was not detected at rs4910623 in *OR52B4* (nominal  $p > 0.05$ ) or at any of the 52 known AMD risk variants (Bonferroni-corrected  $p > 0.05$ ) possibly due to limited power in the relatively small sample. Our findings identified new loci specific to anti-VEGF treatment response in CNV, and suggest that mechanisms governing risk of AMD and response to treatment may be distinct.

Purpose: Primary open-angle glaucoma (POAG) is clinically classified into high tension glaucoma (HTG), in which elevated intraocular pressure (IOP) is a major feature and normal tension glaucoma (NTG), in which the IOPs are consistently within the statistically normal population range. Genome-wide association studies identified several genetic variants associated with POAG, and these can be classified into two types of genetic variants. One is a genetic variant associated with IOP elevation (IOP-related genetic variant), while the other is a genetic variant associated with a vulnerability of optic nerve (non-IOP-related genetic variant). The present study was conducted to investigate the additive effects of genetic variants associated with POAG. Methods: Nine variants identified as IOP-related genetic variants, including rs1052990 (near gene: *CAV2*), rs11656696 (*GAS7*), rs59072263 (*GLCC1/ICA1*), rs2472493 (*ABCA1*), rs58073046 (*ARHGEF12*), rs2286885 (*FAM125B*), rs6445055 (*FNDC3B*), rs8176743 (*ABO*), and rs747782 (*PTPRJ*), and 11 variants identified as non-IOP-related genetic variants, including rs3213787 (*SRBD1*), rs735860 (*ELOVL5*), rs1063192 (*CDKN2B*), rs1900004 (*ATOH7*), rs10483727 (*SIX6*), rs4619890 (*AFAP1*), rs11969985 (*GMDS*), rs3785176 (*PMM2*), rs1192415 (*TGFBR3*), rs2745572 (*FOXC1*), and rs35934224 (*TXNRD2*), on genome-wide association studies, were genotyped for 762 Japanese participants, including the patients with NTG ( $n = 261$ ) and HTG ( $n = 255$ ) and 246 control subjects. The total number of risk alleles of the 9 IOP-related, 11 non-IOP-related, and 20 IOP-related or non-IOP-related genetic variants were calculated for each participant as genetic risk scores (GRSs), and the association between these GRSs and POAG (NTG or HTG) was evaluated. Results: The GRS ( $9.1 \pm 1.9$ , mean  $\pm$  standard deviation) of 9 IOP-related variants in patients with HTG was significantly higher ( $P = 0.011$ ) than that ( $8.7 \pm 1.8$ ) in control subjects. The GRSs of 11 non-IOP-related variants in patients with NTG ( $14.7 \pm 1.9$ ) and HTG ( $14.8 \pm 1.7$ ) were significantly higher ( $P < 0.0001$ ) than that ( $14.0 \pm 2.0$ ) in control subjects. The GRSs of 20 IOP-related or non-IOP-related variants in patients with NTG ( $23.6 \pm 2.6$ ) and HTG ( $23.9 \pm 2.5$ ) were significantly higher ( $P < 0.0001$ ) than that ( $22.7 \pm 2.6$ ) in control subjects. Conclusion: These data support that POAG is a polygenic disorder by additive effects of multi-locus genetic variants associated with POAG.

**Genome-wide gene expression profiling in the retina of common marmosets exposed to hyperopic or myopic defocus reveals large-scale sign-of-defocus-specific changes in gene expression, pathway switching, and strong left-right eye yoking.** A. Tkatchenko<sup>1,2</sup>, D. Trillo<sup>3</sup>, A. Benavente-Perez<sup>2</sup>, T. Tkatchenko<sup>1</sup>. 1) Dept of Ophthalmology, Columbia University, New York, NY; 2) Dept of Pathology and Cell Biology, Columbia University, New York, NY; 3) SUNY College of Optometry, New York, NY.

Previous studies demonstrated that the eye can compensate for both minus- and plus-lens defocus. However, the ability of the retina to recognize the sign of defocus has been a subject of much controversy. Comprehensive information about transcriptome changes underlying compensation for lens imposed defocus has also been lacking. The purpose of this study was to identify sign-of-defocus-specific transcriptome changes in the primate retina and elucidate retinal signaling pathways underlying lens compensation at the whole-genome level. In 4 groups of marmosets (3 animals each), -5D or +5D lenses were applied to the right eye for 10 days or 5 weeks. The left eye was fitted with a plano lens control. Following lens treatment, retinæ were harvested and used to perform whole-genome gene expression profiling using RNA-seq. A total of 119 genes were differentially expressed between -5D-treated eyes and the contralateral plano control eyes after 10 days of treatment, 309 genes were differentially expressed between -5D eyes and control eyes after 5 weeks of treatment. In +5D eyes compared to controls, 79 genes were differentially expressed after 10 days, and 740 genes were differentially expressed after 5 weeks of treatment. Comparison of differential genes from the four experimental groups revealed that each experimental condition leads to differential expression of a unique set of genes with very little overlap between the datasets and a large degree of yoking between left and right eyes. Although no genes were differentially expressed in opposite directions between -5D and +5D lens treatment groups at 10 days, 13 genes were differentially expressed in opposite directions at 5 weeks. Pathway analysis revealed that there was almost complete transition from one set of pathways to another between 10 days of treatment and 5 weeks of treatment for both -5D and +5D experimental groups. Our data suggest that retina can distinguish between hyperopic and myopic defocus and responds to defocus of different sign by activation of largely distinct pathways. There is also, however, strong yoking between left and right eyes at the gene expression level. The response to both hyperopic and myopic defocus over time is characterized by signaling pathway switching.

Orofacial clefts (OFCs), including cleft lip and/or palate (CL/P) and cleft palate (CP), are among the most common birth defects in humans. Approximately 1 in 700 newborns are affected; however, the prevalence of OFCs differs widely across populations. Although genome-wide association studies have successfully identified at least 26 risk loci for OFCs, these loci only account for part of the heritability, leaving a gap to be filled by contributions of rare variants, copy number variants (CNVs), epigenetics or interactions. CNVs are segments of the genome that exist in different copy numbers in the population. Copy number variations (or CNVs) can encompass genes leading to dosage imbalances and therefore, contribute to an abnormal phenotype. Here, we report the ongoing genome wide survey of CNVs associated with OFCs using the data from the first GWAS for OFCs in the African population. A total of 3,178 participants were genotyped on the pre-release consortium version of Illumina Multi Ethnic Genotyping Array (MEGA), and imputation was done into the 1000 Genomes Phase 3 reference imputation panel using IMPUTE2. These included 814 cases of CLP, 205 cases of isolated CP, and 2,159 related and unrelated controls. Over 45million SNPs were imputed including the 2.2million SNPs in the Multi Ethnic Genotyping Array. We are using PennCNV combined with statistical analysis to identify potential CNVs associated with OFCs. These analyses integrate multiple sources of information to infer CNVs call for individual samples, in addition to using family information to generate family based calls and to determine the *de novo* or inherited origin of the CNV. The ascertainment of CNVs from SNP array data offer an excellent opportunity to identify common CNVs associated with common diseases and this has resulted in the discovery of both *de novo* and inherited CNVs. Our CNV analysis on GWAS data will help elucidate the molecular etiology of orofacial clefts, and will improve our understanding of how multiple forms of genetic variation act together to influence these craniofacial phenotypes.

**Fluctuating dermatoglyphic asymmetry and familial recurrence of cleft lip/palate in a high-prevalence cluster of South America.** *J. Ratowiecki<sup>1</sup>, J.S. Lopez Camelo<sup>1,2,3</sup>, F.M. Carvalho<sup>3,4,5</sup>, C.A. Brandon<sup>6,8</sup>, A.R. Vieira<sup>6,7,8</sup>, M.L. Marazita<sup>6,8,9</sup>, I.M. Orioli<sup>3,5</sup>, E.E. Castilla<sup>1,2,3,4</sup>, F.A. Poletta<sup>1,2,3</sup>*. 1) ECLAMC (Latin-American Collaborative Study of Congenital Malformations at CEMIC-CONICET, Centro de Educación Médica e Investigaciones Clínicas, Buenos Aires, Argentina; 2) CONICET (National Research Council of Argentina), Argentina; 3) INAGEMP (Instituto Nacional de Genética Médica Populacional), Brazil; 4) ECLAMC at Laboratório de Epidemiologia de Malformações Congênitas, Instituto Oswaldo Cruz, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil; 5) ECLAMC at Laboratório de Malformações Congênitas, Departamento de Genética, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; 6) Departments of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 7) Pediatric Dentistry, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 8) Center for Craniofacial and Dental Genetics, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA, USA; 9) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA, USA.

Non-syndromic orofacial clefts, notably cleft lip with or without palate (CL/P), are common congenital anomalies with complex and heterogeneous etiology. A high prevalence of CL/P was previously identified in the Argentine Patagonia, probably associated with Amerindian ancestry and low socioeconomic status. While it is known that there is a relationship between abnormal dermatoglyphics and birth defects, there are relatively few studies investigating dermatoglyphic asymmetry and familial risk of CL/P, and as far as we know, this is the first report in South America populations. The aim of this study was to compare levels of fluctuating dermatoglyphic asymmetry among non-syndromic CL/P probands with different degrees of family recurrence, versus unrelated controls, from a high-CL/P-prevalence cluster in South America. The sample included 168 individuals (84 CL/P cases and 84 unrelated controls) ascertained by ECLAMC (The Latin-American Collaborative Study of Congenital Malformations) hospitals in Patagonia. Dissimilarity score of fingerprint patterns was used as an indicator of bilateral fluctuating asymmetry. For each CL/P case we calculated the family history score (FHS) from pedigree data, using the observed risk in first-degree relatives, and the expected frequency according to family size and population risk prevalence. Individuals were then distributed in 3 groups: (1) Unrelated controls (without family history of CL/P), (2) CL/P cases with low FHS, and (3) CL/P cases with high FHS. Means and standard deviations were calculated for each FHS group and sex. Differences among groups were analyzed with two-way ANOVA including FHS group, sex, and an interaction term (FHS group\*sex). We observed statistically significant differences between FHS groups ( $p = 0.025$ ) with a higher asymmetry in cases with higher FHS; but not between sexes, nor evidence of interaction FHS group\*sex. Our results suggests that higher FHS (higher genetic load of susceptibility) could influence the developmental instability in CL/P cases. Bilateral asymmetry in dermatoglyphic patterns could be a good phenotypic indicator to identify families where the developmental instability is playing a role in the causal model of CL/P, and therefore to obtain more homogenous groups of cases for linkage/association studies conducted to identify major genes for CL/P.

**2183T**

**Robinow, Ter Haar, Teebi or a new syndrome? Complex genotype with distinctive craniofacial features.** *F. Uysal<sup>1</sup>, B. Turkgenç<sup>2</sup>, S.G. Temel<sup>3</sup>*. 1) Department of Paediatrics, Uludag University, Bursa, Turkey; 2) University of Acibadem, Acibadem Genetic Diagnostic Center, Istanbul, Turkey; 3) Department of Histology & Embryology, Uludag University, Bursa, Turkey.

We report a 45 days old boy who initially presented with the history of antenally diagnosed omphalocele, growth retardation and craniofacial features in 2009. He was the only born from a non-consanguineous marriage at term. Main clinical findings included hypertelorism, prominent forehead, nevus flammeatus, prominent eyes, megalocornea, lowset ears, broad nasal root, long philtrum, short frenulum, high palate, thinner upper lip, malocclusion of the teeth, gingival hypertrophy, micrognathia, 5th finger clinodactyly and rocker bottom feet. Echocardiography demonstrated LV hyper-trabeculation with myocardial thickness 6 mm, moderate tricuspid regurgitation, mild tricuspid valve dysplasia and LV non compaction. LV systolic functions were normal. Cranial and 3D calvarium BT demonstrated closure of metopic and sagittal sutures. The diameter of calvarium from anterior to posterior is minimally elevated (scaphocephaly?/dolicocephaly?) according to the lateral one; suggesting sagittal synostosis. Sequencing of possible genes responsible from the phenotype like *Wnt5a*, *SH3PXD2B*, *BRAFV600E*, *KRAS*, *MEK1* and *MEK2* genes revealed normal genotype. The whole genome chromosome SNP microarray analysis was also normal. Exome sequencing revealed several candidate gene variants homozygous c.1954C>T (p.Arg652Trp) missense variant in *POTEE* gene, homozygous c.874G>A (p.Arg292Cys) missense variant in *PIK3C2B* gene, and compound heterozygote missense c.7687C>T (p.Gly2563Ser) and c.5212T>C (p.Ile1738Val) variants in *ODZ4* gene. Segregation analysis was confirmed with Sanger sequencing. Complex genotype will be discussed with the phenotypic features and pathway interactions of the candidate genes. Functional studies and RNA sequencing are ongoing projects to explain the complex genotype.

**Clinical aspects associated with orofacial clefts in patients of smile operation in a Colombian population.** *J. Martinez<sup>1</sup>, I. Briceno<sup>1</sup>, L. Arias<sup>1</sup>, A. Zarate<sup>1</sup>, A. Collins<sup>2</sup>.* 1) Bioscience, Univ de La Sabana, Chia, Colombia, Colombia; 2) University of Southampton.

**Objectives:** To present descriptive epidemiology of Orofacial Clefts and to determine the association of syndromic forms with antenatal high-risk conditions, preterm birth, and comorbidities among nested-series of cases.

**Methods:** A study of nested-series of cases was conducted. Frequencies of cleft type, associated congenital anomalies, syndromic, non-syndromic and multiple malformation forms, and distribution of Orofacial Clefts according to sex and affected-side were determined. Odds ratios were calculated as measures of association between syndromic forms and antenatal high-risk conditions, preterm birth and comorbidities. A total of three hundred and eleven patients with Orofacial Clefts were assessed in a 12-month period. **Results:** The most frequent type of Orofacial Clefts was cleft lip and palate, this type of cleft was more frequent in males, whereas cleft palate occurred more often in females. The most common cases occurred as non-syndromic forms. Aarskog-Scott syndrome showed the highest frequency amongst syndromic forms. Hypertensive disorders in pregnancy, developmental dysplasia of the hip, central nervous diseases and respiratory failure showed significant statistical associations ( $p < 0.05$ ) with syndromic forms. **Conclusions:** These data provide an epidemiological reference of Orofacial Clefts in Colombia. Novel associations between syndromic forms and clinical variables are determined. In order to investigate causality relationships between these variables further studies must be carried out.

Non-syndromic cleft lip with or without cleft palate (NSCL/P) is the most common craniofacial birth defect in humans, affecting approximately 1 in 700 births worldwide. NSCL/P has complex etiology and heterogeneous phenotypic presentation including differences in prevalence by sex. Approximately twice as many males are affected with NSCL/P than females, and the source of this disparity is largely unknown. Interactions between genetic effects and sex effects have been hypothesized to help explain some of the differences seen in NSCL/P prevalence. To this end, we examined gene-by-sex interactions in a worldwide sample of 2142 NSCL/P cases and 1,700 controls recruited from 18 sites across 13 countries from North America, Central/South America, Asia, Europe and Africa. Joint tests of genetic and gene-by-sex effects were tested genome-wide (6,926,378 SNPs with MAF>0.05) using logistic regression assuming an additive genetic effect and adjusting for 18 principal components of ancestry. We further interrogated loci with suggestive results from the joint test ( $p < 1E-05$ ) by examining the gene-by-sex effects from the same model. Suggestive results ( $p < 1E-05$ ) for the joint test were observed in 133 loci. From these regions, one genome-wide significant gene-by-sex effect in the 10q21 locus (rs72804706;  $p=6.69E-09$ ; OR=2.62[1.89, 3.62]) and 16 suggestive gene-by-sex effects were observed. At the 10q21 locus, the risk of NSCL/P is estimated to increase with additional copies of the minor allele for females, but the opposite effect for males. This locus lies within an intergenic region downstream of *IPMK*, whose impact on craniofacial development is unknown. Our observation that the impact of genetic variants on orofacial clefting risk differs for males and females at this locus may further our understanding of the genetic architecture of orofacial clefting and the sex differences underlying clefts and some other birth defects. R01DE016148, X01HG007485, K99DE024571, R01-DE011931.

Orofacial clefts (OFCs) are common, complex birth defects with extremely heterogeneous phenotypic presentations. Two common subtypes – cleft lip alone (CL) and cleft lip and palate (CLP) – are often combined for genetic analysis (i.e. cleft lip with or without cleft palate, CL/P). In such studies of CL/P, the underlying assumption is that the effect on risk of cleft may be identical for both CL and CLP subgroups. However, such investigations cannot separate variants for which the risk of OFC differs by subtype. Despite substantial data supporting a shared etiology between CL and CLP, recent evidence suggests that subtype-specific risk factors and/or genetic modifiers may distinguish these two phenotypes. Therefore, identification of genetic factors that act as modifiers of cleft subtypes is critical for understanding the substantial variability of OFCs between individuals. We performed genome-wide association scans for genetic modifiers by directly comparing 450 CL cases with 1692 CLP cases recruited from 13 countries around the world. Gene-based scans of low-frequency variants (MAF<1%) revealed three genes (*C8orf34*, *TMEM246*, and *CDC42EP3*) significantly associated with cleft type. In the scan of common SNPs (MAF>1%), a 16q21 locus was strongly associated with cleft type ( $p=5.6 \times 10^{-8}$ ), which replicated in an independent sample of 360 CL and 725 CLP cases from Brazil, the Philippines, and Mongolia. Furthermore, the 16q21 alleles that increased CL risk were found at highest frequencies among individuals with a family history of CL compared to those with histories that included CLP ( $p=0.003$ ). We further investigated the potential modifying behavior of the 16q21 locus on known CL/P risk loci with gene-gene interaction analyses and found significant interactions between the modifier locus and 8q21 ( $p=0.012$ ) and 9q22 ( $p=0.023$ ). In these interactions, the risk of CL increased only in the presence of both the CL/P risk allele and the 16q21 modifier; CLP risk was unchanged by the modifier. 16q21 contains several biologically plausible candidates including *LINC00922*, a long-non-coding RNA with putative gene regulatory function and *CDH11*, a craniofacially expressed protein that regulates extracellular matrix production. This study demonstrates the existence of common and low-frequency phenotypic modifiers for OFCs and further elucidates the complex genetic architecture of OFCs by identifying biologically plausible elements responsible for phenotypic heterogeneity.

**2187F****Ballooning of redundant myelin sheaths in DS may resolve with Ca<sup>2+</sup> as seen in the mouse.** *A.N. van Hoek, A. Ramirez, M. Sauer, L. Dai, J.R. Korenberg.* University of Utah, Salt Lake City, UT.

The conduction speed of an action potential is greatly enhanced by myelination and is significantly related to cognition. In DS (trisomy 21) conduction is disturbed, reflected by abnormal fMRI, and in the Ts65Dn and DS mouse models for Chr 21 genes (Olig1, Olig2, Claudin 8) myelin and conduction are abnormal. The extent to which myelin is abnormal or related to brain or cognitive dysfunction, is unknown. Reasoning that myelin thickness is linearly related to conduction speed, we examined myelin in DS. We determined myelin structure and immunohistochemical (IHC) distribution of MBP (myelin basic protein), claudin 11 (tight junction protein tethering neighboring myelin layers), and GFAP (glial fibrillary acidic protein) by confocal and electron microscopy in Ts65Dn and control mice, in the non-human primate *Macaca fascicularis*, and in a brain kindly donated from a 76-year-old woman with DS. The IHC results indicated that the pattern of antibody labeling was similar to the macaque brain. EM revealed subsets of axons with compact myelin. However in the macaque, and exaggerated in DS, ballooned myelin with “onion” shapes of disorganized lamellae (>35, DS) were seen surrounding small axons. In both DS (fixed with 4%-paraformaldehyde (PA) & 0.2% glutaraldehyde in PBS) and macaque (fixed with 4%-PA in PBS), the pattern of ballooning revealed an elegant helical pattern, maintained by radial spokes of tight junctions that tether points in the layers, preventing total disruption of myelin. In mouse, ballooning but not helices were seen when the primary fixative (4% PA) included PBS, but not when 100 mM calcium acetate replaced PBS, revealing mostly compact myelin. These data show that the presence of calcium may be adequate to alter and possibly reverse ballooning. We propose that the ballooning in DS tissue may be in part present in vivo, caused by gene dosage effects of chr 21 genes affecting myelin and amplified by DS hypocalcemia. The low calcium ballooning may indicate that divalent cations may be needed to neutralize the negatively charged polysialic acids present in the oligodendrocyte glycoocalyx in order to form closely apposed myelin layers. In support of this is that mouse models overexpressing polysialic acids show myelin ballooning. The results indicate a mechanism of age-related myelin disturbance in DS that would decrease conduction velocity and cognitive processing, and it suggests a novel calcium mediated target for therapeutics of DS and DS-AD.

Chung<sup>6</sup>, The DDD Study.* 1) Center for Integrative Genomics, University of Lausanne, Lausanne, VD, Switzerland; 2) GeneDx, Gaithersburg, MD, United States; 3) Cooper Medical School of Rowan University, Division of Genetics, Camden, NJ, United States; 4) Manchester Centre for Genomic Medicine, Central Manchester University Hospitals NHS Foundation Trust, Manchester Academic Health Sciences Centre, St Mary's Hospital, Manchester, United Kingdom; 5) Institute of Human Development, University of Manchester, Manchester, United Kingdom; 6) Department of Pediatrics, Columbia University, New York, NY, United States; 7) Department of Medical Genetics, Oslo University Hospital, Oslo, Norway; 8) HudsonAlpha Institute for Biotechnology, Huntsville, AL, United States; 9) Center for Medical Genetics, Keio University School of Medicine, Tokyo, Japan; 10) APHP, GH Pitié Salpêtrière, Department of genetics, Paris, France; 11) Sorbonne Universités, UPMC Univ Paris 06, UMR S 1127, Inserm U 1127, CNRS UMR 7225, ICM, Paris, France; 12) Department of Translational Medicine, Section of Pediatrics, Federico II University, Naples, Italy; 13) Telethon Institute of Genetics and Medicine (TIGEM), Naples, Italy.

The ALF domain defines the *AFF1*, *AFF2*, *AFF3* and *AFF4* transcription factor paralogs, which are components of the transcriptional super elongation complex and regulate expression of genes involved in neurogenesis and development. We identified six individuals with *de novo* missense variants in the ALF degron, a signal for protein degradation by the ubiquitin-degradation system. They present with a recognizable pattern of anomalies including microcephaly, global developmental delay, intellectual disability, brain atrophy, seizures, dysmorphic features, horseshoe kidney, a mesomelic form of skeletal dysplasia resembling Nievergelt/Savarirayan type and other skeletal features, only partially overlapping the *AFF4* variants-associated CHOPS syndrome. A seventh *AFF3* patient who has a *de novo* missense in the *AFF3* ALF but outside of the degron exhibits a milder phenotype with autistic behavior and no dysmorphic features. The three described CHOPS individuals and two more patients we identified carrying *de novo* variants in the degron of *AFF4* allow to define that obesity and congenital heart defects are specific to individuals with *AFF4* variants, whereas *AFF3* degron variants are associated with seizures, failure to thrive and a distinctive skeletal dysplasia. Consistent with a causative role of *AFF3* variants in this syndrome, a previously reported individual with a microdeletion encompassing the ALF-domain of *AFF3* exhibited overlapping clinical features. Since the corresponding mice deletion better recapitulates this patient's bones malformations than the ablation of the entire orthologous gene, we hypothesize a gain-of-function mechanism in the *AFF3* patients. Murine models fully lacking the orthologous gene displayed skeletal anomalies, kidney defects, and brain and neurological anomalies. In conclusion, although ALF proteins were reported to be partially redundant, the phenotypes associated with *AFF3* and *AFF4* variants are clinically distinct and show only minimal phenotypic overlap.

**Microdeletion of Xp22 encompassing *SHOX* and *ARSE*, showing incomplete penetrance and variable expressivity.** *B. Simpson, H. Saal, R. Hopkin.* Division of Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

The phenotype of deletions at Xp22.33-p22.31 are rare and poorly delineated. We evaluated a 15-month-old patient who presented with facial dysmorphism, developmental delay, hypotonia, noisy breathing, left inguinal hernia, strabismus and short stature. SNP microarray revealed a 6.9Mb deletion of Xp22.33-p22.31, which encompasses over 30 genes, five of which (*CSF2RA*, *XG*, *SHOX*, *ARSE*, and *NLGN4X*) have been associated with clinical phenotype in humans. The patient had dysmorphic features consistent with chondrodysplasia punctata 1, which can be caused by deletions of *ARSE*. He had depressed nasal bridge, short nasal septum and midface hypoplasia. He had short stature ( $Z=-2.33$ ) and a familial history of short stature, which is consistent with a *SHOX* deletion. The *CSF2RA* gene has been associated with pulmonary alveolar proteinosis, which is not suspected in this patient at this time. Interestingly, a half-brother was also found to have the same deletion without the typical facies or clinical findings besides short stature ( $Z=-3.03$ ) and mild developmental delay. The patient's parents are not available for evaluation. Our patient does have other siblings, all half-brothers, some with similar facial features, though no clinical testing has been performed to date. One half-brother with similar facies and strabismus also carries the diagnosis of autism spectrum disorder (ASD), which has been associated with the *NLGN4X* gene. Our patient, though young, does not have any early features of an ASD diagnosis. These observations suggest a broad constellation of findings can be seen with deletions in this region of the X chromosome. However, variable expressivity and non-penetrance may be seen as demonstrated by the asymptomatic sibling. We are in the process of evaluating our proband's siblings as well as characterizing 18 other individuals followed in our center with overlapping deletions to help more clearly define the anticipated phenotype(s).

**CRISPR/Cas9 engineering to generate an isogenic model of the 3-Mb 22q11.2 syndromic deletion.** Y.T. Lin, N.P. Paranjape, A.P. Wiita. Department of Laboratory Medicine, University of California, San Francisco, San Francisco, CA.

Copy number variation (CNV) in the genome, due to gains or losses of specific DNA regions, can be causative of human disease. However, unlike single gene disorders, CNV-associated syndromes can arise from complex underlying genetic bases that translate to diverse phenotypic outcomes that are not fully understood. Recently, CRISPR/Cas9 has been employed to engineer CNVs up to 2 Mb to study the implication of these structural changes in disease (Kraft et al. 2015, Cell Rep 10:833), but it remains unclear if engineering larger CNVs is feasible. As a proof-of-principle, we sought to develop an isogenic model of the 22q11.2 deletion syndrome (DS), the most common microdeletion disorder in humans. The 22q11.2 locus is highly susceptible to genomic rearrangements due to the presence of low copy repeats (LCR), with 85% of 22q11.2DS patients carrying a single-copy ~3-Mb deletion flanked by the two repeat regions LCR22A and LCR22D. Using a recently-described strategy (Tai et al. 2016, Nat Neurosci 19:517), we took advantage of these regions of nearly-identical sequence to design a single guide that targets both LCRs simultaneously to generate the microdeletion via non-homologous end joining on the resulting breakpoints. In initial gene dosage screening by qPCR, we achieved an encouraging success rate of nine out of 44 (20%) isogenic clones harboring the deletion. We further validated the ~3 Mb deletion by SNP microarray. We hypothesized that even clones with the same genetic change may exhibit patient-relevant variable phenotypic effects. We therefore characterized three deletion-positive clones using label-free quantitative proteomics. As expected, we found a significant decrease in the mean expression of proteins encoded in the deletion locus, with moderate clone-to-clone variation, compared to the mean expression of other genes. Notably, we identified 27 and 14 genes outside the 22q11.2 region that were up- and down-regulated, respectively, by more than two-fold in the deletion clones versus wild-type. While we are currently replicating this analysis, these initial findings suggest our proteomic approach may reveal genes outside the CNV region that could play a role in the variable outcomes of 22q11.2DS. Taken together, we show that the single guide strategy can efficiently generate CNVs up to ~3 Mb. These approaches can be used for downstream functional studies in cell line, stem cell, and murine models to reveal the spectrum of effects of syndromic CNVs.

**Exome sequencing-based pipeline identifies functional variants within chromosome 1 associated with the risk of non-syndromic cleft palate.** S. Beiraghi<sup>1</sup>, W. Looman<sup>2</sup>, H. Stessman<sup>3</sup>, U. Radhakrishna<sup>4</sup>, B. Van Ness<sup>3</sup>, A.K. Mitra<sup>3</sup>. 1) Pediatric Dept, 6-150 Moos, Univ Minnesota, Minneapolis, MN; 2) School of Nursing, University of Minnesota, Minneapolis, MN, USA; 3) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, USA; 4) Department of Obstetrics and Gynecology, Oakland University William Beaumont School of Medicine, Royal Oak, Michigan, United States of America.

**Background** Nonsyndromic cleft palate only (nsCPO) is a common congenital craniofacial developmental malformation in humans. Genetics variants governing the risk of nsCPO has yet to be unraveled completely. **Methods:** We performed exome sequencing on 4 subjects (2 affected sons, mom and dad) to identify novel genetic variants associated with the risk of non-syndromic nsCPO. Recent studies have identified variants in chromosome 1, including the gene GRHL3, with genome-wide significant association with nsCPO. Therefore, our focus was to discover additional risk associated single nucleotide polymorphisms (SNPs) within this chromosome. Peripheral blood was obtained following informed consent, genomic DNA was isolated and Exome sequencing was performed on Illumina's HiSeq2500 next-generation high-throughput sequencing system. Exome sequencing data was processed using Galaxy and variants were called using SAMtools and GATK Unified Genotyper. Common overlapping variants were filtered out using Western European (CEU) genomes in the 1000 Genomes Project. Variants were annotated using human reference database (GRCh37.75), snpEFF and ClinVar. **Results:** Exome sequencing identified 349,569 variants in Chromosome 1. When we looked for variants for which the Proband and affected sibling were homozygous and the parents are heterozygous, 8 variants followed our strict filtering criteria (QUAL>30; with dbSNPv137 rs IDs and present in 1000G database; likely effect predicted by snpEFF; clinical annotation available in ClinVar). Among the SNPs found significant are genes implicated in congenital diseases, including Charcot-Marie-Tooth. This disease is also characterized by hammer toe. Interestingly, both the affected children have Morton's toe (which we will be demonstrating in the pedigree figure). **Conclusions:** Our results thus confirmed the presence of functional variants within chromosome 1 as risk factors for nsCPO.

**2192T**

**Genotype-phenotype correlation in WAGR syndrome: Large deletion of chromosome 11p in a patient with classical and non-classical symptoms of the syndrome.** P.N. Moretti<sup>1,2</sup>, V.S. Souza<sup>2,3</sup>, G.C.R. Cunha<sup>2,3</sup>, S.F. Oliveira<sup>1,3,4</sup>, J.F. Mazzeu<sup>4,5,6</sup>, A. Pic-Taylor<sup>2,3,4</sup>. 1) Departamento de Morfologia e Genética, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Brazil; 2) Laboratório de Embriologia e Biologia do Desenvolvimento, Departamento de Genética e Morfologia, Instituto de Ciências Biológicas, Universidade de Brasília, Brasília, Brazil; 3) Programa de Pós-graduação em Biologia Animal, Universidade de Brasília, Brasília, Brazil; 4) Programa de Pós-graduação em Ciências da Saúde, Universidade de Brasília, Brasília, Brazil; 5) Hospital Universitário, Universidade de Brasília, Brasília, Brazil; 6) Faculdade de Medicina, Universidade de Brasília, Brasília, Brazil.

WAGR syndrome affects different body systems and is clinically characterized by the presence of Wilms' tumor, aniridia, genitourinary alterations and intellectual disability (ID). The molecular diagnosis for the syndrome is based in the deletion of the *WT1* and *PAX6* genes, which have essential function in the urogenital system and ocular development, respectively. Here we describe a patient with clinical findings associated with WAGR syndrome such as neuropsychomotor development delay and aniridia, and other malformations not previously described in patients with the syndrome. We performed blood collection, followed by karyotypic analysis and Chromosome Microarray Analysis using Cytoscan 750K (Affymetrix). The karyotype was normal (46, XX) and microarray analysis revealed a 10 Mb deletion in the short arm of chromosome 11, different than others reported in the literature. The deletion encompasses 41 coding genes, and include the critical region for the WAGR syndrome, with total deletion of *WT1* and *PAX6* genes, confirming the diagnosis of the syndrome. As a contiguous gene syndrome, the size and content of the deletion may account for phenotypic variations observed among patients with WAGR syndrome. Our patient present non-classical symptoms such as hypotonia/hypertonia; inguinal hernia; syndactyly/clynodactyly and patent foramen ovale, and other symptoms not described in other subjects with deletion, like pulmonary stenosis, retrognathia and short stature. We are currently analyzing gene functions and interactions to determine which genes could explain the phenotypic variation observed in our patient in comparison to other patients with WAGR syndrome.

**Syndromic cleft genes implicated in non syndromic forms: Towards translational phenotypes?** B. Demeer<sup>1,2,5</sup>, M. Basha<sup>1</sup>, O. Boute<sup>3</sup>, L. van Malderg<sup>4</sup>, M. Mathieu<sup>6</sup>dramard<sup>5</sup>, R. Helaers<sup>1</sup>, C. Gbaguidi<sup>6</sup>, N. Revencu<sup>1,7</sup>, B. Bayet<sup>8</sup>, B. Devauchelle<sup>6</sup>, M. Vikkula<sup>1,7</sup>. 1) Human Molecular Genetics, de Duve Institute, Université catholique de Louvain, Brussels, Belgium; 2) EA 4666, LNPC, Université Picardie Jules Verne Amiens, France; 3) human genetics department, CLAD nord de france Amiens University hospital, Amiens, France; 4) Human genetics unit, CHU Besançon, Besançon, France; 5) Human genetics unit, CLAD nord de France, CHU Amiens Picardie, Amiens, France; 6) Maxillo-facial department, CHU Amiens Picardie, Amiens, France; 7) Center for Human Genetics, Cliniques universitaires Saint Luc, Brussels, Belgium; 8) Centre Labiopalatin, Division of Plastic Surgery, Cliniques universitaires Saint Luc, Brussels, Belgium.

Cleft lip with or without cleft palate (CL/P) and cleft palate (CP) are the most common craniofacial birth defects with an approximate incidence of ~1/700. In 30% of cases, clefts are seen in syndromic forms likely caused by genetic factors. Non syndromic forms (NS) are believed to be caused by a combination of genetic and environmental factors. Several genome-wide association studies have proposed a few loci in NSCL/P. A few genes have been implicated in both syndromic and non-syndromic forms of CL/P. Moreover, there are families with NSCL/P following Mendelian transmission with low penetrance and variable expressivity. These two points suggest that a strategy of studying genes or pathways associated with syndromic forms as the cause of NS clefts could be productive. To this end we decided to perform whole exome sequencing on patients with NS cleft, after having ruled out *IRF6* mutations and cytogenetic anomalies. Patients from 12 families with CP, 10 families with CL/P, 2 families with velopharyngeal insufficiency, and 6 sporadic CP cases were selected. Several likely causative variants were identified in five families: in *GHRL3*, *TP63*, *LRP6* and *TBX1*. Clinical reassessment confirmed the isolated occurrence of cleft with variable expressivity in affected patients, as well as low penetrance, given the number of unaffected carriers. Our study illustrates the involvement of genes known to be mutated in syndromic clefts, in non syndromic CL/P. It raises the question of an important part of the "missing heritability" of NSCL/P possibly being explained by modest-to-medium penetrant variants in such genes.

**2194W**

**Genetic variants in a patient with pancreatitis after propofol administration.** J.B. Cordero<sup>1</sup>, R.J. Rooney<sup>2</sup>, J.C. Han<sup>2,3,4</sup>, C.L. Simpson<sup>1</sup>. 1) Department of Genetics, Genomics, and Informatics, University of Tennessee Health Science Center, Memphis, TN; 2) Department of Pediatrics, University of Tennessee Health Science Center, Memphis, TN; 3) Department of Physiology, University of Tennessee Health Science Center, Memphis, TN; 4) Children's Foundation Research Institute, Le Bonheur Children's Hospital, Memphis, TN.

WAGR syndrome is a rare genetic condition caused by heterozygous chromosome 11p13 deletion. This region contains *PAX6*, which is vital to embryonic development of many systems, including the endocrine pancreas. Propofol is a commonly used sedative hypnotic agent administered as a fat emulsion for procedural and critical care sedation. Hepatic enzymes mainly responsible for propofol metabolism are *UGT1A9*, *CYP2B6* and *CYP2C9*. Despite its wide use, case reports indicating acute pancreatitis induced by propofol poses concerns about its safety and serious adverse effects in patients with inherited metabolic disorders such as glycogen storage disease and children with preexisting hypertriglyceridemia. We studied the genetic variants in a 12-year-old patient with WAGR, obesity and hypertriglyceridemia who developed pancreatitis after propofol infusion. We sought to determine if variations elsewhere in the patient's genome or in the hemizygous alleles within the WAGR deletion could have contributed to the adverse reaction to propofol. Whole exome sequencing (WES) was performed on the patient. Variants were annotated using wANNOVAR and SNVs with biologically meaningful functional annotation were prioritized. SNVs were then analyzed individually for association with drug absorption, distribution, metabolism, excretion and links to pancreatitis, hypertriglyceridemia and propofol metabolism. Gene relations to phenotypes were derived from GWAS catalog, OMIM, GeneCards, PharmGKB, NCBI Gene and PubMed. From the WES variant data, we identified 5 associated genes for propofol metabolism, 24 for hypertriglyceridemia and 15 for pancreatitis. Heterozygous variants within *CYP4F2*, *APOE*, *CASR*, *ABO*, *FUT2*, and *TPMT* were predicted to have protein pathogenicity by a majority of prediction algorithms. We also found a rare variant of *CYP2B6* (rs58871670) in close proximity to a known *CYP2B6* variant (rs3745274) which is associated with decreased propofol metabolism. Several variants related to propofol metabolism, hypertriglyceridemia and pancreatitis appear to have placed the patient at higher threshold of risk to develop acute pancreatitis. However, we are not certain what combination of variants contributed to the patient's adverse reaction to propofol. The findings suggest that the patient's adverse drug reaction is not due to the WAGR region deletion, but a complex interaction of factors including genetic variations and underlying risk factors such as hypertriglyceridemia.

**2195T**

**Whole-exome analysis of late-onset Alzheimer's disease reveals novel candidate genes involved in cognitive function.** C. Preuss<sup>1</sup>, X. Wang<sup>1</sup>, G. Ananda<sup>1</sup>, S. Neuner<sup>1</sup>, V. Phillip<sup>1</sup>, A. Saykin<sup>2</sup>, K. Nho<sup>2</sup>, B. Lamb<sup>2</sup>, A. Uyar<sup>1</sup>, B. Lodgson<sup>3</sup>, K. Karaturi<sup>1</sup>, C. Kaczorowski<sup>1</sup>, M. Sasner<sup>1</sup>, G. Howell<sup>1</sup>, G. Carter<sup>1</sup>. 1) The Jackson Laboratory, Bar Harbor, ME; 2) Stark Neurosciences Research Institute, Indiana University, IN; 3) Sage Bionetworks, Seattle, WA.

**Background:** Alzheimer's disease (AD) is the major cause of dementia in the aging population worldwide. Despite a strong heritable component for this complex polygenic disease, the underlying causes for cognitive decline in late-onset AD remain largely unclear. **Methods:** Here, we conducted whole-exome analysis using data from the Alzheimer's Disease Sequencing Project (4840 cases, 4294 controls) to identify the individual burden of common and rare pathogenic coding variants in AD. Single variant association, collapsed burden and gene set enrichment analysis were combined to identify novel candidate genes and pathways associated with cognitive function. We validated our association results in an independent longitudinal cohort of sporadic AD with 818 participants. Mouse models with cognitive decline were used to translate findings and prioritize candidate genes for functional validation. **Results:** We identified common coding variants in a novel locus (*SLC6A17*,  $p < 1 \times 10^{-6}$ ) with exome-wide significance and validated variants in known candidate genes (*APOE*, *MAPT*, *MS4A6A*) previously associated with cognitive function in AD. The lead SNP (rs41281364) in *SLC6A17* was replicated in a cohort from the Alzheimer's disease neuroimaging initiative ( $p = 0.008$ ) measuring CSF tau burden, an independent predictor of cognitive decline in AD patients. The glutamate transporter correlated with amyloid precursor expression in the hippocampus of a mouse model of AD ( $\rho = 0.618$ ,  $p = 7.3E-09$ ) and is associated with cognitive decline ( $p = 0.006$ ,  $n = 9$  per group (impaired vs. unimpaired)) in aged AD mice. In addition to the common variant burden, gene-based analysis of rare deleterious variants identified novel candidates implicated in disease (*CEACAM1*, *CD93*, *PLA2G4D*,  $p < 1 \times 10^{-7}$ ). Rare deleterious variants are significantly enriched ( $p < 0.05$ , Bonferroni adjusted) in pathways associated with cognitive function, including serotonergic signaling and amyloid- $\beta$  clearance. **Conclusions:** Taken together, our results highlight that both common and rare coding variants contribute to the complex architecture of AD. Moreover, we demonstrate that variants with moderate-to-large effects in new biological candidates (*SLC6A17*, *PLA2G4D*, *HTR4*) along the functionally interacting glutamatergic and serotonergic signaling pathways affect cognitive decline in AD.

## 2196F

**African haplotypic background mitigates the effect of APOE  $\epsilon$ 4 risk allele in Alzheimer disease.** F. Rajabli<sup>1</sup>, B.E. Feliciano-Astacio<sup>2</sup>, K. Celis<sup>3</sup>, K.L. Hamilton-Nelson<sup>1</sup>, L.D. Adams<sup>1</sup>, A.R. Betancourt<sup>2</sup>, H. Acosta<sup>3</sup>, A. Chinea<sup>4</sup>, G.S. Bird<sup>5</sup>, C. Reitz<sup>6</sup>, R. Macdonald Department of Human Genetics, University of Miami, Miami, FL, USA; 8) Department of Epidemiology and Biostatistics, Institute for Computational Biology, Case Western Reserve University School of Medicine, Cleveland, Ohio, USA.

**Background:** Late-onset Alzheimer's disease (LOAD) is a progressive neurodegenerative disorder. The *apolipoprotein E gene (APOE)  $\epsilon$ 4 allele (ApoE4)* is a major genetic risk factor for LOAD in non-Hispanic white (NHW) populations but has attenuated effects in African American (AA) and Hispanic (HI) populations. The underlying reasons for differential ApoE4 effects across the populations are not clear. Our goal in this study is to assess the relevance of the local ancestral background to the differential effect of the ApoE4 in AA and HI, due to the admixed nature of these populations. **Methods:** ApoE4 and genome-wide genotyping (with IlluminaMEGA and GSA arrays) were performed in 2,937 AA (1,083 cases, 1,854 controls) and 286 Puerto Rican (PR) HI samples (162 cases, 124 controls). Local ancestry was calculated using SHAPEIT (with 1kGP reference) followed by RFMix (using HGP reference panels). Association between the affection status and the ApoE4 genotype in the presence of the local ancestry was analyzed using Fisher's Exact test. **Results:** Overall: ApoE4 dose associated with LOAD risk in AA (heterozygotes-OR=2.23, CI:1.8-2.7,  $p < 2.2 \times 10^{-16}$ ; homozygotes-OR=7.65, CI:5.1-11.6,  $p < 2.2 \times 10^{-16}$ ) and PR (heterozygotes-OR=2.12, CI:1.0-4.6,  $p = 0.033$ ; homozygotes-OR=7.97, CI:1.1-347.1,  $p = 0.02$ ) populations, but with reduced effect size compared to NHW populations (heterozygotes-OR=3.2, CI:2.8-3.8; homozygotes-OR=14.9, CI:10.8-20.6). **Local Ancestry:** Results showed that PR and AA individuals with European local ancestry have a stronger ApoE4 effect than those with African local ancestry (Table 1). The local ancestry was nominally associated with AD in logistic regression model.

Ethnic Groups	APOE Genotype	Local Ancestry	p-value	OR	2.50%	97.50%
AA	$\epsilon$ 3 $\epsilon$ 4 vs $\epsilon$ 3 $\epsilon$ 3	African	2.06E-9	2.11	1.64	2.72
		European	5.81E-9	2.88	1.99	4.21
	$\epsilon$ 4 $\epsilon$ 4 vs $\epsilon$ 3 $\epsilon$ 3	African	<2.2e-16	5.85	3.74	9.35
		European	2.72E-13	20.7	7.11	82.47
PR	$\epsilon$ 3 $\epsilon$ 4 vs $\epsilon$ 3 $\epsilon$ 3	African	1	1.07	0.29	4.25
		European	0.008	3.7	1.28	12.52

**Conclusion:** These results suggest those PR who inherited an African APOE region have a lower risk of LOAD, similar to that described for AA. This supports the hypothesis that the differential effect of ApoE4 in ethnic groups is due to ancestral variation around APOE. Thus, AA and PR individuals with the APOE region from African populations may harbor common protective factors that may help mitigate the effect of the detrimental ApoE4.

**Dissecting the sex-specific basis of APOE  $\epsilon$ 4 allele effect on longevity.** P.R.H.J. Timmers<sup>1</sup>, P.K. Joshi<sup>1</sup>, J.F. Wilson<sup>1,2</sup>. 1) Centre for Population Health Sciences, University of Edinburgh, Edinburgh, United Kingdom; 2) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, United Kingdom.

The Apolipoprotein E  $\epsilon$ 4 allele is linked to higher risk of developing Alzheimer's disease (AD) as well as a higher risk of overall mortality. Recent research suggests the APOE effect on lifespan and cognitive decline is stronger in women (Joshi et al. 2016; Lipnicki et al. 2017); however, it is currently unclear whether the difference in lifespans is due to sex-specific aetiology, or is a consequence of fewer men surviving until the onset of AD. Using UK Biobank data on 224,166 parental lifespans, we separate men and women by socioeconomic strata, and combine this with 13,927 cases of parental AD (4863 fathers, 9064 mothers) to investigate how the effects of APOE vary depending on expected lifetime. We found that the mortality hazard ratio of APOE increases from 2.03 to 2.08 in men and 2.08 to 2.15 in women when comparing the bottom and top strata. Curiously, we found no evidence of an increase in self-reported parent prevalence of AD in the higher mortality ratio groups. Further analysis suggests that groups with the same expected lifespan will have the similar APOE mortality hazard ratios, regardless of sex. In other words, the observed sex-specific effect of APOE on lifespan is primarily driven by the sex-specificity of lifespan itself and the age-related effects of APOE  $\epsilon$ 4, rather than sex-specific aetiology of AD. **References:** Joshi, P.K. et al., 2016. **Age-related changes in white blood cell gene expression associated with skeletal fragility.** E. Quillen<sup>1</sup>, J.P. Glenn<sup>1</sup>, J. Foster<sup>1</sup>, A. Sheldrake<sup>1</sup>, L.A. Cox<sup>1</sup>, D.P. Nicoletta<sup>2</sup>, T.L. Bredbenner<sup>2</sup>. 1) Department of Genetics, Texas Biomedical Research Institute, San Antonio, TX; 2) Mechanical Engineering Division, Southwest Research Institute, San Antonio, TX.

Inflammaging – increased chronic inflammation in the elderly – is a frequently-cited contributor to diseases of aging, a growing segment of overall morbidity and mortality. The goal of this study is to determine if age-related changes in gene expression of white blood cells are associated with increased bone fragility using a baboon model. No work was done on living animals and no animals were euthanized specifically for this study. Total RNA was extracted from white blood cells collected at necropsy and mRNA libraries were generated using the KAPA Stranded mRNA-Seq kit for sequencing on the Illumina HiSeq2500. Reads were aligned to the *Papio anubis* genome using the STAR aligner, normalized to read counts per sample, and converted to a log-fold scale. Welch's t-tests were used to identify transcripts with significantly different expression between 38 middle-aged female baboons (14.7±2.7 years, human equivalent 44.1) and 44 elderly female baboons (25.8±1.6 years, human equivalent 77.4). 949 transcripts with nominally significant ( $\alpha = 0.05$ ) results from the t-tests were evaluated for association with age-adjusted measures of skeletal fragility in an independent sample of 54 female baboons. Skeletal fragility is a major risk factor for fracture but is incompletely indexed by the most common clinical indicator, bone mineral density. Alternative measures of bone quality of the femur were generated post-mortem including: structural stiffness in the habitual loading direction; fracture strength in a non-habitual loading direction equivalent to a side ways fall; collagen content and cross-linking; and, tissue density and percent mineralization in cortical bone. All analyses were performed while controlling for age and body size of the baboons. Eight transcripts were linked to measures of skeletal fragility and bone loss using a significance cutoff of  $p < 1 \times 10^{-4}$ . These include the baboon homologues of *RALGPS2*, *CMTR*, *SLC16A6*, and *E2F7* linked to gross measures of bone robustness. The majority of these genes have previously been linked to apoptosis or cell differentiation. Expression of *XIAP*, a regulator of apoptotic cell death was also associated to the tensile strength of the bone while expression of *RAB23*, a regulator of chondroprogenitor cells was associated with fracture resistance in a fall simulation. Finally, *PI4K2A*, a regulator of cell growth was associated with collagen content in the bone. This work was funded by NIH/NIAMS R01 AR064244 and R01 AR060341.

**The genomic basis of human lifespan.** P. Joshi<sup>1</sup>, N. Pirastu<sup>1</sup>, K. Kentistou<sup>1</sup>, K. Fischer<sup>2</sup>, T. Esko<sup>2</sup>, Z. Kutalik<sup>3,4</sup>, J.F. Wilson<sup>1,5</sup> on behalf of the LifeGen consortium. 1) Centre for Global Health Research, University of Edinburgh, Edinburgh, United Kingdom; 2) Estonian Genome Center, University of Tartu, University of Tartu, Tartu, 51010, Estonia; 3) Institute of Social and Preventive Medicine, Lausanne University Hospital, Lausanne, 1010, Switzerland; 4) Swiss Institute of Bioinformatics, Lausanne, 1015, Switzerland; 5) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Edinburgh, EH4 2XU, UK.

Genomic analysis of longevity offers the potential to disentangle the underlying effects of lifestyle and disease on mortality and to illuminate the biology of human aging, but until now power for discovery has been limited. Here, using 29 population cohorts with genome-wide data and information on 606,000 **parent lifespans**, we discover two new, genome-wide significant variants affecting longevity (near HLA-DQA1/DRB1 and LPA). We also recapitulate previously identified associations with longevity at APOE and CHRNA3/5 and validate, at a lower level of significance, previous suggestions that common variants at CDKN2A/B, SH2B3 and FOXO3A influence longevity. Next we show that, amongst two hundred traits considered, giving up smoking, educational attainment, openness to new experience and HDL cholesterol levels are most positively genetically correlated with lifespan; whilst susceptibility to coronary artery disease (CAD), cigarettes smoked per day, lung cancer, insulin resistance and body fat are most negatively correlated. We suggest that the effect of education on lifespan is principally mediated through smoking, whilst the effect of obesity appears to act via CAD. Using instrumental variables, we quantify the effect of disease susceptibility and lifestyle factors, and suggest that an increase of one body mass index unit reduces lifespan by 4 months, whilst one year of education adds 11 months to expected lifespan.

**Genomics of the aging hematopoietic system.** *E. Bader*<sup>1,2</sup>, *V. Bruat*<sup>1</sup>, *E. Gbeha*<sup>1</sup>, *P. Awadalla*<sup>1,2</sup>. 1) Informatics, Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Hematopoiesis is a tightly controlled, dynamic process that continuously replenishes the populations of cells that circulate in blood. Dysregulation of circulating blood cells can negatively impact health, as they are essential for immune functions and oxygen transport. Increased age is associated with dysfunctional blood cell phenotypes and an overall decline in immune functioning, known as immunosenescence, which likely contributes to an increased incidence of age-related disease. Although age is generally associated with poor blood health and disease, a small population of elderly individuals remain healthy throughout their lifetime. Characterizing the genomic and transcriptomic landscape of blood cells in this population can provide insights into the mechanisms that preserve blood health. We exploit Canada's largest population cohort, the Canadian Partnership for Tomorrow Project (CPTP), a resource that provides extensive health and environment data as well as biological samples, to identify elderly individuals with superior blood health. We evaluate the health of an individual's blood using information from complete blood count (CBC) data, which includes blood phenotypes such as the proportions of different cellular populations and red cell distribution width. We observe an association between abnormal blood phenotypes and disease prevalence, demonstrating that blood phenotypes are informative of an individual's overall health. Additionally, individuals with poor blood health often develop abnormal blood phenotypes for a subset of CBC variables acquired sequentially, suggesting an initial event may contribute to downstream events. Differential gene expression analyses that compare young and old individuals with extremely healthy or poor blood health demonstrate that age and blood health alter expression of different sets of genes. Differentially expressed genes are regulated by non-coding variants, which may explain their differences in expression between individuals across age categories with varying blood phenotypes. To further characterize regulatory mechanisms that maintain or diminish blood health we are measuring chromatin accessibility in multiple cell populations. Our results suggest that some of the blood phenotypes reported in a CBC are better indicators of blood health irrespective of age, and therefore can potentially be used for more appropriate stratification and risk assessment of patients.

**Identifying genetic variants associated with leukocyte telomere length in African Americans.** *A. Little*<sup>1</sup>, *J. Wilson*<sup>2</sup>, *A. Aviv*<sup>3</sup>, *A. Reiner*<sup>4,5</sup>, *T. Thornton*<sup>1</sup>. 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Department of Physiology and Biophysics, University of Mississippi Medical Center, Jackson, MS 39216; 3) Center of Human Development and Aging, Rutgers, The State University of New Jersey, New Jersey Medical School, Newark, NJ 07103, USA; 4) Department of Epidemiology, University of Washington, Seattle, WA 98195, USA; 5) Division of Public Health Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA 98109, USA.

Leukocyte telomere length (LTL) is a complex trait that is influenced by genetic factors as well as environmental factors such as smoking and sedentary lifestyle. Genome-wide association studies (GWAS) of LTL, performed largely in European ancestry cohorts, have identified LTL-regulating genes that provide mechanistic insights into the potential roles of LTL dynamics (birth LTL and its age-dependent shortening). However, little is known about LTL-regulating genes in African Americans (AfAs). Recent studies have established that AfAs have longer LTL than white Americans on average. Racial differences in LTL and LTL-regulating variant genes that determine LTL dynamics may have a role in the predilection to common diseases such as CVD and cancer. To gain better insight into the genetic determinants of LTL in AfAs, we performed a meta-GWAS in a total of 3408 AfAs using whole genome sequence data from the NHLBI TOPMed project (N= 2410 AfAs from the Jackson Heart Study) along with 998 AfAs from Women's Health Initiative, where genotyped data was imputed to 1000 Genomes. Two loci had  $P < 5 \times 10^{-8}$  in AfAs: chromosome 10 (*OBFC1*) and a potentially novel inter-genic SNP on chromosome 9. An additional suggestively associated locus for LTL in AfAs ( $P = 6 \times 10^{-6}$ ) was identified on chromosome 4 intronic to *ZNF827*, which interestingly is involved in remodeling of telomeric chromatin. Of the 12 SNPs previously associated with LTL in European populations, only two replicated in our study of LTL in AfAs (*OBFC1* and *TERT*). Replication studies of the two putatively novel LTL-associated loci are ongoing in additional AfA samples. These results provide evidence that there are both shared and distinct genetic components contributing to LTL across multi-ethnic populations.

Dental caries is a heritable trait but evidence about implicated genomic regions has emerged only from small studies. We performed a fixed effects inverse-variance weighted meta-analysis (MA) of GWAS for dental caries in 26,792 individuals from 8 studies of European ancestry and 1 study of Hispanics/Latinos. Association analyses used age- and sex-standardized residuals of clinically assessed dental caries DMFS index, the sum of decayed, missing and filled tooth surfaces, excluding third molars. Genotypes were imputed in each individual study to 1000 Genomes v3 imputation panel. Three novel loci showed evidence for association with caries (*PITX1-c4orf66*, *CA12* and *AHCTF1*,  $P < 5 \times 10^{-8}$ ). Using approximate conditional analysis we further identified additional independent signal in the *PITX1-c4orf66* region. Gene-based analysis (MAGMA) of MA results additionally highlighted the *TBL2* gene as being implicated in caries ( $P < 2 \times 10^{-6}$ ). The *PITX1-c4orf66* and *CA12* associations were supported in 146,341 individuals with self-reported oral health data from UK biobank (question "Do you have any of the following? - Dentures";  $P = 2.0 \times 10^{-19}$  and  $P = 2.0 \times 10^{-4}$  respectively), while the third SNP and its proxies were not available in UK biobank dataset. The *PITX1* locus has been previously shown in mice to exhibit preferential expression in the developing mandible, pituitary gland and teeth covering the tooth-forming region in the mandible. Loss of function mutations in *CA12* is reported to result in defects in fluids and carbonate secretions including such disease as pancreatitis and xerostomia (dry mouth syndrome). Using GREML, we estimated SNP-based heritability for the DMFS index in two participating studies ( $h^2_{\text{SNP}} = 0.18$ ,  $se = 0.09$  and  $h^2_{\text{SNP}} = 0.39$ ,  $se = 0.14$ ). We applied linkage-disequilibrium score regression to calculate genetic correlation (rg) between dental caries and 77 disease traits with available summary association statistics from GWAS. The correlations with waist-hip ratio adjusted for body mass index ( $rg = 0.25$ ,  $se = 0.06$ ,  $P = 5.2 \times 10^{-6}$ ), waist and hip circumference ( $rg = 0.22$ ,  $se = 0.05$ ,  $P = 1.6 \times 10^{-6}$  and  $rg = 0.15$ ,  $se = 0.05$ ,  $P = 0.005$ , respectively), years of schooling ( $rg = -0.13$ ,  $se = 0.05$ ,  $P = 0.004$ ), body mass index ( $rg = 0.14$ ,  $se = 0.06$ ,  $P = 0.01$ ), and inflammatory bowel disease ( $rg = 0.18$ ,  $se = 0.07$ ,  $P = 0.01$ ) were significant at  $FDR < 0.05$ . This meta-analysis and follow-up investigations highlighted genetic architecture of dental caries and well as its relationship with other disease traits.

**2203W****Understanding relationships between longevity and physical senescence using Mendelian randomization approach.**

S. Ukraintseva, K. Arbeeve, Y. Wang, H. Duan, I. Zhabnikov, A. Kulminski, A. Yashin. Duke University, Durham, NC.

Mendelian randomization (MR) is an important approach to studying human aging since it can help clarify biological mechanisms underlying statistical associations between the principal outcome of aging (lifespan/longevity) and various health and senescence related phenotypes. MR uses genetic variants as instrumental variables to establish whether such phenotypes are causally related to longevity. In this study, we employed MR approach to assess the causal relationships between several traits (mediators) characterizing physical senescence, and survival to the age 85 and beyond (outcome), using logistic regression, and genotyping and phenotypic data available from three longitudinal human studies (Cardiovascular Health Study (CHS), Framingham Heart Study (FHS), and Health and Retirement Study (HRS)). SNPs in *NRG1* and *NRG3* genes that have previously been associated with the phenotypes of physical senescence were used as instrumental variables. We found that the rate of decline in BMI between ages 65 and 85; peak ages (ages at maximum) of the weight and BMI, after which they start to decline towards extreme ages; and Rosow-Breslau index of physical ability to walk half a mile, climb the stairs and do a housekeeping work, at ages 65+, were significant mediators of longevity in our study. These results suggest that manifestation of physical senescence even without an accompanying disease is major limiting factor for longevity.

**2204T**

**Allele-specific expression in healthy centenarians.** *L.C. Tindale<sup>1,2</sup>, N. Thiessen<sup>1</sup>, S. Leach<sup>1</sup>, A.R. Brooks-Wilson<sup>1,2</sup>.* 1) Canada's Michael Smith Genome Sciences Centre, BC Cancer Agency, Vancouver, Canada; 2) Department of Biomedical Physiology and Kinesiology, Simon Fraser University, Burnaby, Canada.

The genetic basis of healthy aging and longevity remains largely unexplained. One hypothesis as to why long-lived individuals do not appear to have a decreased number of common-complex disease risk alleles, is that despite carrying these risk alleles, they express the disease-linked variants at a lower level than the wild type allele. We have sequenced the transcriptomes of four healthy centenarians and four mid-life controls using whole blood in a pilot study. We hypothesized that the centenarians will have an overall pattern of decreased expression of disease-associated alleles. This would effectively allow them to favour expression of the non-risk allele, despite also carrying the disease-causing variant. Heterozygous SNPs act as indicators to determine if one copy of the DNA is more highly expressed. This difference in expression between the two haplotypes of a diploid individual is referred to as allele-specific expression (ASE). The ASE analysis is currently in progress. Molecular signatures may distinguish between disease states, and many conditions have an inflammatory component that affects immune cells. CIBERSORT was used to estimate cell fractions with neutrophils being the most abundant source of RNA, followed by CD8 T cells, resting NK cells, and monocytes. In the present study, whole blood is an appropriate tissue in which to achieve our goal of conducting a hypothesis generating analysis about overall disease risk and patterns of ASE, which may be contributing to disease.

Hamilton<sup>1</sup>.* 1) RTI International, Research Triangle Park, NC; 2) Icahn School of Medicine at Mount Sinai, New York, NY; 3) California Pacific Medical Center, San Francisco, CA; 4) University of California, San Diego, San Diego, CA; 5) University of Maryland School of Medicine, Baltimore, MD; 6) National Institute on Aging, Bethesda, MD; 7) Wake Forest School of Medicine, Winston-Salem, NC; 8) University of California, Irvine, Irvine, CA; 9) Institute for Aging Research, Hebrew SeniorLife and Harvard Medical School, Boston, MA; 10) Columbia University, New York, NY; 11) Boston University, Boston, MA; 12) National Human Genome Research Institute, Bethesda, MD.

The PhenX Toolkit (<https://www.phenxtoolkit.org/>) is a web-based catalog of standard measures to facilitate biomedical research. Use of PhenX (consensus measures for Phenotypes and eXposures) measures enables cross-study analyses for increasing statistical power and replicating results. In May 2017, PhenX convened nine experts to develop content for a new Geriatrics domain, which will include common measures for research in older adults. The Working Group will address the scope with 15 priority measures; identify open source protocols that pose low burden for study participants and investigators; identify measures that address phenotypes specific to geriatrics; and enhance existing PhenX measures with content for older adults. The measures recommended by the Working Group and brief descriptions will be presented. We will also present PhenX Toolkit bioinformatics tools and features, and collaborative efforts with NIH Common Data Element (CDE) Initiatives and the database of Genotypes and Phenotypes (dbGaP). The PhenX Toolkit currently includes over 500 measures from 24 research domains, with additional depth for Substance Abuse and Addiction, Mental Health, Tobacco Regulatory, and Sickle Cell Disease research. For each measure, the Toolkit provides detailed instructions (e.g., required training and equipment), features (e.g., Spanish language versions), and bioinformatics support (e.g., data dictionaries, REDCap compatible modules) to facilitate implementation and data analysis. The PhenX Toolkit is widely used, with more than 2,500 registered users worldwide and 755 visitors per day on average. This web-based resource has been recommended in more than 200 NIH funding opportunity announcements. We are celebrating the 10-year anniversary of the PhenX Toolkit and 5 additional years of funding that will allow us to continue to be responsive to the evolving needs of the research and clinical communities. *Funding provided by a Genomic Resource Grant (U41 HG007050-05) from NHGRI, with co-funding from the National Institute on Drug Abuse (NIDA) and the Office of the Director, National Institutes of Health (OD).*

**Does parent-to-offspring transmission of telomeres contribute to telomere length heritability in humans?** D.A. Delgado<sup>1</sup>, C. Zhang<sup>1</sup>, L.S. Chen<sup>1</sup>, F. Jasmine<sup>1</sup>, M.G. Kibriya<sup>1</sup>, S. Roy<sup>1</sup>, R. Paul-Brutus<sup>1</sup>, H. Ahsan<sup>1,2,3,4</sup>, B.L. Pierce<sup>1,2,3</sup>. 1) Department of Public Health Sciences, University of Chicago, Chicago, IL; 2) Department of Human Genetics, University of Chicago, Chicago, IL 60615; 3) Comprehensive Cancer Center, University of Chicago, Chicago, IL 60615; 4) Department of Medicine, University of Chicago, Chicago, IL 60615.

Leukocyte telomere length (TL) shortens with age and is a potential biomarker of risk for age-related diseases. TL is a heritable trait with two potential sources of heritability ( $h^2$ ): inherited variation in non-telomeric regions (e.g., SNPs) and inherited variability in the lengths of telomeres themselves. Prior family-based and SNP-based  $h^2$  studies have not attempted to disentangle these two sources. Here, we attempt to detect "direct" inheritance of telomeres by studying the association between identity-by-descent (IBD) sharing at chromosome ends and phenotypic similarity in TL. We measured genome-wide SNPs for a sample of Bangladeshi adults with substantial cryptic relatedness ( $n=5,069$ ). TL was measured for each individual using qPCR or Luminex-based methods. We estimated IBD sharing (0, 1, or 2) at each chromosome end using 180 uncorrelated SNPs to approximate the total number of telomeres shared IBD for each participant pair ( $T_{\text{shared}}$ ). We then estimated the association between  $T_{\text{shared}}$  and the difference in TL between relative pairs ( $TL_{\text{diff}}$ ), adjusting for the pair's kinship coefficient ( $\Phi$ ) estimated from genome-wide SNPs. Among 583 sibling pairs,  $T_{\text{shared}}$  showed a non-significant inverse association with  $TL_{\text{diff}}$  ( $P=0.57$ ), as did  $\Phi$  ( $P=0.37$ ). Among 945 cousin pairs,  $T_{\text{shared}}$  was inversely associated with  $TL_{\text{diff}}$  ( $P=0.04$ ), while the inverse association for  $\Phi$  was not significant ( $P=0.22$ ), suggesting that sharing telomeres IBD contributes to pairwise similarity in TL. In analyses including all relative pairs ( $\Phi > 0.05$ ), the association between  $T_{\text{shared}}$  and  $TL_{\text{diff}}$  was inverse for both  $T_{\text{shared}}$  ( $P=0.003$ ) and  $\Phi$  ( $P=0.40$ ), but interpretation of this result is complicated by 1) the strong correlation between  $T_{\text{shared}}$  and  $\Phi$  when analyzing all relative pairs and 2) the possibility that embryonic telomere reprogramming dilutes the contribution of shared telomeres to TL similarity for distant relatives (who are separated by many reprogramming events). SNP-based  $h^2$ -partitioning analyses of all participants (using GCTA) had similar limitations, although we observed evidence of enrichment of  $h^2$  at chromosome ends. In summary, we provide preliminary evidence that sequence similarity at chromosome ends (a proxy for sharing telomeres IBD) contributes to TL  $h^2$ , implying that variation in TL in parental germ cells influences TL in offsprings' embryonic cells despite telomere "reprogramming" during embryonic development.

**2207T**

**Telomere length across many human tissues.** K. Demanelis<sup>1</sup>, L. Chen<sup>1</sup>, J.A. Doherty<sup>2</sup>, J. Shinkle<sup>1</sup>, M. Sabarinathan<sup>1</sup>, H. Ahsan<sup>1</sup>, F. Jasmine<sup>1</sup>, M.G. Kibriya<sup>1</sup>, B.L. Pierce<sup>1</sup>, Genotype-Tissue Expression (GTEx) Consortium. 1) Department of Public Health Sciences, University of Chicago, Chicago, IL; 2) Huntsman Cancer Institute, University of Utah, Salt Lake City, UT.

Telomeres shorten over the life-course in most human cell types, and telomere length (TL) is a potential biomarker of aging and risk for age-related disease. However, the relationships among TL, aging, and disease have been primarily studied using leukocyte TL. In order to better understand variation in TL across tissue types and tissue-specific aging, we measured relative TL (RTL, telomere abundance relative to a diploid gene) in 33 tissue types from 435 individuals (age 20-70) in the Genotype-Tissue Expression Project (GTEx). RTL was measured for 3,123 tissue samples (up to 12 tissue types per donor) using a Luminex assay and validated using whole blood TL estimates from whole genome sequencing. We analyzed the relationships among RTL and covariates using linear mixed models. Mean RTL was shortest in whole blood and longest in testis. RTL did not differ by sex, but African Americans had longer RTL compared to Caucasians ( $p=0.07$ ). The percent variation explained by individual and tissue was 16% ( $p < 10^{-16}$ ) and 34% ( $p < 10^{-16}$ ), respectively. Among the 20 tissues with  $>50$  samples measured, RTL negatively correlated with age in 17 tissues, 13 of which were statistically significant ( $P < 0.05$ ), ranging from  $-0.42$  ( $p=3 \times 10^{-15}$ ) for whole blood to  $-0.20$  ( $p=0.02$ ) for prostate. No tissue showed a significant positive association between RTL and age. Tissues with stronger associations between RTL and age had shorter mean RTL. The age-adjusted partial correlations between tissue-specific RTL and whole blood RTL were positive for all tissues (except ovary) and statistically significant ( $P < 0.05$ ) for 10 tissues, with the strongest correlations observed for suprapubic skin ( $r=0.48$ ,  $p=3 \times 10^{-6}$ ), muscle ( $r=0.36$ ,  $p=0.02$ ) and pancreas ( $r=0.32$ ,  $p=7 \times 10^{-5}$ ). Using GTEx RNA-Seq data, we observed no clear association between expression of components of telomerase and RTL within any tissue. However, in testis, expression of *TERT* (telomerase reverse transcriptase) was strikingly high compared to other tissues, consistent with its high mean RTL. Our results describe, for the first time, substantial heterogeneity in TL and age-related TL shortening across many human tissues. The cross-tissue correlations among RTL measures provide a foundation for the interpretation of epidemiological studies of leukocyte TL, aging, and disease. Ongoing and future analyses of these data include studies of gene expression correlates of RTL and the impact of genetic variation on RTL within and across tissues.

**GWAS replicates known asthma variants validating self-reported childhood asthma diagnosis in the COPDGene Study.** L.P. Hayden<sup>1,2</sup>, M.H. Cho<sup>2,3</sup>, B.A. Raby<sup>2,3</sup>, T.H. Beaty<sup>4</sup>, E.K. Silverman<sup>2,3</sup>, C.P. Hersh<sup>2,3</sup> on behalf of the COPDGene Investigators. 1) Division of Respiratory Diseases, Boston Children's Hospital, Boston, MA; 2) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, MA; 3) Division of Pulmonary and Critical Care Medicine, Brigham and Women's Hospital, Boston, MA; 4) Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD.

**PURPOSE** Childhood asthma is a phenotypically and genotypically distinct asthma subtype, with an estimated heritability of 80%. While childhood asthma is a known risk factor for development of reduced lung function and chronic obstructive pulmonary disease (COPD) in adulthood, few studies have evaluated self-reported childhood asthma in subjects with COPD. We hypothesized that a history of childhood asthma would be associated with decreased lung function and increased risk for COPD in adult smokers, and that a genetic association study would re-identify previously described variants associated with asthma. **METHODS** We evaluated current and former adult smokers in the COPDGene Study. Subjects were of non-Hispanic white (NHW) or African American (AA) race and 45-80 years of age. Childhood asthma was defined by self-reported asthma, diagnosed by a medical professional, with onset at <16 years or during childhood. Subjects with and without history of childhood asthma were compared on measures of lung function. Genome-wide association was performed in NHW and AA populations separately, and subsequently combined in meta-analysis. Eight established asthma SNPs were examined for association with childhood asthma in this GWAS. **RESULTS** Among 10,199 adult smokers, 730 (7%) reported a history of childhood asthma. Childhood asthmatics had reduced lung function and increased odds of developing COPD (OR 2.51, 95% CI 2.07-3.05). Among NHWs, 391 (6%) had childhood asthma, and GWAS identified one genome-wide significant association in *KIAA1958* (rs59289606,  $p=3.7 \times 10^{-8}$ ). However, among AAs, of which 339 (10%) had childhood asthma, and in a meta-analysis combining NHW and AA subjects, no results reached genome-wide significance. Four of eight previously established asthma SNPs examined were associated with childhood asthma in the current GWAS: *IL1RL1* (rs3771180) and *ORMDL3/GSDMB* (rs12936231) in NHWs, *KCNIP4* (rs4697177) in AAs and *LRRC32* (rs7130588) in meta-analysis (Bonferroni adjusted  $p < 0.02$  for all comparisons). **CONCLUSIONS** Self-report of childhood asthma in adult smokers from COPDGene identifies a meaningful population who demonstrate the demographic, clinical, and genetic characteristics known to be associated with childhood asthma. This validates use of self-reported childhood asthma in this population. This GWAS identified a new variant in *KIAA1958* as associated with childhood asthma in NHWs, which has not previously been seen in respiratory disease.

**2209W**

**Newborn metabolomics and risk of episodic wheezing in childhood: Findings from the INSPIRE study.** K.K. Ryckman<sup>1</sup>, B.M. Donovan<sup>1</sup>, P.J. Breheny<sup>2</sup>, E.K. Larkin<sup>3</sup>, T. Gebretsadik<sup>4</sup>, K.N. Turi<sup>3</sup>, T.V. Harter<sup>4</sup>. 1) Department of Epidemiology, University of Iowa College of Public Health, Iowa City, IA; 2) Department of Biostatistics, University of Iowa College of Public Health, Iowa City, IA; 3) Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 4) Department of Biostatistics, Vanderbilt University Medical Center, Nashville, TN.

Asthma is a complex, multifactorial disease that results in significant illness and death worldwide. Mitochondrial dysfunction has been implicated in the etiology of asthma, but there are critical gaps in our understanding of its contributing role. Newborn metabolic screening represents a unique data source that can be leveraged with perinatal and environmental exposures to further our understanding of mitochondrial dysfunction and asthma etiology. Our objective was to determine if newborn metabolite levels are associated with an increased risk of experiencing episodic wheezing in early childhood. Demographic and clinical data was collected from the Infant Susceptibility to Pulmonary Infections and Asthma Following RSV Exposure Study (INSPIRE) and linked to newborn metabolite data measured 24-72 hours after birth as part of the Tennessee Newborn Screening Program. Over 1,900 infants born during the summer months were enrolled over a two year period (June 2012-March 2014) from pediatric practices located in Middle Tennessee, with on-going follow-up. Episodic wheezing at 1, 2, and 3 years of age was categorized into 4 groups (no wheezing, 1-3 episodes, 4-12 episodes and >12 episodes) by number of wheezing episodes experienced in the past twelve months per ISAAC standards. The association between 32 amino acid and acylcarnitine metabolites with the categorical wheezing outcome was assessed at 1, 2 and 3-years of age using separate proportional odds regression models. Several unadjusted metabolite associations were significant after Bonferroni correction ( $p < 0.001$ ). Increasing levels of C10:1 were associated with increasing number of wheezing episodes at 2-years (OR 2.15, 95% CI 1.43-3.23) and 3-years (OR 2.57, 95% CI 1.60-4.13) of age, while increasing levels of C18:2 were associated with increasing number of wheezing episodes at 1-year (OR 1.37, 95% CI 1.11-1.70) and 2-years of age (OR 1.49, 95% CI 1.18-1.87). Linoleoylcarnitine (C18:2) is derived from linoleic acid, a polyunsaturated fatty acid, that has been implicated in airway hyperresponsiveness, epithelial injury and asthma severity. Our next step will be to link existing genome-wide association data for this cohort to the newborn metabolite measurements to further examine this pathway and its role in childhood wheezing and asthma. Identification of specific metabolites and their related genetic pathways may provide valuable information about the etiology of asthma and targets for primary prevention.

**Influence of guideline adherence and ADRB2 SNPs in predicting exacerbation frequency in asthma patients.** A. Santani<sup>1,2</sup>, N. Sood<sup>1</sup>, J. Connolly<sup>1</sup>, F. Mentch<sup>1</sup>, L. Vazquez<sup>1</sup>, P. Sleiman<sup>1,3</sup>, H. Hakonarson<sup>1,3</sup>. 1) Center for Applied Genomics, The Children's Hospital of Philadelphia; 2) Department of Pathology and Laboratory Medicine, University of Pennsylvania; 3) Department of Pediatrics, University of Pennsylvania.

Asthma is the leading chronic disease in children. Several studies have identified genetic biomarkers associated with susceptibility and severity in both adult and pediatric cases. In this study, we evaluated outcome in 470 African American (AA) and European American (EA) pediatric cases all of whom were regular users of controlling medications, such as inhaled corticosteroids and leukotriene inhibitors, and frequent users of reliever drugs, such as short acting beta agonists. Patients were stratified by genotype using two single nucleotide polymorphisms (SNPs) in the beta-2 adrenergic receptor (ADRB2) gene – rs1042713 and rs1042714, previously associated with asthma drug response outcome. We controlled for adherence to National Heart, Lung and Blood Institute (NHLBI) guidelines using deep mining of electronic health record (EHR) data to determine treatment course. Of the 470 cases, 446 had an updated Asthma Care Plan (ACP), 421 had PFT data, all 470 had a prescription for at least one ICS medication and for B2AR agonist drug. Data analyses were performed in two stages – 1) we separately compared the effects of genotype on outcome in AA and EA cases and 2) we combined AA and EA cohort in a meta-analysis of the same outcome. In all instances the main outcome (i.e. dependent variable) was mean frequency of exacerbations per year. Relevant independent variables in all instances were genotype (both rs1042713 and rs1042714), asthma severity and treatment. Additionally, for the combined meta-analysis, race was included as a variable in the combined meta-analysis. Using exacerbation frequency as the dependent variable, treatment according to the guidelines was relatively significant ( $P = 0.060$ ), whilst mutations rs1042713 and rs1042714 were markedly statistically significant (with  $P = 0.007$  and  $P = 0.004$ , respectively). Genotyping results demonstrated that homozygous carriers of the rare alleles for both SNPs were significantly more likely to experience asthma exacerbations ( $P < 0.01$ ), and this effect was largely driven by patients of African American ancestry ( $P < 0.01$ ). Taken together, our results demonstrate that patients homozygous for the minor alleles of rs1042713 and rs1042714 genotypes may derive less benefit from corticosteroid medications, particularly those of African American ancestry.

**A simulated evaluation of data-driven algorithms for addressing clinical heterogeneity in complex traits.** A.O. Basile<sup>1</sup>, A. Ulloa<sup>2</sup>, A. Lucas<sup>2</sup>, A.T. Frase<sup>2</sup>, V. Abedi<sup>2</sup>, H.L. Kirchner<sup>2</sup>, C.B. Manney<sup>2</sup>, J.B. Leader<sup>2</sup>, M.D. Ritchie<sup>1,2</sup>. 1) Department of Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA; 2) Biomedical and Translational Informatics Institute, Geisinger Health System, Danville, PA.

Complex diseases are often heterogeneous in nature; instead of representing a single condition, they may be comprised of multiple disorders, with varying symptoms, clinical presentations, and biological etiology. Trait heterogeneity is a confounding variable often overlooked in genetic approaches. It complicates patient diagnoses, and decreases statistical power to detect associations and risk attributed to susceptibility variants. The copious amounts of biomedical data in Electronic Health Records (EHRs) can be leveraged using data-driven approaches to overcome heterogeneity and detect patient subgroups. However, for an algorithm to be appropriate, it must be robust to noisy extraneous variables and missingness, appropriate for mixed data, and computationally practical. We performed *in silico* evaluations using data simulated with the Madelon algorithm to examine the performance of machine learning approaches in homogeneous data classification. 5,000 subjects with known outcome labels predicted by variables drawn from a Gaussian distribution with varying proportions of noise were simulated. Evaluated algorithms include icluster, similarity network fusion (SNF), generalized low rank models (GLRM), autoencoders, and manifold learning algorithms including local linear embedding (LLE), local tangent space alignment (LTSA), Hessian eigenmapping (HLLE), modified local linear embedding (MLLE), isomap, multi-dimensional scaling (MDS), spectral embedding, and t-distributed stochastic neighbor embedding (t-SNE). Algorithmic performance was evaluated using the average silhouette coefficient. The top methods, in order of performance, were LLE, spectral embedding, SNF, Isomap, t-SNE with PCA, and GLRM with PCA. These successful algorithms will be used to identify clinically meaningful subgroups in 49,000 patients with Chronic Obstructive Pulmonary Disease (COPD) from the Geisinger Health System MyCode® Community Health Initiative.

**Disease associations of the zinc receptor GPR39 in the DiscovEHR**

**Study cohort.** G.E. Breitwieser<sup>1</sup>, S. Krishnamurthy<sup>1</sup>, J. Overton<sup>2</sup>, J. Reid<sup>2</sup>, J. Robshaw<sup>1</sup>, D. Carey<sup>1</sup>, R. Metpally<sup>1</sup>, DiscovEHR collaboration. 1) Functional and Molecular Genomics, Weis Center for Research/Geisinger Clinic, Danville, PA; 2) Regeneron Genetics Center, Tarrytown, NY.

Zn<sup>2+</sup> is a transition metal essential for life. Deficiencies, seen in 2-3% of the United States population, cause hyosmia, hypogeusia, dermatitis, alopecia, susceptibility to infections and seizures, slow wound healing, and compromised gonadal function. Zn<sup>2+</sup> is both a first and second messenger, and physiological concentrations of extracellular Zn<sup>2+</sup> activate GPR39, a Family A G protein-coupled receptor most closely related to the ghrelin subfamily. *GPR39*<sup>-/-</sup> mice are viable, but have depression and anxiety-like behavior, increased seizures in response to kainate, immune system dysfunction, slowed wound healing, and increased fat accumulation in response to high fat diet. GPR39 plays an antagonistic role to ghrelin and motilin receptors in the stomach and intestine, slowing gastric emptying and secretion, and gastrointestinal motility. To define the importance of GPR39 in human disease, we identified rare missense, frameshift, premature termination and synonymous variants in whole exome sequences for 51,289 individuals in the DiscovEHR cohort. We found patients having rare heterozygous mutations in the zinc binding site, the pH sensor, cysteines participating in disulfide bonds, residues in highly conserved Family A motifs, and putative phosphorylation sites. Optimized Sequence Kernel Association Tests (SKAT-O) were run on binned LOF/missense (LOF/MIS) variants and separately on rare synonymous (SYN) variants having significant changes in codon usage bias. Only 2 patients were in both the LOF/missense and rare synonymous groups, and they were removed prior to SKAT-O analyses. All ICD9 codes in the electronic health record with at least three independent instances per individual were used for SKAT-O. Both groups yielded a common set of phenome-wide disease associations, including benign prostate hyperplasia with urinary obstruction (LOF/MIS  $p < 1.06E-09$ ; SYN  $p < 1.13E-09$ ), benign hypertension (LOF/MIS  $p < 9.8E-06$ ; SYN  $p < 1.3E-05$ ), psoriatic arthropathy (LOF/MIS  $p < 1.4E-06$ ; SYN  $p < 1.5E-06$ ) and diseases of hair or hair follicles (LOF/MIS  $p < 1.3E-04$ ; SYN  $p < 9.7E-07$ ). The convergence of results for both LOF/missense and rare synonymous variants suggests that haplo-insufficiency of *GPR39* may underlie the identified disease associations. Results argue that rare synonymous variants may be an untapped resource for both validating and extending the associations derived from rare LOF/missense variants. Supported by funds from Geisinger Health System & Regeneron.

**Background:** Craniofacial development gives rise to the closely related traits of head circumference (HC) and intracranial volume (ICV). Final HC is largely determined by 6 years of age. Previous studies have identified common genetic variants for infant HC and adult ICV. This study aims to identify common and lower frequency variants for both final HC and final craniofacial dimension (as assessed through a joint analysis of HC with ICV). **Participants and methods:** Genome-wide association analysis was performed in 11 population based cohorts with either whole genome sequencing information ( $n=1,762$ ; UK10K consortium), genotype imputation to a joint UK10K/1KG panel ( $n=8,285$ ) or genotype imputation to the Haplotype Reference Consortium (HRC) panel ( $n=8,834$ ). All participants were aged 5.5 years or older and of European ancestry. The entire HC meta-analysis included 18,881 participants, with a replication in a further independent sample of 973 adults, aged 18-85 years. Joint analysis of HC and ICV (craniofacial dimension) included 26,577 additional participants aged 9-98 years from the CHARGE / ENIGMA consortia with a total sample size of 45,458. **Results:** After conditioning on known variants, association with head circumference was seen at 3 loci, including a signal at a low frequent variant in the 5' UTR of the  $\Delta 133$  isoform of *TP53* (rs35850753, EAF 0.022, beta 0.21 SD,  $p$  value  $2.0e-08$  discovery,  $4.5e-05$  replication,  $9.4e-10$  combined). Joint analysis of a final intracranial dimension identified also association at 6 loci at the genome-wide significant level in addition to those identified for either HC or ICV alone. **Discussion:** *TP53* is known to co-ordinate cranial neural crest growth and differentiation in animal models. *p53*-dependent neuroepithelial apoptosis, as a result of mutations in *TCOF1*, has been identified as primary mechanism underlying the pathogenesis of Treacher Collins syndrome, a congenital disorder of craniofacial development. rs35850753 tags both rs35850753 ( $r^2=1$ ) and rs78378222 ( $r^2=0.43$ ) that have been robustly linked to neuroblastoma. rs78378222 is also involved in a range of other human cancers and its hypomorphic allele is known to impair proper termination and polyadenylation of *TP53* transcripts. These results support a role for *TP53* transcripts in human craniofacial development.

**2214F**

**Pathogenic and likely pathogenic mutations identified in apparently normal individuals of Arab descent.** *A. Alkhateeb*. Biology Department, Jordan University of Science and Technology, Irbid 22110, Irbid, Jordan.

Arab genome is one of the least studied as compared to other ethnicities. Lots of variants that might be unique to the Arab population are still to be characterized. Here, and as a spin off another study, we exome-sequenced a set of unrelated Arabic individuals. Six exomes were analyzed through Ingenuity Variant Analysis tool. We limited our analysis to extremely rare mutations with a frequency of less than 0.001. We identified four damaging mutations; three are novel and one that is reported only once. None of the four mutations are present in the Exome Aggregation Consortium (ExAC) database. Two of the mutations are classified by Ingenuity as pathogenic; c.3955-1G>C in NALCN gene, and p.M296\* in the PALB2 gene. The other two are classified as likely pathogenic; p.D959fs\*5 in CACNA1S gene, and p.S200fs\*7 in PMS1 gene. The presence of these debilitating mutations in apparently normal individuals shows the uniqueness of the Arab exome and the need to characterize it more to have a better understanding of its genetic background.

**2215W**

**Widespread prevalence of a CREBRF variant amongst Māori and Pacific children is associated with weight and height in early childhood.** *S.D. Berry<sup>1</sup>, C.G Walker<sup>1</sup>, K. Ly<sup>1</sup>, R.G. Snell<sup>1</sup>, P.E. Ataoa Carr<sup>2</sup>, D. Bandara<sup>1</sup>, J. Mohal<sup>1</sup>, T.G Castro<sup>1</sup>, E. Marks<sup>1</sup>, S.M.B. Morton<sup>1</sup>, C.G. Grant<sup>1,4,5</sup>*. 1) Centre for Longitudinal Research He Ara ki Mua, University of Auckland, Auckland, Auckland, New Zealand; 2) School of Biological Sciences, University of Auckland, Auckland, Auckland, New Zealand; 3) National Institute of Demographic and Economic Analysis, University of Waikato, Hamilton, New Zealand; 4) Department of Paediatrics: Child and Youth Health, University of Auckland, Auckland, New Zealand; 5) Starship Children's Hospital, Auckland District Health Board, Auckland.

Investigating a large and ethnically diverse cohort from the Pacific region, we aimed to replicate and extend the recently reported findings that a CREBRF genetic variant is strongly associated with body mass index in Samoans. A birth cohort of more than six thousand children was utilised. In this study, genotyping of two markers (rs12513649 and rs37386328) was undertaken in Māori, Pacific, European and Asian individuals in the cohort. We report that these CREBRF genetic variants are not confined to Samoans but are prevalent in all other Pacific populations sampled, including Māori. We found that the rs37386328 variant was significantly associated with growth at four years of age. On average, we observed allele-specific increases in weight ( $p=0.004$ , +455 g), height ( $p=0.007$ , +0.70 cm) and waist circumference ( $p=0.004$ , +0.70 cm) at four years of age. The rs37386328 variant was not associated with birthweight ( $p=0.129$ ). We replicated the finding that a CREBRF variant is associated with increased body mass. We then built on the original findings by demonstrating the prevalence of the rs12513649 and rs37386328 variants in multiple Pacific population groups and by demonstrating that the rs37386328 variant is associated with growth in early childhood. Pacific population groups experience a disproportionately high burden of obesity, starting in early childhood. This new knowledge offers potential for evidence-based interventions aimed at establishing healthy growth trajectories from the earliest possible age.

**2216T**

**The impact of MUC5B and KLK4 genes on dental caries.** *T. Cavallari, H.M Salomão, S.J Moysés, S.T Moysés, R.I Werneck.* Pontifícia Universidade Católica do Paraná, Curitiba, Brasil.

The objective of this study was to identify the participation of *KLK4* and *MUC5B* genes polymorphisms on the susceptibility to dental decay. The studied population sample was composed of individuals who were affected (case) and unaffected (control) by dental decay, with 12 years old or more, paired by age and gender. The participants were recruited at the PUCPR (Pontifícia Universidade Católica do Paraná), using ICDAS criteria. Buccal cells were collected; the DNA was extracted and amplified using PCR. Uni-, bi- and multivariate analyses were performed. Two hundred patients were recruited, 122 (61%) women and 78 (39%) men. During the descriptive analysis, statistically significant results were found for ethnicity ( $p = 0.014$ , OR = 0.036), biofilm ( $p < 0.001$ , OR = 10.887) and gingivitis ( $p < 0.001$ , OR = 5.444). For genetic analyses, statistically significant results were found in the additive model for markers *rs2735733* ( $p < 0.001$ ), *rs2249073* ( $p < 0.001$ ) and *rs2857476* ( $p < 0.001$ ) for *MUC5B* gene and *rs224267* ( $p = 0.009$ ) for *KLK4* gene. The results from this study suggest that genetic polymorphisms of *MUC5B* and *KLK4* gene can influence in the development of dental caries.

**Leveraging tissue specific omics data to estimate the disease/traits-related tissues.** *R. Chen, Q. Wei, Q. Wang, H. Yang, Y. Ji, X. Zhong, B. Li.* Vanderbilt genetic institute, Vanderbilt University, Nashville, TN.

Genome-wide association studies (GWAS) have identified numerous causal loci associated with human complex traits and diseases. However, translating the discoveries into the understanding of mechanisms of complex traits and diseases remains a major challenge. Genes usually exert their functions in the tissue-specific manner, suggesting that the underlying molecular mechanisms are cell-type specific in general. Many efforts of linking causal genes to specific phenotype require tissue specific information to assure the accuracy and enhance the power in the detection of casual signals. Given the complexity of gene regulation and functionality in biology systems, the relevant tissues in which the genetic causality is manifested are obscure and have not been comprehensively explored. In this study, we systematically explored omics data across all tissues in GTEx to identify complex traits/diseases associating tissues. In particular, we focused on gene expression for this purpose, reasoning that expression of traits/disease associating genes have distinct expression patterns in relevant tissues and thus are able to infer the relevant tissues. We leveraged the extensive genetic findings in GWAS Catalog and assigned appropriate genes as the causal genes. Since the causal genes are generally unknown, we assign genes that are either proximal to GWAS loci or genes in which GWAS loci are located as the causal genes. We observed that the causal genes for a specific trait are highly expressed in the relevant tissues than others, exhibiting profound tissue-specificity. For example, using GTEx data, the top tissues with the greatest tissue-specificity for schizophrenia are all brain tissues, and the tissue with the most tissue-specific expression for blood traits is liver. To further test whether non-protein coding genes exhibit similar patterns, we explored pseudo-genes and lncRNA genes but these genes were not able to identify relevant tissues, indicating that these non-coding genes are unlikely to play significant roles in genetic etiology of complex diseases. Finally, using coding genes, we comprehensively inferred tissues in GTEx for complex traits with >20 GWAS loci, and using blood traits as example we found that utilizing correct tissues improves the prioritization of known causal genes, implying its potential usefulness in identifying causal genes from GWAS discoveries.

**2218W**

**Will big data close the missing heritability gap?** *G.A. de los Campos*<sup>1,2</sup>, *H. Kim*<sup>3</sup>, *A. Grueneberg*<sup>4</sup>, *A.I. Vazquez*<sup>1</sup>, *S. Hsu*<sup>4,5</sup>. 1) Epidemiology & Bio-statistics, Michigan State University, East Lansing, MI; 2) Statistics & Probability, Michigan State University, East Lansing, MI; 3) Duke Clinical Research Institute, Duke University, Durham, NC; 4) Physics and Astronomy, Michigan State University, East Lansing, MI; 5) Vice President for Research and Graduate Studies, Michigan State University, East Lansing, MI.

Despite the important discoveries reported by Genome-Wide Association Studies (GWAS), for most traits and diseases the prediction R-squared (R-sq.) achieved with genetic scores remains considerably lower than the trait heritability—a problem often described as the missing heritability (MH) gap. The gap between the trait heritability and prediction R-sq. achieved with genomic scores has two components. First, the amount of variance captured by a set of SNPs can be smaller than the trait heritability due to imperfect linkage disequilibrium between the alleles at the SNPs used for prediction and those at causal loci. A second component of the gap between the trait heritability and prediction R-sq. is given by the accuracy of the estimated effects. According to the framework just outlined, the use of sequence data and of very large datasets for model training should lead the end (or to a substantial reduction) of the MH gap. Until recently this hypothesis could not be tested empirically; however, this situation is rapidly changing as very large biomedical data sets from biobanks become available. In this study we propose a methodology that uses data and feature (i.e., SNPs) partitions to produce (an estimate of) a surface response relating prediction R-sq. with model complexity (e.g., # of SNPs) and the size of the data used to train the model. The proposed approach combines results from single-marker-phenotype associations with Bayesian whole-genome regression models and yields an estimate of the maximum prediction R-sq. that could be achieved with a SNP set. We applied the proposed methodology to data from the interim release of the UK-Biobank using various statistical methods for selecting SNPs and estimating their effects. Focusing on human height as a model trait and using 80,000 records for model training we achieved a prediction R-sq. in testing ( $n=22,221$ , unrelated to the training set) of 0.24 (95% CI: 0.23-0.25). Our estimates show that prediction R-sq. increases with sample size reaching a plateau at values that ranged from 0.1 to 0.37 for (GWAS-selected) SNP sets of 500 and 50,000, respectively. Soon much larger data sets will become available. Using the estimated surface response, we forecast sizable improvements in prediction R-sq. with larger sample size. We conclude that Big Data will lead to a substantial reduction of the MH gap, thus paving the ground towards a more intensive use of genomic information in precision medicine.

**Performance of polygenic scores across ancestrally diverse populations.** *L. Duncan*<sup>1</sup>, *H. Shen*<sup>1</sup>, *J. Pritchard*<sup>2</sup>, *M. Feldman*<sup>3</sup>, *K. Harris*<sup>4</sup>, *B. Domingue*<sup>5</sup>. 1) Psychiatry, Stanford University, Stanford, CA; 2) Genetics, Stanford University, Stanford, CA; 3) Biology, Stanford University, Stanford, CA; 4) Sociology & Public Policy, University of North Carolina at Chapel Hill, NC; 5) Education, Stanford University, Stanford, CA.

Polygenic scores (i.e. weighted metrics of phenotype-associated alleles) are now widely used in research and by companies like 23&Me. The majority of the genome-wide association studies (GWAS) on which these scores are based were conducted in European ancestry (EA) individuals. Questions remain regarding how well scores work in non-EA populations and whether, like Mendelian phenotypes, ancestry-related differences in phenotype-associated alleles may partially explain phenotypic differences across populations. To address these questions, we extracted data about predictive performance of polygenic scores (measured in phenotypic variance explained) from a review of 450 published papers and analyzed genotype and phenotype data (BMI, height) in the Adolescent Health dataset. We also tested the correlation between means of polygenic score distributions (for each of the 1000Genomes populations) with epidemiological data about mean height for relevant countries of origin, for the 1000Genomes populations. Across multiple phenotypes, polygenic prediction in African Americans (AA) was less strong than in EA individuals (AA on average 31% of variance explained in EA). The same was not true for Latino and Asian samples; predictive performance was usually better than in EA samples. Across the 1000Genomes populations, mean polygenic scores for each population were positively correlated with average height of individuals in regions from which the 1000Genomes data were obtained ( $r=.63$ ,  $p=.009$ ). Consistent with population genetic models (e.g. Scutari et al. 2016), prediction was worse in AA individuals when using EA GWAS data to weight polygenic scores. The same was not true for Latino and Asian samples. This could be due to sampling error, but also suggests that the relative importance of genetic and environmental effects may vary across populations. The positive correlation between mean polygenic scores for height, and mean phenotypic height, suggest that differences in polygenic scores across populations may contribute to population level differences in phenotypes. However, without evaluation of relevant environmental factors, it would be inaccurate to conclude that genetic differences explain observed phenotypic differences. Here we use the example of height, but this caveat is just as important for other complex genetic phenotypes.

**Two novel loci detected and 10 known loci confirmed for estimated glomerular filtration rate in over 56,000 African Americans: The Million Veteran Program.** T.L. Edwards<sup>1</sup>, J. Hellwege<sup>1</sup>, A. Giri<sup>1</sup>, O. Wilson<sup>2</sup>, E.S. Torstenson<sup>1</sup>, C.P. Kovesdy<sup>3</sup>, K.A. Birdwell<sup>4</sup>, C. Roumie<sup>5</sup>, E. Siew<sup>6</sup>, M. Matheny<sup>6</sup>, C. Chung<sup>6</sup>, D.R. Velez Edwards<sup>8</sup>, C. O'Donnell<sup>1</sup>, A. Hung<sup>2</sup> On behalf of The VA Million Veteran Program. 1) Division of Epidemiology, Department of Medicine, Institute for Medicine and Public Health, Vanderbilt Genetics Institute, Vanderbilt University Medical Center, Tennessee Valley Healthcare System (626)/Vanderbilt University, Nashville, TN; 2) VA TVHS Nashville, Division of Nephrology & Hypertension, Vanderbilt University, Nashville, TN; 3) Nephrology Section, Memphis VA Medical Center, Memphis TN; 4) Division of Nephrology, Department of Medicine, Vanderbilt University Medical Center, Nashville, TN; 5) VA TVHS Nashville, Department of Medicine, Vanderbilt University, Nashville, TN; 6) VA TVHS Nashville, Department of Bioinformatics, Vanderbilt University, Nashville, TN; 7) VA Boston Healthcare, Section of Cardiology and Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 8) Vanderbilt Genetics Institute, Vanderbilt Epidemiology Center, Department of Obstetrics and Gynecology, Vanderbilt University Medical Center; Tennessee Valley Health Systems VA, Nashville, TN.

African Americans (AAs) have a higher risk of progressing to end stage renal disease (ESRD) than non-Hispanic European Americans. Genetic variants influencing kidney function have been identified through genome-wide association studies (GWAS) of chronic kidney disease and ESRD, as well as estimated glomerular filtration rate (eGFR) in AAs, however, small sample sizes have hindered discovery. We have performed a GWAS of eGFR in 56,253 AAs from the Million Veteran Program (MVP). eGFR was regressed on to common genetic variants (minor allele frequency > 1%) imputed to the 1000 Genomes reference panel adjusted for age, sex, body mass index and the top ten principal components. Analyses were performed by strata of diabetes and hypertension status, estimates from which were aggregated with fixed effects meta-analysis. A total of 799 SNPs representing 12 loci exceeded genome-wide significance. The most significant association was at a previously known locus, *SPATA5L1/GATM* on chromosome 15 (p-value =  $2.02 \times 10^{-39}$ ). Two novel loci were detected between *TRIM69* and *C15orf43* (rs144803907; p-value =  $4.50 \times 10^{-9}$ ) and near *OLFR690* (rs75113983; p-value =  $2.25 \times 10^{-8}$ ). Other previously reported signals detected include: *HBB* (p-value =  $1.54 \times 10^{-16}$ ), *FBXL20* (p-value =  $7.51 \times 10^{-11}$ ), *UNCX* (p-value =  $9.29 \times 10^{-11}$ ), *SLC47A1* (p-value =  $3.92 \times 10^{-10}$ ), *SLC22A2* (p-value =  $7.50 \times 10^{-10}$ ), and *UBE2Q2* (p-value =  $5.12 \times 10^{-9}$ ). Among the known loci, this is the first significant observation in African ancestry populations, emphasizing the transethnic nature of genetic variation contributing to eGFR levels. Evaluation of genetically predicted gene expression (GPGE) with MetaXcan identified increasing expression of *DUOX2* in left ventricle of the heart (p-value =  $1.16 \times 10^{-19}$ ) with decreasing eGFR, not *SPATA5L1* or *GATM*, even though these genes fall under the same GWAS peak. GPGE associations where increasing gene expression is associated with increasing eGFR include *SHF* in subcutaneous adipose (p-value =  $1.60 \times 10^{-9}$ ), *SH2D2A* in visceral adipose (p-value =  $4.19 \times 10^{-13}$ ), and *PNMT* in tibial nerve (p-value =  $3.32 \times 10^{-8}$ ). Overall, this is the largest GWAS of eGFR in AAs to date, which replicates previously identified loci from whites, detects two novel loci, and is the first to evaluate genetically predicted gene expression associations with eGFR in AAs.

**Slit2-Robo1 signaling may play a role in spontaneous preterm birth.** M. Karjalainen<sup>1,2</sup>, H. Tiensuu<sup>1,2</sup>, A.M. Haapalainen<sup>1,2</sup>, M. Ojaniemi<sup>1,2</sup>, M. Rämetsä<sup>1,2</sup>, M. Hallman<sup>1,2</sup>. 1) PEDEGO Research Unit, and Medical Research Center Oulu, University of Oulu, Oulu, Finland; 2) Department of Children and Adolescents, Oulu University Hospital, Oulu, Finland.

**Background and aims:** Spontaneous preterm birth (SPTB) is a major global healthcare problem associating with significant mortality and morbidity. SPTB has a genetic background with a potential role for both maternal and fetal genetic factors. Placental tissue has a regulatory role in the onset of labor and delivery. Here, our aim was to identify biological mechanisms leading to SPTB by combining the findings of a genome-wide association study (GWAS) with those of transcriptomics of placental tissue. **Methods:** We started by performing a GWAS to find susceptibility genes for SPTB. The study population comprised SPTB infants (gestational age, GA <36 weeks,  $n = 247$ ) and infants born at term (GA 38-41 weeks,  $n = 419$ ) from Oulu and Tampere University Hospitals, Finland. DNA samples were genotyped with the Illumina HumanCoreExome BeadChip. Association analysis was performed with SNPTEST, v. 2.5.2, under the additive model. The arising candidate genes were compared to genes showing significant expression level changes in SPTB placentas. Expression changes of selected genes were verified by qPCR in SPTB ( $n = 24$ ) and term ( $n = 27$ ) placentas. Immunohistochemistry was further used to visualize the expression patterns in the placental tissue. **Results:** In GWAS, we detected several suggestive association signals ( $p < 10^{-5}$ ). The most significant pathway was Axon guidance ( $p = 2 \times 10^{-7}$ ). When we screened the transcriptomic data for overlapping findings, we detected that one of the genes with suggestive signals, *SLIT2* encoding slit guidance ligand 2, was upregulated in SPTB placentas. Using qPCR, we further verified that *SLIT2* and the gene encoding its receptor, roundabout guidance receptor 1 (*ROBO1*), are upregulated in SPTB compared to term placentas. By immunohistochemistry, we detected that both Slit2 and Robo1 are localized to villous and extravillous trophoblasts. **Conclusions:** *SLIT2* was identified as a potential susceptibility gene for spontaneous preterm birth both in GWAS and in transcriptomics of placental tissue. We propose that Slit2-Robo1 signaling plays a role in SPTB. To replicate the finding, we will analyze the most promising *SLIT2* SNPs in another study population of SPTB and term infants. Further studies include silencing of *SLIT2* and *ROBO1* in trophoblasts to identify the downstream genes and their functions.

**2222T**

**Adult height and risk of cardiometabolic disease.** *E. Marouli<sup>1</sup>, F. Del Greco M.<sup>2</sup>, C. Astley<sup>3</sup>, Z. Kutalik<sup>4</sup>, R.J.F. Loos<sup>5</sup>, J. Hirschhorn<sup>6</sup>, P. Deloukas<sup>1</sup>*; 1) William Harvey Research Institute, Barts and The London School of Medicine and Dentistry, Queen Mary University of London, London, UK; 2) Institute for Biomedicine, Eurac Research, Affiliated Institute of the University of Lübeck, Bolzano, Italy; 3) Boston Children's Hospital and Broad Institute, MA, USA; 4) Institute of Social and Preventive Medicine, Lausanne University Hospital, Lausanne, Switzerland; 5) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA; 6) Broad Institute of Harvard and MIT, Cambridge, MA, USA.

Consistent with epidemiological observations that suggest phenotypic correlation between height and other traits or disease, many common variants associated with human adult height in GWAS have been reported to have pleiotropic effects. The latest large-scale genetic study of height identified 520 associated variants (of which 83 are low-frequency or rare), which were enriched for nominal associations with several cardiometabolic traits (in the opposite direction). To further investigate the observed pleiotropy between height and cardiometabolic traits including disease and test whether there is any causal relationship, we considered all 864 height-associated variants, which explain ~27% of height heritability, in ~150,000 individuals from the UK Biobank (UKBB) study. We calculated an unweighted height genetic score and tested its association with BMI, blood pressure (BP), smoking status, hypertension, coronary artery disease (CAD) and type 2 diabetes (T2D). We observed that individuals with more height-increasing alleles had a reduced risk for both CAD, odds ratio (OR) of 0.83 for top vs bottom quintile (95% CI 0.91-0.76,  $P=4.2E-05$ ), and T2D, OR=0.87 (95% CI 0.81-0.94,  $P=5.77E-04$ ). Initial analyses suggest that the effect of the height genetic score on CAD is not mediated through BMI, T2D, smoking status, or hypertension, as the adjusted model did not result in attenuation of the signal. We found significant associations of the height score with known CAD risk factors ( $P<0.0001$ ) such as BMI, blood pressure and WHR, but not with smoking (ever-smoking vs. never smokers;  $P=0.208$ ). We further performed Mendelian Randomization (MR) analyses in UKBB in order to investigate whether the effect of height on CAD and T2D might be causal. The estimate from the MR-Egger method for a causal effect between genetically determined height (inverse normal rank transformed) and CAD was: beta -0.14 (95% CI, -0.25 to -0.02,  $P=0.016$ ), but no significant causal effect was observed for T2D: beta 0.021 (95% CI, -0.11 to 0.15,  $P=0.75$ ). In conclusion, our results so far indicate that that higher height status (instrumented by the 864 variants), reduces the odds of CAD risk by 13%, but has no effect on T2D risk. The observed association may be mediated by shared biological processes for height and CAD development, including lipid levels (data to become available in Q4).

**GWAS of early childhood caries in an Appalachian population.** *E. Orlova<sup>1</sup>, M.K. Lee<sup>2</sup>, E. Feingold<sup>1,2,3</sup>, D.W. McNeil<sup>4</sup>, R.J. Crout<sup>5</sup>, R.J. Weyant<sup>6</sup>, M.L. Marazita<sup>1,3,7</sup>, J.R. Shaffer<sup>1,3</sup>*; 1) Dept. of Human Genetics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 2) Dept. of Biostatistics, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, PA; 3) Center for Craniofacial and Dental Genetics, Dept. of Oral Biology, School of Dental Medicine, University of Pittsburgh, Pittsburgh, PA; 4) Depts. of Psychology, and Dental Practice & Rural Health, West Virginia University, Morgantown, WV; 5) Dept. of Periodontics, School of Dentistry, West Virginia University, Morgantown, WV; 6) Depts. of Dental Public Health, and Information Management, School of Medicine, University of Pittsburgh, Pittsburgh, PA; 7) Clinical and Translational Sciences Institute, and Department of Psychiatry, School of Medicine, University of Pittsburgh, Pittsburgh, PA.

Early childhood caries (ECC) is a complex, multifactorial disease with multiple environmental and genetic etiological factors, and serious consequences for the child's subsequent oral health and quality of life. It is the most common chronic disease of childhood, affecting almost one in four children nationwide, and disproportionately impacts vulnerable populations including ethnic/racial minorities and low SES groups. Although ECC is known to be heritable in part, few associated genetic loci have been identified. Here, we report a GWAS of ECC in 447 Caucasian, non-Hispanic children of up to six years of age, recruited through the Center for Oral Health Research in Appalachia study (COHRA-1). ECC was assessed by intraoral examination by a dentist or research dental hygienist. DNA from saliva samples was genotyped on the Illumina Human610 Quadv1 B array and imputed to the 1000 Genomes Project phase 1 (June 2011) reference. Logistic regression while adjusting for age, sex, and the first principal component of ancestry was used to test association under the additive genetic model for 3.37 million common ( $MAF > 5\%$ ) SNPs passing quality filters. No significant associations ( $p\text{-value} < 5 \times 10^{-8}$ ) were found, but 11 loci were associated at a suggestive level ( $p\text{-value} < 10^{-5}$ ). The top result of the ECC GWAS was rs1582413 ( $p\text{-value} 1.48 \times 10^{-7}$ ; OR 2.76; 95% CI 1.89-4.04), within an intron of the gene *MYT1L*, which encodes a neuronal transcription factor. Identifying genetic variants predisposing to caries in primary dentition may ultimately inform downstream caries treatment and prevention efforts, and help alleviate disparities in disease burden currently impacting disadvantaged groups. This work was made possible by the following grants: U01-DE018903, R01-DE014899, and R03-DE024264.

## 2224W

**Novel genes identified by integrating genome-wide association analysis with transcriptomics in severe chronic obstructive pulmonary disease and quantitative emphysema.** P. Sakornsakolpat<sup>1,2</sup>, J.D. Morrow<sup>1</sup>, P.J. Castaldi<sup>1</sup>, C.P. Hersh<sup>1</sup>, E.K. Silverman<sup>1</sup>, A. Manichaikul<sup>3</sup>, M.H. Cho<sup>1</sup>. 1) Channing Division of Network Medicine, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) Department of Medicine, Faculty of Medicine Siriraj Hospital, Mahidol University, Bangkok, Thailand; 3) Center for Public Health Genomics, Department of Public Health Sciences, University of Virginia, Charlottesville, VA.

**Background:** Genome-wide association studies (GWAS) have revealed multiple loci associated with chronic obstructive pulmonary disease (COPD [MIM 606963]) and related traits. Analyses combining GWAS with gene expression data, using a gene expression model in reference datasets, may provide insight into genetic regulation at these loci and provide genes for further functional analysis. We hypothesized that applying these methods to COPD and related traits could provide evidence of genetic regulation of previously identified and potentially novel loci. **Methods:** We obtained GWAS summary statistics from a meta-analysis of severe COPD (n = 3,497 cases and 5,704 controls), emphysema assessed as low attenuation area at -950 Hounsfield units (HU) (%LAA-950), and emphysema assessed by HU at 15<sup>th</sup> percentile of the CT lung density histogram (Perc15) (n = 12,031). We applied the PrediXcan / MetaXcan model to using transcriptome reference databases based on whole blood (n = 6,588 genes) and lung (n = 6,448 genes) from the Genotype-Tissue Expression (GTEx) project. We used a Bonferroni threshold correcting for the number of genes in each database. To provide further evidence of colocalized signals, we applied Bayesian colocalization to significant genes. We also performed pathway enrichment analysis on the top associated genes. **Results:** We identified genes regulated at previously identified loci from GWAS of COPD and related traits, and also identified novel associations (at sub-genome-wide significant loci), including *WNT3* for severe COPD, *SNTB2* and *DCBLD1* for %LAA-950, and *PSMA4*, *SNTB2*, and *ITGA1* for Perc15. However, most GWAS and expression quantitative loci (eQTL) showed poor evidence of colocalization, suggesting that the GWAS and eQTL may be driven by distinct variants. Pathway analysis of nominally significant genes for severe COPD was suggestive of over-representation of genes regulating Wnt signaling pathway and ferrous iron binding, while TCR signaling and signaling events of B cell receptor were over-represented in %LAA-950 analysis (false discovery rate < 0.05). **Conclusions:** Integrating a reference transcriptome may improve power and identify genes regulated by phenotype-associated variants, though some of these associations may be driven by LD. Further work to confirm these findings and identify the role of specific genetic variants in regulating gene expression may lead to new insights regarding how GWAS loci confer susceptibility to disease.

## 2225T

**Ayurveda based deep phenotyping, a likely game changer for gene hunt in complex traits.** B.K. Thelma<sup>1</sup>, G. Juyal<sup>1,6</sup>, A. Pandey<sup>1</sup>, N. Rana<sup>1</sup>, S. Negi<sup>2</sup>, U. Kumar<sup>3</sup>, B. Bhat<sup>4</sup>, R.C. Juyal<sup>5</sup>. 1) Department of Genetics, University Delhi South Campus, New Delhi-110021, India; 2) National Institute of Pathology, Safdarjung Hospital Campus, New Delhi-110029, India; 3) Department of Rheumatology, All India Institute of Medical Sciences, New Delhi-110029, India; 4) Department of Ayurveda, Holy Family Hospital, New Delhi-110025, India; 5) Regional Centre for Biotechnology, Gurugram, Haryana-122008, India; 6) Current Address: School of Biotechnology, Jawaharlal Nehru University, New Delhi-110067, India.

**Objective:** To date, an appreciable amount of genome wide association studies (GWASs) have been performed for several complex traits. Despite their impeccable design and large cohorts, our knowledge on genetic architecture of diseases has been limited and thus hindering the progress in the area of predictive, preventive and personalised medicine (PPPM). One of the reasons for such restricted success is attributed to clinical heterogeneity demanding exploration of complementary approaches which will enable effective phenotypic characterization of individuals to obtain homogeneous study cohorts. Apart from OMICS approach, we believe Ayurveda, the traditional system of medicine practised in India adopts/uses effective deep phenotyping and this may propel a revolution in the outcome of complex trait genetics research. In this pilot study, we performed a GWAS of Rheumatoid arthritis (RA) (Amavata in Ayurveda) patients and healthy controls, who were deeply phenotyped into vata, pitta and kapha prakriti on the basis of Ayurveda. **Methods:** Genotyping data of 246 RA cases and 310 controls was retrieved from the total genotype data generated on Illumina Human660W Quad Bead-Chip genotyping platform, used in a recent RA GWAS study performed in the laboratory. Prakriti-wise test of association and Random forest analyses were employed. **Results:** 244 (vata=49; pitta=117; kapha=78) RA cases and 293 (vata=33; pitta=175; kapha=85) controls were included in the analysis. High quality genotype data for 480418 SNPs passed quality control. Prakriti-wise test of association and Random forest analyses revealed prakriti specific functionally relevant RA genes with significant effect sizes. **Conclusions:** Our findings suggest that Ayurveda based stratification of patients may enable investigations of homogeneous subsets of patients which in turn may aid in a better development of multi-omics signature based prognostic and diagnostic markers. It is also expected to generate insights into personalized nutritional and therapeutic intervention strategies.

**Genomic features of loci associated with multiple complex traits in genome-wide association studies.** Y.-F. Wang<sup>1</sup>, T.-Y. Wang<sup>1</sup>, Y. Zhang<sup>1</sup>, H. Zhang<sup>1</sup>, J.J. Shen<sup>1</sup>, M. Guo<sup>1</sup>, J. Yang<sup>1,2</sup>, P.C. Sham<sup>3</sup>, Y.L. Lau<sup>1,2</sup>, W. Yang<sup>1,2,3</sup>.

1) Paediatrics & Adolescent Medicine, The University of Hong Kong, Hong Kong, Hong Kong, Hong Kong; 2) Shenzhen PID Diagnostic and Therapeutic Laboratory, HKU-Shenzhen Hospital, Shenzhen, China; 3) Centre for Genomic Sciences, LKS Faculty of Medicine, The University of Hong Kong, Pokfulam, Hong Kong.

Genome-wide association studies (GWAS) have revealed many genomic regions associated with multiple traits, known as cross-phenotype (CP) associations. These regions may harbor genes and regulatory elements of special significance to human diseases and may help reveal shared disease mechanisms. Making use of the rich data from GWAS, we demonstrated that sequences in CP regions are more conserved, especially in the 3'-untranslated regions. As expected, functional elements, such as DNase-I hypersensitive sites, transcription factor binding sites and histone modification regions, were more enriched in CP regions. Based on these observations, we further found that the trait-associated variants in CP loci generally exert larger effects on disease susceptibility across a range of different diseases and traits. From the GWAS Catalog, we found that the variants associated with multiple diseases are more likely to be nonsynonymous, whereas independent variants in the same locus associated with different traits may function under different cellular context, suggesting complex regulatory mechanisms underlying multiple disease associations. In summary, these results may provide new insight into the genomic features of CP loci, and help better understand regulatory mechanisms underlying CP loci.

**2227W**

**A novel relationship between GWAS-identified sleep traits loci in sleep duration variation in healthy adults.** X. Xu, A.T. Magis, J.C. Lovejoy. Arivale Inc., 710 2nd Avenue, Suite 410, Seattle, WA, 98104.

**Background:** Sleep is increasingly recognized as an important lifestyle contributor to health. Chronic sleep disturbances (e.g., sleep deprivation, insomnia, large night-to-night sleep duration variation) are significantly associated with obesity, cardio-metabolic diseases, psychiatric disorders and all-cause mortality. Although sleep duration and disruption are affected by various environmental factors, heritability has been estimated at ~40% for sleep duration and ~25-45% for insomnia. Recently, GWAS analyses identified a few genetic loci associated with sleep duration and insomnia. The goal of this study is to further explore the effects of those SNPs in sleep duration variation. **Method and Results:** De-identified data from individuals in a commercially-available lifestyle coaching program (Arivale Inc., Seattle, WA) were collected starting from July 2015. The Arivale program involves health coaching on exercise, nutrition, stress management and other wellness goals, including sleep. Data from a total of 1832 Arivale program individuals were included in the present analysis. The study population included 50.6% females and 85.4% European-Americans. Their average age was 49.7 years, and average BMI was 26.6 kg/m<sup>2</sup>. Upon joining the Arivale program, each individual was provided a Fitbit Charge HR™ (San Francisco, USA) to record daily activity and sleep information. Fitbit Charge HR™ is a wristband that tracks all-day activity and sleep. Whole genome sequencing (WGS) was performed using whole blood samples and Illumina HiSeq X10 with sequencing mode PE150 (Illumina Inc., San Diego, USA). We collected nightly sleep data from each individual for 12-month time period, and calculated the individual's habitual sleep duration and sleep duration variation. A total of 19 previously identified sleep related SNPs were tested. General linear regression was performed to evaluate the relationships with sleep duration variation. It has been reported that rs113851554 in *MEIS1* gene is the strongest association for insomnia symptoms. In our study, rs113851554 also shows significant (FDR < 0.05) effect on sleep. In general, carriers exhibit 16-minutes higher sleep duration variations than homozygous. **Conclusion:** This study replicated previous identified sleep associated loci, and further explored the relationships with sleep duration variation. Our novel findings provide new insights into the biology of sleep and circadian rhythms in humans.

**2228T**

**Structural variation influencing complex traits and metabolomic measurements.** A. Sabo<sup>1</sup>, P. Mishra<sup>1</sup>, W. Salerno<sup>1</sup>, T. Chiang<sup>1</sup>, B. Yu<sup>2</sup>, A. Morrison<sup>2</sup>, G. Metcalf<sup>1</sup>, D. Muzny<sup>1</sup>, R. Gibbs<sup>1</sup>, E. Boerwinkle<sup>1,2</sup>. 1) Baylor College of Medicine, Houston, TX; 2) Human Genetics Center, University of Texas Health Science Center, Houston, TX.

Previous studies of the genetic architecture of complex traits have focused on the role of single nucleotide variation (SNV), but in fact structural variation (SV) covers more of the genome than single nucleotide variation. We performed Nimblegen whole exome capture followed by Illumina sequencing for 9,343 individuals from a large sample of European-Americans (EA) and African-Americans (AA) from the longitudinal ARIC cohort study. The data were processed using the integrated Mercury pipeline, followed by SV analysis using the XHMM software to identify rare copy number variants (CNVs). Although there has been intense effort on the detection and calling of SVs, there is very little work on modeling the genotype-phenotype relationship of SVs. We identified rare CNVs in 6,951 samples of European descent and 2,392 samples of African American descent, and investigated their impact on multiple core phenotypes and metabolomic measurements. We identified 36,390 CNVs, of which 11% were deletions, 26% duplication, and 63% were copy number variations - with both deletions and duplication detected in different samples. Most of the CNVs detected were relatively small and rare; 82% were smaller than 100kb, and 77% had a combined deletion and duplication MAF <1%. We have implemented both CNV level and gene level genotype-phenotype analysis of 245 metabolomic measurements and 20 core phenotypes from the ARIC study. We have transformed the phenotype to normality and included principal components in the model, and analyzed the two cohorts separately. We have confirmed previously identified association of proline dehydrogenase 1 copy numbers with plasma proline levels. We have identified several statistically significant novel findings in the AA cohort, which were replicated with nominal significance ( $p_{val} < 0.05$ ) in the EA cohort. These include association of CNVs overlapping *UGT2B11* gene with arginine levels, *ANKRD30B* with creatinine levels, and *FAM21B* with homocitrulline levels. The confirmation of these results is currently ongoing.

**2229F**

**Genetic polymorphisms of LIN28B and MKRN3 in association with precocious puberty.** K. Lee<sup>1</sup>, J. Yee<sup>2</sup>, H. Kim<sup>1</sup>, J. Kim<sup>1</sup>, H. Gwak<sup>2</sup>. 1) College of Pharmacy, Chungbuk National University, Cheongju, Daejeon, South Korea; 2) College of Pharmacy & Division of Life and Pharmaceutical Sciences, Ewha Womans University, Seoul, Korea.

Precocious puberty is clinically defined as the development of secondary sexual characteristics before the age of 8 years in girls and 9 years in boys. Puberty timing is known to be regulated by complex interactions of environmental, genetic, nutritional and socioeconomic factors. Although the function of genes is not completely known, MKRN3 and LIN28B are regarded as important genes for precocious puberty. But, there are few studies conducted on these genes for precocious puberty in Korea and no study done in boys. Therefore, we aimed to investigate the effect of MKRN3 and LIN28B gene mutations on precocious puberty in both girls and boys. The follow-up of the Ewha Birth & Growth Cohort study was conducted annually since 2005 including children age 3, 5, 7, 8 and 9 years. The first clinical follow-up of puberty was assessed in 9-year-olds in 2011 and children aged 7 to 9 years at 2011 to 2012 were recruited for this study. Four SNPs of MKRN3 gene (rs2239669, rs12441827, rs657457 and rs12148769) and two SNPs of LIN28B gene (rs314280, rs314276) were selected based on the data from previous studies and the minor allele frequency (MAF) of 15% or above. A total of 110 girls and 90 boys were included in the analyses. There were 96 girls (87.3%) in Tanner stage 1, 14 girls in stage 2 (12.7%), and no one belonged to stage 3. Among boys, 44 were found to be in stage 1 (48.9%), 34 (37.8%) in stage 2, and 12 (13.3%) in stage 3. The genotyping assay results indicated linkage disequilibrium (LD) between rs2239669 and rs657457 in MKRN3 and rs314280 and rs314276 in LIN28B. High probability of precocious puberty was shown in girls with G allele for rs314280 and C allele for rs314276 and in boys with G allele for rs657457 and TT homozygous for rs12441827. We identified that SNPs of MKRN3 and LIN28B were partially associated with precocious puberty. Exact mechanisms involved in MKRN3 and LIN28B mutations need to be investigated and an ongoing effort to find other factors associated with the puberty should be maintained.

## 2230W

**Finland, combining the population isolate structure with nationwide health care data for gene discovery.** A. Palotie<sup>1,2,3,4</sup>, J. Koskela<sup>1,2,3</sup>, I. Surakka<sup>1</sup>, P. Häppölä<sup>1</sup>, P. Heikkula<sup>1</sup>, M. Alanne-Kinnunen<sup>1</sup>, M. Perola<sup>1,5</sup>, V. Salomaa<sup>5</sup>, M.J. Daly<sup>1,2,3</sup>, S. Ripatti<sup>1</sup>. 1) Institute for Molecular Medicine, Finland, University of Helsinki, Helsinki, Finland; 2) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 3) The Stanley Center for Psychiatric Research and Program in Medical and Population Genetics, The Broad Institute of MIT and Harvard, Cambridge, MA, USA; 4) Department of Medicine, Department of Neurology and Department of Psychiatry Massachusetts General Hospital, Boston, MA, USA; 5) Institute of Health and Welfare, Helsinki, Finland.

Finland is the largest population isolate in Europe, which provides benefits in identification of rare and low frequency variants. Due to its small founder population, multiple genetic bottlenecks and rapid population growth a set of rare, deleterious variants have been enriched and are present in a frequency of 0.005-0.05. The 36 recessive diseases, called the Finnish Disease Heritage, best demonstrate this bottleneck effect. However, this feature is not limited to recessive, Mendelian variants; the power to identify deleterious variants that are potential drug targets has been demonstrated using population and birth cohorts as well as disease collections linked to national health records (Lim et al, 2014, Stoll et al 2013, Flannick et al 2014). The Nordic Countries have unique health care registers that cover health information of every resident for their entire life span. The 11-digit personal identification number links data from all different registries. The Finnish phenotype data resources combined with GWAS, WES and WGS data and efficient variant imputation (Surakka et al doi:<https://doi.org/10.1101/080770>) enable unique study designs. For example, in a PheWAS against 200 clinical outcomes we identified a Finnish enriched loss of function variant in the ANPTL8 gene protective for type 2 diabetes and high triglycerides. Another example is prediction of mortality using phenotypic cross disease categories like life time drug usage and life time cumulative number of hospitalization (YODA Score, Years of Drugs Applied), in population cohorts of 23 000 individuals (Finnish) (hr=1.023 per YODA year, p<2e-16; hr=1.074 per month of hospitalization, p<2e-16 respectively). These analyses and abilities to re-contact study subjects enable to identify potential shared genetic backgrounds over traditional diagnostic boundaries. Potentially they provide tools for preventive public health measures and can identify low frequency variants that can pinpoint new cellular pathways that contribute to disease pathogenesis and as a consequence might provide potential drug discovery targets. To further strengthen the Finnish data resource, we have, together with international collaborators, initiated a study that aims to combine genome and health register data from up to 500 000 Finnish individuals. This study is likely to provide a widely usable data resource for genetic analyses, drug target discovery and reference data for implementation of genomics in health care.

## 2231T

**Whole exome sequencing reveals a novel candidate gene, HSPA1L, for spontaneous preterm birth.** J.M. Huusko<sup>1,2</sup>, M.K. Karjalainen<sup>1</sup>, G. Zhang<sup>2</sup>, B.E. Graham<sup>3</sup>, E.G. Farrow<sup>4</sup>, N.A. Miller<sup>4</sup>, J.C. Murray<sup>5</sup>, B. Bedell<sup>6</sup>, F.L. Bødker<sup>6</sup>, K. Christensen<sup>6</sup>, S.M. Williams<sup>3</sup>, M. Rämetsä<sup>1</sup>, S.F. Kingsmore<sup>7</sup>, K.K. Ryckman<sup>8</sup>, M. Hallman<sup>1</sup>, L.J. Muglia<sup>2</sup>. 1) PEDEGO Research Unit and Medical Research Center Oulu, University of Oulu and Department of Children and Adolescents, Oulu University Hospital, Oulu, Finland; 2) Division of Human Genetics, Center for Prevention of Preterm Birth, Perinatal Institute, Cincinnati Children's Hospital Medical Center, Department of Pediatrics, University of Cincinnati College of Medicine, March of Dimes Prematurity Research Center Ohio Collaborative, Cincinnati, OH; 3) Department of Epidemiology and Biostatistics, Case Western Reserve University School of Medicine, Cleveland, OH; 4) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO; 5) Department of Pediatrics, University of Iowa, Iowa City, IA; 6) Institute of Public Health, University of Southern Denmark, Odense, Denmark; 7) Rady Children's Institute for Genomic Medicine, Rady Children's Hospital, San Diego, CA; 8) Department of Epidemiology, College of Public Health and Department of Pediatrics, Carver College of Medicine, University of Iowa, Iowa City, IA.

**Background and aims.** Preterm birth is the single leading cause of infant mortality and morbidity. The etiology of preterm birth is complex, and both environmental and genetic factors contribute to the overall risk. However, the genetic bases for preterm birth remain largely unknown. Our aim was to investigate presence of rare, likely damaging nucleotide variants in families with recurrent spontaneous preterm birth (SPTB). **Methods.** We performed a whole exome sequencing (WES) for 17 mothers from seven families with recurrent SPTB. Mothers were of Northern Finnish origin, and DNA samples were collected in Oulu University Hospital, Finland. WES was performed using Illumina HiSeq 2500, followed by generation and alignment of sequence data. Variant calls resulting from sequenced exomes were annotated and filtered using Ingenuity Variant Analysis. Variants passing the quality requirements were prioritized according to their frequency, pathogenicity and mode of inheritance. Only genes harboring rare (MAF <1% in European populations), likely damaging variants were subjected into pathway analysis (Ingenuity). Findings were replicated using additional set of WES data including 192 mothers (giving birth preterm) of European origin. **Results.** We identified multiple rare exonic missense variants in genes common for several affected mothers belonging to different Finnish families. One of these genes encodes the heat shock protein family A (Hsp70) member 1 like (*HSPA1L*). *HSPA1L* belongs to the Glucocorticoid receptor signaling pathway that was the most significant pathway within a group of mothers with recurrent preterm births. Rare, likely damaging, variants within *HSPA1L* were also seen in the replication set. Furthermore, *in silico* functional analysis of one of the rare variants, seen in two Finnish families, suggested that the variant generates an additional phosphorylation site that could affect the protein-binding kinetics. **Conclusions.** We found rare likely damaging missense variants in *HSPA1L* within four Finnish families with recurrent SPTB. This finding was supported by additional replication data as well as by *in silico* assessments. One of the rare damaging variants potentially alters the post-translational modification of the protein and thus could affect the protein-binding properties.

**Introduction:** Alpha-1 antitrypsin deficiency demonstrates that rare coding variants of large effect can influence chronic obstructive pulmonary disease (COPD) susceptibility. To identify such rare coding variants, we utilized an extreme-phenotype study design and conducted whole exome sequencing analysis in multiple cohorts of severe COPD. **Methods:** We sequenced 1019 unrelated subjects from the COPD Gene study; cases had FEV<sub>1</sub> < 50% predicted, and controls had normal lung function and age > 55. We also sequenced 1579 related subjects from the Boston Early-Onset COPD Study (probands age < 53, FEV<sub>1</sub> < 40% predicted) and the International COPD Genetics Network study (ICGN) (probands age < 65, FEV<sub>1</sub> < 60% predicted). We conducted three complementary analyses, including gene- and pathway-based association tests for 1) very rare variants (MAF < 0.1%), 2) predicted deleterious variants (MAF < 1%), and 3) a family-based analysis using the gene-based segregation method (GESE). Unrelated subjects were sequenced in two batches and analyzed using SeqMeta and the resampling method in SKAT combined with Fisher's method. Family-based data were analyzed on lung function using MONSTER. We additionally sought evidence for overlap between case-control and family-based data using network methods. **Results:** In the analysis of very rare and rare predicted deleterious variants, we found that SeqMeta gave spurious results in genes with multiple low-count variants; no genes were significant using Fisher's method. Top pathways in the COPD Gene data included *GATA3* and Th2 cytokine gene expression (p = 6.7e-06) for very rare variants, and the Jak-STAT pathway for rare deleterious variants (p=3.0e-05), neither of which replicated in family-based analyses. Using GESE in the family-based data, we identified two significant genes segregating in multiple pedigrees: *TBC1D10A* and *RFPL1*. We found no significant overlap of top results in case-control and family studies; however, network analysis found genes with p-value < 0.05 were significantly close to each other in a protein-protein interaction (PPI) network. We also observed several rare variant in genes previously identified that were nominally significant after conditioning on the known GWAS variant. **Conclusions:** These results likely reflect heterogeneity of genetic risk, insufficient power, and limitations of annotation. Ongoing efforts include expanding the sample size and further examination of GWAS

**2233W****Enhanced methods to investigate the role of *Trans*-eQTL to complex**

**traits.** C. Giambartolomei<sup>1</sup>, N. Mancuso<sup>1</sup>, H. Shi<sup>1</sup>, B. Strober<sup>2</sup>, A. Battle<sup>2</sup>, B. Pasaniuc<sup>1</sup>. 1) UCLA, Department of Pathology & Laboratory Medicine, Geffen School of Medicine, 10833 Le Conte Ave, Los Angeles, U.S.A; 2) Johns Hopkins University, 3400 N. Charles St., Baltimore, MD 21218, U.S.A.

Most GWAS and eQTL overlap have largely focused on the role of local (*cis*) regulation of gene expression to complex traits. Unfortunately, only a limited fraction of GWAS signals can be explained by *cis*-eQTL variants. On the other hand, *trans*-eQTLs may have broader effects on the transcriptome and may have important phenotypic consequences as they are known to be tissue-specific. The contribution of distal *trans* gene expression regulations to GWAS is not well explored, mostly because of the difficulty in assessing *trans* regulation (lower effects coupled with the multiple-testing burden imposed by the number of genome-wide tests performed). Here we introduce new methods to co-localize *trans*-eQTL signals with GWAS overlap and quantify the contribution of *trans*-eQTLs to disease risk. Our approaches build on recently proposed methods for *cis*-eQTL co-localization that allow for multiple causal variants to yield estimates of local correlation in the *trans*-effects on gene expression and effects on complex traits. Our approaches only require summary association statistics (both eQTL and GWAS). We validate our methods using extensive simulations starting from real data and show that our methods outperform existing approaches while also providing an interpretation of *trans*-eQTL/GWAS co-localization. We analyze large-scale GWAS of more than 50 complex traits joined with gene expression across 44 tissues (GTEx) to identify GWAS loci explained by *trans* regulation of putative risk genes. We also quantify the *cis* versus *trans* contribution to disease using genetic correlation and examine the location of the disease-relevant eQTL by distance of the regulated gene. This helps us better understand the location of disease variants influencing expression and the relevance of the *cis* versus *trans* distinction.

**2234T****Connection of RAB8A and MED16 with implications on 5'-deoxy-5-fluorouridine response.**

C.M. Murtagh, C. Lucas, A.L. Stark. University of Notre Dame, Notre Dame, IN.

Treatment plans can be individualized to optimize drug response in cancer patients with a better understanding of how genetics influences protein expression and drug response. Our goal was to utilize genetic associations between protein levels and drug response to identify functional candidates for capecitabine therapy optimization. Capecitabine is an oral prodrug used in breast cancer treatment; 5'-deoxy-5-fluorouridine is the activated form of the drug used for *in vitro* studies. We identified three SNPs localized to the short arm of chromosome 19 in RAB8A that were associated with MED16 protein expression and 5'-deoxy-5-fluorouridine response in lymphoblastoid cells. RAB8A is a member of the RAS superfamily, highly conserved, and implicated in tumorigenesis. Past studies have revealed that MED16 is a coactivator involved in the transcriptional regulation of many RNA-polymerase II dependent genes and plays a role in Vitamin D reception, which may affect calcium homeostasis, cell proliferation, and cell differentiation. Thus, expression of MED16 may significantly alter transcription levels of RNA-polymerase II dependent genes and affect functions such as cell proliferation which are abnormal in cancerous cell cycles. No current literature links MED16 or RAB8A with chemotherapy or cancer survival. We knocked down RAB8A using siRNA in MCF7 breast cancer cells and assessed MED16 expression and capecitabine response. Decreased expression of MED16 is hypothesized to lead to poorer capecitabine outcomes, suggesting that MED16 is a contributor to capecitabine response. Results from this study hope to indicate that further research should be performed regarding the potential of MED16 to serve as a prognostic marker for individuals treated with capecitabine.

Zhang<sup>2</sup>, K. Xiang<sup>2</sup>, Z.H. Yang<sup>2</sup>, S.M. Liu<sup>3</sup>, X. Tao<sup>3</sup>, NA. Gengdeng<sup>3</sup>, W.S. Zheng<sup>1,5</sup>, Y.B. Guo<sup>1,5</sup>, T.Y. Wu<sup>3</sup>, X.B. Qi<sup>2</sup>, B. Su<sup>2</sup>. 1) School of Medicine, Tibetan University, Lhasa, Tibet Autonomous Region, China; 2) State Key Laboratory of Genetic Resources and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming 650223, China; 3) National Key Laboratory of High Altitude Medicine, High Altitude Medical Research Institute, Xining 810012, China; 4) Kunming College of Life Science, University of Chinese Academy of Sciences, Beijing 100101, China; 5) College of Animal Science and Technology, Gansu Agricultural University, Lanzhou 730070, China.

Tibetans are well adapted to hypoxic environment at high altitude. Compared with lowlanders moving to high altitude, Tibetans have relatively low hemoglobin concentrations that is considered a protection from high altitude polycythemia (overproduction of red cells). But how high can Tibetans live remains an open question. We analyzed hemoglobin profiles of nearly 9,000 Tibetan individuals from 20 geographic populations permanently residing at elevations from 2,227m to 5,018m. With the use of a nonlinear regression model, we identified an elevation turning point around 4,500m showing sharp increases of hemoglobin concentration and polycythemia prevalence. This elevation turning point likely marks the altitude limit for Tibetans. Our findings of an Hb turning point in Tibetans have several implications. First, although Tibetans are likely the most adapted population for high altitude in the world, an elevation of more than 4,500m still serves as a big challenge for them. Second, the identification of an altitude limit implicates an incomplete adaptation of Tibetans to high altitude although they have been living there since late Paleolithic time. This seems to explain the not-yet-fixed adaptive mutations (~80%) previously identified in the two hypoxic genes (*EPAS1* and *EGLN1*). In other words, natural selection has not finished its task and may still be in action. Finally, as hemoglobin concentration is only one of the adaptive physiological traits in Tibetans, other traits like resting ventilation, blood oxygen saturation and pulmonary vasoconstriction response should also be studied to further test the proposed turning point of 4,500m.

**2236W**

**Polymorphisms associated with skin, hair and eyes color for forensic phenotyping purposes in Brazilian population.** C. Fridman, F.A. Lima, F.T. Gonçalves. Dept of Legal Medicine, Ethics and Occupational Health; Medical School, University of São Paulo, São Paulo, Brazil.

Human pigmentation is a variable and complex trait determined by exposure to ultraviolet radiation, age diseases, hormones, and genetic factors. Some polymorphisms in pigmentation genes have been associated with the phenotypic diversity of skin, hair and eyes color in homogeneous populations. Forensic DNA Phenotyping (FDP) is benefiting forensic science in several countries, helping in criminal investigations due to its ability to suggest, with good accuracy, the possible phenotypes for externally visible characteristics (EVCs) in samples of unknown origin. Herein, we evaluated the associations between the SNPs present in the genes *SLC24A5* (rs1426654; rs16960620; rs2555364), *TYR* (rs1126809) and *ASIP* (rs6058017) with skin, hair and eyes color in individuals of the Brazilian population in order to point out the possible use of these markers in forensic practice in admixed populations. The volunteers answered a questionnaire in which they self reported these characteristics for comparison between genotypes and phenotypes. The results showed that for the SNPs rs2555364 and rs1426654 the ancestral allele was associated with characteristics of black skin color, brown or black hair and brown eyes. In addition, the ancestral allele of the SNP rs6058017 was significantly associated with black skin color and brown eyes. Inversely, the variant alleles of these SNPs are correlated with fair pigmentation characteristics for the evaluated EVCs, corroborating the previous studies performed in different populations. These results show that molecular information may be useful for the inference of EVCs, and the FDP technique is an important tool for forensic studies in Brazil.

**2237T**

**Whole genome sequencing in severe chronic obstructive pulmonary disease.** D. Prokopenko<sup>1,2</sup>, P. Sakornsakolpat<sup>1,2</sup>, H. Loehlein Fier<sup>3,4</sup>, D. Qiao<sup>1,2</sup>, C. Lange<sup>1,4</sup>, T.H. Beaty<sup>6</sup>, J.D. Crapo<sup>6</sup>, E.K. Silverman<sup>1,2</sup>, COPDGene Investigators, NHLBI TOPMed Investigators. 1) Channing Division of Network Medicine, Brigham and Women's Hospital, Boston, USA; 2) Harvard Medical School, Boston, USA; 3) Working Group of Genomic Mathematics, University of Bonn, Bonn Germany; 4) Department of Biostatistics, Harvard School of Public Health, Boston, USA; 5) Johns Hopkins Bloomberg School of Public Health, Johns Hopkins University, Baltimore, USA; 6) National Jewish Health, Denver, USA.

Whole-genome sequencing (WGS) offers comprehensive coverage of the genome, which gives several advantages over exome sequencing, including improvements in calling of coding regions and interrogation of impactful variants in non-coding regions. As part of the NHLBI Trans-Omics for Precision Medicine (TOPMed) program, we submitted DNA samples from the COPDGene and Boston Early-Onset COPD studies for sequencing from 830 severe COPD cases with a mean forced expiratory volume in 1 second (FEV<sub>1</sub>) of 33±11. Current and ex-smoker controls (n=1070) had FEV<sub>1</sub> ≥ 85% predicted. For association analysis we identified population substructure in the samples using the rare variant Jaccard method and grouped variants into non-overlapping windows using a spatial clustering approach. We performed single-variant, indel, and region-based analysis both genome-wide and in candidate genes and controlled for effects of population stratification. We further assessed the overlap of variants between sequencing and Haplotype Resource Consortium imputation using reference panels. Results: We performed analyses in 1794 total subjects, with separate analyses in non-Hispanic White (NHW) and African American (AA) individuals. We confirmed a known association region near *HHIP* (combined p=1.6x10<sup>-9</sup>) and identified near-significant variants near *TNS1* in NHW and *SERPINA6* in AA subjects. The top association in *SERPINA6* in the AA is a common variant and not explained by the known *SERPINA1* COPD susceptibility Z or S alleles (conditional P = 9x10<sup>-6</sup>) nor other known *SERPINA1* variants. No association was seen in non-Hispanic whites. In regions around 22 variants recently described as genome-wide significant in COPD, we found nominally significant variants which were not present in imputation reference panels. In general for rare variants, even with a high imputation quality, we see a drop in concordance when compared with sequenced data. Conclusions: Whole-genome sequencing can identify large numbers of potentially functional and deleterious variants, and will serve as an important resource for identifying causal variants at known and novel loci for COPD. We anticipate including additional 7300 subjects into our analysis, which will increase our power. Future plans include testing COPD-related phenotypes and fine-mapping of known signals.

**2238F**

**GWAS of fingerprint patterns.** E. Feingold<sup>1</sup>, J. Chernus<sup>1</sup>, J. Bowser<sup>1</sup>, J. Roosenboom<sup>1</sup>, S. Rajagopalan<sup>1</sup>, K. Neiswanger<sup>1</sup>, E.J. Leslie<sup>1</sup>, J. Carlson<sup>1</sup>, C. Sanchez<sup>1</sup>, T. Soejima<sup>1</sup>, A. Czeizel<sup>2</sup>, J.T. Hecht<sup>3</sup>, E.E. Castilla<sup>4</sup>, J. Salamanca<sup>5</sup>, I.M. Orioli<sup>6</sup>, F.A. Poletta<sup>7</sup>, S. Weinberg<sup>1</sup>, M.L. Marazita<sup>1</sup>. 1) University of Pittsburgh, Pittsburgh, PA, USA; 2) FCCHD, Budapest, Hungary; 3) University of Texas McGovern Medical Center, Houston, TX, USA; 4) ECLAMC, Rio de Janeiro, Brazil; 5) Hospital Infantil Universitario Niño Jesús, Madrid, Spain; 6) Federal University of Rio de Janeiro, Rio de Janeiro, Brazil; 7) CEMIC: Center for Medical Education and Clinical Research, Buenos Aires, Argentina.

Human fingerprint patterns are a highly heritable phenotype known to be associated with important diseases such as schizophrenia and heart disease. Understanding fingerprint genetics may help dissect the underlying biology of such diseases, as well as providing insight into more general developmental processes. Fingerprints can be conceived of as a high-dimensional phenotype with various measures on each finger. Beyond classification into common pattern types (arches, loops, and whorls), more refined phenotypes such as ridge counts have been developed. Using the correlation structure of pattern types across study subjects' ten fingers, we constructed several multi-finger phenotypes and performed genome-wide association scans on them. The subjects are a set of approximately 1400 individuals recruited from the Pittsburgh Orofacial Cleft Study—a larger study of the genetics of cleft lip and palate. After imputation, genotypes were available for seven million SNPs. Since subjects include cleft cases, their cleft-free relatives, and control families from several populations, a mixed model was used to account for population structure and relatedness in performing the GWAS. Results showed differing levels of genetic control for different fingers and patterns. Signals included replication of genes previously reported for other fingerprint phenotypes as well as several newly-nominated loci. This work was supported by NIH DE016148.

**Replication of HLA association with podoconiosis in diverse Ethiopian ethnic groups.** T.T. Gebresilase<sup>1,2</sup>, C. Finan<sup>7,8</sup>, D. Suvegas<sup>6</sup>, T. Sisay<sup>6</sup>, A. Aseffa<sup>3</sup>, A. Adeyemo<sup>4</sup>, C. Rotimi<sup>4</sup>, G. Davey<sup>4</sup>, E. Zeggini<sup>6</sup>, M. Newport<sup>5</sup>, F. Tekola-Ayele<sup>5</sup>. 1) Bioinformatics Directorate, Armauer Hansen Research Institute (AHRI), Addis Ababa, Ethiopia; 2) Unit of Health Biotechnology, Institute of Biotechnology, College of Natural and Computational Sciences, Addis Ababa University, Ethiopia; 3) Wellcome Trust Brighton and Sussex Centre for Global Health Research, Brighton and Sussex Medical School, Falmer, Brighton, UK; 4) Centre for Research on Genomics and Global Health, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, USA; 5) Epidemiology Branch, Division of Intramural Population Health Research, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, USA; 6) Wellcome Trust Sanger Institute, Hinxton, Cambridge, UK; 7) Institute of Cardiovascular Science, Faculty of Population Health, University College London, London, U.K.; 8) Farr Institute of Health Informatics, University College London, London, U.K.

Podoconiosis is a non-infectious geochemical disease of the lower leg resulting from long term exposure of bare feet to clay soil of volcanic origin. Little is known about the soil component that triggers the disease but progress has been made towards understanding host susceptibility. Previous Genome-Wide Association Study (GWAS) conducted in Wolaita, Southern Ethiopia, indicated variants in the *HLA* class II region to be associated with podoconiosis. In the current study, we aimed to validate this finding in the original and two other independent ethnic groups in Ethiopia using a replication samples consisting of 943 cases and 949 controls. DNA obtained from saliva was genotyped using the Illumina HumanOmni25-8 v.1-2 chip at Wellcome Trust Sanger Institute (WTSI), UK. A total of 22 SNPs in the *HLA-II* region reached genome-wide significance ( $p < 5E-8$ ) with rs9270911 being the most highly associated variant ( $P = 5.512E-10$ ; OR1.53; 95 % CI 1.34 -1.74). Gene-set analysis using MAGMA showed enrichment of KEGG Type I diabetes mellitus (FDR-adjusted  $p$ -value =  $3.17E-09$ ) pathways. Overall, our findings confirm an important role of antigen-presentation and T cell mediated response in the pathogenesis of the disease, and future work should focus in elucidating functional consequences of these variants.

**Fetal genome-wide meta-analysis of gestational age and preterm delivery.** X. Liu<sup>1</sup>, D. Helenius<sup>2</sup>, A. Buil<sup>2</sup>, B. Feenstra<sup>1</sup> for the iPSYCH-BROAD Group and Early Growth Genetics Consortium. 1) Department of Epidemiology Research, Statens Serum Institut, Copenhagen, Denmark; 2) Institute of Biological Psychiatry, Sankt Hans Psychiatric Hospital, Roskilde, Denmark.

**BACKGROUND:** Preterm birth, defined as birth at less than 37 weeks of gestation, is a major cause of infant morbidity and mortality. In European countries, the preterm birth rates in 2010 ranged from 5.2-10.4% and 60-75% of infant deaths occurred among babies who were born prematurely. Despite evidence that genetic factors contribute to preterm delivery (PTD) and gestational age (GA) at delivery, robust genome-wide significant associations with genetic variants have not yet been identified. **OBJECTIVES:** As a prime example of a complex phenotypic outcome, preterm birth is influenced by a multitude of environmental and genetic factors each of which has a small effect. The present study aim to discover genetic loci in the fetal genome associated with birth timing through a large genome-wide meta-analysis of infants with GA information. **MATERIALS AND METHODS:** Our study design is a meta-analysis of genome-wide association studies in a large number of cohorts within the Early Growth Genetics consortium, as well as other studies such as the Initiative for Integrative Psychiatric Research (iPSYCH). So far, the studies committing to the meta-analysis allow us to include genetic data from more than 60,000 infants. Within each discovery cohort, the participants' genotypes will be imputed from the Haplotype Reference Consortium (HRC) or 1000G Phase3 reference panels. Association testing will be performed in each cohort, and results will be combined using an inverse-variance weighted fixed-effects approach. **OUTCOME:** Collectively data from the contributing cohorts represent the largest study sample to date aimed at identifying genetic variants associated with PTD/GA. The meta-analysis is currently underway and results will be presented. These efforts will allow us to gain a better understanding of the human pregnancy and the timing of birth; knowledge that may ultimately lead to improved measures of prevention and therapy.

Hospital, Nagoya, Japan; 3) Department of Preventive Medicine, Nagoya Univ. Graduate School of Medicine, Nagoya, Japan; 4) Laboratory of for Genotyping Development, RIKEN, Yokohama, Japan; 5) Division of Epidemiology, Center for Public Health Sciences, National Cancer Center, Tokyo, Japan; 6) Tohoku Medical Megabank, Tohoku University, Sendai, Japan; 7) Division of Biomedical Information Analysis, Iwate Tohoku Medical Megabank, Iwate, Japan; 8) Department of Public Health, Nagoya City Univ. Graduate School of Medicine, Nagoya, Japan.

Usual sleep duration is heritable with heritability estimates being around 40%. Candidate gene association studies for sleep duration identified a number of potential loci, though the results were inconsistent. A GWAS of sleep duration have identified and replicated two SNPs near PAX8 and CBWD2 [Gottlieb DJ 2015]. Another large-scale GWAS using the UK biobank replicated association with PAX8 and identified new locus, VPK2, and confirmed the association with VPK2 in other samples [Jones SE 2016]. However, any locus has neither reached genome-wide significance in the other GWAS nor been replicated in independent samples presumably due to limitations in sample size. Therefore, we conducted a genome-wide association meta-analysis of sleep duration, including GWAS from the biggest three cohort studies in Japan, the Japan Multi-Institutional Collaborative Cohort (J-MICC) Study, the Japan Public Health Center-based prospective (JPHC) Study and the Tohoku Medical Megabank Project (TMM). Phenotype information was obtained from self-administered questionnaires at the entry into each cohort study. The ethics committees of all participating institutions approved the protocol for each cohort study, and all participants provided written informed consent with some exceptions (details omitted). Genotyping was performed with the Illumina Infinium OmniExpressExome-8 BeadChip. Imputation of autosomal SNPs was performed using IMPUTE2 and Minimac3 to a reference panel of the 1000 genome Project (phase 3) in the J-MICC and JPHC studies, and TMM, respectively. Population substructure was captured by principal component (PC) analysis on the sample of typed genotypes. After stringent quality control, GWAS of sleep duration as a quantitative trait was performed in each cohort adjusted for age, gender and the first 5 PCs, using SNPTEST and a self-made software based on mixed-effect model for the J-MICC and JPHC Studies, and TMM, respectively. In total, 6,730,804 SNPs in 31,703 participants passed our quality control criteria. In this meta-analysis, we found one locus significantly associated with sleep duration with genome-wide level ( $P$ -value  $< 5 \times 10^{-8}$ ). This include novel genes, such as CUX2, ALDH2 and HECTD4 at 12q24.1, where the smallest  $P$ -value =  $1.54 \times 10^{-8}$  was found at rs76892715. We also found two suggestive loci ( $P$ -value  $< 5 \times 10^{-7}$ ), KCNK2 at 1q41 and FABP6 at 5q33.3. These loci were not identified in the former GWAS of sleep duration and warrants further exploration.

**Genome-wide association study of complement activity pathways: The Cooperative Health Research in South Tyrol (CHRIS) study.** D. Noce<sup>1,2</sup>, L. Foco<sup>2</sup>, C. Fuchsberger<sup>2</sup>, M. Gögele<sup>2</sup>, A. De Grandi<sup>3</sup>, R. Würzner<sup>1</sup>, C. Lass-Flörl<sup>1</sup>, P.P. Pramstaller<sup>2,3,4</sup>, D. Orth-Höller<sup>1</sup>, C. Pattaro<sup>2</sup>. 1) Division of Hygiene and Medical Microbiology, Medical University of Innsbruck, Austria; 2) Institute for Biomedicine, Eurac Research, Affiliated Institute of the University of Lübeck, Bolzano, Italy; 3) Department of Neurology, General Central Hospital, Bolzano, Italy; 4) Department of Neurology, University of Lübeck, Lübeck, Germany.

**Purpose:** The complement system (CS) is a fundamental component of the innate immune response. It enhances antibodies' and phagocytic cells' ability to remove pathogens from organisms. The CS can be activated via three distinct pathways known as classical, lectin, and alternative. Deficiencies in each pathway are associated with chronic renal disease, age-related macular degeneration, immunological diseases and atypical hemolytic uremic syndrome, among others. To gain insight on the genetic basis of CS activity, we conducted genome-wide association studies (GWAS) of the three pathways in a general population sample. **Methods:** CS activity was assessed in 4990 18-to-93 year old participants (55% female) of the Cooperative Health Research in South Tyrol (CHRIS) study, using the WIESLAB commercial assay. For each pathway, activity was regressed over sex, age, plate, and date of experiment using linear mixed effect models (LMMs). GWAS of the LMM residuals were performed on the dosage levels imputed based on the Haplotype Reference Consortium v1.1 reference panel. GWAS were run with EPACKTS on SNPs with minor allele frequency of  $>0.01$  and imputation quality  $r^2$  of  $>0.3$ , and accounting for population relatedness. **Results:** We observed and accounted for modest genomic inflation:  $\lambda$  from 1.00 to 1.06. Three loci were identified for the alternative pathway on chromosomes 1q31 ( $p = 8.8e-10$ ), 6p22.1 ( $p = 4.7e-14$ ), and 12p12.2 ( $p = 1.8e-9$ ), respectively. The 6p22.1 locus was also associated with the classical pathway ( $p = 1.4e-35$ ). Three loci were identified in association with the lectin pathway on chromosomes 1p36.22 ( $p = 7.3e-11$ ), 9q34.2 ( $p = 7.6e-45$ ), and 10q21.1 ( $p = 1.4e-260$ ), respectively. All identified loci map to complement proteins responsible for the activation of the single pathways, and explain over 3.2%, 4.5%, and 34.9% of the variability of the classical, alternative, and lectin pathways, respectively. **Conclusions:** This is the largest genome-wide screening of the CS activity conducted to date. Associations were identified at loci carrying genes known to be involved in CS activity. The large variance explained by the identified loci opens up the opportunity for Mendelian randomization studies aimed at assessing causality between CS activation and complex diseases in the general population.

**2243T****GWAS reveals loci associated with velopharyngeal insufficiency.** *J. Roosenboom<sup>1</sup>, J. Chernus<sup>1</sup>, E.J. Leslie<sup>1</sup>, M. Ford<sup>2</sup>, E. Feingold<sup>3</sup>, J.R. Shaffer<sup>3</sup>, S.M. Weinberg<sup>1</sup>, M.L. Marazita<sup>1,3</sup>.*

1) University of Pittsburgh, Center for Craniofacial and Dental Genetics, Pittsburgh, PA, USA; 2) Childrens Hospital of Pittsburgh, Cleft Craniofacial Center, Pittsburgh, PA, USA; 3) University of Pittsburgh, Department of Human Genetics, Pittsburgh, PA, USA.

Velopharyngeal insufficiency (VPI) often results in hypernasal speech. VPI is caused by a failure to seal off the opening in the pharynx where the nasal cavity communicates with the oral cavity. VPI is often associated with orofacial clefting, especially when the secondary palate is affected. However, VPI can also be present in the absence of an overt cleft palate, suggesting an abnormality the structure or function of the soft palate musculature or an anatomical discrepancy in the size/shape of the pharynx. The genetic basis of VPI as an isolated trait is poorly understood. We performed a GWAS on 1689 individuals who had been evaluated for VPI. Our cohort was comprised of individuals with isolated lip clefts (no secondary palate involvement), unaffected relatives from families with a history of clefting and unaffected population controls. Assessment of VPI was made by a speech pathologist, based on either in person interviews or evaluation of standardized speech videos. A total of 92 participants showed evidence of VPI. The association analysis was carried out in EMMAX on ~350K genotyped and imputed SNPs (MAF > 5%), with age, sex and spoken language indicated as covariates in the model. Our preliminary results revealed two genome-wide significant loci ( $p < 5E-08$ ): rs3781583 in *LRP5* on chr11q13.2 and rs12922822 on chr16p12.3. *LRP5* is a co-receptor for *WNT* signaling and required for cranial neural crest cell migration in zebrafish. Furthermore, it is associated with oropharyngeal skeletal disease and therefore a good candidate gene for VPI. The second SNP was located in a gene desert, and probably has some long-range effects on other genetic regions. These are the first reported genetic association results for isolated VPI.

**A genome-wide association study of anorexia nervosa suggests a risk locus implicated in dysregulated leptin signaling.** *X. Wang<sup>1</sup>, H. Hakonarson<sup>1,2,3</sup>, D. Li<sup>1</sup>.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA; 3) Department of Pediatrics, The Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Anorexia nervosa (AN) is a complex and often chronic eating disorder characterized by the inability to maintain a normal healthy body weight and a persistent fear of weight gain, resulting in extreme emaciation and even death in some cases. Previous genetic and epidemiological studies have indicated a multifactorial etiology, where both genetic and environmental factors contribute to disease risk. As sample sizes have increased, genome-wide association studies (GWASs) of AN have begun to identify risk variants. To further elucidate the genetic architecture of AN, we performed a GWAS using data from our previously published study consisting of 1,033 AN cases by excluding 212 patients with AN who experienced diagnostic crossover during the course of their illness. We hypothesized that this reduction in phenotypic heterogeneity, despite the fact that AN and BN may share some genetic risk factors, would enhance gene discovery. Analysis of phenotypic variability led to the identification of a specific genetic risk factor that approached genome-wide significance (rs929626 in *EBF1* (Early B-Cell Factor 1);  $P=2.04 \times 10^{-7}$ ; OR = 0.7; 95% confidence interval (CI) = 0.61-0.8) with independent replication ( $P = 0.04$ ), suggesting a variant-mediated dysregulation of leptin signaling may play a role in AN. Multiple SNPs in LD with the variant support the nominal association. This demonstrates that although the clinical and etiologic heterogeneity of AN is universally recognized, further careful sub-typing of cases may provide more precise genomic signals. In this study, through a refinement of the phenotype spectrum of AN, we present a replicable GWAS signal that is nominally associated with AN, highlighting a potentially important candidate locus for further investigation.

**Genome-wide association studies of eye color in Han Chinese and Uyghur populations.** L. Wang<sup>1,2</sup>, S. Wu<sup>1,2</sup>, J. Tan<sup>2</sup>, Y. Yang<sup>2,3</sup>, K. Tang<sup>1</sup>, S. Xu<sup>1</sup>, L. Jin<sup>1,2,3</sup>, S. Wang<sup>1,2</sup>. 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences-Max Planck Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, 320 Yue Yang Road, 200031 Shanghai, China; 2) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, 200433 Shanghai, China; 3) Fudan-Taizhou Institute of Health Sciences, 1 Yaocheng Road, 225300 Taizhou, Jiangsu, China.

The iris controls the amount of light reaching the retina and functions as the diaphragm of the eye. Previous studies have identified genetic variants in several genes associated with human eye color in Europeans. However, there is no report of eye color related variants in East Asians. In this study we performed a genome-wide association study on eye color (assessed by Martin-Schultz eye color scales) in 2938 Han Chinese. We found two non-synonymous SNPs in *OCA2* independently associated with eye color (rs1800414:  $p=5.34 \times 10^{-28}$ ; rs74653330:  $p=3.39 \times 10^{-15}$ ). The findings were replicated in a second genome-wide scan on 690 Uyghur samples (rs1800414:  $p=8.58 \times 10^{-10}$ ; rs74653330:  $p=1.35 \times 10^{-8}$ ). Interestingly, we discovered a strong interaction between rs74653330 and rs12913832, a previously reported pigmentation related variant affecting the expression of *OCA2* ( $p=1.74 \times 10^{-8}$ ,  $\beta=-1.93$ ). The effect of rs74653330 could significantly increase when individuals also carry derived alleles of rs12913832. We also demonstrated that despite of the subtle differences of eye color in East Asians, a multinomial logistic regression model could also be used to predict eye color in Uyghur (AUC is 0.77 for Dark brown, 0.72 for light brown and 0.92 for green surround brown).

**Pinpointing GWAS signals: Indels vs. SNPs.** S.A. Gagliano<sup>1</sup>, S. Sengupta<sup>1</sup>, C. Sidore<sup>2</sup>, A. Maschio<sup>2</sup>, F. Cucca<sup>2,3</sup>, D. Schlessinger<sup>4</sup>, G.R. Abecasis<sup>1</sup>. 1) Center for Statistical Genetics, University of Michigan, Ann Arbor, Michigan, USA; 2) Istituto di Ricerca Genetica e Biomedica, Consiglio Nazionale delle Ricerche (CNR), Monserrato, Cagliari, Italy; 3) Dipartimento di Scienze Biomediche, Università degli Studi di Sassari, Sassari, Italy; 4) Laboratory of Genetics, National Institute on Aging, US National Institutes of Health, Baltimore, Maryland, USA.

It is unclear whether insertion and deletion variants (indels) are more likely to influence complex traits than more abundant SNPs. By definition, each indel adds or omits nucleotide(s), potentially increasing its impact. On the other hand, some indels are in low complexity regions (LCRs) that are less likely to include genes, potentially decreasing impact. We sought to understand whether SNPs or indels are more likely to impact human health, and to quantify the gain by routinely including indels in GWAS. We comprehensively characterized indels, and assessed association with 120 quantitative traits (related to cardiovascular and blood traits, among others) from the SardiNIA study. Then, at trait associated loci we assessed the relative enrichment of indels to SNPs. In brief, SardiNIA consists of a genotyped and richly phenotyped set of over 60% of the adult population in Sardinia's Lanusei valley. Each sample was genotyped on four different Illumina Infinium arrays. We imputed individuals successfully genotyped on all arrays (N=6602) using Minimac3 based on a Sardinian reference panel (4x coverage; N indels=1.1M; N SNPs=24M) of 3839 individuals. 928,605 polymorphic autosomal indels remained for analysis after imputation quality thresholds were applied. Only 8% (72,218) of the indels mapped to LCRs, and 5% (33,016) were singletons. For each of the 120 traits, we ran association analyses in EPACKS, using inverse-normalized residuals in the Efficient Mixed Model Association eXpedited (EMMAX) test, adjusting for age and sex. 51 of the traits tested had SNPs and/or indels ( $MAF \geq 1\%$ ) reaching genome-wide significance ( $p \leq 5E-8$ ), 33 of which had at least one indel reaching significance. There were 495 indels associated with at least one trait. We then investigated whether indels are more likely than SNPs to be "causal". To obtain an estimate of indel enrichment among potentially causal variants we assessed the proportion of indels to SNPs within 1Mbp of associated loci (N=89) compared to the rest of the genome for variants  $MAF \geq 1\%$ . We weighed the proportions by the association signals. Indels were not significantly enriched (estimate=1.28;  $p=0.7$ ). Assuming indels and SNPs have equal causality, we obtained 95% credible sets of potentially causal variants. One set contained solely a frameshift indel (rs200748895, posterior probability=0.99). Of variants with a posterior probability  $\geq 0.1$ , 6% (10/170) were indels. Our results suggest potential gain in adding indels to GWAS.

**Mutual allelic constraint in a human taste receptor gene cluster shows evidence of gene-gene interaction and may influence human reproductive partner compatibility.** R. Subaran, S. Munne. CooperGenomics, Livingston, NJ.

Gene-gene interactions in humans have been notoriously difficult to study, often calling for a number of statistical comparisons so large that the effect and sample sizes required are prohibitive. Here, we sought to identify gene-gene interactions that might affect reproductive phenotypes, limiting our pairwise comparisons, a priori, to a set of alleles we hypothesized to have strong effects on reproductive phenotypes. We scanned a large cohort of individuals from Northern Europe for pairs of alleles, within this filtered set, that bear the signatures of gene-gene interaction. This led us to identify multiple, separate, syntenic allele pairs where the underrepresentation of specific two-locus genotypes was statistically significant and could not be readily explained by canonical models of distance-based linkage disequilibrium (LD) and/or population admixture. One of these allele pairs spans a set of genes that are implicated in reproductive partner selection in mammals, and that are already known for long and unusual patterns of LD. Another pair is made up of alleles at distal ends of a human taste receptor gene cluster. We found that the presence of the minor allele in one gene in this cluster, strongly constrains the frequency of the major allele in the partner gene several hundred kilobases away, despite the absence of strong general LD between the two loci. To rule out the possibility of population stratification driving this observed effect, we tested for the presence of this pattern across multiple 1000 Genomes populations and found it to be recapitulated in all out-of-Africa populations. Therefore we conclude that alleles at these taste receptor loci have undergone continued mutual incompatibility for tens of thousands of years and may represent a gene-gene interaction involved in reproduction or reproductive partner choice.

**High-risk genetic variants in genes involved in endothelial cell glyco-lyx function in thrombotic storm.** K. Nuytemans<sup>1</sup>, L. Gomez<sup>1</sup>, N. Hoffman<sup>1</sup>, P. Whitehead-Gay<sup>1</sup>, N. Alves<sup>1</sup>, A. Beecham<sup>1</sup>, N. Dueker<sup>1</sup>, C.S. Kitchens<sup>2</sup>, D. Erkan<sup>3</sup>, L.R. Brandao<sup>4</sup>, A.H. James<sup>5</sup>, R. Kulkarni<sup>6</sup>, T.L. Ortel<sup>6</sup>, J.M. Vance<sup>1</sup>, M.A. Pericak-Vance<sup>1</sup>. 1) John P. Hussman Institute for Human Genomics, University of Miami, Miami FL; 2) University of Florida, Gainesville; 3) Hospital for Special Surgery, Weill Medical College of Cornell University, New York, NY; 4) Hospital for Sick Children, Toronto, ON, Canada; 5) Duke University Medical Center, Durham, NC; 6) Michigan State University, East Lansing.

Thrombotic storm (TS; [www.thromboticstorm.com](http://www.thromboticstorm.com)) is a rare and severe clinical phenotype that occurs in a small subset of patients with venous thromboembolic disease. It is characterized by more than two acute arterial and/or venous thromboemboli, frequent events in unusual locations, progressive/recent unexplained recurrence and frequent refractory and/or atypical response to therapy. We hypothesize that rare high-risk genetic variants contribute to the underlying hypercoagulability state in TS. We performed whole exome sequencing (WES) in 1 multiplex family of 3 affecteds, 18 trios and 26 additional probands. Due to the rarity and severity of the phenotype, variants are filtered on functionality (nonsense, missense and splice), conservation and frequency (<5% in 1000genomes). We performed sharing analyses in the family and tested two different models in the trios; *de novo* and recessive model. We screened the remaining probands for variants in identified candidate genes. We identified 52 rare functional *de novo* variants and 85 rare functional compound heterozygous variant combinations. Interestingly, two of the *de novo* variants are in genes (*SLC26A2*, *CHPF2*) involved in the formation of chondroitin sulfate (CS), while a compound heterozygous variant combination affects *STAB2*, a CS metabolism gene. Sharing analyses in the family identified rare variants in known thrombotic factors as well as in *PAPSS2*, a gene working with *SLC26A2* to supply sulfate groups for molecule sulfation. Screening the remaining probands led to the identification of additional variants in these genes in another nine patients. In summary, we identified CS variants in approximately a quarter of the TS patients. CS plays an important role in the endothelial cell layer, the glycocalyx, protecting the blood vessel and harboring multiple molecules of the blood anticoagulation systems. The sulfated CS sidechains on proteoglycans create the negative charge of the barrier, preventing permeability and binding of platelets. They also bind absorbed (anticoagulant) molecules from the plasma, such as antithrombin. Additionally, CS on thrombomodulin increases its efficiency at inactivating thrombin. Our data suggests that variants involved in chondroitin sulfate formation are conferring risk for TS. Additional analyses evaluating burden of variants in other glycocalyx genes in all probands are ongoing. .

**2249T****Genetic typing of DC-SIGN in recurrent vulvovaginal candidiasis.** *N. Kalia<sup>1</sup>, S. Kaur<sup>2</sup>, J. Singh<sup>1</sup>, M. Kaur<sup>2</sup>.*

1) Department of Molecular Biology and Biochemistry, Guru Nanak Dev University, Amritsar, India; 2) Department of Human Genetics, Guru Nanak Dev University, Amritsar, India.

**Statement of purpose:** Vulvovaginal Candidiasis (VVC) is a disease condition characterised by the excessive growth of *Candida* species, a dimorphic yeast normally present in the vagina in small numbers. Its symptoms include excessive secretion of curdy white vaginal discharge and severe itching. It can be acute or recurrent, where recurrent VVC (RVVC) is defined as four or more episodes of symptomatic acute VVC per year. This disease condition occurs in 75% women of child bearing age with a global annual incidence of 1-2 % of all women. Several molecules of innate and adaptive immune system are implicated in etiology and pathogenesis of RVVC. Dendritic cell specific intracellular adhesion molecule-3 grabbing non-integrin (DC-SIGN), also known as CD209, is a pattern-recognition receptor which bind to carbohydrate residues in the cell wall of many pathogens including fungi. It is involved in processing and presentation of these antigens resulting in generation of immune responses. Objectives of the present study were to evaluate DC-SIGN gene polymorphism in susceptibility to RVVC. **Methods used:** The study protocol was approved by Institutional Ethics Committee. After obtaining written informed consent, blood samples were collected from 42 cases, diagnosed by a gynaecologist and 42 age-matched healthy controls without any recurrent vaginal complaints. For the diagnosis of RVVC, European (IUSTI/WHO) guidelines on the management of vaginal discharge were used. Genomic DNA was isolated from the blood samples using inorganic method. Genotypic analysis of rs4804801 SNP of DC-SIGN gene was carried by PCR-RFLP using restriction enzyme HincII. All statistical analyses were performed using SPSS version 16.0. **Summary of Results:** High frequency of variant allele 'T' and heterozygous genotype was observed in cases (19.05%; 38.10%) as compared to controls (14.28%; 28.57%). Frequency of wild allele 'A' and its homozygous genotype was observed to be low in cases (80.95%; 61.90%) comparative to controls (85.71%; 71.43%). Homozygous variant genotype was completely absent in both the studied groups. However, none of these differences were found to be statistically significant ( $p > 0.05$ ), which can be attributed to the small sample size employed in the present study. This variant of DC-SIGN may be associated with risk towards RVVC.

**The Million Veteran cohort: A high quality and diverse resource of genetic data for large-scale analysis to enable personalized medicine.** *Y. Shi<sup>1</sup>, H. Hunter-Zinck<sup>1</sup>, M. Li<sup>1,9</sup>, N. Sun<sup>2,9</sup>, J. Huang<sup>1</sup>, C. Pan<sup>2,6</sup>, J. Gelernter<sup>3,8</sup>, P.S. Tsao<sup>2,6</sup>, C.J. O'Donnell<sup>1,5</sup>, T.L. Assimes<sup>2,6</sup>, E.R. Hauser<sup>1,7</sup>, H. Zhao<sup>3,8</sup>, S. Pyarajan<sup>1,5</sup> on behalf of the VA Million Veteran Program.* 1) VA Boston Healthcare System, Boston, MA; 2) VA Palo Alto Health Care System, Palo Alto, CA; 3) VA Connecticut Healthcare System, West Haven, CT; 4) Durham VA Medical Center, Durham, NC; 5) Harvard Medical School, Boston, MA; 6) Stanford University School of Medicine, Stanford, CA; 7) Duke University, Durham, NC; 8) Yale School of Public Health, New Haven, CT; 9) University of Utah, Salt Lake City, UT.

The Million Veteran Program (MVP) aims to integrate a patient's genetic data with the clinical record for personalized medicine in the care of U.S. veterans. The MVP is enabling large scale genome-wide association studies (GWAS) of complex human diseases. A successful GWAS requires rigorous quality assurance (QA) and quality control (QC) to minimize genotyping errors. Furthermore, large cohorts such as the MVP can provide evidence to improve best practices in genotyping technology and algorithms. Here, we describe the QC/QA on genotypic data for the first 396,197 samples in MVP cohort. Approximately 4,500 samples genotyped with MVP 1.0 array were grouped into a batch to call genotypes using the Affymetrix Power Tools software. After the advanced marker QC with batch specific information for accurately calling rare markers, 657,459 (95.74%) of the original 686,682 genotyped markers were retained. A rigorous sample QA/QC procedure including gender mismatch, genotype concordance, PCA, and relatedness analysis produced a cohort with above 95% call rate. The median sample concordance for 5,000 pairs of intentional duplicates is  $> 99.8\%$ . Concordance is excellent for common markers ( $MAF > 10\%$ ) with 94% of these markers having discordance rates of less than 1%. Even for rare markers ( $MAF < 0.1\%$ ), 74% of markers in this MAF bin have discordance rates less than 1%, demonstrating that we can consistently call rare variants. Although the vast majority of the MVP samples are close to reference populations of European origin in their genetic makeup, many MVP sample exhibit admixture with respect to the African and the Asian population supergroups in 1000 Genomes Phase 3 references samples. The overlapping markers between the MVP population and ExAC database are stratified by their MAF values in the major continental populations to evaluate coverage of functional variants across the genomes of in diverse populations. All five-ancestry groups have similar in common variants counts. The African population has slightly more common variants due to the Genome wide imputation booster for African ancestry population and the Non-Finnish European population has the most rare variants. The completed QC analysis of the 396,197 samples demonstrates that the MVP is a high quality and diverse resource for researchers seeking to understand the complex interactions between genetics, the environment, and medicine. .

Rivadeneira<sup>1,3,5</sup>, J.B.J van Meurs<sup>1,5</sup>, H.A Moll<sup>1</sup>, A.M Ikram<sup>1,3,5</sup>, A.G. Uitterlinden<sup>1,3,5</sup>, R. Kraaiji<sup>1</sup>. 1) INTERNAL MEDICINE, ERASMUS MC, ROTTERDAM, Netherlands; 2) Department of Paediatrics, Erasmus MC, Rotterdam, Netherlands; 3) The generation R Study, Erasmus MC, Rotterdam, Netherlands; 4) Department of Gastroenterology and Hepatology, Erasmus MC, Netherlands; 5) Dept Epidemiology, Erasmus MC, Erasmus MC, Netherlands.

**Introduction:** It is known that the microbiome is dynamic through the life course and is still in developing phase during childhood, although this has not been studied yet in large population-based cohort studies. To examine the shifts in gut microbiome in children and elderly, we profiled the gut microbiome of two extensively phenotyped cohorts: the Rotterdam Study (RS, elderly) and the Generation R birth cohort (GenR). **Materials & Methods:** Over 1,700 faecal stool samples in the RS cohort and over 3,000 in the multi ethnic GenR cohort were collected and stored at -20°C. The V3-V4 regions of 16S ribosomal RNA gene were sequenced using Illumina MiSeq technology. Reads were clustered into Operational Taxonomic Units (OTUs). Comparative analysis of microbiome diversities and composition of the two cohorts was done in R and R packages vegan and MaAsLin. In both cohorts only samples from subjects with North-European ancestry and in the RS cohort only samples within the age range of 51-62 years were included in the analyses. We adjusted for BMI, sex, technical covariates, and multiple testing by FDR ( $q < 0.05$ ). **Results:** In total, 1,081 RS and 1,463 GenR samples were included in the analysis ( $n = 2,544$ ). After quality filtering 770 genus-level OTUs were obtained. We observed significant clustering of both cohorts based on Bray-Curtis dissimilarity (PERMANOVA,  $p = 0.001$ ) and a higher alpha diversity (Shannon Index) in RS than in GenR (ANOVA,  $p < 2.2e-16$ ). Our analysis revealed that 175 OTUs were more abundant in RS, while 137 OTUs were more abundant in GenR ( $q < 0.05$ ). Largest differences were observed for genera from family *Lachnospiraceae* including *Anaerostipes* and *Blautia* that were more abundant in RS, and genera from families *Ruminococcaceae* and *Bacteroidaceae* including *Faecalibacterium* and *Bacteroides* that were more abundant in GenR. **Conclusion:** Comparing the gut microbiome compositions in 2,544 children and adults showed significant clustering of the cohorts based on beta diversity and significantly different alpha-diversities between children and adults. A total of 312 OTUs were found to have differential abundances between the two cohorts with genera from the *Lachnospiraceae* family being more abundant in adults and genera from the *Ruminococcaceae* and *Bacteroidaceae* families being more abundant in children. Further analysis is needed in order to understand the mechanisms of these bacteria and their relationship with their host metabolism pathways.

## 2252T

**Genome-wide association study of cranial vault shape reveals novel loci at 15q26.3 and 17q11.2.** M. Lee<sup>1</sup>, J. Roosenboom<sup>1</sup>, J.C. Carlson<sup>2</sup>, E.J. Leslie<sup>1</sup>, E. Feingold<sup>3</sup>, M.L. Marazita<sup>1</sup>, J.R. Shaffer<sup>1</sup>, S.M. Weinberg<sup>1</sup>. 1) Center for Craniofacial and Dental Genetics, Department of Oral Biology, University of Pittsburgh, Pittsburgh, PA; 2) Department of Biostatistics, University of Pittsburgh, Pittsburgh, PA; 3) Department of Human Genetics, University of Pittsburgh, Pittsburgh, PA.

Genome-wide association studies (GWAS) have identified about two dozen loci associated with aspects of human facial shape. The cranial vault, a region comprised of interlocking flat bones surrounding the cerebral cortex, is strongly influenced by brain size and shape. Although cranial vault morphology has both clinical and evolutionary relevance, little is known about the genetic basis of normal vault shape in humans. Following the paradigm observed for other craniofacial traits, we hypothesize that normal variation in the cranial vault may be influenced by genes that lead to cranial defects but different genetic variants within such genes. We performed GWAS on three vault measures [maximum cranial width (MCW), maximum cranial length (MCL) and cephalic index (CI)] in a sample of 4,389 healthy individuals of European ancestry from two cohorts: 2,260 unrelated individuals (TDFN) genotyped on the Illumina OmniExpress + Exome v1.2 array and 2,129 related and unrelated individuals (OFC) genotyped on the Illumina HumanCoreExome array. Both cohorts were imputed to the 1000 Genomes phase 3 reference panel. All measures were adjusted by sex, age and body size, then subjected to GWAS either in PLINK adjusting for ancestry principal components (TDFN cohort) or in EMMAX (OFC cohort). We then performed genome-wide meta-analyses using Stouffer's p-value method. Significant associations at two loci were observed: one was at 15q26.3 (lead SNP rs2924767,  $p = 2.107 \times 10^{-9}$ ) for MCW and the other was at 17q11.2 (lead SNP rs72841279,  $p = 5.29 \times 10^{-9}$ ) for MCL. No significant associations were observed for CI. The genes *MEF2A*, *ADAMTS17*, and *NLK* at the associated loci are known to play roles in craniofacial development, making them potential candidates. These results provide further insight into genetic pathways and mechanisms underlying normal variation in human craniofacial morphology. This study represents the first reported genome-wide significant associations for human cranial vault shape. This research was supported by an NIDCR grant U01-DE020078 (SMW, MLM), R01-DE016148 (MLM, SMW), and X01-HG007821 (MLM, SMW, EF).

**2253F**

**Pharmacogenomic study of antithyroid drug-induced cutaneous reaction.** P. Chen<sup>1,2,3,4</sup>, T. Chang<sup>2</sup>. 1) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 2) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan, Taiwan; 3) Graduate Institute of Medical Genomics and Proteomics, National Taiwan University, Taipei, Taiwan, Taiwan; 4) Graduate Institute of Clinical Medicine, National Taiwan University, Taipei, Taiwan, Taiwan.

Graves' disease (GD) is an autoimmune thyroid disorder with clinical and academic importance. Treatments for patients with GD usually include antithyroid drugs (ATDs, including methimazole, carbimazole and propylthiouracil), radioactive iodine, and/or surgery. The adverse reactions of ATDs range from fever, rash, gastrointestinal distress to more severe ones, such as hepatotoxicity, vasculitis, as well as the potentially fatal complication, agranulocytosis. We took a pharmacogenomics approach to study the most common adverse effect, ATD-induced cutaneous reaction (TICR, including skin rash, urticarial and itching). Patients with TICRs were initially identified according to chart reviews (first-stage study) based on the discontinuation of the initial medication within two months after use as well as narratives recorded. Patients with TICR have later been actively searched for from the outpatient department at NTUH for confirmation (second-stage study). We identified 24 patients with TICRs between 2001 and March 2014 in our first-stage study. We used 427 GD patients without cutaneous reactions as the controls (GD controls). Then, we actively recruited additional 24 TICR patients between March 2016 and June 2016 for the second-stage study. The results were compared with other 470 GD controls. We performed genome-wide SNP genotyping, HLA imputation using SNPs and direct HLA genotyping. The analyses were carried out by using PLINK. GWAS using Affymetrix Axiom Genome-Wide CHB 1 single nucleotide polymorphism (SNP) Array (a total of 549,828 autosomal SNPs and 10,728 X-chromosomal SNPs after quality control process) showed an excess of small *P* values at the tail of the quantile-quantile distribution plot, but only limited evidence of inflation caused by population stratification (genomic inflation factor  $\lambda_{GC} = 1.0154$ ). We discovered that the association on chromosome 3p21.31 ( $P_{\text{first-stage}} = 0.000251$ ,  $P_{\text{second-stage}} = 0.03455$ ,  $P_{\text{combined}} = 5.25 \times 10^{-6}$ ) might deserve reporting. The HLA region was thoroughly investigated; we detected no significant association signal within the HLA region on chromosome 6p21. In conclusion, we discovered that SNPs on chromosome 3p21.31 might be associated with TICR. However, the association signals did not reach genome-wide significance level. Further increase of sample size is needed to achieve a definitive conclusion.

**Characterization of CYP2D6 by whole genome sequencing.** A.L. Halpern<sup>1</sup>, N. Gonzaludo<sup>2</sup>, O. Schulz-Trieglaff<sup>2</sup>, E. Fritzius<sup>3</sup>, J. O'Connell<sup>3</sup>, E.H. Margulies<sup>2</sup>, M.A. Eberle<sup>1</sup>, R.J. Taft<sup>1</sup>. 1) Illumina, San Diego, CA; 2) Illumina, Mission Bay, San Francisco, CA; 3) Illumina, Chesterford Research Park, UK.

*CYP2D6* plays a critical role in drug metabolism and many known 'star allele' haplotypes are predictive of drug response. Clinical use of *CYP2D6* data requires not just determination of single-variant genotypes but resolution of diplotypes (i.e. pairs of full-gene haplotypes). Though sequencing can provide more information about phasing of variants than traditional genotyping methods such as qPCR or microarrays, approaches employing short read sequencing struggle to resolve haplotypes over multiple kilobases. A catalog of accurate, known haplotypes, however, could facilitate inference of sample diplotypes. We show by simulation that diplotypes of official star alleles can be distinguished from one another with accuracy >99.5%. However, such an approach critically depends on the completeness and accuracy of the haplotype catalog. To assess the accuracy and completeness of existing *CYP2D6* star alleles, we generated whole-genome sequencing (WGS) data at >30x depth for 96 samples characterized by the Genetic Testing Reference Materials Coordination Program (GeT-RM). Sequence data for the 70 samples that are consented for public release can be obtained from the European Nucleotide Archive (PRJEB19931). Using just the protein-altering variants we were able to identify diplotypes consistent with the previous GeT-RM consensus results in 94% of samples. More than half of the time, however, this criterion results in genotype conflicts at  $\geq 5$  known-variant loci, and results in ambiguity between alternative diplotypes with different protein products 25% of the time, often with consequences for predicted drug response. A parsimony-based criterion using all *CYP2D6* variants still produces known-variant genotyping conflicts in >80% of samples, including conflicts in predicted proteins >50% of the time. These conflicts are not driven by unknown genetic variation - the median number of novel variants not represented in the star alleles is one. Variant calls made in >3000 additional samples with WGS data exhibit similar trends. These data indicate that *CYP2D6* calling from WGS data can be used to reproduce existing test results, but also underline the incompleteness of current star allele definitions. Calling diplotypes based on the existing nomenclature system for *CYP2D6* (with WGS data or other test methods) can produce ambiguous or potentially incorrect functional predictions, emphasizing the need for a comprehensive characterization of *CYP2D6* haplotypes.

**Translating pharmacogenetics: An electronic phenotyping algorithm and survey study of diverse BioMe biobank patients treated with ACE inhibitors.** H. Naik<sup>1</sup>, M.Y. O'Connor<sup>2</sup>, S.C. Sanderson<sup>3,4</sup>, N. Pinnell<sup>1</sup>, M. Dong<sup>1</sup>, A. Killie<sup>1</sup>, A. Owusu Obeng<sup>5,6</sup>, O. Gottesman<sup>5</sup>, N. Abul-Husn<sup>5</sup>, S.A. Scott<sup>1,7</sup>. 1) Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 2) Department of Medical Education, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 3) Clinical Genetics Department, Great Ormond Street Hospital, London, WC1N 3JH; 4) Department of Behavioural Science and Health, University College London, WC1E 6BT; 5) Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY 10029; 6) Department of Pharmacy, the Mount Sinai Medical Center, New York, NY 10029; 7) Sema4, a Mount Sinai venture, Stamford, CT 06902.

Previous studies have determined that the general public is interested in receiving pharmacogenetic information; however, little is known about knowledge and attitudes on pharmacogenetics among patients treated with medications that have a known adverse event risk. To assess these perspectives, we surveyed patients enrolled in the BioMe biobank at Mount Sinai who were treated with angiotensin converting enzyme inhibitors (ACEi), as ACEi are a very commonly prescribed antihypertensive, yet up to 1% of patients develop life-threatening angioedema (ACEi-AE). Electronic phenotyping algorithms were developed for the BioMe biobank patient data, which identified 199 ACEi-AE cases and 876 controls, defined as patients on an ACEi for  $\geq 2$  years without evidence of AE (plus other exclusions). Chart review determined that the case and control algorithms had sensitivities of 100% (95% confidence interval: 95-100%) and positive predictive values of 98.6% and 97.3%, respectively. Notably, cases differed from controls by age (61 vs. 58 years,  $p < 0.01$ ), gender (67% vs. 49% female,  $p < 0.01$ ) and self-reported race (62% vs. 27% African American,  $p < 0.01$ ), consistent with known risk factors for ACEi-AE. An anonymous survey was mailed to all 1075 patients and 91 were returned (9% response rate). Respondents were comparable by gender (52% female), ethnically diverse (47% European, 23% African, 24% Hispanic, and 6% other), had a mean age of 61.9 years, and 14 (15%) had confirmed ACEi-AE. Over a third of patients reported that prescribing physicians had not discussed with them the concepts of interindividual drug response variability (40%) or adverse event risk (including ACEi-AE and cough; 34%), and 73% of patients were previously unaware of pharmacogenetics. However, most patients agreed they would be interested in having pharmacogenetic testing if the results could improve dose selection (82%), prevent side effects (88%), provide a cheaper medication alternative (79%), and/or affect their family members (68%). Moreover, the majority of patients (67%) indicated that pharmacogenetic testing results would positively influence their compliance to medication use. In addition to identifying an innovative approach to define biobank cohorts for pharmacogenomic studies on rare adverse events, these results indicate that awareness of pharmacogenetics among patients is low, but their interest in pharmacogenetic testing is high, which could translate to improved medication compliance.

**Defining the opportunity: The IGNITE CPIC Prescribing Study.** L. Wiley<sup>1</sup>, A. Holmes<sup>2</sup>, M. Rosenman<sup>3</sup>, J. Murray<sup>4</sup>, J. Hicks<sup>5</sup>, F. Fitzhenry<sup>6</sup>, M. Matheny<sup>7</sup>, J. Cimino<sup>8</sup>, N. Limdi<sup>9</sup>, C. Aquilante<sup>8</sup>, L. Cavallari<sup>9</sup>, G. Lipori<sup>9</sup>, A. Winterstein<sup>9</sup>, A. Beitelshes<sup>10</sup>, D. Lempkin<sup>10</sup>, S. Tuteja<sup>11</sup>, P. Empey<sup>12</sup>, H. Ong<sup>13</sup>, M. Levy<sup>13</sup>, J. Denny<sup>13</sup>, J. Peterson<sup>13</sup>, *IGNITE Network Pharmacogenomics Working Group*. 1) University of Colorado School of Medicine, Aurora, CO; 2) Richard M. Fairbanks School of Public Health, IUPUI, Indianapolis, IN; 3) Indiana University School of Medicine, Indianapolis, IN; 4) Meharry Medical College, Nashville, TN; 5) Moffitt Cancer Center, Tampa, FL; 6) Nashville Veterans Affairs Medical Center, Nashville, TN; 7) University of Alabama Birmingham, Birmingham, AL; 8) University of Colorado School of Pharmacy, Aurora, CO; 9) University of Florida, Gainesville, FL; 10) University of Maryland School of Medicine, Baltimore, MD; 11) University of Pennsylvania, Philadelphia, PA; 12) University of Pittsburgh, Pittsburgh, PA; 13) Vanderbilt University, Nashville, TN.

The Clinical Pharmacogenetics Implementation Consortium (CPIC), established in 2009, has developed clinical practice guidelines for use of 30 drug-gene pairs. However, the overall value of using pharmacogenomic variants to tailor therapies depends on the incidence of prescribed medications with an actionable pharmacogenomic association. Prescribing trends across the US can change rapidly due to economic and medical stimuli. This study seeks to assess the opportunity for tailoring prescriptions with CPIC Level A variants across multiple types of health systems and population demographics within the Implementing GeNomics In pracTice (IGNITE) Network Pharmacogenomics Working Group. To accomplish this objective, we will use retrospective prescription data for adult patients at participating health systems to assess both total opportunity (e.g., number of patients receiving targeted drugs) and prescribing trends over time. For all adult patients prescribed at least one CPIC Level A drug, each site will extract patient level data for all CPIC Level A drugs and a selection of alternative therapies for these drugs for the past 5 years starting January 1<sup>st</sup>, 2011 (or earliest point after this date for which prescribing data are available). Monthly and total number of inpatient and outpatient visits will also be collected to adjust total prescription count by total healthcare system volume. Preliminary data from Vanderbilt University Medical Center show that between Jan 2011 and Sep 2015, 395,723 individuals had exposure to one or more CPIC Level A drugs with 162,819 (41%) patients exposed to two or more drugs. Of those patients exposed to multiple CPIC Level A drugs, there was a median of 2 drugs per patient (max = 14) and 28,106 (7%) having four or more CPIC level A drugs. The three most common drugs across the entire study period were: oxycodone (n=175,551), simvastatin (n=90,114) and citalopram (n=51,430). The number of patients exposed to 1+ CPIC drugs per year increased 29% from 2011 to 2014 (last full year of study) while the average number of unique patients seen monthly increased 15% over the same time-period (2011-2014). Data collection is ongoing at multiple IGNITE and Affiliate sites and should be available for presentation by fall. In summary, there is increasing volume of patients receiving CPIC Level A drugs over the past 5 years at the Vanderbilt University Medical Center.

**Phenotypic consequences of the genetic regulation of expression of the Mendelian disease gene *CFTR*.** X. Zhong, E.R. Gamazon, P. Straub, A. Konkashbaev, P. Evans, N.J Cox. Vanderbilt Genetics Institute, Nashville, TN.

A disease-causing gene can increase disease risk through two complementary modes: disrupting either the protein coding or the regulation of the gene. Recessive mutations in the gene *CFTR*, which encodes a membrane protein and chloride channel, are known to cause cystic fibrosis (CF), one of the most common Mendelian diseases. It is less clear, however, whether non-coding regulatory variants of *CFTR* exert roles in disease predisposition. Here, we report results of studies on *CFTR* using BioVU, a biobank linked to complete medical records. The effects of common regulatory non-coding variants were aggregated into their target gene's genetically-regulated gene expression (GReX) using PrediXcan. We calculated GReX of *CFTR* in tissues with quality predictors, and tested for associations with disease in ~10K Caucasians. Our results demonstrated three major phenotypic patterns: 1) CF and its canonical phenotypes ('bronchiectasis', 'pneumonia', 'diseases of pancreas', 'chronic sinusitis', and 'nasal polyps' etc.) emerged as the top associations, but further adjusting for  $\Delta F508$ , a coding mutation that is the most common cause of CF, these previously top associations were no longer significant; 2) CF and its canonical phenotypes remained top associations even after conditioning on  $\Delta F508$  but the associations were attenuated; 3) a distinct set of phenotypes (other than CF-related phenotypes) emerged as top associations (e.g., increased expression of *CFTR* in 'Esophagus-GastroesophagealJunction' was associated with cardiac phenotypes such as cardiac conduction disorders, cardiac arrhythmia, paroxysmal tachycardia etc. ), and stratification on  $\Delta F508$  did not attenuate the associations. These patterns suggested different scenarios regarding the SNP-based tissue-specific expression predictors: 1) the predictor captured mainly the effect of  $\Delta F508$ ; 2) the predictor captured  $\Delta F508$  mutation as well as additional genetic contributions to CF-related phenotypes; and 3) the predictor captured genetic contributions independent of  $\Delta F508$  that relate to non-CF phenotypes. In conclusion, we demonstrated that regulatory variants of *CFTR* contributed to disease risk in a tissue-specific manner, leading to different phenotypic consequences. Our analyses supported the complementary roles of coding and noncoding variants in disease susceptibility as well as the continuum from Mendelian to common diseases with complex inheritance.

**Designing of an efficient genotyping chip for discovery and pan-disease screening in the VA's Million Veteran Program.** S. Pyarajan<sup>1,5</sup>, Y. Shi<sup>1</sup>, M. Lji<sup>1,9</sup>, J. Moser<sup>10</sup>, S. Muralidhar<sup>10</sup>, L. Fiore<sup>1,4,7</sup>, T. O'Leary<sup>10</sup>, J. Concato<sup>3,8</sup>, J.M. Gaziano<sup>1,5</sup>, P. Tsao<sup>2,6</sup> on behalf of the VA Million Veteran Program. 1) VA Boston Healthcare System, Boston, MA; 2) VA Palo Alto Health Care System, Palo Alto, CA; 3) VA Connecticut Healthcare System, West Haven, CT; 4) Boston University School of Medicine, Boston MA; 5) Harvard Medical School, Boston, MA; 6) Stanford University School of Medicine, Stanford, CA; 7) Boston University School of Public Health, Boston MA; 8) Yale School of Public Health, New Haven, CT; 9) University of Utah, Salt Lake City, UT; 10) VA Office of Research and Development, Washington DC.

The Million Veteran Program (MVP) is a national program initiated by the Department of Veterans Affairs (VA) to collect consented biosamples for personalized medicine research from one million Veterans. The MVP has already collected over 570,000 samples and is expected to reach over one million in the next 4-5 years. To genotype all MVP participants at low cost, a custom high-density genotyping array, was designed on the Affymetrix Axiom® platform for genotyping the MVP samples. The MVP 1.0 array was designed enable investigation of markers of potential clinical significance for a wide variety of human conditions and diseases. We started with the Axiom® Biobank Genotyping Array as the backbone and designed a set of custom markers for inclusion on the array. The groups of curated marker that were included include primary SNPs and indels based on association with diseases or traits of interest including markers from the genes reported by ACMG for incidental findings, Psychiatry associated markers, candidates marker for RA association, genome-wide imputation booster for AA ancestry etc. The MVP 1.0 array includes 723,305 probesets investigating 686,682 markers. Markers from over 3,400 genes regions have been included. Additionally, over 800 clinical conditions, with an emphasis on conditions of high prevalence in US Veterans, are covered by potentially associated markers on the array. Markers for genome wide coverage for common (MAF > 5%) genetic variation of individuals of European and African ancestry were selected by an imputation aware algorithm. Our results indicate good performance for most of the markers including call rates across samples, concordance across duplicates for even very low frequency markers. Our genotyping data quality assessment indicates that overall, the MVP 1.0 Array is an efficient low cost genotyping array that can be used not only as a pan-disease screening array to design future more comprehensive and potentially expensive "omic" assays for MVP samples but also for discovery with efficient imputation.

Boerkoel<sup>1</sup>, A. Elliott<sup>2</sup>, C. Hajek<sup>1</sup>, I. De Vivo<sup>1</sup>, M. Sincan<sup>1</sup>, S. Puumala<sup>2</sup>. 1) Sanford Health, Sioux Falls, SD; 2) Genome.One, Sydney Australia; 3) Sanford Research, Sioux Falls, SD; 4) Harvard T.H. Chan School of Public Health, Boston, MA; 5) Oregon Health Sciences University, Portland, Oregon.

Health care disparities, which arise in part from inadequate access and knowledge, in underserved rural settings frequently lead to delayed diagnosis and inadequate management of complex chronic and rare diseases. These disparities are magnified by the consequential patient disengagement. We hypothesized that engaging patients to become agents of their own health through self-assessment and computational analysis partially addresses the knowledge and access gaps contributing to rural health care disparities. To address this, we converted validated questionnaires to an interactive electronic self-assessment tool embedded within the patient portal of the electronic medical record. To enable computational analysis, questionnaire and intake form responses were mapped to appropriate ontologies. Following refinement with the medical system customer relations and focus groups, we selectively launched this tool as part of a precision prevention initiative within a rural primary care setting. We present the process and logic underlying this engagement method as well as our initial results on patient interaction with the tool, educational initiatives encouraging patient uptake, and clinician response to the tool. .

Human height is a highly heritable trait. Although hundreds of genetic loci associated with adult human stature have been successfully identified in the recent large-scale genetic association studies, these findings were mostly derived from European population. Particularly, the contribution of rare and low-frequency variants has been largely unknown in East Asian population, and they are supposed to be population specific. To identify rare and low-frequency variants in Japanese population, we constructed an imputation reference panel ( $N = 3,541$ ) by integrating whole genome sequence data obtained from 1,037 Japanese individuals (average depth:  $\times 30$ ) with that of 1000 genome project ( $N = 2,504$ ). After confirming the improved accuracy of the imputed variants, we performed genome-wide association study in 159,095 Japanese individuals who participated in the BioBank Japan project using  $> 27$  million imputed sequence variants across autosomes. We detected 354 significantly and independently associated loci ( $P < 5.0 \times 10^{-8}$ ), and 64 of them were novel. Among the 354 lead variants including 26 insertion-deletions, 8 (2.3%) were rare (minor allele frequency [MAF]  $< 1\%$ ), and 15 (4.2%) were low-frequency ( $1\% \leq \text{MAF} < 5\%$ ). We evaluated these lead variants in 30,303 individuals in the independent sets of three Japanese population-based cohorts, and observed 344 variants (97%) showed the same directional effects, and nominal associations at 246 variants (70%) in the same direction. Conditional analysis of the associated loci revealed that 127 identified loci (36%) contained two or more independent association signals ( $P_{\text{conditional}} < 5.0 \times 10^{-8}$ ). Furthermore, we identified genes with multiple associated rare and low-frequency nonsynonymous variants at *SLC27A3* and *CYP26B1* genes ( $P$  for SKAT-O =  $1.94 \times 10^{-38}$ , and  $1.33 \times 10^{-46}$ , respectively), which were also replicated by evaluating three Japanese population-based cohorts. These results underscore the advantages of studying diverse population to reveal rare and low-frequency variants associated with human complex traits, and provide insights into the genetic components of adult human height.

Recurrent pregnancy loss (RPL) is a frequently occurring human infertility-related disease. It is considered a public health problem because of its high incidence and prevalence (1% - 5% of women worldwide). There are known causes of RPL such as antiphospholipid syndrome, chromosomal abnormalities, uterine anatomical abnormalities and thrombophilia. However, the 50% of all cases are idiopathic suggesting that genetic mechanisms may be involved in the development of the disease. RPL is considered a complex pathology because of the variety of molecular pathways and genes implicated in the reproductive success. Concerning the molecular aetiology of RPL several studies have had limitations in identifying the disease's genetic causes. In such scenario, next generation sequencing (NGS) provides a potentially interesting tool for research into RPL causative mutations. The present study involved whole-exome sequencing, for the first time, in 49 unrelated women affected by idiopathic RPL. We performed a bioinformatic analyses searching for non-synonymous sequence variants within a subset of 234 RPL genes made from a systematic review of literature. Interspecific alignments were performed to look for variants within conservative domains. All conserved gene variants were validated by Sanger sequencing. We identified 27 coding variants (22 genes) potentially related to the phenotype (41% of patients). The affected genes, which were enriched by potentially deleterious sequence variants, belonged to distinct molecular cascades playing key roles in implantation/pregnancy biology such as trophoblast-endometrium adhesion, coagulation pathways, angiogenesis, immunological modulation, metabolism, extracellular matrix remodeling, cell proliferation, differentiation, apoptosis and steroidal nuclear receptor activation. These results suggest that RPL has polygenic inheritance because mutations in many genes may be contributing to the phenotype. The NGS and bioinformatics approaches presented here represent an efficient way to find mutations, having potentially moderate/strong functional effects, associated with RPL aetiology. After the *in vitro* functional validation, we expect that these mutations and genes could represent molecular biomarkers in women with idiopathic RPL.

The GTEx database is a large public resource of transcriptomic data with linked genotype data, currently including 8,555 biological samples spanning 53 tissue types from 544 individuals. This resource has proven invaluable for numerous investigations into human biology, including as a resource of gene expression using software such as PrediXcan for powerful gene-based association tests. While the data is of high value, it is notable that 84% of the subjects in GTEx are of European descent, in contrast to the genetic diversity present in the USA and beyond. Therefore, it is of great interest to quantify the extent to which PrediXcan predictive models trained on GTEx perform on ethnically diverse subjects. To do so, we compare a range of models from the PrediXcan PredictDB and other predictive models derived from recent developments in machine learning to measured expression on 39 African American and 20 Puerto Rican transcriptomes derived from peripheral blood. We discuss our findings in the context of prediction accuracy and consequences for using PrediXcan on non-European study subjects. Finally, we apply our best-performing validated training models across a set of blood-based and non-blood-based phenotypes.

**RATIONALE:** Asthma is a complex disease with striking disparities across racial and ethnic groups, which may be partly attributable to genetic factors. One of the main goals of the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA) is to discover genes conferring risk to asthma in populations of African descent. **METHODS:** We performed a genome-wide meta-analysis of asthma association across CAAPA studies (using a total of 4,827 cases and 5,397 controls), genotyped on the African Diaspora Power Chip (ADPC), and imputed using the whole genome sequence reference panel from CAAPA itself. Statistical models appropriate to each study design were used to perform tests for association, and results were combined using the weighted Z-score method. We tested for replication of genome-wide significant results in two European cohorts (218+324 and 28,399+128,843 cases and controls respectively) and African ancestry subjects from the BioMe biobank (910+3,325 cases and controls). **RESULTS:** SNPs rs787160 and rs17834780 (chromosome 2 hg19 base pair position 144650140 and 144638809, respectively) were significantly associated with asthma case-control status ( $p=5.07e-09$  and  $=2.44e-08$  respectively). These SNPs were not associated with asthma in Europeans, but rs787160 was marginally associated with asthma in African ancestry subjects from the BioMe biobank ( $p=3.15e-02$ , with the same direction of effect as seen in the discovery data set). The combined p-value for rs787160 across both the CAAPA discover and BioMe replication is  $3.7e-9$  (Fisher's method). SNPs rs787160 and rs17834780 are intergenic to the *Rho GTPase Activating Protein 15 (ARHGAP15)* and *Glycosyltransferase like Domain Containing 1 (GTDC1)* genes. *ARHGAP15* is expressed in high levels in lymph node cells, peripheral blood mononuclear cells, CD8 T-cells, and B-lymphocytes, while *GTDC1* is expressed in high levels in lung and peripheral blood leukocytes. Glycosyltransferase plays a role in adhesion of environmental factors to epithelial cells, which could in turn play a role in risk to asthma. **CONCLUSIONS:** We identified a novel association signal for asthma and markers on chromosome 2q14, which may be specific to African ancestry. Currently further replication is underway in an additional 6,607 subjects of African ancestry.

**Association study of placebo-treated patients from 35 clinical trials suggests genetic contribution to the placebo response.** A. Wuster<sup>1,2</sup>, A. Haug-Baltzell<sup>1,3,4</sup>, T. Bhangale<sup>1,2</sup>, T.W. Behrens<sup>1</sup>, R.G. Graham<sup>1</sup>. 1) Human Genetics Dept, Genentech Inc, South San Francisco, CA; 2) Bioinformatics and Computational Biology Dept, Genentech Inc, South San Francisco, CA; 3) Arizona Biological/Biomedical Sciences Program, University of Arizona, Tucson, AZ; 4) Genetics GIDP, University of Arizona, Tucson, AZ.

The most common cause of Phase III clinical trial failure is an indistinguishable response rate between placebo and treatment arms. Since placebos are generally regarded as adequate controls, this has historically been accepted as indicative of a lack of drug efficacy. However, recent findings implicating specific genetic variants with a higher propensity for response under placebo treatment (e.g. rs4680, which causes a 3-4x reduction in the activity of the dopamine metabolism gene *COMT*) suggest a possible genetic basis for the placebo response. This indicates a potential for trial failure due to inadequately matching likely placebo responders between trial arms and highlights the need for further research into the genetic basis of the placebo response and its interaction with drug molecular pathways. Unfortunately, most work to date has been limited to analgesia and does little to uncover a generalized understanding of placebo genetics. We performed whole genome sequencing to 30x coverage of 11,817 patients from 35 clinical trials spanning 10 diseases (Rheumatoid Arthritis (RA), Asthma, Age-related Macular Degeneration, Colorectal Cancer, Idiopathic Pulmonary Fibrosis, Diabetic Retinopathy, Chronic Obstructive Pulmonary Disease, Inflammatory Bowel Disease, Systemic Lupus Erythematosus and Interstitial Lung Disease). To identify variants associated with placebo response, we performed genetic association analysis on patients who had been assigned to the control arm of each trial, contrasting individuals who responded to treatment, as defined by each trial's primary clinical endpoint, to non-responders. We then compared and combined trial-specific results using a meta-analysis approach. Preliminary results suggest that a variety of genetic variants affect a patient's propensity for response in a placebo arm, but the variants are largely disease-specific. For example, response in the control arm of RA trials is potentially associated with variation near *RHBDL3* (Rhomboid Like 3), *EBF2* (Early B-Cell Factor 2) and, intriguingly, *OPCML*, which encodes a likely opioid-binding protein. However, none of the previously reported analgesia-related variants, including rs4680, were significantly associated with RA placebo response. Our findings ultimately suggest that the biological origin of the placebo response is variable between disease areas.

**The Precision Medicine Initiative All of Us Research Program: Innovative access to unprecedented data.** A. Ramirez<sup>1</sup>, A. Philippakis<sup>2</sup>, A. Kho<sup>3</sup>, H. Xu<sup>4</sup>, G. Abecasis<sup>5</sup>, G. Hripacsak<sup>6</sup>, P. Harris<sup>1</sup>, S. Katherisan<sup>2</sup>, D. Glazer<sup>7</sup>, J. Denny<sup>1</sup>. 1) Medicine, Vanderbilt Univ, Nashville, TN; 2) Broad Institute, Cambridge, MA; 3) Northwestern University, Chicago, IL; 4) UT Health Science Center, Houston, TX; 5) University of Michigan, Ann Arbor, MI; 6) Columbia University, New York City, NY; 7) Verily Life Sciences, South San Francisco, CA.

The Precision Medicine Initiative All of Us Research Program is designed to recruit and engage at least one million participants reflecting the diversity of the United States. These participants will complete health surveys and undergo baseline physical measures as well as have the option to share their electronic health record data and biospecimens for future genetic and other biomarker testing. The Data and Research Center (DRC) was charged with storing, curating, and securing data and making it available to a broad community of traditional and non-traditional researchers. The DRC team includes Vanderbilt University Medical Center, Broad Institute, Verily Life Sciences, Columbia University, University of Michigan, and other subawardees. The DRC working with All of Us partners including many enrolling Health Care Provider Organizations, the Participant Center led by Scripps Research Institute, the Participant Technologies Systems Center led by Vibrent Health, the world's largest research-cohort biobank at the Mayo Clinic, and a strong leadership team at the National Institutes of Health has developed a robust internal operational system and research data stack. Beta testing of the infrastructure began with real participants on May 31, 2017. All data in the DRC is hosted in a cloud based platform to facilitate research in an open and collaborative manner. Data initially arrive in a raw data repository (RDR) and then is processed into a curated data repository (CDR) using structured data ontologies. The Observational Medical Outcomes Partnership (OMOP) common data model is being used for EHR data. To enable this structure, broad data access policies are being developed that leverage the cloud infrastructure. Researchers will engage in a dynamic user platform including cohort builder tools and notebook based analysis capabilities that facilitate collaboration and scale to large analyses. Furthermore, the DRC will be the primary source of support for researchers accessing data and is developing training and outreach efforts to engage a diverse spectrum of users. The DRC aims to support world class research optimizing this unparalleled data source for the benefit of human health. This presentation is a key part of efforts to engage world-class researchers including the ASHG community in development of this intentionally dynamic framework.

**Data-driven approach to dietary phenotypes for nutrigenomics in UK Biobank.** J.B. Cole<sup>1,2,3</sup>, J.N. Hirschhorn<sup>3,4</sup>. 1) The Broad Institute of MIT and Harvard, Cambridge, MA; 2) Massachusetts General Hospital, Boston, MA; 3) Boston Children's Hospital, Boston, MA; 4) Harvard Medical School, Boston, MA.

Diet is a complex multifactorial trait of specific and highly related measures which together have demonstrated strong genetic underpinnings ( $h^2 \sim 30\%$ ). However, previous studies on the genetics of diet have been limited in power in terms of both sample size and the proportion of genetic variance dietary variables can explain individually. Therefore, we utilized dimensionality reduction techniques on comprehensive UK Biobank diet data to optimize phenotypes for genetic discovery. A final genotyping QC dataset of 139,185 individuals was obtained by removing UK Biobank and UK BiLEVE recommended genomic exclusions (N=408 and N=406, respectively), sex mismatches (N=191), and non-European-derived Caucasians as defined by a thorough analysis of genetic ancestry (N=13,543). We have begun extensive efforts on curating over 300 relevant diet fields from both the lifestyle and environment and 24-hour diet recall questionnaires. Each field for any given participant can have both multiple answers (up to 24) and multiple instances (up to 5), contributing to the complexity in parsing appropriate and informative diet-related variables, all the while emphasizing its vast potential. Preliminary GWAS analysis on 10 UK Biobank univariate dietary traits (e.g. overall frequency of fish intake, cheese intake, alcohol intake, etc.) demonstrated 0 genome-wide significant signals. Thus, moving forward we plan to conduct two distinct, yet complementary, unbiased data-driven approaches to define and optimize traits for genome-wide association study (GWAS) analysis. The final phenotypic dataset, with over 1000 individual variables, will then be subjected to a principal components analysis (PCA) to extract orthogonal summary variables explaining greater phenotypic variance than any individual variable alone. We will additionally conduct a PCA on the genetic-covariance matrix of significantly heritable variables using a linear mixed model approach to maximize the genetic variance explained by top PCs. The top PCs derived from these two complementary PCA approaches will then be used as GWAS phenotypes. We will return these new composite dietary phenotypes to the UK Biobank resource. This analysis will not only help us understand the phenotypic and genetic relationships between the different foods we eat, but is also robustly suited to identify novel genetic determinants of diet and provide valuable information for future research efforts in metabolism and medicine.

**A broad survey of the relationship between autozygosity and fitness-related and sociodemographic traits in the UK Biobank.** *E.C. Johnson<sup>1,2</sup>, M.C. Keller<sup>1,2</sup>*. 1) Department of Psychology and Neuroscience, University of Colorado Boulder, Boulder, CO; 2) Institute for Behavioral Genetics, University of Colorado Boulder, Boulder, CO.

The body of literature on the association between very distant inbreeding (measured using  $F_{ROH}$ , the proportion of the genome contained in runs of homozygosity (ROHs)) and complex traits in humans is growing, but remains smaller than the body of literature examining the relationship between inbreeding depression and Mendelian disorders. Characterizing the relationship between  $F_{ROH}$  and complex traits can lead to a better understanding of their evolutionary history and genetic architectures. Using genome-wide single nucleotide polymorphism (SNP) data from over 100,000 individuals in the UK Biobank project, we explored the relationship between autozygosity (as measured by  $F_{ROH}$ ) and more than 30 traits, including several potentially related to fitness. Preliminary results indicate that increased autozygosity is significantly associated with several traits likely related to fitness, such as birth weight, height, and fluid intelligence, consistent with a prediction of purifying selection biasing causal variants toward being (partially) recessive; further, the relationships between inbreeding and birth weight and height remained significant after controlling for average household income and years of educational attainment.  $F_{ROH}$  was also related to several sociodemographic traits such as income and socioeconomic status. The direction of causation for these relationships is less clear, because these traits may directly influence level of outbreeding in parents and be passed down culturally or genetically to offspring. In general, interpretation of relationships between  $F_{ROH}$  and traits must be made with a good deal of caution, because of the potential for third variable or reverse causation explanations of the relationship.

**2268F**

**Fine-mapping of tobacco and alcohol associated loci in around 900K participants.** *M. Liu, GSCAN Consortium*. Institute for Behavioral Genetics, University of Colorado Boulder, Boulder, CO.

Alcohol and tobacco use are common causes of preventable deaths. Genome-wide association studies (GWAS) have found a handful of significant functional variants (such as *CHRNA5* and *GCKR* for nicotine and alcohol respectively) that are now under being tested in biological models. However, to discover these variants, we would require a well-powered GWAS with large enough sample sizes to produce meaningful results and reduce false positives. The GWAS & Sequencing Consortium of Alcohol and Nicotine Use (GSCAN) have conducted a GWAS meta-analysis with around 1 million participants and found a total of greater than 200 novel loci amongst 6 phenotypes: Cigarettes per Day (CPD, N=259,485), Age of Initiation (AI, N=257,272), Smoking Initiation (SI, N=966,878), Smoking Cessation (SC, N=467,073), Drinker non-Drinker (DND, N=787,983) and Drinks per Week (DPW, N=695,140). Most of the results, except for a few studies that used either 1000G phase 3 or their own internal panel, used the Haplotype Reference Consortium panel. We characterized these loci by applying a conditional analysis to find independent variants in these loci. We have also begun the process of fine-mapping within the loci. The conditional analysis was done with a sequential forward selection method to identify independent variants within the significant loci (defined as 1MB around the significant variant). In the conditional analysis, we found 1 independent variant out of 1 loci for AI, 49 independent variants out of 18 loci for CPD, 81 independent variants out of 22 loci for SC, 431 independent variants out of 134 loci for SI, 106 independent variants out of 67 loci for DND and 152 independent variants out of 47 loci for DPW. The average imputation quality for common variants (minor allele frequency (MAF) > 1%) was 0.89 (SD=0.11) and the imputation quality of variants with a MAF of < 1% but greater than .1% was 0.74 (SD=0.19). From here, we are confident that despite using imputed results, we would still find plausible and rare (with MAF as low as .1%) variants within the 18 loci. Furthermore, we also have plans to explore these significant loci and expect to present pathway analysis results at the conference. We anticipate that our results will show new promising loci/variants that can be used in understanding the mechanisms of addiction.

**Background:** Biomarkers enable early disease detection, risk stratification and provide insights into disease mechanisms. Typically, biomarkers are identified using prospective epidemiologic studies which are long, expensive and have low power. We hypothesized that we could apply genetic predictors of biomarker variability derived from an epidemiological cohort to an electronic health record (EHR) population and use phenome-wide scanning to predict novel biomarker-disease associations. **Methods:** We selected 53 biomarkers measured in the Atherosclerosis Risk in Communities study (n=7,740 subjects) and used Bayesian sparse linear mixed modeling to calculate weightings across 739,681 SNPs. These weightings were used to compute a genetically predicted value for each biomarker in a population of 37,153 genotyped individuals with EHRs. We tested the association between each genetic predictor and 1,139 clinical EHR diagnoses. **Results:** The underlying genetic architectures of the biomarkers varied considerably and were reflected in the distributions of the predicted biomarkers in the EHR cohort. These distributions ranged from trimodal for biomarker levels that were heavily driven by SNPs with relatively large effect sizes (e.g. vWF protein levels) to approximately normally distributed for highly polygenic phenotypes (e.g. waist circumference). We selected 42 biomarker-disease associations *a priori* as positive controls, and 28/42 were significant at FDR  $q < 0.1$ . There were 349 additional associations (known and novel), including pack-years of smoking (associated with alcohol use and obesity), waist circumference (psoriasis and venous thrombosis), white blood cell count (anxiety disorder and bronchitis), magnesium levels (kidney stones and chondrocalcinosis), platelet count (antibiotic poisoning), monocyte count (tonsillitis), FEV1/FVC (emphysema), vWF protein levels (venous and arterial thrombosis), triglycerides (arterial diseases) and LDL cholesterol (septicemia). We validated a novel association between low LDL and septicemia using a separate EHR cohort (n=22,281) and confirmed an increased risk of septicemia in low LDL-cholesterol (LDL-C < 60 mg/dl) versus normal LDL-C (> 90 and < 130 mg/dl) subjects (OR=3.54 [90% CI: 2.81-4.46],  $p < 2 \times 10^{-16}$ ). **Conclusions:** The design we describe leverages the strengths of epidemiological and EHR data sets. By testing for cross-data set associations, the design can efficiently identify novel biomarkers of disease risk.

**New insights into the genetic architecture of complex human traits from Bayesian mixture model analyses in a large dataset.** *J. Sidorenko<sup>1,2</sup>, L.R. Lloyd-Jones<sup>1</sup>, A. Metspalu<sup>2</sup>, T. Esko<sup>2,3</sup>, P.M. Visscher<sup>1,4</sup>, M.R. Robinson<sup>1,5</sup>.*

1) Institute for Molecular Bioscience, The University of Queensland, Brisbane, Queensland, Australia; 2) Estonian Genome Center, University of Tartu, Tartu 51010, Estonia; 3) Broad Institute of the Massachusetts Institute of Technology and Harvard University, Cambridge 02142, MA, USA; 4) Queensland Brain Institute, The University of Queensland, Brisbane, Queensland 4072, Australia; 5) Department of Computational Biology, University of Lausanne, 1011 Lausanne, Switzerland.

Introduction of linear mixed models (LMM) to human genomics has demonstrated that a large proportion of the complex trait heritability can be captured by jointly accounting for all common genetic variants. LMM can be used to obtain SNP markers effects with best linear unbiased prediction properties (BLUP), which have been shown to improve genomic prediction over genetic predictors obtained from large-scale meta-analyses. The classical LMM, however, assumes that there is a single distribution of genetic effects, implying that all markers contribute to SNP-based heritability. This approach can be improved through the use of a Bayesian mixture model framework, where a mixture of normal distributions of SNP effects, including a zero effect, is adopted instead. Here, we gain new insights into the underlying genetic architecture of complex human traits by applying a Bayesian mixture model (BayesR) with five normal distributions of genetic effects (each variant potentially explaining 1, 0.1, 0.01, 0.001% or none of the trait genetic variance) to 17 quantitative traits in the UK Biobank (140,720 European participants and 954,662 common SNPs with MAF > 1%). We demonstrate a high degree of polygenicity for all traits, with most of the SNP-heritability (38-85%, mean 65%) attributable to genetic markers that each contribute just 0.001% to the total genetic variance. We find evidence of large effects, cumulatively explaining 3 to 6% of the SNP-heritability, for traits such as age at menopause, menstrual cycle length, and heel bone mineral density. We demonstrate how this Bayesian framework can be used to test for sex-specific effects, finding limited evidence across all traits for regions of the genome that contribute differing amounts of variance among the sexes. We replicate our findings in a sample taken from the Estonian Biobank (EGCUT, N= 15,299) and show that a genetic predictor created from a BayesR analysis in a large cohort with individual-level data outperforms genetic predictors created from a large-scale meta-analysis for height, with increased prediction accuracy into independent cohort over 30% ( $R^2$  0.24 vs. 0.16). Together, these results highlight the potential of Bayesian mixture models to provide better inference for SNP detection, flexibly test for interactive effects and improve genomic prediction.

Genome-wide association studies (GWAS) have identified thousands of common variants associated with polygenic traits and diseases. These common variants are largely non-coding and thus present challenges for definitively implicating genes within an associated locus. Identifying causal rare coding variants can directly point to causal genes, but generally requires sequencing data, which, until now, has only been done in sample sizes smaller than that of GWAS. Thus, the role of rare variants in contributing to heritability and implicating causal genes remains largely unknown. Initial exome-sequencing studies suggest that the required sample sizes for detecting robust associations will be at least comparable to those needed for GWAS, but a systematic study to assess the actual sample size requirements has not been conducted. To better understand the role of rare coding variation in polygenic traits and the implications for future sequencing studies, we analyzed exome-sequencing data for three anthropometric traits where GWAS has been successful: height, body mass index (BMI) and waist-hip ratio adjusted for BMI (WHR). We performed single variant and gene-based tests for these traits in 25,774 samples across five different ancestries that contributed to the Exome Aggregation Consortium (ExAC), from the GoT2D, T2DGENES and MIGen consortia. We performed both single variant association tests and aggregate gene-based tests of rare variants. We were able to replicate multiple single-variant associations with known common variants, but no individual rare variant has reached exome-wide significance. In gene-based tests for height, we identified exome-wide significant associations with rare variants in a known skeletal dysplasia gene (*ACAN*), and another novel gene (*EIF1AD*). Our results for BMI and WHR adjusted for BMI did not show any exome-wide significant variants or genes, although we observed an enrichment of lower p-values in genes known to cause syndromes with obesity as a feature. Together, these results indicate that the current sample of >25,000 individuals is substantially underpowered to discover rare coding variants associated with the same traits where GWAS was successful at comparable sample sizes. Much larger sample sizes will be needed in order to identify the rare coding variants associated with polygenic traits that could directly implicate biologically relevant genes.

**Copy number variation associated with white blood cell phenotypes in the eMERGE Network.** M.R. Palmer<sup>1</sup>, A. Gordon<sup>1</sup>, I.B. Stanaway<sup>2</sup>, D.S. Carrell<sup>3</sup>, J.T. Glessner<sup>4</sup>, H. Hakonarson<sup>5</sup>, P. Piessig<sup>6</sup>, E. Larson<sup>2</sup>, G.P. Jarvik<sup>1</sup>, D.R. Crosslin<sup>2</sup>, The electronic Medical Records and Genomics (eMERGE) Network. 1) Department of Medicine, Division of Medical Genetics, University of Washington, Seattle, WA; 2) Department of Biomedical Informatics and Medical Education, University of Washington, Seattle, WA; 3) Kaiser Permanente Washington Health Research Institute, Seattle, WA; 4) Molecular Neurogenetics Unit and Psychiatric and Neurodevelopmental Genetics Unit, Center for Genomic Medicine, and Department of Neurology, Massachusetts General Hospital, Boston, MA; 5) The Children's Hospital of Pennsylvania, Philadelphia, PA; 6) Marshfield Clinic Research Institute, Marshfield, WI.

**Background** White blood cell counts (WBC) and cell type differentials are collected in the course of standard medical care, as lower or higher levels from baseline could be an indicator of a variety of diseases. Genome wide association studies have identified variants associated with WBC phenotypes in cohorts of European and African ancestry (Nalls et al. 2011; Keller et al. 2014; Crosslin et al. 2012; 2013). Structural variation is another possible source of genetic influence on WBC phenotypes, but few association studies have been carried out with copy number variants (CNVs). **Methods** We extracted total leukocyte counts and differential proportions of neutrophils, lymphocytes, monocytes, eosinophils, and basophils of outpatients from electronic health records for participants in the Electronic Medical Records and Genomics (eMERGE). We used PennCNV to call CNVs from Illumina Human660 W-QuadV1 genotyping data. We performed linear regressions of median leukocyte counts, lymphocytes, monocytes, neutrophils and logistic regressions of basophils (controls 0-0.6%, cases 0.61-6.0%) and eosinophils (controls 0-1.8%, cases 3.0-34.6%) with ParseCNV-called CNV Regions (CNVR) in PLINK (Glessner et al. 2013). We adjusted for the covariates age, sex, median BMI, and eigenvectors 1-10 derived through principal component analysis. **Results** A total of 8447 participants met all inclusion criteria (Crosslin et al. 2012), passed quality control, and were included in at least one WBC phenotype. With a P-value threshold of  $5 \times 10^{-4}$  to correct for multiple testing (Glessner et al. 2013), twelve CNVRs from leukocyte counts association met this threshold, eleven from neutrophils, five from lymphocytes, seven from monocytes, three from eosinophils, and six from basophils. A deletion at 10q23.33 (776.3kb; MAF=0.3%) was associated with neutrophil differential ( $\beta=8.40$ ;  $p=3.0 \times 10^{-4}$ ). This region contains the genes *CYP2C18*, *CYP2C19*, *CYP2C8*, *CYP2C9*, *HELLS*, and part of *TBC1D12*. Mutations in *HELLS* have been linked to cases of immunodeficiency-centromeric instability-facial anomalies syndrome (Thijssen et al. 2015). A 3.0kb duplication at 20q13.33 (MAF=5.7%;  $\beta=0.32$ ,  $p=2.3 \times 10^{-4}$ ) was associated with monocyte differential. This region overlaps genes *LIME1*, *SLC2A4RG*, *ZGPAT*, which are all expressed in hematopoietic tissues. **Conclusions** We found associations of CNVRs for all the phenotypes, including novel and replication findings. Some include genes associated with inflammatory and immune phenotypes.

**Utilizing protein quantitative trait loci to identify functional candidates from genome-wide association studies.** S. Sivertson, A. Stark. University of Notre Dame, IN.

While genomewide association studies (GWAS) have focused on identification of single nucleotide polymorphisms, there remains a paucity of information on how these associations, including repeated and validated associations, are connected to function. Quantitative trait loci (QTL) mapping has been utilized for mRNA, protein, methylation, microRNA in order to help annotate these findings. We interrogated 198 protein QTL (pQTLs) associations published in 2014 with the NHGRI-EBI GWAS database in the fall of 2016 in order to find any recent associations that could be attributed to a protein. Over 9% of the pQTLs identified had further trait associations identified, including HIV-1 control, hematological parameters and red blood cell traits, colorectal cancer, the age at onset of menarche, height, Parkinson's Disease, and fasting glucose-related traits. We then compared the protein with the GWAS results and prioritized interesting targets for functional follow-up based on literature and known pathways. Interestingly, rs10505477 has shown repeated association with colorectal, gastric, and prostate cancer and is a pQTL for *MPND*. Previously, these GWAS associations had hypothesized that it was acting through *MYC*, the nearby major coding gene. However, the SNP itself is located within the *CASC8* gene and we used siRNA to knockdown *CASC8* and assessed *MPND* expression as well as *MYC* expression in order to demonstrate the importance of *MPND* in this association. Future research could be done on the remaining traits and demonstrate the importance of utilizing QTL data in association interpretation.

**Integrative fine-mapping of 34 complex phenotypes.** R. Johnson<sup>1</sup>, G. Kichaev<sup>2</sup>, K. Burch<sup>2</sup>, B. Pasaniuc<sup>3,4</sup>. 1) Department of Mathematics, University of California, Los Angeles, Los Angeles, CA 90024, USA; 2) Bioinformatics Interdepartmental Program, University of California, Los Angeles, Los Angeles, CA 90024, USA; 3) Department of Human Genetics, University of California, Los Angeles, Los Angeles, CA 90024, USA; 4) Department of Pathology and Laboratory Medicine, University of California, Los Angeles, Los Angeles, CA 90024, USA.

Genome-wide association studies (GWAS) have identified thousands of variants in the genome that reproducibly associate with complex disease. However, most variants uncovered in GWAS are not directly biologically causal, but rather, are correlated with the true causal variant(s) through linkage disequilibrium. Statistical fine-mapping aims to prioritize Single Nucleotide Polymorphisms (SNPs) in regions surrounding a significant association peak to discern the true causal variants. Here, we apply PAINTOR, an integrative probabilistic fine-mapping framework that combines summary association statistics (i.e. Zscores) with functional genomic annotation data, to prioritize possible causal variants for a set of traits and diseases. As not all functional annotations are relevant to a trait under study, we first identify informative epigenetic marks using forward selection for each trait. We then construct a trait-specific integrative functional model to refine the set of SNPs in every GWAS region. Our study analyzes GWAS from 34 complex phenotypes which consist of over 4,347 regions in total. We demonstrate in this data that by applying leveraging functional data, we can reduce the number of SNPs required for follow-up in order to capture 95% of the causal variants. We provide an atlas of "credible sets" that we make available to the research community.

**Probabilistic assignment of causal genes at transcriptome-wide significant risk loci.** *N. Mancuso*<sup>1</sup>, *G. Kichaev*<sup>2</sup>, *H. Shi*<sup>3</sup>, *C. Giambartolomei*<sup>1</sup>, *A. Gusev*<sup>2,4</sup>, *B. Pasaniuc*<sup>1,2,5</sup>. 1) Dept of Pathology and Laboratory Medicine, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Dept of Bioinformatics, UCLA, Los Angeles, CA; 3) Dept of Epidemiology, Harvard T.H. Chan School of Public Health, Boston, MA; 4) Program in Medical and Population Genetics, Broad Institute of MIT and Harvard, Cambridge, MA; 5) Dept of Human Genetics, UCLA, Los Angeles, CA.

Transcriptome-wide association studies (TWASs) have identified thousands of genes whose locally-regulated expression is associated to complex traits and diseases. Since complex correlations between predicted expression levels at a given locus can yield multiple associated genes in TWAS, for the vast majority of risk loci it remains unclear which gene is causally impacting disease risk. Here we introduce a new probabilistic framework to estimate posterior probabilities for genes to be causal at TWAS significant loci. Our approach mirrors the recently introduced methods for statistical fine-mapping of causal genetic variants to yield sets of genes that contain the causal gene at a given credibility (e.g., 90%) to increase accuracy in functional follow-up. Our proposed framework accounts for both the correlation structure among genetic variants (i.e. linkage disequilibrium, LD) as well as correlations in the expression of genes (i.e. co-expression of genes at a given region in the genome). In detail, we model the distribution of TWAS statistics using a multi-variate normal distribution parametrized by LD, eQTL weights and causal gene effect sizes. We integrate effect sizes within a Bayesian approach and compute the marginal posterior probability of a gene being causal. We validated our approach through extensive simulations starting from real genotype data in 1000 Genomes and realistic heritability levels for gene expression data. We find that our method outperforms existing co-localization methods with the largest performance gain when multiple causal genes at a locus impact trait. In the analysis of TWAS results for lipids, we find that several genes with well-studied functional impact on HDL are highly ranked using our method. For example, *APOA1* and *LIPC*, genes believed to play a role in HDL levels, were ranked with marginal posterior probabilities of  $> 0.99$ . Overall, we find a single gene in the 90% credible set for 30 / 94 risk loci for HDL, LDL, and triglycerides with 2.6 genes on average (s.d. = 1.8). Finally, we analyze 65 large-scale TWAS across multiple traits and diseases to localize the credible set of causal genes at known GWAS risk loci.

**The Macaque Genotype and Phenotype (mGAP) database: a novel resource to support genetic disease model development and translational research in nonhuman primates.** *B. Ferguson*, *B.N. Bimber*, *L. Shorey*, *H. Rosoff*, *M. Yan*, *L. Carbone*, *E. Spindel*, *A. Vinson*. Primate Genetics Section, ONPRC, Oregon Health Sciences Univ., Portland, OR.

Rhesus macaques, the most broadly studied nonhuman primate (NHP), offer outstanding opportunities for the translational study of complex human genetic diseases. Leveraging the similar natural disease spectrum as humans, a diverse range of rhesus macaque disease models has been established, including models of cardiovascular disease, addiction, age-related macular degeneration, developmental disorders, cognitive decline, colitis, and infectious diseases such as zika and simian immunodeficiency virus (SIV). The discovery of similar genetic disease associations in macaques and humans underscores the value of macaques for the genetic analysis of complex traits, and for the potential testing of pharmacogenomics treatments. To support expanded use of the rhesus macaque for genetic analysis, model characterization, and therapeutic development, we are genomically characterizing an expansive, pedigreed rhesus macaque colony housed at the Oregon National Primate Research Center (ONPRC). We selected a set of 2,245 Indian-origin rhesus macaques, members of a single, 9 generation pedigree, for genomic analysis. The study subjects include those with phenotypic data collected on cardiovascular disease endophenotypes, age-related macular degeneration, cognitive measures, colitis, endometriosis, S/HIV response, and behavioral measures, among others. We are using a combination of whole genome sequencing (WGS) and genotyping-by-sequencing (GBS) to identify genome-wide sequence variants in these subjects. We have established a custom, publically accessible database to share these data: the Macaque Genotype and Phenotype database (mGAP; <https://mgap.ohsu.edu>). In the future, the genotype database will be expanded to include clinical measures extracted from electronic health records. Thus the mGAP database will enable investigators to 1) identify potential new disease models, based on predicted functional variants, 2) identify animals with particular sequence variants of interest, 3) identify genotypes in animals with selected phenotype measures, and 4) query phenotype measures among macaques based upon selected genotypes. **Conclusion:** mGAP provides a unique opportunity for investigators to identify potential NHP genetic disease models to advance the study and treatment of human disease.

**Examining sex differences in genetic effects on subcortical brain structures.** K. Grasby on behalf of The Enhancing Neuro Imaging Genetics through Meta-Analysis (ENIGMA) Consortium. Psychiatric Genetics, Queensland Institute of Medical Research, Herston, QLD, Australia.

Individual differences in subcortical brain morphometry are highly heritable. Several genetic variants have been identified that influence the volume of subcortical structures, and these variants are structure specific rather than general in effect. Sex differences have also been observed in the volume of subcortical structures. Here we assess if genetic variants influencing subcortical brain structures differ between females and males. We present preliminary results from sex-stratified GWAS meta-analyses on seven subcortical structures derived from T1-weighted magnetic resonance imaging scans from ~6000 females and ~5400 males from 22 cohorts from the ENIGMA consortium. This sample is a subset of the larger ENIGMA consortium analyses on variation in subcortical structures among ~30,000 individuals. The subcortical structures analysed were the nucleus accumbens, amygdala, caudate nucleus, hippocampus, globus pallidus, putamen, and thalamus. The volume of these structures were calculated with validated and freely available software, and mean volume calculated from the left and right hemispheres. Genotypic data were imputed to the 1000 genome reference panel. Preliminary results in this discovery meta-analysis identified four genome-wide significant loci, three were novel. One intergenic locus (14q22.3), which we have previously reported as significant in a meta-analysis that combined females and males, was associated with putamen volume in females and in males in these stratified analyses. Tests of heterogeneity showed that the top hit in males was significantly stronger in effect in males than in females ( $p < 1.658e-10$ ). Of the novel loci, one was an intronic locus (11q15.2) within SPON1 associated with nucleus accumbens volume in females. The second was an intronic locus (2q34) within ERBB4 associated with amygdala volume in males. The third was an intergenic locus (13q21.31) associated with putamen volume in males. Several loci passed a suggestive level of significance ( $p < 1e-6$ ), each of these suggestive associations were trait and sex specific. We plan to extend these findings with data from the UK Biobank. We will present SNP heritability and genetic correlation with psychiatric and cognitive traits using the results from the second round of meta-analysis.

**In silico evaluation of a more comprehensive pharmacogenetic profile for predicting opiate metabolizer phenotype.** F.R. Wendt<sup>1,2</sup>, A. Sajantila<sup>3</sup>, R. Chakraborty<sup>1</sup>, G. Pathak<sup>1</sup>, A.E. Woerner<sup>2</sup>, R.S. Moura-Neto<sup>4</sup>, B. Budowle<sup>1,2,5</sup>. 1) Institute for Molecular Medicine, University of North Texas Health Science Center, Fort Worth, TX; 2) Center for Human Identification, University of North Texas Health Science Center, Fort Worth, TX; 3) Laboratory of Forensic Biology, Department of Forensic Medicine, University of Helsinki, Helsinki, Finland; 4) Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil; 5) Center of Excellence in Genomic Medicine Research (CEGMR), King Abdulaziz University, Jeddah, Saudi Arabia.

**Purpose:** The pharmacogene encoding CYP2D6 is highly polymorphic and confers poor, intermediate, extensive, and ultrarapid phase I metabolism of many endogenous toxins and foreign compounds, including opiates. The pharmacogenetics of opiate metabolism is particularly important due to the relatively high incidence of addiction and overdose of opioid analgesics. Recently, trans-acting opiate metabolism/analgesic response enzymes (UGT2B7, ABCB1, OPRM1, and COMT) have been included in pharmacogenetic studies for better prediction of metabolic response of ante- and post-mortem patients. Many studies are limited in that subject selection favors presence/absence of phenotype and places less emphasis on individual demography, resulting in substructured sample cohorts. Additionally, studies that attempt to predict phenotypic state often rely on single nucleotide polymorphism (SNP)-targeted genotyping approaches which inherently cannot detect novel/rare polymorphisms. In contrast, gene-targeted massively parallel sequencing (MPS) can identify additional polymorphisms that refine previous pharmacogenetic predictions. **Methods:** 1000 Genomes Project data for ~15,000 SNPs were analyzed in two phases: (1) Describe population genetic variation and summary statistics for five opiate metabolism genes in self-reported healthy individuals from five super- and 26 sub-populations; and (2) Assess how comprehensive full-gene information refines metabolizer phenotype (MP) estimates. Both phases were performed using RStudio, Excel-based workbooks, Genetic Data Analysis, and TreeView. **Results:** A summary is provided of population statistics, variant effect predictions, and clustering of populations based on polymorphisms associated with opiate metabolism. Comparisons of standard inferences using SNP-targeted versus full-gene predictions indicate that a full-gene approach provides significantly decreased CYP2D6 activity scores (qualitative measure of phenotype based on CYP2D6 diplotype) ( $p < 0.001$ ). These results indicate that some extensive metabolizers may be incorrectly classified due to damaging polymorphisms elsewhere in the gene. Finally, logistic regression indicates little association between CYP2D6 MP and genotype-predicted activity of downstream enzymes. **Conclusions:** These results provide a population genetic baseline for pharmacogenetically relevant polymorphisms and demonstrate that full-gene information should be considered for phenotype predictions.

**2279T**

**Drug target genes associated with clinical phenotypes in the genetically isolated population of Finland are more likely to succeed in pharmaceutical development.** R. March<sup>1</sup>, M. Cunha<sup>1</sup>, C. Elks<sup>1</sup>, A. Platt<sup>1</sup>, M. Alanen-Kinnunen<sup>2</sup>, S. Lemmelä<sup>3</sup>, V. Salomaa<sup>2</sup>, P. Jousilahti<sup>2</sup>, M. Daly<sup>4</sup>, D. Goldstein<sup>1,2</sup>, A. Palotie<sup>3,4</sup>. 1) Centre for Genomics Research, IMED Biotech Unit, AstraZeneca, Cambridge, United Kingdom; 2) Institute for Genomic Medicine, Columbia University, USA; 3) Institute for Molecular Medicine, Helsinki, Finland; 4) Broad Institute of MIT and Harvard, USA; 5) Institute of Health and Welfare, Helsinki, Finland.

Drug target genes (DTG) associated with disease are believed to be more likely to succeed in pharmaceutical development. Recent research, however, suggests that most meaningful genetic associations are driven by missense or loss of function variants. Such variants are often rare and may be more easily detected in populations that have undergone population bottlenecks, such as Finland. In contrast, genes associated with drug response may escape negative selection and remain at relatively high prevalence. We tested these hypotheses through a partnership between AstraZeneca's Centre for Genomics Research and the University of Helsinki. First, we compared DTG from 17 AstraZeneca programs for which the pharmaceutical outcome (successful/unsuccessful FDA approval) was known. We identified one or more genetic variants associated with drug response and/or relevant clinical phenotypes for most (10, 59%) of the DTG (PubMed, AstraZeneca data on file). Consistent with earlier reports, genetic associations were present in 7 (78%) of successful drug programs versus 3 (33%) of unsuccessful drug programs. The associated gene variants included missense and predicted loss of function variants in ExAC, a database of whole exome sequence from 60,706 unrelated individuals. The mean MAF of DTG variants associated with pharmaceutical success in all populations was 0.14 (95% CI -0.02 to 0.2). These variants were modestly enriched in Finns (mean 1.8, 95% CI 0.17 to 1.29, top: *PARP* rs11571833 with an enrichment odds ratio of 1.8). Second, we identified clinical phenotypes associated with variants in DTG for candidate drugs and compared the frequency of these variants in Finns with those for non-genetically isolated populations. We scanned for associations between genetic variants in selected genes and clinical phenotypes in over 20,000 Finns, comparing the allelic frequencies from the top-hits with those available from ExAC. We identified one or more genetic variants associated with a clinical phenotype for all genes, except for *IL33*. Most of these variants were enriched in the Finnish population (top: *CDK12* rs200488621 with an enrichment odds ratio of 26.6), suggesting that due to founder events, variants with phenotypic effects may have increased frequency in Finland. Our results suggest that DTG associations, especially in genetically isolated populations such as Finland, can increase success in pharmaceutical development. Validation studies are required to confirm these results.

Over the past decade, genome-wide association studies (GWAS) have successfully identified thousands of disease loci, but the vast majority of this research has focused on populations of European descent. As clinics have begun adopting prediction using genetic risk scores, a key open question surrounds the transferability of findings across populations. Population genetic theory indicates that effects of linkage disequilibrium (LD), allele frequencies, and genetic architecture will impact transferability of risk scores, even if all causal alleles have the same biological effect in all populations; however, there has been a dearth of empirical data to demonstrate this. We have recently identified directional inconsistencies in polygenic risk scores across populations for several well-studied traits and diseases, such as height and type II diabetes. Here, we use several approaches to understand and improve GWAS transferability: 1) we model risk prediction accuracy with coalescent simulations, 2) we empirically assess prediction accuracy in multi-ethnic schizophrenia GWAS cohorts, and 3) we develop novel statistical methods to improve cross-population prediction accuracy. Our complex trait simulation framework models genotypes and phenotypes for multiple continental populations, and shows that correlations between true and inferred risk are typically highest in the population from which summary statistics were derived. Additionally, scores inferred from European GWAS are unpredictably biased in other populations. Using results from the Psychiatric Genetics Consortium, we find that East Asian schizophrenia risk is better predicted by summary statistics from smaller East Asian cohorts (13k cases and 16k controls) than from ~3-fold larger European cohorts (37k cases and 113k controls, Nagelkerke's  $R^2 = 0.104$  vs 0.066). To address these issues, we implemented a Kalman filter that uses LD to correct effect size estimates to improve inference of trans-ethnic polygenic scores from summary statistics. Extensions of this work to include local ancestry will be particularly relevant in recently admixed populations. Simulations and empirical data both indicate that risk scores from large-scale European GWAS may have limited value in non-European samples, owing to both mean and variance shifts, and highlights the need for the development and adoption of improved polygenic risk methods, as well as the inclusion of more diverse individuals in medical genomics.

**Genomic characterization of the immunoglobulin heavy chain variable gene locus in individuals of African, Asian, and European descent reveals signatures of elevated haplotype diversity.** *O. Rodriguez<sup>1</sup>, W. Gibson<sup>2</sup>, M. Emery<sup>1</sup>, G. Deikus<sup>1</sup>, M. Pendleton<sup>1</sup>, W.A. Marasco<sup>4,5</sup>, R. Sebra<sup>1</sup>, E.E. Eichler<sup>3</sup>, A.J. Sharp<sup>1</sup>, M. Laird Smith<sup>1</sup>, A. Bashir<sup>1</sup>, C.T. Watson<sup>2</sup>.* 1) Department of Genetics and Genomic Sciences, Icahn School of Medicine of Mount Sinai, New York, NY; 2) Department of Biochemistry and Molecular Genetics, University of Louisville School of Medicine, Louisville, KY; 3) Department of Genome Sciences, University of Washington, Seattle, WA; 4) Department of Cancer Immunology & AIDS, Dana-Farber Cancer Institute, Boston, MA; 5) Department of Medicine, Harvard Medical School, Boston MA.

Genes encoding the heavy chains of antibodies, critical components of adaptive immunity, are located in the human immunoglobulin heavy chain locus (IGH). 67% of the ~1MB locus is composed of segmental duplications and 41% is composed of additional repeat elements. The locus remains under-characterized, due to the inability of standard high-throughput technologies to resolve the complexity, and despite increasing evidence supporting a role for IG polymorphism in the immune response. Therefore, the development of improved genomic resources and tools for more effectively studying IG genetic diversity is needed. As a critical first step, we have leveraged PacBio sequencing to generate high-quality haploid assemblies from fosmids spanning the IGH V gene cluster of an African (NA19240), East Asian (NA18555), and European (NA12878) individual, facilitating continued descriptions of novel germline variation, and the first direct comparison of locus-wide IGHV haplotypes from different ethnicities. A total of 4,307 single nucleotide variants (SNVs) were identified among these individuals, with varying numbers of unique SNVs per haplotype (range=105-948). 48% of the SNVs were not present in 1000 Genomes Project calls, including SNVs within coding and known IG regulatory regions, translating into the discovery of 16 novel IGHV alleles. Comparisons to hg19 and hg38 also revealed the presence of five large structural variants (SVs), ranging from 9.5-75 Kb. Considering both SNV and SVs, each of the characterized haplotypes were unique. The longest block of shared identical sequence between the individual haplotypes was 6.2 Kb, and per haplotype IGHV gene counts ranged from 42 to 55. Shared alleles among the haplotypes were observed for only 8 IGHV genes. Further demonstrating signatures of elevated diversity, intra-individual metrics revealed that locus-wide IGHV SNV densities within each haplotype were 2.2- to 4.2-fold higher than those observed outside of IGHV. Within IGHV, SNV densities were highest within segmental duplications, IGHV coding segments, and adjacent up/downstream non-coding regions. Together, our results provide a rich set of reference assemblies for the genomics community and indicate that germline haplotype diversity within the IGHV locus is among the highest in the human genome. Further studies are warranted to fully characterize the extent of IG germline variation at the population level and elucidate its role in Ab repertoire development and disease.

**2282T**

**Isolated population from Runta, Boyacá: Findings related to founder effect of the nonsense variant of the HGSNAT gene.** *L.J. Torres<sup>1</sup>, H.M. Velasco<sup>2</sup>, Y. Sanchez<sup>3</sup>, S. Santos<sup>4</sup>, T. Vinasco<sup>5</sup>.* 1) Torres Leandra. Master Human Genetics, Universidad Nacional De Colombia, Bogota, Bogota, Colombia; 2) Velasco Harvy M, MD, Master Human Genetics, Universidad Nacional De Colombia, Bogota, Bogota, Colombia; 3) Sánchez Yasmin, MD, Universidad Pedagógica y Tecnológica de Colombia, UPTC, TUNJA, Colombia; 4) Santos Sidney. PhD, Head, Laboratory of Human and Medical Genetics, Universidade Federal do Pará. Belém, Brazil; 5) Vinasco Tatiana, MS, Laboratory of Human and Medical Genetics, Universidade Federal do Pará. Belém, Brazil.

**OBJECTIVE:** To describe the phenomena of genetic isolate through the findings of the founder effect in a group of MPS III in Boyacá, Colombia.

**METHODS:** Study of a large pedigree in Runta, Boyacá. Analysis of the pathogenic variant responsible for MPS III. Biochemical analysis for MPS IIIA/B. HGSNAT sequencing. Typification of 6 STRs adjacent to the variant found in 69 inhabitants of Runta and 78 healthy controls from Tunja. Haplotype analysis. Calculation of WHE. F-statistics. Carriers study on 198 settlers included in the group. Calculation of the time of the mutation onset through ESTIAGE and DMLE v 3.1. **RESULTS:** Seven related, alive and affected individuals were found on a large pedigree of 14 patients (7 deceased), detecting the 1360 C>T nonsense variant in HGSNAT, and thus confirming MPSIIIC. The ancestral haplotype of the mutation was present in 88.9% of Runta inhabitants with differences in Fst (0.16) between Runta and Tunja people. A very high frequency of heterozygotes (34%) was observed during the study of carriers. The average age of the ESTIAGE mutation was 41 (CI 95% 35-48) and 39 generations (CI 95% 35-46), which was estimated by using DMLE v 3.1. **CONCLUSIONS:** An ancestral haplotype was identified, although it was not found in the control population. This evidence supports the existence of a founder effect for the variant c.1360 C>T in the Runta village, and an approximate time of origin of the mutation of 1000 years. In consequence, this may be a pre Hispanic mutation, possibly of Muisca origin, that has managed to remain until the present day. This population could be classified as genetic isolate.

**2283F**

**Local adaptation shaped the genetics of psychiatric disorders and behavioral traits in European populations.** *R. Polimanti<sup>1</sup>, M. Kayser<sup>2</sup>, J. Gelehrter<sup>1</sup>.* 1) Yale University School of Medicine, West Haven, CT; 2) Erasmus University Medical Center, Rotterdam, Rotterdam, the Netherlands.

Recent studies have used genome-wide data to investigate evolutionary mechanisms related to behavioral phenotypes, identifying widespread signals of positive selection (i.e., variants with beneficial effects on individual fitness increase in population frequency). Here, we conducted a genome-wide investigation to study whether the genetics of these traits was affected by local adaptation (i.e., adaptation in response to selective pressure related to the local environment), performing a high-resolution polygenic risk score (PRS) analysis in 23 European populations with respect to variables related to geo-climate diversity (geographical coordinates, temperature, daylight, precipitation rate, and humidity), pathogen diversity (bacteria, protozoa, and virus), and language phonological complexity (consonants, segments, and vowels). The analysis was adjusted for the genetic variation of European populations to ensure that the differences detected would reflect differences in environmental exposures. The top finding was related to the correlation between winter minimum temperature and schizophrenia PRS ( $z = 3.84$ ,  $p = 1.28 \times 10^{-4}$ ). Additional significant geo-climate results were also observed with respect to bipolar disorder PRS (Maximum Sunny Daylight:  $z = -2.93$ ,  $p = 3.42 \times 10^{-3}$ ), depressive symptoms PRS (Latitude:  $z = 3.47$ ,  $p = 5.38 \times 10^{-4}$ ), major depressive disorder PRS (Maximum Precipitation Rate:  $z = -3.21$ ,  $p = 1.33 \times 10^{-3}$ ), subjective well-being PRS (Minimum Relative Humidity:  $z = -2.95$ ,  $p = 3.22 \times 10^{-3}$ ). Beyond geo-climate variables, we observed three findings related to pathogen diversity and language phonological complexity: openness-to-experience PRS correlated with protozoan diversity ( $z = 3.56$ ,  $p = 3.82 \times 10^{-4}$ ) and language consonants correlated with conscientiousness PRS ( $z = -2.97$ ,  $p = 2.98 \times 10^{-3}$ ) and extraversion PRS ( $z = 2.87$ ,  $p = 4.13 \times 10^{-3}$ ). In summary, we report the first evidence regarding the role of local adaptation in shaping the genetic architecture of psychiatric disorders and behavioral traits in European populations. Specifically, our study identified several putative signals of local adaptation and many of them appear to be supported by known epidemiological and molecular data.

**Detecting variation maintained by balance between recurrent mutation and selection in human populations.** *N. Koelling<sup>1,2</sup>, A.O.M. Wilkie<sup>1</sup>, G. McVean<sup>2</sup>, A. Goriely<sup>1</sup>.* 1) MRC Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom; 2) Big Data Institute, Li Ka Shing Centre for Health Information and Discovery, University of Oxford, Oxford, United Kingdom.

Highly penetrant *de novo* mutations (DNM) associated with certain congenital disorders, such as Apert syndrome, have been observed at levels up to 1000-fold higher than the background mutation rate and occur more commonly with increasing paternal age. A possible explanation for this is that these mutations confer a selective advantage to the spermatogonial stem cell in which they arise, leading - over time - to an enrichment of sperm carrying the mutation. However, the selfish spermatogonial selection (SSS) of these mutations is balanced by their deleterious phenotype in the offspring, resulting in their absence from healthy populations. We hypothesized that a similar balance of positive selection in the germline and negative selection on the organism may be acting on other sites, where the impact of a mutation may be less deleterious, and that we might detect these sites as hotspots of rare but recurrent mutations in population-level variation data. We developed a statistical method to identify sites with signatures of such recurrent independent mutation events, and validated it using simulations. Applying our method to data from the exome aggregation consortium (ExAC), we identified 343,962 candidate sites showing a signature of recurrent mutation. As expected, these recurrently mutated sites showed features such as an enrichment in C>T transitions at CpG dinucleotides, which are known to have elevated mutation rates. Other sites were associated with cell proliferation: recurrent mutation sites were found close to hotspots of cancer mutations from COSMIC (including hundreds of mutations at the exact same codon) and in genes involved in clonal hematopoiesis, such as *DNMT3A* and *JAK2*. In addition, we also recovered milder known selfish mutations, such as an *FGFR2* variant encoding p.S252L, which has been associated with Crouzon syndrome. Finally, these sites were also enriched in independent sets of DNM, confirming that we could identify locations recurrently mutated in the germline. We identified a subset of variant sites that may be exhibiting a balance between positive germline and negative organismal selection by accounting for nucleotide context, somatic mutations and technical artefacts. These included variants in genes associated with SSS as well as novel genes and thus support this strategy for the discovery of new candidate disease genes associated with increased paternal age.

**New favored haplotype alleles in human adaptation to high altitude in Andes.** T. Stobdan<sup>1</sup>, A. Akbari<sup>2</sup>, P. Azad<sup>1</sup>, D. Zhou<sup>1</sup>, O. Poulsen<sup>1</sup>, O. Appenzeller<sup>3</sup>, G.F. Gonzales<sup>4</sup>, A. Telenti<sup>5,6</sup>, E.H.M. Wong<sup>5</sup>, E.F. Kirkness<sup>5</sup>, J.C. Venter<sup>5,6</sup>, V. Bafna<sup>7</sup>, G.G. Haddad<sup>1,8,9</sup>. 1) Division of Respiratory Medicine, Department of Pediatrics, University of California, San Diego, La Jolla, CA 92093, USA; 2) Department of Electrical & Computer Engineering, University of California, San Diego, La Jolla, CA 92093, USA; 3) Department of Neurology, New Mexico Health Enhancement and Marathon Clinics Research Foundation, Albuquerque, NM 87122, USA; 4) High Altitude Research Institute and Department of Biological and Physiological Sciences, Faculty of Sciences and Philosophy, Universidad Peruana Cayetano Heredia, Lima 31, Peru; 5) Human Longevity Inc., San Diego, CA 92121, USA; 6) J. Craig Venter Institute, La Jolla, CA 92037, USA; 7) Department of Computer Science & Engineering, University of California, San Diego, La Jolla, CA 92093, USA; 8) Department of Neurosciences, University of California, San Diego, La Jolla, CA 92093, USA; 9) Rady Children's Hospital, San Diego, CA 92123, USA.

**Background:** Human high altitude adaptation or mal-adaptation, such as chronic mountain sickness (CMS), is explored to understand the physiological and molecular mechanisms that underlie long-term (generational) exposure to hypoxia. This direct high altitude adaptation experiment-in-nature can be utilized to understand evolutionary processes in humans and to understand diseases where hypoxia plays part in their pathophysiology. **Results:** Here we report the results of an analysis of the largest whole-genome-sequencing of CMS and non-CMS individuals, identified candidate genes and functionally validated these candidates in a genetic model system (*Drosophila*). We used PreCIOS algorithm that uses Haplotype Allele Frequency score to separate haplotypes carrying the favored allele from the non-carriers and accordingly prioritize genes associated with CMS or non-CMS. Haplotypes in eleven candidate regions were significantly different between CMS and non-CMS. A closer examination of individual genes in these regions revealed the involvement of previously identified candidates (e.g., *SENP1*) and also unreported ones *MC2R*, *SGK3*, *COPS5*, *PRDM1* and *IFT122* in CMS. The majority of SNPs were in non-exonic regions of these candidate genes. Remarkably, in addition to genes like *SENP1*, *SGK3* and *COPS5* which are hypoxia-inducible factor-dependent (HIF-dependent), our study revealed for the first time HIF-independent gene *PRDM1* and hormonal receptor gene *MC2R*, indicating an involvement of various systems and pathways in high altitude adaptation. Furthermore, we down-regulated the orthologs of each candidate gene in *Drosophila* and tested for hypoxia tolerance. We observed that down-regulating orthologs of *SGK3*, *COPS5*, *TCF54*, *PRDM1* and *IFT122* significantly enhanced their hypoxia tolerance. **Conclusions:** Our study reveals the involvement of both HIF-dependent and independent mechanisms in human adaptation to high altitude. The PreCIOS algorithm applied on a large number of genomes identifies involvement of both new and previously reported genes in selection sweep, highlighting the involvement of multiple hypoxia response systems. Since the overwhelming majority of SNPs are in non-exonic (and possibly regulatory) regions, we speculate that this molecular adaptation allows for more flexibility in adjusting the physiological responses to environmental challenges such as hypoxia.

**Genetic structure of pre-Columbian remains of the Malambo culture in the Lower Magdalena, Colombia.** M. Noguera<sup>1</sup>, A. Gómez<sup>1</sup>, I. Briceño<sup>1,2</sup>, J. Bernal<sup>3</sup>, W. Rivera<sup>4</sup>, J. Martín<sup>4</sup>. 1) Bogotá, Colombia, Institute of Human Genetics, Faculty of Medicine, Pontificia Universidad Javeriana, Bogotá D.C., Colombia Kra 7 ·40-62; 2) Grupo Genética Humana.Facultad de Medicina,Universidad de la Sabana. Chía, Colombia; 3) Universidad Tecnológica de Bolívar. Cartagena, Bolívar, Colombia; 4) Grupo Memorias del Caribe, Facultad de Antropología.Universidad del Norte. Barranquilla, Atlántico. Colombia.

**Introduction:** Ancient DNA studies, allow determining population dynamics of the pre-Columbian cultures and clarifying the genetic continuity and discontinuity. In the Malambo culture in the department of Atlántico, preliminary findings of pottery and lithic objects, can be complemented with the genetic study of human remains and their relationship with the archeology of Northern South America and the Caribbean. **Objective:** To study the population structure of the communities of Lower Magdalena and the Caribbean, based on bioarchaeological analysis and ancient DNA extracted from skeletal remains supplied by the MAPUKA Museum, at the Universidad del Norte in Barranquilla, Colombia. **Materials and Methods:** A bioarchaeological (genetic-archaeological) study of the Malambo tradition was carried out. The hypervariable-I region of mitochondrial DNA was analyzed after being successfully amplified and sequenced. Sequences were analyzed using CLC main Workbench software: Multiple sequence alignment with the revised Cambridge reference Sequence. HVR-I segments were aligned to the consensus sequence. Arlequín 3.5.2 was used to analyze the intrapopulations and interpopulations levels. Phylogenetic Networks were constructed through the Median Joining (NJ) algorithm, comparing the study samples with other paleo-Colombians. **Results:** Only one haplogroup was observed in four individuals, in which the G16361A mutation was found. This mutation was recently described to define sub-haplogroup B2j) in Venezuela, which suggests a genetic continuity in Northern South America. **Conclusión:** Identification of subhaplogroup B2j) in the individuals belonging to the pre-Columbian population of Malambo and recently reported in a contemporary inhabitant of the Venezuelan coast, could support a human migration route to or from the Orinoco river valley.

**Comparative whole genome variation and architecture in a pediatric African American and Caucasian dataset.** P. Sleiman, L. Tian, H. Hakonarson. Center Applied Genomics, CHOP, Philadelphia, PA.

Admixed populations, including African Americans, remain underrepresented in genetic research. We have generated whole genome sequencing data on 900 pediatric samples comprising 532 children of African American ancestry and 368 of European ancestry representing one of the largest pediatric and African American whole genome datasets generated to date. All samples were sequenced to a depth of ~30X using a PCR free library prep on an Illumina X10. Alignment to GRCh37 and variant calling was carried out using the DRAGEN cloud (Edico Genome). Variant annotations were generated using SnpEff, and Variant Effect Predictor (VEP) for RefSeq and Ensembl GENCODE gene models in addition to ANNOVAR outputs for the UCSC knowGene models. Structural variants (SVs) were called using MANTA (Illumina) and copy number variants (CNVs) using CANVAS (Illumina). Increased single nucleotide variation has been well established in African genomes, however, to our knowledge no large scale studies have systematically estimated the burden of variation in admixed populations taking local ancestry into account. Having generated local ancestry estimates across the admixed genomes we present a local ancestry-based overview of the distribution and burden of rare variants, SVs and CNVs in the African and European segments in the admixed AA individuals as well as a global comparison with the European ancestry samples in our cohort.

Tibetans are well adapted to high-altitude hypoxia. Previous genome-wide scans have reported many candidate genes. But only a few of these candidates were studied. In this study, we reported a hypoxia gene (*GCH1*, GTP-cyclohydrolase I), involved in maintaining NOS function and normal blood pressure, harbors many potentially adaptive variants in Tibetans. We re-sequenced an 80.8kb fragment covering the entire gene region of *GCH1* in 50 unrelated Tibetans. Combined with the published data, we demonstrated that there were many *GCH1* variants showing deep divergence between highlander Tibetans and lowlander Han Chinese. Neutrality tests confirmed the signal of Darwinian positive selection on *GCH1* in Tibetans. Moreover, the association analysis indicated that the Tibetan version of *GCH1* is significantly associated with multiple physiological traits in Tibetans, including blood nitric oxide concentration, blood oxygen saturation and hemoglobin concentration. Taken together, we propose that *GCH1* plays a role in the genetic adaptation of Tibetans to high altitude hypoxia.

**Improving genotype imputation in population isolates using identity by descent.** *M. Abney, A. El Sherbiny.* Dept Human Gen, Univ Chicago, Chicago, IL.

Genotype imputation, using standard imputation software, for a sample from an isolated population can result in unexpectedly high error rates in certain classes of markers. In particular, using an external reference panel can result in a high rate of false positive calls while also failing to impute the potentially large number of private variants. Even though sequencing a strategically chosen internal reference panel can significantly improve accuracy, we find that there are still often a subset of markers for which imputation accuracy is low. Here we present a method that leverages the identity by descent information captured in the framework set of markers to further improve imputation quality, often dramatically for some sets of markers. We also provide a method for optimally selecting the individuals for the internal reference panel. Unlike other approaches the methods presented here work equally well when individuals are of known or unknown relatedness (i.e. cryptically related) and whether there is a known pedigree or not. Our imputation method can be used on its own or can integrate the output from standard imputation methods to provide the highest imputation accuracy. We apply our method to real genotype data from an isolated population and find, for instance, that heterozygous concordance rates improve significantly, and that, when used together with a method such as IMPUTE2 using 1000 Genomes reference data, our method outputs imputed genotypes that are as accurate as if an internal reference panel were also used. That is, without sequencing an internal reference panel our method obtains imputation quality approximately as accurate as if an internal reference panel had been sequenced.

**Consanguinity, IBD, and ROH: Detangling their complex relationship.** *A. Severson<sup>1</sup>, N. Rosenberg<sup>2</sup>.* 1) Genetics, Stanford University, Stanford, CA; 2) Biology, Stanford University, Stanford, CA.

Identity by descent (IBD) and runs of homozygosity (ROH) are two measures commonly used to describe genomic sharing. IBD evaluates sharing across individuals while ROH evaluates sharing within an individual. Empirical estimates of IBD and ROH have revealed that these measures are correlated. Moreover, it has been shown that increased quantities and lengths of IBD and ROH tracks correlate with increased consanguinity. It is not surprising that higher levels of inbreeding produce more ROH, but the increased IBD within the population is less intuitive. To investigate the effect of consanguinity on IBD and ROH, we first consider the effect on time to the most recent common ancestor (TMRCA). We employ a dioecious, diploid Wright Fischer model with different consanguinity regimes. We model sibling mating, cousin mating, double cousin mating, and uncle-niece mating. For each consanguinity regime, we are able to model the effect of the fraction of consanguineous mating pairs on TMRCA in the entire population. We find that with differing magnitudes that increasing consanguinity decreases TMRCA. This is not only true for the products of consanguineous unions, but also for more generally "unrelated" individuals in the population. Moreover, this result recapitulates empirical findings of the correlation between consanguinity, ROH, and IBD. Next, we will run simulations to explicitly extend the findings from TMRCA to ROH and IBD.

**Evolutionary rate and the human transcriptome: Function, mechanism, and disease genes.** *P. Evans, N. Cox, E. Gamazon.* Gen Med, Vanderbilt University, Nashville, IL.

The development of mechanistic explanatory models of protein sequence evolution has broad implications for our understanding of cellular biology, population history, and disease process. Several molecular features have been proposed as potential causal factors for the rate of protein evolution. Here I analyze a variety of gene properties, including expression level, expression breadth, gene age, network interaction, and heritability, and quantify their contribution to protein sequence divergence. We find that many factors contribute independently and we present strong evidence for the importance of gene function. Most notably, co-expression network connectivity and gene expression heritability provide the best univariate models for protein evolutionary rate. Heritability, a measure of the influence of the regulatory genome, is a novel and, important determinant of evolutionary rate. Furthermore, we use the GTEx human transcriptome resource to examine the forces that shape protein evolution in a multi-tissue framework; in particular, analysis of gene expression using this resource. We implement a self-organizing map (SOM) neural network to jointly analyze all examined potential factors and to account for nonlinear effects, utilizing it to develop a dispensability score for each gene. Methodologically, we demonstrate that genome-wide studies of disease may be enhanced by incorporating the determinants of evolutionary rate into the search for disease genes. Our study presents a comprehensive analysis of a range of factors that constrain molecular evolution and proposes a novel framework for the study of protein function and disease mechanism.

Yangla<sup>3</sup>, H. Zhang<sup>1</sup>, X.M. Zhang<sup>1</sup>, Y.B. Guo<sup>2</sup>, S.H. Xu<sup>5,8,9</sup>, H. Chen<sup>6</sup>, S.G. Zhao<sup>2</sup>, Y. Cai<sup>2</sup>, S.M. Liu<sup>7</sup>, T.Y. Wu<sup>7</sup>, B. Su<sup>7</sup>.* 1) State Key Laboratory of Genetic Resources and Evolution, Kunming Institute of Zoology, Chinese Academy of Sciences, Kunming, Yunnan, China; 2) College of Animal Science and Technology, Gansu Agricultural University, Lanzhou 730070, China; 3) High Altitude Medical Research Center, School of Medicine, Tibetan University, Lhasa 850000, China; 4) Kunming College of Life Science, University of Chinese Academy of Sciences, Kunming 650204, China; 5) Chinese Academy of Sciences Key Laboratory of Computational Biology, Max Planck Independent Research Group on Population Genomics, CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, CAS, Shanghai 200031, China; 6) Center for Computational Genomics, Beijing Institute of Genomics, Chinese Academy of Sciences, Beijing 100101, China; 7) National Key Laboratory of High Altitude Medicine, High Altitude Medical Research Institute, Xining 810012, China; 8) School of Life Science and Technology, ShanghaiTech University, Shanghai 200031, China; 9) Collaborative Innovation Center of Genetics and Development, Shanghai 200438, China.

The genetic adaptation of Tibetans to high altitude hypoxia likely involves a group of genes working in the hypoxic pathway, as suggested by previous studies. To test the adaptive role of the previously reported candidate gene *EP300* (histone acetyltransferase p300), we conducted resequencing of a 29.83kb gene region of *EP300* in 80 unrelated Tibetans. The allele-frequency and haplotype-based neutrality tests detected signals of Darwinian positive selection on *EP300* in Tibetans, with a group of variants showing allelic divergence between Tibetans and lowland reference populations including Han Chinese, Europeans and Africans. Functional prediction suggested the involvement of multiple *EP300* variants in gene expression regulation. More importantly, genetic association tests in 226 Tibetans indicated significant correlation of the adaptive *EP300* variants with blood nitric oxide (NO) concentration. Collectively, we propose that *EP300* harbors adaptive variants in Tibetans, which may contribute to high altitude adaptation through regulating NO production.

**De novo genomic assembly and assessment of inbreeding in a severe bottleneck population.** A.F. Scott, D.W. Mohr. Inst Gen Med, Blalock 1034, Johns Hopkins Med Sch, Baltimore, MD.

Population bottlenecks lead to small populations with increased inbreeding and random genetic drift, the loss of genetic variability, reduced reproductive success, and higher mortality as a result of a poorer ability to respond to environmental insults (e.g., infectious diseases). Once species enter “extinction spirals” their populations continue to decrease until they can no longer be sustained. As biodiversity in natural populations decreases world-wide due to climate change, habitat loss, illegal animal trade and other reasons the reduction of genetic plasticity will have wide-spread consequences. We studied the aftermath of a population bottleneck in the Hawaiian monk seal (*Neomonachus schauinslandi*), a species with approximately 1400 animals, whose population declined to, perhaps, fewer than 100 individuals in the 1890s as a result of over hunting. In 1983, the National Oceanic and Atmospheric Administration (NOAA) launched a vigorous species recovery effort. We created a high-quality *de novo* genome assembly using a combination of optical mapping and linked-read sequencing (Mohr et al, 2017) in which we identified 98% of the expected protein coding genes in 170 scaffolds whose median length (N50) is over 29 Mb. The linked-read sequencing produced phased haplotype blocks that could be compared to the frequently sequenced human NA12878 “gold standard” genome. As expected, the Hawaiian seal has significantly reduced heterogeneity that is approximately ten percent of that found in humans. Although a higher than expected number of congenital abnormalities has not been observed in the wild we did note marked reduction of heterogeneity within the MHC genes in the seal, suggesting that these animals may be at a heightened risk of decline or extinction due to pandemic disease. Reference: Mohr et al <http://biorxiv.org/cgi/content/abstract/128348v2>.

**Dietary adaptation of *FADS* genes varied geographically in Indian populations.** D. Wang<sup>1</sup>, K. Ye<sup>1</sup>, O. Bar-Yosef<sup>2</sup>, A. Keinan<sup>1,3,4</sup>. 1) Computational Biology and Biological Statistics, Cornell University, Ithaca, NY; 2) Department of Anthropology, Harvard University, Cambridge, MA; 3) Cornell Center for Comparative and Population Genomics, Cornell University, Ithaca, NY; 4) Center for Vertebrate Genomics, Cornell University, Ithaca, NY.

The fatty acid desaturase (*FADS*) genes encode rate-limiting enzymes for the biosynthesis of omega-6 and omega-3 long-chain polyunsaturated fatty acids (LCPUFAs) from plant-derived precursors. While LCPUFAs can be absorbed directly from meat/seafood-based diets, their biosynthesis is essential to compensate for their absence in plant-based diets. We have previously reported geographically and temporally varying patterns of *FADS* genetic adaptation to diet in Europe, with one haplotype (D) adaptive to plant-based diets in farmers by enhancing LCPUFAs biosynthesis and another haplotype (M2) adaptive to meat/seafood-based diets in pre-Neolithic hunter-gatherers by diminishing LCPUFAs biosynthesis. In South Asia, while we have reported adaptation of *FADS* genes to plant-based diets, it is still unknown whether the diverse demographic history and dietary habits among subgroups of Indians resulted in geographically varying adaptive patterns. Here, we compiled a large data set representing 52 populations across India and applied imputation to create a uniform set of variants. First, we observed drastic frequency variation across geography: opposite frequency patterns between Andaman Islanders (D: 3.13%; M2: 50.0%) and mainland Indians (D: 84.3%; M2: 5.75%); even among mainland Indians, the frequency of D varies, ranging from 66.6% in the Kharia population to 94.4% in the Kurumba population with a general trend of higher frequency in western Indians than in eastern ones. Moreover, we found that the frequencies of haplotype D in present-day Indian populations are significantly associated with the percentage of ancestral north Indian (ANI) ancestry ( $p = 0.031$ ), and with their language families ( $p = 0.041$ ). Formal haplotype-based selection tests reveal the presence of geographically varying selection signals while considering different demographic history. Overall, the geographically varying patterns of allele/haplotype frequency in South Asia are consistent with the geographically varying dietary patterns: the meat/seafood-based diets of Andaman Islanders, and the plant-based diets in mainland Indians with western Indians relying more heavily on plant and eastern Indians on seafood.

**2295F**

**Detect co-evolution of genes in admixed populations with genome-wide data.** M. Zhou<sup>1</sup>, H. Wang<sup>2</sup>, X. Li<sup>1</sup>, S. Redline<sup>2</sup>, H. Tang<sup>2</sup>, X. Zhu<sup>1</sup>. 1) Case Western Reserve University, Cleveland, OH; 2) Harvard Medical School, Boston, MA; 3) Stanford University, Stanford, CA.

Co-evolution of genes is an important topic in population genetics. However, detecting co-evolution in human population is often challenged owing to the experimental constraints. Our previous study suggested such co-evolution can be detected by testing the correlation of local ancestry in recently admixed populations such as African Americans or Hispanic populations. However, our previous study only examined co-evolution occurred on different chromosomes. Within a chromosome, a challenge of detecting co-evolution is to control the confounding due to admixture linkage disequilibrium (LD). In this study, we developed a method to eliminate the bias caused by admixture LD when searching for co-evolution on the same chromosome. We applied this method to search for co-evolution in three African American cohorts: (1) the Candidate Gene Association Resources (CARE) study; (2) the Family Blood Pressure Program (FBPP); (3) the Women's Health Initiative (WHI), with a total of 16,252 unrelated African Americans. We tested pairwise correlations of local ancestry on each chromosome for each of the three cohorts while excluding those pairwise loci with genetic distance less than 70cM in order to eliminate the high correlation because of admixture LD. The genomic control values were 0.90, 0.82 and 0.81 for CARE, FBPP, and WHI, respectively, suggesting our method leads to a conservative type I error rate. We next meta-analyzed the results from the three cohorts. The genomic control value for the meta-analysis was 1.03. Our results revealed 11 significant pair regions on multiple chromosomes after correcting for multiple tests ( $P$ -value $<3e-6$ ). Those pair regions located multiple genes that have been previously reported under natural selection pressure. We observed *LRR7* was negatively correlated with Duffy blood locus *ACKR1*, and *DIP2C* was negatively correlated with *PCDH15*, a gene with a key role in development and function of sensory hair cells. Our analysis suggests our method is powerful to identify co-evolution in recently admixed populations.

**2296W**

**Where is Brazil? Placing admixed Brazilian populations in a global genetic map.** A. Arcanjo Silva<sup>1,2,3</sup>, S. Oliveira<sup>2</sup>, N. Klautau-Guimaraes<sup>2</sup>, J. Walker<sup>2</sup>, M. Batzer<sup>2</sup>. 1) Colégio Marista de Brasília Ensino Médio, Brasília, Distrito Federal, Brazil; 2) Departamento de Genética e Morfologia, Universidade de Brasília, Brasília, Distrito Federal, Brazil; 3) Biological Sciences, Louisiana State University, Baton Rouge, Louisiana, United States.

The state of the art of the knowledge about the relationship between genetic variability and the dynamics of human populations is a result of years of describing allelic and genotypic frequencies. The patterns of variation for genetic markers in coding and non-coding regions are not the same, since mutations in coding regions might have significant impact in one's ability to survive. These different patterns can help clarify the relationship between populations. Many markers were described that could efficiently identify samples with European ancestry from those with African ancestry and Asian ancestry. In a globalized world, where migrations occur frequently, genetic constitution and ancestry is not so well established. In some populations, especially the ones originated by recent colonization such as Brazil, the genetic constitution is a mix of the genetic constitution of its founders. The main goal of this work is to estimate the genetic variability that is accessed by neutral genetic markers, which describe the variability relationships among population groups in an unbiased way, in two knowingly admixed Brazilian populations, placing Brazil in a global genetic map. To achieve that, a panel of 100 Alu insertions was used in a set of 1125 worldwide samples, including 160 samples from two admixed Brazilian populations, Brasília and Kalunga. The insertion panel showed a tenfold increase in the number of linked loci to each locus in Brasília, Kalunga and Utah when compared to African, European, Asian and Indian populations. Which is mainly due to the recent admixture of different populations in the making of those populations (250 years). Kalunga clusters with the African populations, but still shows differentiation due to being admixed, Brasília clusters with both the European and the Middle-Eastern groups, being the last one more genetically similar to Brasília than the first due to an African genetic component. The population groups cannot be considered homogeneous, despite at least one population of each group not showing population differentiation to the other populations of its group. In conclusion, Brazilian admixed populations tend to cluster with the populations in which the genetic constitution is more similar to their own: instead of clustering with African or European populations, Brasília clustered with other admixed populations with similar genetic founders, while Kalunga clustered with African populations due to its great African ancestry.

The human leukocyte antigen G (*HLA-G*) is a non-classical HLA class I gene which presents limited protein variability and restricted expression to certain tissues. *HLA-G* has immunomodulatory properties, inhibiting immune responses when interacting with specific Natural Killer and T cell receptors, such as KIR2DL4, ILT2 and ILT4. On the other hand, the *HLA-A* locus is one of the most variable genes of the human genome and its encoded molecules are expressed in nearly all nucleated cells. *HLA-A* associates with endogenous peptides and presents them on the cell surface to T CD8+ cells. Balancing selection has been well documented for the *HLA-A* coding segment, mainly at the region encoding the peptide-binding site, which is associated with the presence of many frequent and divergent coding alleles in worldwide populations. Likewise, many studies have detected signatures of balancing selection at the *HLA-G* promoter. However, it is not clear whether balancing selection is indeed operating at the *HLA-G* locus, or if it is a hitchhiking effect caused by the selective pressures acting on its neighbor gene, *HLA-A*, since they are separated by approximately 100Kb. Here we evaluate the *HLA-A* and *HLA-G* variability in 405 individuals from the Southeast Brazil. Each locus was entirely evaluated by using Next Generation Sequencing (NGS), and haplotypes were determined by a bioinformatics workflow that combines the physical associations detected directly at the NGS data and the computational inference from PHASE algorithm. *HLA-A* and *HLA-G* haplotypes were then combined as extended haplotypes. The results indicate that *HLA-G* and *HLA-A* are in strong linkage disequilibrium. For instance, 94% of the A\*01 alleles are associated with the *HLA-G* promoter 010102a, and 95% of the A\*23 alleles are associated with the *HLA-G* promoter 0104a. Although some *HLA-A* alleles may occur with different *HLA-G* promoters, each main *HLA-G* lineage (G010101, G010102, G0103 and G0104) is primarily associated with a different set of *HLA-A* coding alleles. Both the *HLA-G* promoter and the *HLA-A* coding segment present signatures of balancing selection, which is stronger for the *HLA-A* coding region. Thus, it is possible that the balancing selection operating at the *HLA-A* locus is also shaping the *HLA-G* promoter frequencies, downplaying its direct role on *HLA-G*. This work was supported by FAPESP/Brazil (#Grant 2013/17084-2) and the Brazilian Council for Scientific and Technological Development (CNPq/Brazil).

**Rewriting the genetic history of Austro-Asiatic communities in South and Southeast Asia.** M.E. Phipps<sup>1</sup>, D. Tagore<sup>2</sup>, F. Aghkhanian<sup>1</sup>, R. Naidu<sup>1</sup>, P. Majumder<sup>2</sup>, A. Basu<sup>2</sup>. 1) Jeffrey Cheah School of Medicine & Health Sciences, Monash University Malaysia, Sunway City, Selangor, Malaysia; 2) National Institute of Biomedical Genomics, Kalyani, West Bengal, India.

There are large gaps in our knowledge about the peopling of India and South East Asia by AustroAsiatic (AA) language speakers. Today, the majority of AA speakers in Indochina are agriculturalists, and it has been assumed that the spread of rice cultivation is inextricably linked to the spread of the AA language family. However, it is intriguing that tribal communities such as the Gond, Ho, Santal, Bihor, Korwa and Khasi in India, and indigenous Negrito and some Senoi tribes in Malaysia who are all Austroasiatic speakers, represent the last hunter gatherer communities with negligible evidence of knowledge or practice of rice cultivation. We believe that ours is a larger and more comprehensive investigation to elucidate the genetic history and dispersal of AA speakers in this region. We genotyped 496 (Illumina Omni 2.5 and Affymetrix 6) unrelated individuals from eleven AA communities and neighbouring Austronesian, Tibeto Burman and Dravidian groups in Malaysia and India. Our genotype data was then compared with the HGDP dataset for further analysis. Contrary to our initial expectations, Principal Component Analysis and ADMIXTURE revealed that all AA speakers of India were more closely linked to the Senoi, rather than Negritos in Malaysia. In addition there was an appreciable association between these Senoi and Tibeto Burmans. Identical by descent (IBD) and Treemix analyses suggested that in earlier times, the AA of Malaysia and Tibeto Burmans may have initially split from a common ancestral population. It is probable that more recently, some AA groups in Southeast Asia migrated westwards giving rise to the present day Indian AA speakers. D-statistics that was performed provide evidence of extensive gene flow from East Asians (Han Chinese, Dai, Cambodians) towards AA Malaysia and Tibeto Burmans, representing south western migration events. We have not found evidence to support a previous report that linked rice cultivation and the spread of Austroasiatic languages. Therefore, we propose that later migrations and multiple gene flow events within the past two millennia between Austroasiatic, Sino-Tibetan and Dravidian speakers in South and Southeast Asia, have shaped the present day language and genetic structures of populations in this part of the world.

**2299W****Genetic differentiation of Hispanics using ancestry informative markers.**

C.H. Setser, R. Chakraborty, J.V. Planz, R. Barber, A. Eisenberg, D.S. Cross. Molecular and Medical Genetics Department, University of North Texas Health Science Center, 3500 Camp Bowie Blvd., Fort Worth, TX 76107.

There are at least 10,500 unidentified human remains in the US as of August 2015, with 2,041 of presumed Hispanic origin (NamUs 2015). Conventional DNA analysis identifies an individual through comparison with reference profiles. For those with no reference, panels of ancestry informative single nucleotide polymorphisms (SNPs) exist (Kidd 2014, Seldin 2009), but they focus on global differentiation and are not suitable for ancestry determination of admixed populations (e.g. Hispanics). We hypothesize that a small panel of SNPs ascertained from appropriate populations with great genetic differentiation can distinguish ancestry within Hispanic populations. This bioinformatics study uses the Genomic Origins and Ancestry in Latinos (GOAL) dataset of 250 individuals with ancestry from Columbia, Cuba, Dominican Republic, Haiti, Honduras, or Puerto Rico genotyped using the Affymetrix 6.0 chip to develop an informative Hispanic SNP panel. Starting with 897,336 SNPs, we trimmed to 531,878 SNPs using linkage disequilibrium of 0.7. We then calculated pairwise  $F_{ST}$  for each SNP with each population pair using PLINK (Haiti excluded). SNPs that met 0.15 threshold for the four comparisons were included in a 1217 SNP panel. We used STRUCTURE to visualize population separation. To determine if a smaller SNP set could be utilized while retaining information we only used the top ten mean  $F_{ST}$  values from each population and added an extra five to try to distinguish Cuba vs. Dominican Republic for a condensed panel of 56 SNPs. Additionally, we combined 1000 Genomes data (108 Yoruba, 107 Iberian, 103 Chinese) and the GOAL data to verify whether the countries are separating by ancestral lines or geographic region. STRUCTURE analysis showed Honduras was easily distinguished from other countries in the 1217 and 56 SNP panels. Other countries were also separated based on contribution from ancestral populations, however the separation was less than ideal. Notably, Honduras contributed 71% of the SNPs in the 1217 panel. When analyzed with 1000 Genomes data, Honduras separated with the Chinese population for  $K=1-3$ , but was the first GOAL population to separate from the ancestral line. Utilizing an efficient SNP panel consistently separated Honduras from other populations demonstrating proof of concept. Greater separation of country of origin may be seen with a larger dataset and additional substructure information unveiled by principal components analysis.

**2300T****One step for study of transposable element-associated structural variations (TASVs) using de novo assembled Korean genome.** S. Mun<sup>1</sup>, S. Kim<sup>2</sup>, W. Lee<sup>2</sup>, K. Kang<sup>2</sup>, H.S. Kim<sup>3</sup>, K. Han<sup>1</sup>.

Due to advanced sequencing technology, personal genome sequencing is currently possible and indeed many human genomes have been sequenced by next-generation sequencing (NGS) technology. The comparison of the individual genomes revealed a huge genomic difference between human populations and even individuals from closely related ethnic groups. There are many causative agents for the genomic changes. Transposable elements (TEs) are known as one of major factor to cause genomic variations through various mechanisms including *de novo* insertion, insertion-mediated deletion, and TE-TE recombination-mediated deletion. In this study, we carried out *de novo* whole-genome sequencing with multiple insert-size libraries and phasing analysis using statistically aided, long-read haplotyping (SLRH) from one Korean individual (KPGP9). The *de novo* genome assembly results in 31,305 scaffolds with a scaffold N50 size of 13.23Mb. With sequencing results, we performed variant annotations of KPGP9 genome and comparison of non-synonymous SNPs to the seven individual human genomes (KPGP9, AK1, SJK, YH, Yoruba, Venter, and Watson). We identified 97 SNPs that only detected from the Korean individual genomes. Further, through computational data analysis and experimental verification, we revealed that 182 TE-associated structural variation (TASV) insertions and 89 TASV deletions contributed to 64,232 bp (NCAI: -3369 bp) sequence gain and 82,772 bp sequence loss in the KPGP9 genome, respectively. Biological function and clinical implication were annotated for SNPs and TASVs identified. As demonstrated in this study, we release another Korean *de novo* genome and propose Korean common genetic differences by comparison to several ethnic groups. Our finding highlights again the role of TEs as one of major drivers to create structural variations in human individuals.

For the last few years a number of national genomic projects emphasized the diversity and similarity of world populations, shed light onto several aspects of population history and provided substantial assistance to the development of medical genomics. In spite of occupying almost 12% of the world's landmass, and having the ninth largest world population until recently the Russian Federation has not participated in large sequencing projects. To overpass this, Genome Russia project was launched striving to accomplish whole genome sequencing of more than 2,000 samples coming from diverse population groups and ethnic minorities within the Russia. One of the main aims of this project is to construct a haplotype map (HapMap) of the Ethnic Russian for further usage in medical studies. Here we introduce the preliminary Russian haplotype structure based on 41 Western Russian samples (consisting of 12 trios and 5 unrelated individuals) from Novgorod region and Pskov region. We inferred haplotypes from SNP genotypes by using SHAPEIT2 tool [1] (using trios in the analysis allowed us to increase the haplotype phasing quality). Haplotype structure analysis was performed in Haploview [2]. We were able to analyze linkage disequilibrium and haplotype block structure, performed haplotype population frequency estimation and identified tag SNPs relevant to Russian population. These results will allow us to better understand the Russian genome and to create population-specific genotyping microarrays for medical and other studies. 1. J. O'Connell, D. Gurdasani, O. Delaneau, et al. A general approach for haplotype phasing across the full spectrum of relatedness. 2014 2. Barrett JC, Fry B, Maller J, Daly MJ. **Ancestry Hub: For whole-genome local ancestry analysis.** *S. Jiang, L. Ma, Q. Song.* 4DGenome, INC, Atlanta, GA.

Population stratification is a growing concern in genetic-association studies. Admixture has created mosaic chromosomes in human populations; even within the same individual, different segments and different homologous chromosomes may have different ancestral origins. Averaged ancestry at the genome level (global ancestry) is insufficient for detecting population substructures and correcting population stratifications in association studies. Recently, we have reported a new approach for local ancestry analysis, which has been implemented into a software tool called aMAP (ancestry of Modern Admixed Populations). Here, we report that we build up a web-based platform of ancestry hub to do the ancestry analysis. Data analysis requires access to powerful computational infrastructure, high quality bioinformatics software, and personal skills to operate the tools. To solve this challenge, we present a practical solution to the local-ancestry data analysis. We will provide the web tool for using aMAP in ancestry analysis. Our reference panel will contain haplotypes from the 1000 Genomes Project. In the future, we envisage an increase of the reference panels in diversity of reference populations. We setup Hub Online at Amazon storage and S3 based storage to provide easy access to the genotype data and to seamlessly transfer the input data into our local server for analysis. Now it can analyze with Th26 reference populations. The ancestry hub allows users to upload their own genotype data or haplotype data. Currently, the hub supports VCF or 23andme format. Our method also exhibits a tolerance to missing ancestral reference panels, an applicability to genetically close populations, and a capacity for analyzing multi-way admixed individuals. The web-based hub is open source and free for non-commercial users through the link <https://www.ancestry.4dgenome.com/>.

**Relationships between the regulation of gene expression, mutational burden, and recombination in a large population cohort.** *H. Edgington*<sup>1,2</sup>, *I. Alves*<sup>1,2</sup>, *P. Awadalla*<sup>1,2</sup>. 1) Informatics and Biocomputing, Ontario Institute for Cancer Research, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Hill-Robertson interference refers to a process where, in the absence of recombination, beneficial alleles arising on different haplotypes will compete for selective advantage, each preventing the other from reaching fixation. Thus, a proposed advantage of recombination is its utility in bringing advantageous mutations together on one haplotype. In this same manner, deleterious mutations in regions of low recombination may not be purged as efficiently when they exist on different haplotypes. This model describes a purely genetic framework, and does not take into account the activity of genes in which mutations may accumulate. In this study we explore what the relationship is between expression (and consequential exposure to natural selection) and recombination in order to integrate gene action into the Hill-Robertson framework. In order to compare expression differences while accounting for among-individual biases we made use of a phenomenon known as allele-specific expression (ASE), wherein the two copies of the genome at a particular locus are expressed differently. This provides for a within-individual comparison of allelic expression, which controls for the influence of external variation on expression. Additionally, previous work has shown an enrichment of ASE at deleterious variants across the genome, causing those alleles to be downregulated. This suggests the potential for ASE to act as a mechanism whereby individuals are protected from the effects of deleterious mutations. We hypothesized that, similar to the impact of Hill-Robertson interference on population allele frequencies, we might see a positive correlation between linkage disequilibrium among deleterious mutations and the degree of allele-specific expression within a transcribed region. We used a simulation-based approach to estimate allele-specific expression and linkage disequilibrium in data from CARTaGENE, a population cohort of French Canadians. We compared these parameters in order to determine whether haplotypes carrying more deleterious mutations were expressed with lower frequency than more neutral haplotypes, as well as whether linkage among deleterious mutations correlated with the magnitude and consistency of allele-specific expression.

**Tracing maternal lineage of Austronesian-speaking Melanesians and Micronesians in the Solomon Islands.** *M. Isshiki*<sup>1</sup>, *I. Naka*<sup>1</sup>, *R. Kimura*<sup>2</sup>, *T. Furusawa*<sup>3</sup>, *K. Natsuhara*<sup>4</sup>, *T. Yamauchi*<sup>5</sup>, *M. Nakazawa*<sup>6</sup>, *T. Ishida*<sup>1</sup>, *R. Ohtsuka*<sup>7</sup>, *J. Ohashi*<sup>1</sup>. 1) Department of Biological Sciences, Graduate School of Science, The University of Tokyo; 2) Department of Human Biology and Anatomy, Graduate School of Medicine, University of the Ryukyus; 3) Graduate School of Asian and African Area Studies, Kyoto University; 4) Faculty of Nursing, The Japanese Red Cross Akita College of Nursing; 5) Faculty of Health Science, Hokkaido University; 6) Graduate School of Health Sciences, Kobe University; 7) Japan Wildlife Research Center.

Accumulated archaeological, linguistic and genetic evidences suggest that modern Austronesian (AN)-speaking Melanesians are derived from the admixture of indigenous Non-Austronesian- (NAN-) speaking people in Near Oceania and Austronesian- (AN-) speaking people from Southeast Asia. In this study, we analyzed mitochondrial DNA (mtDNA) polymorphisms in D-loop region for two AN-speaking Melanesian populations (Munda and Kusaghe) and an AN-speaking Micronesian population (Rawaki) from New Georgia Island in the western Solomon Islands to trace the maternal lineage of AN-speaking Melanesians. The major mtDNA haplogroups in these three populations originated in Asia and the 'Polynesian motif', which is well-characterized mtDNA marker for Polynesians, was frequently observed in the two AN-speaking Melanesian populations but not in the AN-speaking Micronesian population in New Georgia Island. Principle component analyses also revealed genetic proximity between AN-speaking Melanesians (Munda and Kusaghe) and AN-speaking Polynesians in Tonga. These results suggest that Polynesian ancestors have considerably contributed to maternal gene pool of AN-speaking Melanesians in the Solomon Islands before their expansion to Remote Oceania.

**2305W****Exploration of the ancestral genetic landscape of the Arabian Peninsula.**

*D. Platt<sup>1</sup>, P. Zalloua<sup>2,3</sup>*. 1) IBM T J Watson Research Ctr, Yorktown Hgts, NY; 2) Lebanese American University, School of Medicine, Beirut 1102 2801, Lebanon; 3) Harvard School of Public Health, Boston, MA, USA.

The extreme weather events of the Younger Dryas that left Arabia and most of the southern Levant dry drove Natufian expansion from the southern Levant to the Negev, North East Levant, and Mesopotamia while other cultures emerged in the Zagros and in Anatolia. The first Sumerian city states were established around 6 BCE, and the Dilmun culture in Arabia emerged as a major trading power connecting Sumer to the Harrapan civilization. Besides material remains, many of these cultures, including Natufians, left human remains whose genetic information provides geographical and chronological records of human migration and admixture starting nearly from the time of post glacial expansions to modern times. In this study, we sought to explore the population genetics of the Arabian Peninsula, identify likely ancient source populations, and investigate evidence of ancient migrations and admixture using PCA, ADMIXTURE,  $f_3$ , ALDER, and LDA. ADMIXTURE identified two major contributors to the modern Arabian peninsula populations: an early expansion marked by Natufian aDNA samples, and a component Persian Gulf associated component. PCA distinguishes between the Natufian genetics and the Arabian Peninsula group that ADMIXTURE combines. Gumuz and Somali admixture impacts the Peninsula, Egypt, and the Levant. Admixture between the Natufian genetic component and East Africa show significant negative  $f_3$  statistics admixing in Egypt, and similarly Egyptian and the Natufian genetic component admixing in East Africa in both directions. Ancient Anatolian genetics have penetrated the study region except for Yemen according to  $f_3$ . While we found little gene flow as a candidate for Indo-European admixture in any direction, we did see patterns of expansions carrying Natufian genetics that marked expansion and admixture aligns with that of the proto-Semitic language.

**2306T****Evolutionary patterns of long non-coding RNAs with coding capacity of oligopeptides.**

*W. Lin<sup>1,2</sup>, Z. Wang<sup>1</sup>, Y. Li<sup>3,4</sup>*. 1) Key Lab of Computational Biology, CAS-MPG Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences, Shanghai, P. R. China; 2) University of Chinese Academy of Sciences, Beijing, P. R. China; 3) Shanghai Center for Bioinformation Technology, Shanghai Industrial Technology Institute, Shanghai, P. R. China; 4) Collaborative Innovation Center for Genetics and Development, Fudan University, Shanghai, P. R. China.

**Abstract Background** Long non-coding RNAs (lncRNAs) are characterized with insufficient protein-coding capacity and weak evolutionary constraints. Recently, a fraction of lncRNA transcripts have been detected to bind with ribosomes by deep sequencing, which implied the translational capacity of some lncRNAs. Our study aimed to identify the lncRNAs with function of coding oligopeptides in human, and revealed evolutionary characteristics and selective signatures of these coding lncRNAs. **Results** Putative ORFs of human lncRNAs from NONCODE, LNCipedia and MiTranscriptome databases were aligned with human oligopeptides from EROP-Moscow database. After strict filtering of ambiguous matching, five human lncRNAs were identified to encode known oligopeptides, including *NONHSAT052368.2*, *NONHSAT052369.2*, *NONHSAT052370.2*, *NONHSAT134945.2* and *NONHSAT125858.2*. The lengths of the coding lncRNA ORFs were consistent with that of their encoded oligopeptides. The tissue-specific expression patterns of the coding lncRNAs were strongly associated with the functions of corresponding oligopeptides, such as fertilization and immunity. Human coding lncRNAs were Simians-specific or Hominidae-specific and their ORFs were originated only in Hominidae species, which suggested that they have evolved recently. In Simians-specific coding lncRNAs, substitution rates were decreased upon the emergence of ORFs, indicating signatures of purifying selection on the ORFs. Furthermore, population genetics study based on the 1000 Genomes Project revealed that in most of the coding lncRNAs, nucleotide diversity was decreased along with significant signatures of purifying selection, compared with their neighboring genomic regions. However, *NONHSAT125858.2*, which encoded an oligopeptide involving in antigen recognition, showed a different pattern of balanced selection among the populations. **Conclusion** These results provided the evidence of coding capability for oligopeptides of human lncRNAs. Our study thus proposed a mechanism for creation of functional short peptides from lncRNAs during the Hominidae evolution, which may contribute to Hominidae-specific genetic novelties by tinkering with pre-existing non-coding genes.

**Ohana: Detecting selection in multiple populations by modelling ancestral admixture components.** *J.Y. Cheng*<sup>1,2</sup>, *F. Racimo*<sup>2,3</sup>, *R. Nielsen*<sup>1,2</sup>. 1) Department of Integrative Biology and Statistics, University of California, Berkeley, Berkeley, CA; 2) Natural History Museum of Denmark, University of Copenhagen, Denmark; 3) New York Genome Center, 101 Avenue of the Americas New York, NY 10013.

One of the most powerful and commonly used methods for detecting local adaptation in the genome is the identification of extreme allele frequency differences between populations. In this paper we present a new maximum likelihood method for finding regions under positive selection. The method is based on a Gaussian approximation to allele frequency changes, which allows it to account for interbreeding between populations and retains high power when the test populations are admixed. It can also simultaneously and efficiently compare multiple populations. We evaluate the method using simulated data and compare it to methods using summary statistics. We also apply it to a human genomic data set and identify loci with extreme genetic differentiation between major geographic groups. Most of the genes identified are previously known selected loci relating to hair pigmentation and morphology, skin and eye pigmentation, including the top two genes: *EDAR* and *SLC25A5*. In contrast to previous genomic scans, we include data from Aboriginal Australians, which provide us with additional power to detect selection specific to East Asians. Using this method, we can identify new candidate loci - like *CASC15*, involved in melanoma suppression - and narrow down on the likely causal SNPs in previously reported candidate regions - like *KCNB2*, involved in various neurological functions.

**INTRODUCTION:** There are a limited number of studies from Latin America that have included native populations mainly due to geographic limitations and ethical considerations when interacting with native communities to enroll them in research studies. This project, initiated by the Peruvian National Institute of Health in 2010, represents the first major effort at studying specific native and mestizo communities across Peru, including demographic history, and population migration patterns forming the basis of precision genomic medicine for the Peruvian people. A total of 953 participants from 30 communities (13 mestizo and 17 native) were enrolled in this study, of which we have generated genotype array data for 171 and high coverage whole genome sequence data on 150. **RESULTS:** Our cohort of individuals, including the mestizos, has a much greater contribution from Native American ancestry than previous large-scale sequencing studies. We were able to construct a migration and diversity topography of Peru, which revealed that major cities harbor a high degree of genetic diversity independent of European contributions. Further, using identify-by-descent networks, we illustrate that during pre-Inca, Inca, and Spanish administration the Andean region was central to the population structure of Peru, while post-Spanish independence, the population dynamics seem to shift towards the coast, consistent with history. This is also consistent with high altitude adaptation leading to reduced gene flow into the Andes. We also demonstrate fine-scale population structure within the mestizo communities, identifying admixture between Native American communities in addition to an increase European contribution, both of which need to be considered when performing GWAS and personalized medicine programs. **CONCLUSION:** The genetic background of Native Americans has spread worldwide including in United States. It is expected that almost one million immigrants will come from Andean countries with high levels of Native American background. This population will be classified as "Hispano/Latino" in many studies in United States, but this group is a mixture of individuals with different levels of Native American ancestry and from different Native American sources. For this, we need to better understand the genetic variation and architecture of these native populations, migration patterns, and ethno geographical studies.

**MixFit: Methodology for computing ancestry-related genetic scores at the individual level and its application to the Estonian and Finnish population studies.** *T. Haller<sup>1</sup>, L. Leitsalu<sup>1</sup>, M. Nuotio<sup>2</sup>, T. Esko<sup>3</sup>, D. Boomsma<sup>4</sup>, K. Kyvik<sup>5</sup>, T. Spector<sup>6</sup>, M. Perola<sup>1,2,6</sup>, A. Metspalu<sup>1</sup>.* 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) University of Helsinki, Helsinki, Finland; 3) Vrije University, Amsterdam, Netherlands; 4) University of Southern Denmark, Odense, Denmark; 5) Kings College London, London, United Kingdom; 6) National Institute for Health and Welfare, Helsinki, Finland.

Ancestry information at the individual level is a resource for personalized medicine, demographical and history research, and for tracing back personal history. We report a new method for quantitatively determining personal genetic ancestry based on genome-wide data. Numerical ancestry component scores are assigned to individuals based on comparisons with reference populations. These comparisons are conducted with an existing analytical pipeline making use of genotype phasing, similarity matrix computation and our addition - multidimensional best fitting by MixFit. The method is demonstrated by studying Estonian and Finnish populations in geographical context. We show differences in the genetic composition of these close European populations and how they have influenced each other. We determine ancestry component distribution by geographical region for Estonia and Finland to highlight how these populations have interacted with their neighbors. Sorting the individuals by the birth date allows investigation of time-dependent trends in ancestry component distribution. We perform association analyses between ancestry components and anthropometric traits and report several associations. Our analytical methods apply to studying specific individuals but can be extended to population studies. We map the ancestral composition of Estonia and Finland in the geographical and historical context. The analytical pipeline has been published, MixFit is available at [www.geenivaramu.ee/en/tools/mixfit](http://www.geenivaramu.ee/en/tools/mixfit).

**2310F**

**Discovering rare variants and deciphering a population structure of 386 Mongolian individuals by whole-genome sequencing.** *C. Kim, S.K. Yoo, S. Kim, J.Y. Shin, J.S. Seo.* Genomic Medicine Institute, Seoul National University College of Medicine, Seoul, Gyeong-ki, South Korea.

Here, we present the whole-genome sequencing data for 386 Mongolian individuals which mainly composed of the Buryats and the Khalkha Mongols by average sequencing depth of 17X. We discovered 3.8 million novel single nucleotide polymorphisms (SNPs) which were not previously reported. Moreover, 965,663 SNPs which were rare (minor allele frequency < 0.5%) in the 1000 genome project phase 3 were low frequency or common in our dataset. Series of analysis demonstrated distinctive population structure of the Mongolians from the East Asians. We constructed robust imputation panel for Northern Asian populations which produces great imputation accuracy for rare (mean  $r^2$  of 0.82) and low frequency (mean  $r^2$  of 0.87) SNPs. We identified significant gene flow from the Buryats to the Finnish which was predicted to be occurred in 1,228 ( $\pm 87$ ) year. Moreover, 13.38% of Buryat admixture was predicted in the Finnish genome. In summary, this study illustrated advantage of whole-genome sequencing to build reference panels and to study population history.

**2311W****Large-scale whole genome sequencing of the Estonian population reveals new insights into population history and recent natural selection.**

*M. Metspalu<sup>1</sup>, L. Saag<sup>1</sup>, G. Hudjashov<sup>1,3</sup>, L. Paganì<sup>1,4</sup>, L. Kushniarevich<sup>1,5</sup>, V. Pankratov<sup>6</sup>, M. Mitt<sup>6</sup>, R. Andreson<sup>1</sup>, M. Kals<sup>2</sup>, D. Lawson<sup>2</sup>, T. Esko<sup>2</sup>, R. Mägi<sup>2</sup>, A. Metspalu<sup>2</sup>.* 1) Evolutionary Biology, Estonian Biocentre, Tartu, Estonia; 2) Estonian Genome Center, University of Tartu, Tartu, Estonia; 3) Statistics and Bioinformatics Group, Institute of Fundamental Sciences, Massey University, Palmerston North, New Zealand; 4) Department of Biological, University of Padova, Italy; 5) Integrative Epidemiology Unit, School of Social and Community Medicine, 7 University of Bristol, Bristol BS8 2BN, UK; 6) Institute of Genetics and Cytology of the National Academy of Sciences of Belarus, Minsk, Belarus.

Altogether 2244 whole genomes of geographically diverse individuals from Estonia were sequenced to a median depth of 30x using Illumina HiSeq with TruSeq PCR-free library preparation method. We found 19M SNVs and 6.6M indel variants with allele count larger than two of which 8.4M were novel. To study the fine-scale genetic structure of the Estonian population, we concentrate on a subset of the genomes (N=436), which comprehensively cover rural Estonia to minimize the mixing effect of historical urbanization. We will make an effort to mine the genealogical trees to fine-tune the analysis and exclude outliers. We further combine these genomes with a pan Eurasian panel of high coverage genomes from hundreds of populations. Using haplotype and allele frequency based methods we show that the genetic structure within Estonia is largely in line with the division of *inland* vs. *maritime* Estonia what has been proposed based on archaeological findings. Furthermore, we identify and quantify the relative contributions of the three major genetic domains of the European gene pool in Estonians and estimate split times from linguistically and geographically adjacent populations. We use Finestructure and inter-population doubleton distribution to reveal patterns of genetic sharing between Estonians and other European populations and infer population history in a series of population splits and admixture events in pre-historic and historic times. We used IBDNe to estimate recent changes in effective population size across local communities. And finally, we use the novel Singleton Density Score approach to reveal very recent changes in allele frequencies/natural selection in the Estonian population and compare the results to those found in UK10K. .

**2312T****Association of VASP polymorphisms and infectious disease burden in global populations and identification of candidate resistance haplotypes in sub-Saharan Africa.** *M. Phun, B. Rosenn, D. Glenn, D. Rupasinghe, J. Church, D. Zuzga.* Biology, La Salle University, Philadelphia, PA.

Pathogens employ numerous strategies to breach epithelial barriers. One critical target of pathogens is the host cell cytoskeleton. Pathogens induce cytoskeletal remodeling to disrupt tight junctions and increase the permeability of the epithelium to gain access to underlying tissue. Alternatively, the cytoskeletal machinery may be directly co-opted to facilitate the attachment, invasion, or intracellular motility of pathogens. The vasodilator-stimulated phosphoprotein (VASP) is a processive actin polymerase that induces membrane remodeling through the polymerization of actin cytoskeletal filaments. Interestingly, VASP function is regulated by numerous pathogens to induce remodeling of host cells. If VASP is indeed a conserved target of pathogens, it is plausible that evolutionary pressure on host cells would select for resistant variants of VASP that impair the ability of pathogens to co-opt VASP function. To investigate this possibility, we determined the minor allele frequency (MAF) of VASP single nucleotide polymorphisms (SNPs) across 26 global populations. A heatmap was then constructed to represent the minor allele frequency of >400 SNPs, which revealed increased minor allele frequency in Sub-Saharan African populations that also exhibit disproportionately high burdens of infectious disease compared to global populations. Next, SNPs exhibiting increased MAF in Sub-Saharan African populations and SNPs predicted to impact VASP function were employed in linkage disequilibrium (LD) analysis. SNPs found in LD were then used to reconstruct VASP haplotypes. These haplotypes may represent unique alleles that provide resistance to infectious disease. Future studies will examine the effect of VASP haplotype expression on host-pathogen interactions *in vitro*.

Southeast Asian Malays has historically been considered as a genetically distinct population, although there is emerging evidence to suggest that the genetic architecture is an admixture of four major ancestral populations, comprising the Austronesian, Proto-Malay, East Asian and South Asian. Here we attempt to formally establish the genetic membership of different groups of Southeast Asian Malays, from city-dwelling cosmopolitan Malays to indigenous Malay groups that still rely on the practice of hunter-gatherer subsistence and reside in primary forests. By analyzing at least 2 million autosomal SNPs across the genomes of 40 individuals from 3 indigenous groups and 1 cosmopolitan Malay group, we quantified the extent of genetic differentiation between the city dwellers and forest inhabitants. Our results revealed that the indigenous Malays were genetically more distinct to cosmopolitan Malays, than Northern Gujarati Indians from Southern Tamil Indians, despite the population divergence time between two indigenous Negrito populations to be less than 2KYA, and between the Senoi and Negritos to be less than 4KYA. Thus, even though the divergence between indigenous Malay groups was very recent, differential environmental exposures have introduced substantial variations in the genomes of these indigenous groups.

**Mitogenomes sequencing: Reveals huge diversity in human maternal lineages of Jammu and Kashmir, India.** *I. Sharma*<sup>1</sup>, *V. Sharma*<sup>1</sup>, *P. Kumar*<sup>2</sup>, *E. Rai*<sup>1</sup>, *M. Vilar*<sup>3</sup>, *S. Sharma*<sup>1</sup>. 1) Department of Biotechnology, Shri Mata Vaishno Devi University, Katra, Jammu and Kashmir, 182320, India; 2) Institute of Human Genetics, University of Jammu, Jammu and Kashmir, 180006, India; 3) Human Genographic Project, National Geographic Society, USA.

Jammu and Kashmir (J&K) is a Northern state of the Indian subcontinent. The Societal structure of population is governed by a large number of religious and endogenous ethnic groups. It is believed that J&K had served as a corridor, due to its strategic location in the Himalayan region, for deep in time migrations as well as had been route of various invaders. It is expected that in each spate, invaders brought their own distinct type of gene pool leading to admixture and present day population structure of the region. It's been proposed many a times that most of the migrations, especially invasions, had been male specific thus maternal gene pool of India is relatively conserved while paternal gene pool is relatively diverse. We carried out this study to find the diversity in maternal gene pool of J&K-India. DNA from blood of 83 individuals was subjected to complete mitogenome sequencing, outsourced from Medgenome Labs Pvt. Ltd. DNA is used to perform targeted amplification of the mitochondrial genome by long-range PCR, library was prepared using Illumina TrueSeq kits, and then sequenced to more than 1000X coverage. The sequences obtained were aligned to revised Cambridge mitochondrial Reference Sequence (rCRS) to identify variants in genome. The variants were analysed to assign maternal haplogroups to each individual. We found high diversity with some of new lineages, in the maternal gene pool of this region. Different ethnic groups are the amalgamation of M, U, H, W, R, K, F, D, T, A, C and I haplogroups. This provides genetic evidence that this region has acted as corridor deep in time as well to many recent events; however it has not been restricted to male mediated gene flow. IS\*, ER and SS acknowledge Human Genographic Project and National Geographic Society, USA for providing grant for the study. .

**Recent changes in contemporary effective population size from identical by descent segments.** A. Urnikyte<sup>1</sup>, A. Molyte<sup>1</sup>, V. Kučinskas<sup>1</sup>, Z.A. Kučinskienė<sup>1</sup>. 1) Department of Human and Medical Genetics, Faculty of Medicine, Vilnius University, Santariskiu St. 2, LT-08661 Vilnius, Lithuania; 2) Department of Physiology, Biochemistry, Microbiology and Laboratory Medicine, Faculty of Medicine, Vilnius University, M. K. Čiurlionio St. 21, LT-03101 Vilnius, Lithuania.

**Introduction:** Analysing the effective population size ( $N_e$ ) in different groups of a small specific population we can obtain an insight into the demographic history and dynamics of modern human populations as well as better understanding of known mechanisms of microevolutionary processes. The contemporary Lithuanian population is composed of a complex mixture of former Baltic tribes and states. In this study we aimed to estimate the recent effective population size, by using inferred long segments of identity by descent (IBD), and estimate the effective/census size ratio in the Lithuanian population and to reconstruct the recent past events between the two main ethnolinguistic groups (Aukštaičiai and Žemaičiai) of the Lithuania, since historically these groups probably developed over a long period of time as two independent Baltic tribes. **Methods:** Single-nucleotide polymorphism (SNP) genotyping of 295 samples was performed with an Illumina 770K HumanOmniExpress-12v1.1 array. To infer the history of the recent effective population size we used a non-parametric method, based on the Wright–Fisher discrete-generation model, implemented in the open-source IBDNe v. 04Sep15.e78 software package. **Results:** The recent  $N_e$  values were obtained for 50 generations ago with 95% confidence intervals (CI), assuming a generation time of 25 years. The evaluated  $N_e/N$  ratio was 0.125 (95% CI [0.077; 0.271] for  $g = 2$  (corresponds to 1941), 0.114 (95% CI [0.065; 0.280] for  $g = 1$  (corresponds to 1966), and 0.124 (95% CI [0.065; 0.341] for  $g = 0$  (corresponds to 1991). The estimates of  $N_e$  were approximately one-tenth of the Lithuanian census population size. The reconstructed past events between the two main ethnolinguistic groups (Aukštaičiai and Žemaičiai) of Lithuania showed differences between the groups. **Conclusions:** The obtained values of  $N_e/N$  ratios are small (0.1) compared with other genetics-based estimates between 0.21–0.65. Natural levels of fluctuations such as variance in size, reproduction, sex ratio, and the degree to which generations overlap probably caused the small values of  $N_e/N$ . The true effective size might be contained within the bootstrap confidence interval. Our results will provide comprehensive implications for further fundamental genomic and evolutionary studies. This study is part of the LITGEN project, which was approved by the Vilnius Regional Research Ethics Committee No. 158200-05-329-79, date: 2011-05-03.

**Selection analysis in Chileans identify adaptation signals in Native Americans, highlighting regulatory processes.** L. Vicuña<sup>1</sup>, S. Eyheramendy<sup>1</sup>, F. Martínez<sup>2</sup>. 1) Department of Statistics, Pontificia Universidad Católica de Chile, Santiago, Región Metropolitana, Chile; 2) Departamento de Antropología, Pontificia Universidad Católica de Chile, Santiago, Región Metropolitana, Chile.

Detection of positive selection signatures in populations around the world is helping to uncover human demographic history as well as the genetic basis of diseases. In addition, genetic admixture has been shown to play an important role in shaping human diversity. We look for local adaptation signatures left by ancient hard-sweeps in the admixed Chilean population by performing five statistical tests genome-wide. Further, we search for post-admixture signatures left by soft-sweeps by identifying regions with significant deviations in the mean local Native-American ancestry. These analyses identify novel and previously-reported candidate genes for selection. We also perform enrichment analysis of variant categories in region under selection, and find that signatures inherited from Native-Americans are especially enriched in categories affecting gene expression regulation. Moreover, we find that, for most tests and categories, selected regions have a higher mean local Native-American ancestry, with regulatory variants being among the highest. Finally, through structural spatial analysis, we find non-synonymous variants that are highly differentiated between Native-Americans, Europeans and Chileans, which are associated with high-prevalence diseases among Chileans, like Chagas disease and severe influenza-A (H1N1) infection.

**Analysis and findings in high-depth target sequencing of over 20000 individuals in China.** *H. Xu<sup>1</sup>, L. Sun<sup>2</sup>, X. Jin<sup>1</sup>, J. Akey<sup>3</sup>.* 1) BGI-Shenzhen, Shenzhen, China; 2) Department of Dermatology, Anhui Medical University, China; 3) Princeton university.

To comprehensively delineate population genetics in the Chinese population, we reanalyzed ~1300 genes of ~5Mb in the coding regions and Major Histocompatibility Complex (MHC) of 5-Mb in ~20000 individuals of Han Chinese ancestry with ~45x coverage. We identified ~450000 single-nucleotide variants (SNVs), the majority of which were rare, previously unknown and population-specific. We identified loss-of-function mutations and explored effects of rare protein-truncating variants, which might improve medical and functional interpretation in these regions. We showed fine-scale population structures within China by analyzing common and rare variants. Demography histories were inferred with these 20000 samples of target sequencing, comparing to the results of 3 population models combining large-scale Chinese, African-American and European-American samples. We are also investigating introgression of archaic segments in MHC regions, suggesting impacts of selected introgression of functionally advantageous genes in the immune system.

**Standardized visualization of demographic history.** *Y. Zhou, S. Browning.* University of Washington, Seattle, WA.

Standardized visualization of population history is an urgent need for both theoretical studies and data interpretation in the field of population genetics. Benefiting from the growing amount of available genetic data from populations all over the world, the demographic history of the target population(s) can be fully understood in relation to other reference populations. Usually, these studies need to give the historical relationship among related populations to interpret their conclusions, or as a part of their conclusions. The common solution for visualizing population history is to create the figures line by line with drawing software, and no existing software can provide a standardized visualization for population demographic history. In this study, an R package named *plotms* is developed to visualize the population demographic history in a standardized way. *plotms* is built on *ms*'s input language for demographic history, which can be applied to arbitrary numbers of populations with changing population sizes and any number of waves of migrations. *plotms* is also very easy to use and it currently can read the input of *ms*, MaCs, Cosi, and *msa*. The input from more simulation languages will be supported in the future..

**Principal components analysis with sensible weighting of sequencing variants: Improved inference of fine scale population structure with whole genome sequencing data.** *T.A. Thornton, J.L. Kirk.* Biostatistics, University of Washington, Seattle, WA.

There is great potential for rare variants to be a powerful resource to delineate fine-scale population structure patterns. Whole genome sequencing (WGS) data has an abundance of rare variants, and recent work has demonstrated that rare variants can have differential population structure and greater geographic clustering than common variants. Existing principal components analysis (PCA) methods, such as EIGENSTRAT (Price et al., 2006), have been shown to work well for population structure inference with common variants. However, these PCA-based approaches can fail when applied to WGS data due to the abundance of extremely low frequencies resulting in the genetic relatedness matrix (GRM) used for the PCA becoming unstable. Existing PCA-based approaches for population structure inference give weights to variants according to minor allele frequency (MAF), where variants with the lowest MAF receive the largest weights in the analysis. In reality, for most variant MAF is a poor proxy for ancestry. Here, we propose a new method for population structure inference using whole genome sequencing data where informative weighting of variants is used, where the weight of a variant is based on the amount of information provided for delineating population structure. The method incorporates both entropy and mutual information from classical information theory in statistics. In applications to the 1000 Genomes Project, we demonstrate that our new approach outperforms existing PCA-based approaches and is able to delineate both continental and fine-scale population structure.

**Assessing human diversity patterns using in-silico discovered Alu and LINE-1 mobile insertion elements in the Simons Genome Diversity Project.** *S. Watkins<sup>1</sup>, J. Feusier<sup>1</sup>, C. Goubert<sup>1</sup>, S. Mallick<sup>2</sup>, D. Reich<sup>2</sup>, L.B. Jorde<sup>1</sup>, The SGDP consortium.* 1) Department of Human Genetics, University of Utah, Salt Lake City, UT 84112, USA; 2) Department of Genetics, Harvard Medical School, Boston, Massachusetts 02115, USA.

To assess the population distribution and characteristics of young Alu and LINE-1 mobile element insertions (MEIs), 296 human whole-genome sequences from the Simons Genome Diversity Project (SGDP) were analyzed with the mobile element locator tool (MELT). Jointly-called raw non-reference MEI insertions were screened to remove markers showing strong deviation from Hardy-Weinberg equilibrium, markers with multiple mis-inheritances in a three-generation pedigree, and markers lacking target-site duplications. This WGS sequence-based in-silico discovery process yielded 12,800 Alu and 1,982 LINE-1 elements that are strictly identity-by-descent markers and free from population ascertainment bias. These in-silico based Alu allele frequency estimates were concordant with estimates from traditional PCR-based MEI genotyping. Principal components analyses based on allele-sharing genetic distance estimates for Alu and LINE-1 data sets were congruent with CpG-free and transversion-only SNV data sets. The proportion of Alu and LINE-1 sites that were heterozygous in each individual was highest in Africa, lower in Eurasia, and lowest in the New World. Outside of Africa, heterozygosity decreased in a linear fashion with increasing distance from the African centroid. Admixture analysis using polymorphic Alu insertions successfully quantified world admixture patterns, distinguished San and Mbuti from other Africans, and identified a cline of native American ancestry across northern Asia that was maximal in populations of northeastern Russia. These results demonstrate that MEIs can be reliably ascertained from whole-genome sequences and that they yield results highly concordant with those of other genotyping methods.

**2321T****Archaic-genome-agnostic detection of introgressed segments.** S.R.

Browning<sup>1</sup>, Y. Zhou<sup>1</sup>, B.L. Browning<sup>2</sup>. 1) Department of Biostatistics, University of Washington, Seattle, WA; 2) Division of Medical Genetics, Department of Medicine, University of Washington, Seattle, WA.

We present new methodology and software for detecting archaic introgressed segments, such as those from Neanderthals or Denisovans, in modern human genomes. Our method is similar to S\* [1] in that it uses a scoring algorithm based on linkage disequilibrium and does not require knowledge of the archaic genome sequence. This makes it possible to detect introgressions from as yet unsequenced archaic populations, and to detect introgression when the archaic reference genome has poor sequence coverage in a region or is diverged from the introgressed archaic genome. Unlike S\*, our method can be applied to arbitrarily large samples, enabling detection of low frequency introgressed segments. Our scoring procedure utilizes a genetic map and adjusts for variant density, which permits a single score threshold to be used throughout the genome. In addition, our approach can analyze an entire chromosome without use of a sliding window and thus can gain power when introgressed segments are tiled across a longer region. To test our method, we simulated data on 4000 European individuals and 100 outgroup African individuals, following published models of human and Neanderthal demographic history, with 3% introgression. Our method found 1/3 of the introgressed material, at a false discovery rate of 7.2%. Although some introgressed segments cannot be detected because they are too short, our agnostic method captures a substantial portion of the introgressed sequence. As proof of principal, we apply our method to the 4000 whole genome sequenced individuals of European ancestry from the UK10K study, as well as to populations from the 1000 Genomes Project and to Papuans from the Simons Genome Diversity Project. In the UK10K data, the introgressed segments that we detect comprise on average 0.4% of each individual's genome, and 74% of the detected introgressed variants match the Neanderthal reference genome. [1] Plagnol, V. and J.D. Wall, *Possible ancestral structure in human populations*. PLoS Genetics, 2006. 2:e105.

Ancient DNA (aDNA) has provided a powerful tool for assessing the temporal stability of populations within a geographic locale. In much of mainland Europe, aDNA has revealed a relatively dynamic population history from the Neolithic period through the Bronze Age. Due to their relative isolation, island populations may in general not experience the same population dynamics as mainland populations. The island population of Sardinia in particular has been hypothesized to have a relatively stable and continuous population from the early Neolithic, largely on the basis of modern Sardinian DNA. Here we directly assess continuity using genome-wide capture data (~1.2 millions SNPs) of 26 ancient humans from the island of Sardinia spanning the Neolithic, Copper Age, and Bronze Age, including individuals from the Nuragic culture. Through analyzing read-level DNA damage patterns and estimating modern contamination levels, we authenticate these ancient DNA sequences and removed outlier loci and individuals for downstream analyses. Projecting these ancient individuals on to modern axes of genetic variation, as defined by principal component analysis on a large-scale reference dataset of modern human populations from Sardinia, Europe and the Middle East, reveals no obvious temporal structure within Sardinia within this long time frame. Consistent with previous hypotheses of early migrations in Europe, we observe clustering of these ancient individuals with previously published sequences of ancient humans associated with an "early farming" Neolithic culture. Through the application of multiple population genetic methods and exploratory data analysis tools we find that relative to mainland Europe there has been population stability within the island of Sardinia. Beyond shedding light on Sardinian population history, the relative stability we infer is important for understanding the local frequencies of disease susceptibility alleles.

**2323W****Impacts of European colonization on an indigenous community in**

**British Columbia.** A.C. Owings<sup>1</sup>, B. Petzelt<sup>5</sup>, J.S. Cybulski<sup>4</sup>, R.S. Malhi<sup>1,2,3</sup>. 1) Program in Ecology, Evolution and Conservation Biology, University of Illinois at Urbana Champaign, Champaign Urbana, IL; 2) Department of Anthropology, College of Liberal Arts and Sciences, University of Illinois, Urbana-Champaign, IL; 3) Carl R. Woese Institute for Genomic Biology, University of Illinois, Urbana-Champaign, IL; 4) Research Division, Canadian Museum of History, Gatineau, Quebec, Canada; 5) Metlakatla Treaty Office, PO Box 224, Prince Rupert, British Columbia V8J 3P6, Canada.

Excavations in some of the archaeological sites in the Prince Rupert Harbour region, British Columbia, Canada, have yielded the skeletal remains of over 250 pre-European contact individuals. Their connection to modern living descendants in the area has been demonstrated through DNA analysis and shows genetic continuity back to the late Pleistocene. The sites also enable study of the genetic effects of European colonization. A recent autosomal DNA study found a 57% reduction in effective population size in the living descendants compared to the ancients. Here we present mitochondrial DNA (mtDNA) data for 65 of the ancients and 53 presumed living descendants using both Sanger sequencing and an Illumina MiSeq high-throughput methodology. We find shared haplotypes between the ancient and living groups as might be expected, but some unique haplotypes in each group as well, indicating that some ancient haplotypes may have been lost over time and some may have been gained through gene flow. In addition, we find that mtDNA diversity has decreased by ~50% in one of two living descendant communities, but increased in the other compared to the ancient population. We also present Y-chromosome STR data for 50 ancient and 44 living people obtained through the use of multiplexed Y-STR kits. All ancient individuals had Y-chromosome haplogroups that are typically found in the Americas. Genetic diversity measures such as thetaS and haplotype diversity for the ancient and living individuals show a decrease in Y-chromosome diversity in the living population by roughly 20%. However, the sample size of the living individuals is small due to the ~55% non-indigenous Y-chromosome haplogroups. The Bayesian Skyline Plot method in the program BEAST was used to simulate the demographic changes over time. This is among the first studies to quantify the genetic effects of colonization in an indigenous population in the Americas by the analysis of ancient and living individuals sampled through time. A similar study design can be applied to other indigenous communities to understand the impacts of European colonization - one of the most significant human demographic events in history.

**2324T****Tracing the origin of ancient polynesian human genomes across the**

**Pacific.** P. Salazar-Fernandez<sup>1</sup>, M. Avila-Marcos<sup>2</sup>, E. Hagelberg<sup>3</sup>, K. Sandoval<sup>1</sup>, C.D. Quinto-Cortes<sup>1</sup>, M. Moraga<sup>4</sup>, T. Parks<sup>5</sup>, A. Mentzer<sup>5</sup>, A. Moreno-Estrada<sup>1</sup>. 1) National Laboratory of Genomics for Biodiversity, Irapuato, Guanajuato, Mexico; 2) International Laboratory for Human Genome Research, Queretaro, Mexico; 3) University of Oslo, Norway; 4) University of Chile, Chile; 5) University of Oxford, United Kingdom.

In 2010, mitochondrial DNA extracted from two ancient skulls found in southern Brazil belonged to the haplogroup B4a1a1a, exclusively found in Polynesia. Radiocarbon analyses indicated that these individuals most probably died before the 19th century, prior to any registered transport of Polynesian people to South America by European vessels. Further genome-wide analyses showed a complete Polynesian ancestry for both samples, with Cook Islands as the closest source population. However, scarcity of genotyping data from modern Polynesian populations posed a major limitation for inferring a more specific place of origin for said skulls. Here, we re-analyze these ancient DNA samples using an extended reference panel that comprises over 475 genotyped samples from 18 different locations across the Pacific Ocean. With this data we explore the genetic affinities of the Botocudo skulls at a finer scale to potentially pinpoint their genetic origin, and we demonstrate the importance of assembling diverse genetic reference panels to shed light on the evolutionary past of human remains devoid of archeological context.

**2325F**

**MHC-dependent mate selection within the Health and Retirement Study (HRS).** Z. Qiao<sup>1</sup>, J. Powell<sup>2</sup>, D. Evans<sup>1,3</sup>. 1) University of Queensland Diamantina Institute, Translational Research Institute, Brisbane, Queensland, Australia; 2) Institute for Molecular Biosciences, University of Queensland, Brisbane, Queensland, Australia; 3) Medical Research Council (MRC) Integrative Epidemiology Unit, School of Social & Community Medicine, University of Bristol, Bristol, United Kingdom.

Disassortative mating refers to the phenomenon in which individuals with dissimilar genotypes and/or phenotypes mate with one another more frequently than would be expected by chance. Although the existence of disassortative mating is well established in plant and animal species, the only documented example of negative assortment in humans involves dissimilarity at the Major Histocompatibility (MHC) locus. Unfortunately previous studies investigating mating patterns at the MHC have been hampered by limited sample size and contradictory findings. Inspired by the sparse and conflicting evidence, we investigated the role that the MHC region played in human mate selection using genome-wide association data from 597 European American spouses from the Health and Retirement Study (HRS). First we treated the MHC region as a whole, and investigated genomic similarity between spouses using three levels of genomic variation: SNPs, classical HLA alleles (both 4-digit and 2-digit classifications), and amino acid polymorphisms. The extent of MHC dissimilarity between spouses was assessed using a permutation approach. Second, we investigated fine scale mating patterns by testing for deviations from random mating at individual SNPs, HLA genes, and amino acids in HLA molecules. Third, we assessed how extreme the spousal relatedness at the MHC region was compared to the rest of the genome, to distinguish the MHC-specific effects from genome-wide effects. The multi-locus relatedness analyses showed no significant difference in MHC relatedness between spouses and non-spouse pairs at either the level of SNPs (relatedness coefficient,  $R=0.013$ , one-sided  $p=0.638$ ) or classical MHC alleles ( $R=-0.025$ ,  $p=0.258$ ); however, analyses based on HLA amino acid polymorphisms revealed stronger evidence of dissimilarity ( $R=-0.046$ ,  $p=0.095$ ). In terms of fine mapping, we did not find evidence of excess dissimilarity between spousal pairs at individual SNPs, classical HLA genes or amino acids after adjustment for multiple testing. However, the MHC dissimilarity among spouses was extreme relative to the rest of genome (i.e. only 1.6% of the randomly sampled genomic windows exhibited more extreme dissimilarity than the MHC region), but was as extreme in opposite-sex non-spousal pairs, and therefore the dissimilarity could not be attributed to mate selection. Despite the long-standing controversy, our analyses did not support a significant role of MHC dissimilarity in human mate choice.

**Pseudogenes in the mouse lineage: Transcriptional activity and strain-specific history.** P.M. Muir<sup>1,2,3</sup>, C. Sisu<sup>5,7</sup>, A. Frankish<sup>8</sup>, I. Fiddes<sup>9</sup>, M. Diekhans<sup>9</sup>, T. Keane<sup>9</sup>, M. Gerstein<sup>4,5,6</sup>. 1) Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT; 2) Systems Biology Institute, Yale University, West Haven, CT; 3) Integrated Graduate Program in Physical and Engineering Biology, Yale University, New Haven, CT; 4) Program in Computational Biology and Bioinformatics, Yale University, New Haven, CT; 5) Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT; 6) Department of Computer Science, Yale University, New Haven, CT; 7) College of Health and Life Sciences, Brunel University London, Uxbridge, London, UK; 8) European Molecular Biology Laboratory, European Bioinformatics Institute, Wellcome Genome Campus, Hinxton, Cambridge, UK; 9) University of California, Santa Cruz, CA.

Pseudogenes are ideal markers of genome remodelling. In turn, the mouse is an ideal platform for studying them, particularly with the availability of transcriptional time course data during development (just completed in phase 3 of ENCODE) and the sequencing of 17 strains (completed by the Mouse Genome Project). Here we present a comprehensive genome-wide annotation of the pseudogenes in the mouse reference genome and associated strains. We compiled this by combining manual curation of over 10,000 pseudogenes with results from automatic annotation pipelines. Also, by comparing human and mouse, we annotated 327 new unitary pseudogenes in human with respect to mouse and 210 unitary pseudogenes in mouse with respect to human. (We make our annotation available through a resource website mouse.pseudogene.org.) The overall mouse pseudogene repertoire (in the reference and strains) is similar to human in terms of overall size, biotype distribution (80% processed, 20% duplicated) and top family composition (with many *GAPDH* and ribosomal pseudogenes). However, notable differences arise in the age distribution of pseudogenes with multiple retro-transpositional bursts in mouse evolutionary history and only a single one in human. Furthermore, in each strain ~20% of the pseudogenes are unique, reflecting strain-specific functions and evolution – e.g. the pseudogenization of taste receptors is linked to a change in the diet of the NZO strain. Finally, we find ~15% of the pseudogenes are transcribed, a fraction similar to human. Furthermore, we show that processed pseudogenes are commonly associated with highly transcribed genes. While this can be observed through all of mouse development, the relationship is strongest not at the early embryo stages but later on, after depletion of maternal RNA.

**2327T****Inference of allele-frequency trajectory histories from present genomes.**

Y. Field<sup>1,2</sup>, J.K. Pritchard<sup>1,2,3</sup>. 1) Genetics, Stanford, Stanford, CA; 2) Howard Hughes Medical Institute, Stanford, Stanford, CA; 3) Biology, Stanford, Stanford, CA.

The fundamental objective of population genetics is to understand the dynamics, determinants and consequences of the change in frequency of genetic variants in populations over time. This has broad implications to the studies of human evolution, human history, and medical genetics. Methods have been developed to infer recent changes in allele frequencies from present-day genome data. However, whereas determinants of allele frequency trajectories—from demography to natural selection—are highly dynamic in nature, these methods are limited to infer a single frequency change integrated over an estimated time window and lack temporal resolution. Here we present TRAJECTORY, a coalescent-based statistical method that infers recent changes in allele frequencies from present-day genomes with user-defined temporal resolution. TRAJECTORY models the frequency trajectory as two population size history problems, corresponding to the haplotype groups of the target SNP. To this end we borrow modeling ideas from *fastNeutrino*, an efficient inference of population size histories. To account for recombinations and haplotype phasing error—both of which shuffle the haplotype histories of the derived and ancestral alleles—we extend on modeling ideas from the *Singleton Density Score*, a method that we previously developed to infer a single allele frequency change over a sample-dependent timescale. In addition to providing temporal resolution, TRAJECTORY improves on existing methods in terms of power and further allows for joint modeling of multiple sites to directly infer characteristic trajectories of polygenic adaptation. We will present the method, simulations, validations and example applications demonstrating the new temporal dimension of analysis provided by our method.

**2328F****SG10K: Insights into the genetic architecture of Singaporeans.**

C. Bellis<sup>1</sup>, I.D. Irwan<sup>1</sup>, C.A. Lin<sup>1</sup>, T.H. Koh<sup>1</sup>, C. Wang<sup>2</sup>, W.W. Soon<sup>3</sup>, A. Wilm<sup>4</sup>, C.C. Shih<sup>4</sup>, J. Liu<sup>1</sup>, SG10K Consortium. 1) Human Genetics, Genome Institute of Singapore, Agency for Science, Technology and Research of Singapore (A\*STAR), Singapore; 2) Computational and Systems Biology, Genome Institute of Singapore, A\*STAR, Singapore; 3) Next Generation Sequencing Platform, Genome Institute of Singapore, A\*STAR, Singapore; 4) Scientific and Research Computing, Genome Institute of Singapore, A\*STAR, Singapore.

The unique ethnic diversity inherent within the Singaporean population opens it up as an opportune cohort for population genetics studies. The Singapore population consists of three major ethnic groups; Chinese, Malay, and Indian, which together represent ~80% of the genetic variation across Asian populations. In 2015, the “SG10K project” was initiated with an overarching aim of sequencing the genomes of 10,000 Singaporeans. To date our collaborative partners include SingHealth Duke-NUS Institute of Precision Medicine, Singapore Eye Research Institute, Centre for Personalised and Precision Health, Tan Tock Seng Hospital, National University Health System and several Translational and Clinical Research Flagship Programmes (Heart failure, Parkinson disease). Our main objectives are to (1) comprehensively characterize genetic variation in Singapore population; (2) create a WGS reference panel for accurate genotype imputation in Asian population; and (3) generate a large control dataset for WGS-based genetic association study of diseases. We have adopted a shallow-pass sequencing approach, which on average will cover each base at a depth of approximately 15x. Our analytical pipeline hosted by the National Supercomputing Centre (NSCC), Singapore incorporates GATK (v3.6) and follows GATK best practices. Our initial analytical pipeline test was undertaken on n=1,059 genomes and required approximately 2-3 weeks compute time running on 20 reserved nodes at NSCC. We anticipate providing insight into genetic variation in the local Singaporean population following the first genotype calling pipeline test. Upon completion, this study will provide valuable genetic information to facilitate precision medicine initiatives in Singapore and will empower genetic studies of Singapore and Asian-centric diseases.

**SeleDiff: A scalable tool for testing and estimating selection differences between populations.** X. Huang<sup>1,2</sup>, M. Wang<sup>1,2</sup>, L. Jin<sup>1,3</sup>, Y. He<sup>1</sup>. 1) Chinese Academy of Sciences Key Laboratory of Computational Biology, Chinese Academy of Sciences-Max Planck Society Partner Institute for Computational Biology, Shanghai Institutes for Biological Sciences, Shanghai, 200031, China; 2) Chinese Academy of Sciences, University of Chinese Academy of Sciences, Beijing, 100049, China; 3) State Key Laboratory of Genetic Engineering and Ministry of Education Key Laboratory of Contemporary Anthropology, Collaborative Innovation Center for Genetics and Development, School of Life Sciences, Fudan University, Shanghai, 200433, China.

Genome-wide scan for natural selection is a classical challenge in human genetics. Currently, there are two popular kinds of approaches for detecting signals of natural selection from human genomes. One is based on extended haplotype homozygosity; the other is based on genetic diversity  $\theta$ . The time complexities of these approaches, however, are quadratic with respect to the number of variants or the number of samples. As more and more variants and samples become available in human populations, the quadratic time complexity would limit research community to fast detect signals of natural selection. Moreover, neither of these approaches could quantify the differences of the strength of natural selection between populations. Here, we implemented a scalable tool called SeleDiff for testing and estimating selection differences between populations. Using SeleDiff, we can analyze a simulated dataset containing 300,000 variants and 100,000 samples in 15.7 minutes (wall time) with less than four gigabytes of random access memory (OS: Red Hat Enterprise Linux Server release 6.3; CPU: AMD Opteron™ 6174). Running time analysis showed SeleDiff has linear time complexity with respect to both the number of variants and the number of samples. This linear time complexity would make SeleDiff a fast tool for quantifying signals of natural selection in genome-wide scan.

**2330T**

**Distribution of common and rare variants in an underrepresented population in public genomic databases and the possible impact in precision medicine.** C.S. Rocha<sup>1,3</sup>, B.S. Carvalho<sup>2,3</sup>, I. Lopes-Cendes<sup>1,3</sup>. 1) Department of Medical Genetics, School of Medical Sciences - Unicamp, Campinas, SP, Brazil; 2) Department of Statistics, Institute of Mathematics, Statistics and Scientific Computing; Unicamp, Campinas, SP, Brazil; 3) BRAINN - Brazilian Institute of Neuroscience and Neurotechnology.

Medical treatment is set on the average patient, which leads to inefficiency of some treatments in a proportion of the population. Precision Medicine (PM) has emerged as a concept in which scientific knowledge and technology will come together to provide the basis for more effective and personalized medicine. To implement PM, it is important to determine the genetic profile of a population as the distribution of rare and common variants may have different downstream implications in different population backgrounds. Therefore, we aim to determine the genomic profile of Brazilian individuals and compared it with data available from other population. We performed whole exome sequencing (WES) in 106 subjects and genotyped 264 individuals using the Affymetrix SNP 6.0 array. These are normal/reference individuals from the region of Campinas, SP, BRAZIL. Genomic data produced was deposited in two public databases ([www.bipmed.org](http://www.bipmed.org)), which are part of the Brazilian Initiative on Precision Medicine (BIPMed). Alternative allele frequencies (AAF) were calculated for each variant on both datasets. On the SNP-array study we compared the frequency from 4 populations provided by the manufacturer. Data from WES was compared with populations from the Genome Aggregation Database. In the WES study, we found 624,137 variants (SNVs and INDELs), among them 68,149 (10.9%) were not detected in any other population. Furthermore, 45.51% of the variants detected have AAF of less than 1%, 22.44% of the variants have AAF between 1% and 5%. Comparing variants from the WES study with Clinvar we found 193 variants classified as pathogenic and 33 variants classified as likely pathogenic. In the SNP-array study, the correlation analysis and the PCA showed that our dataset is closer to the CEU population, distant from CHB, JPT and more distant from YRI. We also found 9 SNPs in which the more frequent allele identified in other populations was the less frequent allele in the Brazilians or vice versa. Our results clearly indicate that there are differences in the genomic distribution of both rare and common variants in Brazilian individuals as compared to other populations, and demonstrate the importance of constructing a larger and geographically diverse panel of reference genomic datasets for both rare and common variants, especially for populations which are underrepresented in the currently available public genomic databases.

**2331F**

**Deep learning for reference-free inference of archaic local ancestry.** A. Durvasula<sup>1</sup>, S. Sankararaman<sup>1,2</sup>. 1) Department of Human Genetics, David Geffen School of Medicine, UCLA, Los Angeles, CA; 2) Department of Computer Science, UCLA, Los Angeles, CA.

Statistical analyses of genomic data from diverse human populations have demonstrated that modern human populations trace a small proportion of their genetic ancestry to archaic hominins such as Neanderthals and Denisovans. These analyses were enabled by the availability of archaic genome sequences. Several studies have suggested that archaic admixture has been common in the history of populations even though the ancestral archaic populations have not been identified. This observation motivates the problem of reference-free archaic local ancestry inference, i.e., inferring segments of the genome that trace their ancestry to an archaic population even in the absence of reference archaic sequences. Previous attempts at reference-free archaic local ancestry inference have relied on a small number of features or summary statistics (such as  $S^*$ ), which have limited power and a high false positive rate. Recent advances in deep learning permit the learning of complex, non-linear features that can be useful in a number of inferential tasks. Here, we present a deep neural network for archaic local ancestry inference. The architecture consists of 8 hidden layers (200, 100, 75, 50, 50, 50, 2, 2 nodes) that outputs to 2 neurons, a batch normalization layer, and a softmax activation layer. Each hidden layer is followed by a rectified linear unit activation and a dropout layer. We use coalescent simulations to train the network on a number of features that summarize patterns of genetic variation, amplifying the signal of deep divergence expected from archaic introgression. This allows fast and accurate inference of archaic introgression. We applied this method to 5 genomes from a sub-Saharan African population in a preliminary analysis and find that an average of 2.03% (SD: 0.38) of their genomes is labelled as archaic. This result is in line with previous estimates (Hammer et al. 2011) using less data and lower powered methods, but increases the resolution with which we can understand archaic hominin admixture and demonstrates the potential of directly using present-day human genomes to learn about archaic admixture.

**2332W**

**Variation and genetic control of mutation rates in house mice.** B.L. Dumont. The Jackson Laboratory, Bar Harbor, ME.

Mutation provides the ultimate source of all new alleles in populations, including variants that drive evolutionary adaptation and cause disease. At the same time, the *de novo* mutation rate is itself a quantitative genetic trait that displays striking differences between species and among individuals. Despite the central significance of this variation for genetics and evolution, little is known about the genetic causes of mutation rate heterogeneity or inter-individual variation in mutation rate. Toward these goals, I am conducting two parallel bioinformatic analyses of whole genome sequences from house mice. First, I am utilizing the Collaborative Cross (CC) 8-way recombinant inbred mouse panel as a forward evolution resource to study the accumulation of mutations over ~30 generations of organized outcrossing and inbreeding. I show that the number of accumulated mutations in the genomes of different CC lines varies 3.5-fold. This variation is driven, in large part, by the unique, dynamic genome captured in each CC breeding funnel. Building on this recognition, I perform a genome-wide scan for mutation rate modifiers and identify multiple putative mutator alleles that function in DNA repair and the cellular metabolism of genotoxic compounds. Second, I am mining high-quality genome sequences from 36 inbred laboratory strains to identify variants that are private to individual strains. These private alleles reflect recent germline mutation events that collectively mirror the action of mutational processes at work on a specific genetic background. I use this insight to show that the allelic spectrum of inherited mutations is variable among strains, with closely related strains sharing similar profiles. These findings reveal a genetic component to the nucleotide distribution of *de novo* mutations in the mouse genome. Together, these on-going investigations have unveiled marked complexity in germline mutation rate variation, with multiple genetic factors shaping both mutation frequency and spectrum.

**2333T**

**Patterns of shared signatures of recent positive selection across human populations.** *K.E. Johnson<sup>1</sup>, B.F. Voight<sup>2,3,4</sup>*. 1) Genetics and Gene Regulation Program, Cell and Molecular Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia PA; 2) Department of Systems Pharmacology and Translational Therapeutics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, PA; 4) Institute for Translational Medicine and Therapeutics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Scans for positive selection in human populations have identified hundreds of sites across the genome with evidence of recent adaptation. These signatures often overlap across populations, but the question of how often these overlaps represent a single ancestral event remains unresolved. Signals can be shared across populations, such as the lactase persistence haplotype across Europe; or unique to an individual population, like high altitude-adaptive mutations in Tibetans. If a single selective sweep spread across the globe, the same sweeping haplotype should appear in multiple populations, implying a common selective pressure across diverse populations and environments. Identifying such shared selective events is of fundamental interest, pointing to genomic loci and human traits important in recent history across the globe. Additionally, newly available genomic annotations could help attach these signatures to a potential gene and molecular phenotype that may have been selected across multiple populations. We performed a scan for positive selection using the integrated haplotype score (iHS) on 20 human populations from the 1000 Genomes Project (phase 3), and propose an additional correction for local recombination rate to iHS scans on genomic sequencing data. To create a catalog of shared (i.e., a common ancestral event) and unshared overlapping selective sweeps in these populations, we employed fastPHASE to cluster these haplotypes across populations. We observed more sharing than expected for every within-continent population pair, and with population pairs from every inter-continent grouping. The majority of shared sweeps occurred within a single continent (71%), though we did find instances of sweeps shared across multiple continents. Using additional genomic annotations, we connected multi-population overlapping sweep intervals with possible biological mechanisms at several loci. We identified potential new sites of adaptive introgression, including a shared sweep across Europeans and South Asians at the lincRNA *CT64*. At the glycoporphin locus containing *GYP A/GYP-B/GYPE*, associated with malarial resistance, we identified unshared sweeps in all continental groups studied. Finally, at the alcohol dehydrogenase cluster on chromosome 4, an established target of recent positive selection in East Asians, we identified an independent sweep in an African population whose haplotype is associated with alcohol dependence in African Americans.

**The landscape of genetic variation in Estonians.** *M. Kals<sup>1,2</sup>, T. Nikopenius<sup>1</sup>, R. Mägi<sup>1</sup>, N. Tõnisson<sup>1</sup>, A. Reigo<sup>1</sup>, T. Esko<sup>1,3</sup>, A. Metspalu<sup>1,4</sup>*. 1) Estonian Genome Center, University of Tartu, Tartu, Estonia; 2) Institute of Mathematical Statistics, University of Tartu, Tartu, Estonia; 3) Broad Institute of MIT and Harvard, Cambridge, Massachusetts, USA; 4) Department of Biotechnology, Institute of Molecular and Cell Biology, University of Tartu, Tartu, Estonia.

To describe genetic variation in the Estonian population, we combined 2,420 whole-genome sequencing (WGS) and non-overlapping 2,356 whole-exome sequencing (WES) samples from the Estonian Biobank of the Estonian Genome Center, University of Tartu (EGCUT). WGS individuals were selected randomly by county of birth, followed a PCR-free sample preparation. Libraries sequenced on the Illumina HiSeq X Ten with the use of 150bp paired-end reads to 30x mean coverage. WES samples were enriched for target sequences (Agilent Technologies; Human All Exon V5+UTRs) according to manufacturer's recommendations to a median depth of 70x Combination of WGS and WES data provides better insight to coding regions. EGCUT is a population-based biobank, containing almost 52,000 samples of the adult population (aged  $\geq 18$  years), which closely reflects the age, sex and geographical distribution of the Estonian population. From WGS data only, we identified more than 32M single-nucleotide variants (SNVs) and 2.5M short indels. Among 13M (1.8) novel SNVs (indels), 10M (1.1M) were singletons/doubletons, resulting in average 6,600 novel variants per individual. Furthermore, we compared the overlap of novel variants between 1000 Genome Project Phase 3 EUR panel, UK10K and the Genome of the Netherland Consortium (GoNL) and identified that >98% of the low-frequency ( $0.5 \leq \text{MAF} < 5\%$ ) and common ( $\text{MAF} \geq 5\%$ ) variants exist in the reference databases, but only <40% of the rare variants ( $\text{MAF} < 0.5\%$ ,  $\text{MAC}=1$  and  $\text{MAC}=2$  excluded) were observed in the other European populations. Adding WES samples and focusing on only coding regions (total sample size  $N=4,776$ ) increases the proportion of singletons/doubletons, but number of novel variants remained close to 40%. In summary, we have investigated the genetic variability in the Estonian population. We further estimate the number of expected actionable incidental findings per individual, profile structural variants and focus on functional variants.

**2335W**

**Gene expression predictive performance varies across diverse populations.** *L.S. Mogil, A. Badalamenti, H.E. Wheeler.* Biology, Loyola University Chicago, Chicago, IL.

For many complex traits, gene regulation is likely to play a crucial mechanistic role. How the genetic architectures of complex traits vary between populations and subsequent effects on genetic prediction are not well understood, in part due to the historical paucity of GWAS in populations of non-European ancestry. We used data from the MESA (Multiethnic Study of Atherosclerosis) cohort to study the genetic architecture of gene expression. The goal of this work is to optimize genetic prediction of gene expression within and across populations for use in gene based mapping methods like PrediXcan. Genotype and monocyte gene expression were available in African Americans (AFA, n=233), Hispanics (HIS, n=352), and Caucasians (CAU, n=578). We used elastic net modeling ( $\alpha=0.5$ ) with 10-fold cross validation to optimize genotypic predictors of gene expression in each population. The numbers of genes with 10-fold cross-validated  $R^2 > 0.1$  for each population were AFA=1782, HIS=1899, and CAU=1660. We found the best predicted gene, *CHURC1*, was the same across populations with an  $R^2 > 0.87$  in each population. Out of 327 genes with an absolute value difference of  $R^2 > 0.5$  between AFA and CAU, 184 (56%) were well-predicted genes in AFA that were poorly predicted in CAU. The *TOP1MT* gene had an  $R^2 = 0.64$  in AFA and  $R^2 = 0.008$  in CAU. The driving SNP with the highest weight in the AFA population (rs2467941) had a high MAF in AFA (0.375) but was not present in CAU. Across genes, population pairwise predictive performance was correlated ( $R^2 > 0.5$ ) with the highest predictive performance correlation between HIS and CAU ( $R^2 = 0.604$ ), reflective of the European admixture proportions in the HIS cohort. Using genotype weights trained in MESA to predict gene expression in 1000 Genomes populations as a test set showed that a training set with ancestry similar to the test set is better at predicting gene expression in test populations. The AFA training set prediction for Yoruba (YRI) showed a mean predicted versus observed  $R=0.104$ , while the CAU training set prediction for YRI showed a mean  $R=0.068$ . This work enhances our knowledge of genetic mechanisms underlying gene expression and complex traits in all populations.

**2336T**

**Adaptive eQTLs in human populations.** *M. Quiver, J. Lachance.* School of Biological Sciences, Georgia Institute of Technology, Atlanta, GA.

Adaptive evolution is often due to regulatory sequence change, and expression quantitative trait loci (eQTLs) have allele frequencies that can vary across populations. To identify adaptive loci in human populations, we combined continental estimates of allele frequencies with eQTL data from the Genotype-Tissue Expression (GTEx) project and RegulomeDB. After controlling for the effects of linkage disequilibrium, we calculated population branch statistics (PBS) at each polymorphic site. This allowed us to test whether the strength of selection differs for eQTLs that affect many of tissues, determine which tissues are more likely to be adaptive, and identify outlier eQTLs. We find that eQTLs are more likely to have large allele frequency differences between populations than random SNPs from the 1000 Genomes Project. However, this pattern is largely due to SNP ascertainment bias. It is hypothesized that pleiotropic loci are expected to evolve slowly. Along these lines, our results indicate that pleiotropic eQTLs are less likely to be locally adaptive in human populations. We also find that signatures of positive selection are stronger for tissues that are involved in immune and metabolic function. eQTLs that regulate expression in blood, liver, or skin are enriched for PBS outliers. By contrast, eQTLs that regulate expression in the cerebrum or female-specific tissues have a relative lack of PBS outliers. Scans of positive selection also reveal that the strongest PBS signal in many adaptive regions of the genome is an eQTL. For example, rs2814778 is an adaptive eQTL at the Duffy locus that has experienced strong positive selection for increased malaria resistance in Africa. Taken together, our results suggest that allele frequency changes at eQTLs have played an important role in human adaptation.

**A comparative study of endoderm differentiation in humans and chimpanzees.** L.E. Blake<sup>1</sup>, S.M. Thomas<sup>1</sup>, J.D. Blischak<sup>1</sup>, C.J. Hsiao<sup>1</sup>, C. Chavarria<sup>1</sup>, M. Myrthil<sup>1</sup>, Y. Gilad<sup>1,2</sup>, B.J. Pavlovic<sup>1</sup>. 1) Human Genetics, University of Chicago, Chicago, IL., USA; 2) Genetic Medicine, University of Chicago, Chicago, IL., USA.

There is substantial interest in the evolutionary forces that shaped the regulatory framework that is established in early human development. Progress in this area has been slow because it is difficult to obtain relevant biological samples. Inducible pluripotent stem cells (iPSCs) provide the ability to establish in vitro models of early human and non-human primate developmental stages. Using matched iPSC panels from humans and chimpanzees, we comparatively characterized gene regulatory changes through a four-day timecourse differentiation of iPSCs (day 0) into primary streak (day 1), endoderm progenitors (day 2), and definitive endoderm (day 3). As might be expected, we found that differentiation stage is the major driver of variation in gene expression levels, followed by species. We identified thousands of differentially expressed genes between humans and chimpanzees in each differentiation stage. Yet, when we considered gene-specific dynamic regulatory trajectories throughout the timecourse, we found that 75% of genes, including nearly all known endoderm developmental markers, have similar trajectories in the two species. Interestingly, we observed a marked reduction of both intra- and inter-species variation in gene expression levels in primitive streak samples compared to the iPSCs, with a recovery of regulatory variation in endoderm progenitors. The reduction of variation in gene expression levels at a specific developmental stage, paired with overall high degree of conservation of temporal gene regulation, is consistent with the dynamics of developmental canalization. Overall, we conclude that endoderm development in iPSC-based models are highly conserved and canalized between humans and our closest evolutionary relative.

**Determining the distribution of deleterious variation in population isolates using local ancestry and pedigree data.** J. Mooney<sup>1</sup>, C. Huber<sup>2</sup>, S. Service<sup>3</sup>, J. Sul<sup>4</sup>, C. Marsden<sup>2</sup>, N. Freimer<sup>2</sup>, K. Lohmueller<sup>1,2</sup>, Costa Rica/Columbia Consortium for Genetic Investigation of Bipolar Endophenotypes.

1) Department of Human Genetics, University of California Los Angeles, Los Angeles, CA; 2) Department of Ecology & Evolutionary Biology, University of California Los Angeles, Los Angeles, CA; 3) Center for Neurobehavioral Genetics, Semel Institute for Neuroscience and Human Behavior, University of California Los Angeles, Los Angeles, CA; 4) Department of Psychiatry and Biobehavioral Sciences, Semel Center for Informatics and Personalized Genomics, University of California Los Angeles, Los Angeles, CA.

Isolated populations generally exhibit less genetic diversity and greater genetic drift, which can impact patterns of deleterious genetic variation. However, most isolates examined to date were founded from a single ancestral population. Here we investigate genomic diversity of recently admixed population isolates from Latin America. Specifically, we use whole genome sequence data paired with extended pedigree data for Costa Rican and Colombian population isolates, which were derived from a limited number of founders during 16th-17th centuries, and recently expanded to about 3 million individuals. We used long runs of homozygosity, 2.0Mb or greater, to study how recent demographic history shaped the genomic background of Costa Rican and Colombian individuals. We found that the proportion of the genome that falls within a run of homozygosity (ROH) in Costa Rican and Colombian individuals was similar to 1000 Genomes CLM individuals. However, the individuals with the largest proportions of their genome within a ROH are from isolates. Furthermore, these individuals have some of the largest inbreeding coefficients. Additionally, we observed an increase in the number of homozygous derived deleterious variants within runs of homozygosity. Simulations suggest the significant enrichment of deleterious variation was due to recent inbreeding. Thus, we leveraged extended pedigree data from these isolates to further understand the impact of recent inbreeding on deleterious variation. We identified a significant correlation with an individual's pedigree inbreeding coefficient (F) and proportion of their genome within a ROH. Moreover, pedigree F was significantly correlated with the number of derived deleterious alleles within an individual's genome, suggesting that recent inbreeding has hindered removal of deleterious variants by purifying selection. Finally, we explored how admixture affected genetic diversity in the isolates. We found a positive correlation between pedigree F and the proportion of European (CEU) ancestry. Conversely, pedigree based F was negatively correlated with Native American and African ancestry. Overall, our results suggest that deleterious variants in population isolates may be affected by recent inbreeding and admixture.

**2339T**

**The composition and intensity of *de novo* mutations in the Lithuanian exome.** L. Pranckėnienė, A. Jakaitienė, L. Ambrozaitytė, I. Domarkienė, I. Kavaliauskienė, R. Meškienė, T. Raņčelis, Z.A. Kučinskienė, V. Kučinskas. Department of Human and Medical Genetics, Vilnius University, Vilnius, Lithuania.

Family-based whole-genome and whole exome sequencing data allows the identification of *de novo* mutations that provide more direct measures of mutation rates. According to the Dutch, Danish, and Icelandic genome projects rate of *de novo* single nucleotide variant is about  $1.2 \times 10^{-8}$ – $1.5 \times 10^{-8}$  per nucleotide per generation and increase with father's age. Point mutations can have different effects depending on which site of the genome they occur. A mutation that damages protein structure does not necessarily lead to a detectable human-disease phenotype, and a mutation that predisposes an individual towards a disease is not necessarily evolutionarily deleterious. The main interest of this study was to evaluate the composition and intensity of *de novo* single nucleotide mutations based on the Lithuanian whole exome data. The data set consisted of the Lithuanian population samples. Sequencing data of 48 parent-offspring trios exomes generated by sequencer SOLiD 5500™ and primary analysis performed by Lifescope™. *De novo* single nucleotide variants (DNV) called by two alternative programs VarScan and VarSeq™. Called DNV were filtered, manually reviewed by the IGV and validated by Sanger sequencing. Functional annotation of all identified *de novo* single nucleotide variants were performed using ANNOVAR. Preliminary results of DNV rate before validation step is  $7.7 \times 10^{-8}$  with 95% CI [ $6.4 \times 10^{-8}$ ;  $9.2 \times 10^{-8}$ ] for VarSeq, and  $1.2 \times 10^{-7}$  with 95% CI [ $1.1 \times 10^{-7}$ ;  $1.4 \times 10^{-7}$ ] for VarScan. DNV rate varies between families and is higher for the Lithuanian exome data as compared to  $1.5 \times 10^{-8}$  estimated in other studies. The results raise the question of whether the reported higher DNV rate is at least partially due to a local sequence context and/or possible natural selection on the exome. Therefore, ongoing work is focused on the analysis of probable DNV clusters, influence of sequence context on DNV and the influence of mutation rates on human-chimpanzee divergence based on comparative genomics models. This is the first attempt to evaluate a composition and intensity of *de novo* variants for trios from the Lithuanian population. This study supported by the LITGEN project (VP1-3.1-□MM-07-K-01-013) funded by the European Social Fund under the Global Grant Measure.

**Testing for local adaptation in populations of *Drosophila melanogaster* for olfactory receptor genes.** V. Ramesh, J. Pool. Genetics, University of Wisconsin-Madison, Madison, WI.

The development of the field of population genetics and genomic sequencing has helped scientists better understand an organism's evolutionary history and genetic variation among populations, yet the correlation between genetic variation and the extent to which it can lead to evolutionary change remains unknown. Of particular interest is understanding the genetic architecture underlying variation between populations in regards to the sense of olfaction, as it is not fully understood. To bridge this grey area, this research project tested for the presence of local adaptation which may have acted upon 11 populations of *Drosophila melanogaster* for genes coding for olfactory receptors. This evidence was obtained by analyzing fully sequenced genomes of subjects representing 11 populations of *D. melanogaster* spread throughout the sub-Saharan African range (including a novel wilderness population) and Europe, through window and SNP  $F_{ST}$  statistics. From this analysis, the data collected was converted to quantiles distinguishing unusually high  $F_{ST}$  values in order to identify loci with elevated genetic differentiation that could result from local adaptation. Additionally, a new method was developed using Circos software to aid in graphically depicting genetic differentiation. Preliminary results indicate the lines of variation between the tested populations of *D. melanogaster* as reflective of their geographical deviation from the ancestral population, and located several candidate genes (the tandem paralogs *Or22a* and *Or22b*, plus *Or19b*, *Or33a*, *Or65b*, and *Or67a*) that are likely experiencing natural selection in select populations.

**Genome-wide population analysis of 2,543 microsatellites and STR-SNP haplotypes reveals a novel class of highly diverse polymorphisms.** G. Shin<sup>1</sup>, H. Lee<sup>1</sup>, S.M. Grimes<sup>2</sup>, M. Kubit<sup>1</sup>, I.P. Vogelaar<sup>1</sup>, H.P. Ji<sup>1,2</sup>. 1) Division of Oncology, Stanford University School of Medicine, Stanford, CA 94305; 2) Stanford Genome Technology Center, Stanford University, Palo Alto, CA 94304.

Microsatellites, also referred to as short tandem repeats (STRs), are multiallelic in terms of germline variation as a result of higher mutation rate than SNPs. As a result, STR genotyping is highly informative when characterizing genetic populations. However, significant gaps remain in our knowledge about the population characteristics of microsatellites, the linkage disequilibrium structure of microsatellites and STR-SNP haplotype structure in the human population. Addressing all of these questions, we developed and applied novel targeted sequencing technology (STR-Seq) [1], which can simultaneously genotype thousands of microsatellite loci and phased proximal SNPs (i.e. STR-SNPs haplotypes) with significantly higher accuracy than all other methods including whole genome sequencing. STR-Seq uses single-molecule sequencing in combination with targeted in vitro CRISPR-Cas9 fragmentation. For a given individual, one accurately genotypes thousands of microsatellite in a single assay. For this study, we evaluated 2,543 microsatellite loci from a population of 1,004 individuals [2]. Our analysis included 436 Marshfield loci [3], which has been used to characterize the population sample and an additional 1,915 loci where a proximal SNP was positioned within 100bp of the STR. Thus, over 2.5 million loci were evaluated across the human population. Overall, we identified approximately 2,000 STR genotypes and 1,000 STR-SNP haplotypes per individual. STR-SNP linkage was extremely low (mean  $r^2 < 0.1$ ). We discovered an entirely new class of microsatellite/STRs which are highly polymorphic as noted by having 20 or more alleles. Finally, we identified a significant number of STR-SNP haplotypes and describe the geographical and population differences of these previously undescribed, novel genetic markers. **Reference** 1. **Inverse correlation between mutational and selective forces in human coding regions with distance from gene ends leads to opposite patterns of synonymous and non-synonymous variant prevalence.** Y. Waldman<sup>1</sup>, E. Halperin<sup>2,3</sup>, A. Keinan<sup>1,4,5</sup>. 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Computer Science, University of California, Los Angeles, Los Angeles, CA; 3) Department of Anesthesiology and Perioperative Medicine, University of California, Los Angeles, Los Angeles, CA; 4) Cornell Center for Comparative and Population Genomics, Cornell University, Ithaca, NY; 5) Center for Vertebrate Genomics, Cornell University, Ithaca, NY.

Evolutionary rate varies not only between proteins but also within proteins. While studies, which mainly focused on non-synonymous variation, have associated intra-protein variation with functional and structural constraints, a large portion of the variation is not explained by current models. Here we examine both synonymous and non-synonymous variation in coding regions in humans and the mechanisms behind them. We observed clear but opposite patterns for synonymous and non-synonymous variation. For example, comparing the sequences of more than 10,000 human-mouse orthologous genes, we find that non-synonymous divergence rate decreases as a function of the distance from both '3 and '5 ends of genes while synonymous divergence increases as a function of the distance from both ends of genes. We obtained similar results for other organisms as well (*Drosophila*, *Saccharomyces*, *Candida* and more). Next, we examined what are the underlying mechanisms behind these opposite patterns by analyzing millions of synonymous and non-synonymous variants observed in more than 140,000 fully sequenced human exomes. Results indicate that the depletion in non-synonymous variation as a function of the distance from gene ends is a result of non-uniform selection: non-synonymous variants far from gene ends are much more likely to be damaging (ClinVar) and are therefore under selection. Functional and structural annotation data only partially explains the distribution of damaging non-synonymous variation across coding regions, suggesting that current annotation data is incomplete and/or that other constraints contribute to the observed pattern. Further support comes from non-synonymous somatic mutations in cancer (COSMIC) that show increase in frequency as a function of the distance from gene ends, similar to synonymous variants, presumably because the vast majority of these somatic mutations are under no or weak selection. Similarly, non-synonymous variants present in very low frequencies in human populations (gnomAD), which are presumed to be relatively recent and therefore with less time for selection to operate, also exhibit synonymous variation pattern. These and other results suggest that mutational forces increase the genetic variation as a function of the distance from gene ends while selection acts in opposite direction to remove variation located far from gene ends, hence providing additional and important angle in our understanding of gene architecture.

**Patterns of genetic variation within the Genome Russia Project.** S. O'Brien, G. Tamazian, D. Zhenakova, S. Kliver, N. Cherkasov, I. Evsukov, P. Dobrynin, A. Gorbunova, S. Kolchanova, A. Shevchenko, M. Rotkevich, A. Yurchenko, S. Sidorov, A. Komissarov, K. Krashenninnikova, S. Malov, A. Logachev, S. Simonov, D. Polev, T. Davydova, S. Sivtseva, A. Glotov, V. Osakovsky, A. Novozhilov, V. Brukhin. Theodosius Dobzhansky Center for Genome Bioinformatics, St. Petersburg State University, St Petersburg Ru..

Recently many national genomic projects highlighting the diversity and similarity of world populations have begun, providing insight into population history and aiding in medical genomics. Although Russia is the largest country in the world, we have not formally participated in large sequencing projects. To overcome this, Genome Russia Project was initiated to generate whole genome sequences of more than 2,500 samples coming from diverse populations throughout Russia. The principal aims of the project are: 1.) Characterize of genetic variation of different Russian ethnic groups; 2.) Develop reference database of DNA variation within Russia that can be assessed for medical import; 3.) Identify variants that cause known diseases. 4.) Develop a Russian HapMap; 5.) Explore population natural history in Russia and Eurasia. Sixty trio genome samples representing population groups from 3 regions (Novgorod, Pskov and Yakutia regions) were sequenced and analyzed. We have identified > 10.5 million SNPs and >2.8 million short indels in three populations. Approximately 95% of these are listed in dbSNP or 1000G Project database. We combined the Russian SNP results with genomic variants from 206 recently released Eurasian genomes to assess the PCA plot of population structure of our samples within Eurasian populations. We annotated the identified variants, noting differences in MAF as compared to 1000G data for known variants. To investigate medically relevant variants we note significant MAF differences of trait- and disease- associated SNPs in Russian versus 1000G populations. Consider lactose intolerance which is prevalent in Asian peoples (~90%), while in Europeans is rather low (~5% in Northern Europe). SNP rs4988235 located in LCT locus is a functional SNP that mediates LCT activity, and its G allele tags the lactose intolerant haplotype. This allele is more frequent in European Russian populations as compared to Europeans from 1000G CEU (MAF in Pskov + Novgorod is 0.59; MAF in CEU is 0.26; p-value =  $9.40 \times 10^{-6}$ ) and pronounced in Yakutia (MAF ~0.96; p-value of the difference of Yakut samples vs 1000G CEU is  $1.48 \times 10^{-12}$ ). Thus, Novgorod and Pskov are more lactose intolerant than Europeans, and Yakut have an even higher prevalence of this condition. In sum, we identified variants shared and specific for each population, annotated their presence in known databases; potential pathogenicity; known association with diseases and complex traits.

**1000 high coverage whole-genome sequences representative of the Taiwanese population from Taiwan Biobank.** M. Su<sup>1,2</sup>, C. Lin<sup>1,2</sup>, C. Hsiung<sup>1,2</sup>, H. Chu<sup>1,2</sup>, P. Wu<sup>1,2</sup>, C. Shen<sup>1,2</sup>, F. Liu<sup>1,2</sup>. 1) Taiwan Biobank, Academia Sinica, Taipei, Taiwan; 2) Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan.

The complex migration history (gene flow) among the Taiwanese populations and lack of Taiwanese samples in the 1000 genome reference panel result in lower imputation accuracy, and further hamper genetic research in Taiwan. The Taiwan Biobank (TWB) reports the whole-genome sequences of 1,000 healthy Taiwanese individuals and constructs a population-specific reference panel (1KTWB) for human genetic variation. We sequenced 1,000 samples by PCR-free sequencing with more than 30X coverage genome-wide, aiming to characterize genetic variation down to 0.1% minor allele frequency in the Taiwanese population. Samples were sequenced using Illumina HiSeq 2500 and 4000 sequencers according to the manufacturer's protocol. Sequence reads were aligned to the human reference genome with decoy sequences (version GRCh37d5/hg19d5) using Burrows Wheeler Aligner (BWA-MEM) 0.7.15-r1140. Single nucleotide polymorphisms (SNP) and insertion and deletion (INDEL) calling were performed on all sample's gVCF files jointly using GATK HaplotypeCaller v3.6. Variant Quality Score Recalibration (VQSR) was used to filter variant sites with known SNPs and INDEL variations datasets. 28 million, including 16 million novel, SNPs were characterized. We also detect structural variants, including 3.4 million insertions and deletions. Here we demonstrate the value of high coverage sequencing to boost imputation accuracy at rare and low-frequency variants in Taiwanese population.

**NHGRI Sample Repository for Human Genetic Research: Cell lines and DNA from the 1000 Genomes and HapMap collections.** *E.M. Kelly, T. Dixon, B. Martínez, A.M. Resch.* Coriell Institute for Medical Research, NJ.

Understanding genetic variation across diverse human populations is critical for reconstructing human evolutionary history and identifying the genetic basis of disease. The goal of the NHGRI Sample Repository for Human Genetic Research is to support studies of the human genome, including genetic variation in human populations. The NHGRI Sample Repository maintains and distributes a collection of well-characterized cell line and DNA samples collected for the 1000 Genomes and International HapMap Projects. Whole blood samples collected from anonymized and de-identified donors were contributed with broad consent to data release for future studies including: genotyping and sequencing, gene expression, proteomic studies, and all other types of genetic variation research. Several distinct populations are represented in the 1000 Genomes and HapMap collections, making it one of the most comprehensive and unique datasets of its kind. The NHGRI Sample Repository distributes specimens from these collections to researchers around the globe. Samples are available to qualified researchers from academic, non-profit, government, and commercial organizations. The full catalog can be accessed at <https://catalog.coriell.org/NHGRI>.

**Increasing signal and refining population annotations using a common haplotypes co-association network.** *L. Doroud<sup>1</sup>, S. Hateley<sup>1</sup>, O. Schaedel<sup>1</sup>, H. Guturu<sup>1</sup>, K. Noto<sup>1</sup>, C. Ball<sup>1</sup>, K. Chahine<sup>2</sup>.* 1) AncestryDNA LLC, San Francisco, CA; 2) Ancestry.com DNA, LLC, Lehi, UT.

Common haplotypes are genomic regions shared by multiple individuals likely due to population structure rather than recent identity by descent. While segregation of haplotypes is correlated with ethnicity and genetic communities, analyzing these correlations individually for each haplotype is noisy and cumbersome. Taking advantage of the fact that many haplotypes frequently co-occur within populations, we can cluster co-occurring haplotypes to reduce noise and find refined sub-populations for more meaningful annotation. We propose a novel graph-based approach to group co-associated common haplotypes, ultimately allowing for better annotation of genetic communities. From our database of over four million customers, we used a dataset of over one million customers who have consented to research and constructed a co-occurrence network of observed common haplotypes, revealing 'haplotype families' within sub-populations. Identifying co-occurrence patterns of common haplotypes in the human population at large scale can reveal hidden insights into our species' recent history.

**Partitioning heritability of low-frequency variants reveals relative strength of negative selection across functional annotations.** S. Gazoni<sup>1,2</sup>, A. Ganna<sup>2,3</sup>, A. Schoech<sup>1,2</sup>, P.R. Loh<sup>1,2</sup>, A. Gusev<sup>1,2</sup>, T. Esko<sup>2,4</sup>, A. Palotie<sup>2,3,5</sup>, B.M. Neale<sup>2,3</sup>, S. Sunyaev<sup>2,6</sup>, H.K. Finucane<sup>1,2,7</sup>, A.L. Price<sup>1,2</sup>. 1) Department of Epidemiology and Biostatistics, Harvard T.H. Chan School of Public Health, Boston, MA, USA; 2) Broad Institute of MIT and Harvard, Cambridge, MA, USA; 3) Analytic and Translational Genetics Unit, Massachusetts General Hospital, Boston, MA, USA; 4) Estonian Genome Center, University of Tartu, Tartu 51010, Estonia; 5) Institute for Molecular Medicine Finland, FIMM, University of Helsinki, Helsinki FI-00014, Finland; 6) Division of Genetics, Department of Medicine, Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 7) Department of Mathematics, Massachusetts Institute of Technology, Cambridge, MA, USA.

Although it is widely known that common variant heritability is enriched in functional annotations and concentrated in non-coding variants, little is known about the distribution of the heritability of low frequency variants ( $0.5\% \leq \text{MAF} < 5\%$ ). Here, we partitioned the heritability of both common and low-frequency variants in 41 common diseases and complex traits from the UK Biobank (average  $N = 104\text{K}$ ) across a broad set of functional annotations. We accomplished this by extending stratified LD score regression (Finucane et al. 2015 *Nat Genet*) to low-frequency imputed variants, incorporating estimates of imputation accuracy and a UK10K reference panel, and showing via simulations that this approach produces robust results. Meta-analyzing enrichment results across 26 independent traits, we observed that the low-frequency variant enrichments (LFVE) of each functional annotation are highly correlated to the common variant enrichments (CVE) ( $r = 0.70$ ; s.e. = 0.13), and tend to be even larger for annotations with large CVE (regression slope = 1.78; s.e. = 0.26). We observed very large LFVE for non-synonymous variants (0.45/0.27 % of low-frequency/common variants; LFVE = 42.0x vs. CVE = 7.1x;  $P = 3.9 \times 10^{-8}$  for difference), and large LFVE for coding+UTRs variants (2.49/2.10 % of variants; LFVE = 12.2x vs. CVE = 4.7x;  $P = 2.7 \times 10^{-4}$ ) and regions conserved in primates (2.82/2.12 % of variants; LFVE = 16.5x vs. CVE = 9.4x;  $P = 4.8 \times 10^{-3}$ ). We observed an even stronger difference for some traits, such as non-synonymous variants (LFVE = 53.1x vs. CVE = 7.8x;  $P = 1.2 \times 10^{-4}$ ) and coding+UTRs variants (LFVE = 24.7x vs. CVE = 7.7x;  $P = 2.3 \times 10^{-3}$ ) for height. We performed forward simulations using SLiM2 (Haller & Messer 2017 *MBE*) to link these results to the action of negative selection. We determined that the CVE of an annotation primarily depends on its proportion of sites under selection, whereas its LFVE/CVE ratio primarily depends on the strength of selection. This implies that non-synonymous variants have a lower proportion of deleterious variants than regions conserved in primates, but a higher mean selection coefficient for deleterious variants. Finally, our analyses demonstrate that identifying non-coding variants with high LFVE will help prioritize rare non-coding variants in whole-genome sequencing studies of common diseases and complex traits.

**HLA-A extended promoter and coding variability in a Brazilian population sample by using massively parallel sequencing.** T.H.A. Lima<sup>1</sup>, I.O.P. Porto<sup>1</sup>, L.C. Veiga-Castelli<sup>2</sup>, C.T. Mendes-Junior<sup>3</sup>, E.A. Donadi<sup>4</sup>, E.C. Castelli<sup>5</sup>. 1) São Paulo State University (UNESP), Molecular Genetics and Bioinformatics Laboratory, Experimental Research Unity, School of Medicine, Botucatu, State of São Paulo, Brazil, MS; 2) Department of Genetics, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil, PhD; 3) Departamento de Química, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Ribeirão Preto, Estado de São Paulo, Brasil, PhD; 4) Department of Medicine, School of Medicine of Ribeirão Preto, University of São Paulo (USP), Ribeirão Preto, State of São Paulo, Brazil, PhD; 5) São Paulo State University (UNESP), Molecular Genetics and Bioinformatics Laboratory, Experimental Research Unity, School of Medicine, Department of Pathology, Botucatu, State of São Paulo, Brazil, PhD.

*HLA-A* is one of the most polymorphic genes of the human genome. The *HLA-A* molecule is responsible for displaying small peptides at the cell surface, which in turn may be recognized by T cell receptors as foreign or damaged proteins. Thus, these are critical molecules for the activation of adaptive immune responses. Here we evaluate the *HLA-A* extended promoter and coding sequence variability and haplotypes in a Brazilian population sample (408 individuals from the Southeast Brazil) by using massively parallel sequencing and freely available softwares. Allele, promoter, coding and extended haplotype frequencies, plus the Linkage Disequilibrium (LD) along the *HLA-A* loci, were also calculated. The *HLA-A* variability between nucleotides -1605 and -1 were considered as encompassing the *HLA-A* extended promoter (only the last 300 bases of this segment have been considered at the IPD-IMGT/HLA database so far). At the extended promoter, we detected 100 variable sites, 90% of them presenting polymorphic frequencies, and all arranged into 25 different haplotypes. Each coding *HLA-A* allele group was associated with a unique or a small group of closely related extended promoter haplotypes. The most frequent haplotype detected was associated with coding alleles from the *HLA-A\*02* group. At the coding region (from -300 to +3203, which is the region tracked by the IPD-IMGT/HLA database), we detected 90 different sequences. Among them, 51 are identical to previous described sequences, and the remaining 39 may be considered new *HLA-A* coding alleles. However, these new sequences represent only 1.34% of the coding sequences here detected. The low number of haplotypes detected for the extended promoter and the close relationship among these promoters and the coding alleles are probably consequences of the high Linkage Disequilibrium (LD) along the entire *HLA-A* loci, with many variable sites in complete LD with each other. In addition, the presence of few but highly divergent haplotypes is compatible with the balancing selection signatures already described for this gene. Functional evaluations are still necessary to completely understand if these divergent extended *HLA-A* promoters are related to differential expression patterns. This study was supported by FAPESP/Brazil, Grant 2013/17084-2.

**2349F**

**MC1R regulatory and coding polymorphisms and pigmentation in an admixed population from Brazil.** C.T. Mendes-Junior<sup>1</sup>, A.L.E. Pereira<sup>1,2</sup>, L. Marcorin<sup>3</sup>, M.L.G. Oliveira<sup>2</sup>, N.C.A. Fracasso<sup>2</sup>, G. Debortoli<sup>2</sup>, G.V. Silva<sup>1</sup>, J.D. Massaro<sup>2</sup>, A.L. Simões<sup>2</sup>, E.A. Donadi<sup>3</sup>, E.C. Castelli<sup>4</sup>. 1) Departamento de Química, Universidade de São Paulo (FFCLRP-USP), Ribeirão Preto, SP, Brazil; 2) Departamento de Genética, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 3) Departamento de Clínica Médica, Universidade de São Paulo (FMRP-USP), Ribeirão Preto, SP, Brazil; 4) Departamento de Patologia, Universidade Estadual Paulista (FMB-UNESP), Botucatu, SP, Brazil.

Melanogenesis, the biochemical pathway for human pigmentation, is extremely complex and involves over 120 genes. Different skin, eye and hair phenotypes reflect the accumulation of melanin, which displays two main conformations: eumelanin, a darker pigment that ranges from black to brown, and pheomelanin, a lighter pigment that ranges from yellow to red. The activation of the melanocyte membrane-bound MC1R protein activates a series of reactions that stimulates eumelanin synthesis, while its inhibition results in the production of pheomelanin. Polymorphisms spread across the *MC1R* locus may influence the balance of pheomelanogenesis and eumelanogenesis. The aim of the present study is to identify *MC1R* polymorphisms and haplotypes that are associated with phenotypic traits. A sample of 340 unrelated individuals was obtained from the region of Ribeirão Preto city, northeast region of the São Paulo state, Brazil. The samples were stratified according to eye, skin and hair phenotypes. DNA libraries (HaloPlex Target Enrichment System, Agilent) including the regulatory and coding regions of *MC1R* were submitted to next-generation sequencing (MiSeq, Illumina). Considering the whole extension of the gene (chr16:89978527-89987385; hg19), 120 polymorphic sites were identified. After a rigorous filtering process for removing low quality genotypes and *singletons*, haplotypes encompassing 58 polymorphic sites were obtained. Eighteen SNPs presented phenotype associations, including six (rs11547464, rs1805005, rs1805006, rs1805007, rs1805008, rs1805009) that are currently used in the DNA-based eye and hair color prediction model called HirisPlex. In general, associations hereby identified proved statistically very strong, reaching *p*-values as low as  $2.68 \times 10^{-16}$  and Odds Ratio of 382.500 for rs1805007\*T and red hair. Many polymorphisms coincide with transcription factor or microRNA binding sites. In addition, associations of whole-gene haplotypes with blue eyes, red hair and freckles were also identified. Thus, the characterization of both coding and regulatory regions of *MC1R* corroborates its role in human pigmentation pathway, and highlights the regulatory mechanism encompassing this gene, as well as the impact that polymorphisms have in the pigmentation of admixed individuals. FINANCIAL SUPPORT: FAPESP (Grant 2013/154470) and CNPq/Brazil (Grant 448242/2014-1 and Fellowship 309572/2014 -2).

**Allele frequencies of pathogenic single nucleotide variants in a Japanese population based on a whole-genome reference panel of 2,049 individuals.** Y. Yamaguchi-Kabata, J. Yasuda, Y. Suzuki, N. Fuse, F. Katsuoka, Y. Kawai, H. Kawame, K. Kojima, M. Nagasaki, T. Mimori, O. Tanabe, K. Kinoshita, S. Kure, M. Yamamoto, ToMMo Study Group. Tohoku Medical Megabank Organization, Tohoku University, Aoba-ku, Sendai, Japan.

Clarifying population frequencies of pathological variants is essential to construct infrastructure for genomic medicine for different populations; however, rare variants that may have biological or medical effects have not been clarified for the Japanese population. Here, by analyzing a whole-genome reference panel of a Japanese population based on 2,049 individuals (2KJPN, available at iJGVD; <http://ijgvd.megabank.tohoku.ac.jp/>), we characterized the genomes of Japanese individuals in terms of allele frequency of functional and pathological variants. Among the 28 million autosomal single nucleotide variants (SNVs) in 2KJPN, 6,739 SNVs were identified as pathologically annotated variants that overlap with known pathogenic variants in the Human Gene Mutation Database. In addition, we found that missense and nonsense SNVs in 2KJPN included candidates of expected pathogenic variants. By focusing on 32 genes for 17 congenital metabolic diseases for newborn screening (NBS) in Japan, we identified reported pathogenic variants and estimated their carrier frequencies by variant filtering based on variant annotations and allele frequencies. Most of the NBS genes showed lower risk allele frequencies in 2KJPN than in those with European ancestries, which may help explain the genetic basis for lower incidence rates of congenital metabolic disorders in Japan. However, there are a few exceptions: *PCCA* for propionic acidemia and *SLC25A13* for citrullinemia showed higher risk allele frequencies in 2KJPN than in those with European ancestries. In addition, we identified genome-wide pathogenic SNVs showing higher allele frequencies in 2KJPN than in other ethnic groups, and these SNVs included clinically important variants (e.g. *CDH1* for hereditary diffuse gastric cancer, *APRT* deficiency and *CETP* for cholesterol ester transfer protein deficiency) for personalized medicine and prevention for the Japanese. We are also working on evaluation of pathogenic variants of actionable genes recommended by American College of Medical Genetics and Genomics for incidental or secondary finding, by a more careful approach. Our results and ongoing activities on variant curation would lay the foundation for i) evaluating the relationships of genomic variants and disease prevalence, and ii) improving diagnostic strategies and genetic testing in Japan and East Asia.

**Substantial fraction of genes under recessive selection illuminates a missing component of human variation in population genetics and model organism studies of human disease.** *D.J. Balick<sup>1</sup>, D. Jordan<sup>2</sup>, S. Sunyaev<sup>1</sup>, R. Do<sup>2</sup>.* 1) Genetics Division, Brigham and Women's Hospital, Harvard Medical School, Boston, MA; 2) The Charles Bronfman Institute for Personalized Medicine, Icahn School of Medicine at Mount Sinai, New York, NY.

Much of our knowledge of the biology and prevalence of recessivity in humans stems from model organism research, under the assumption that the underlying mechanisms are highly conserved. However, relevant experimental techniques cannot be performed in humans directly. Complementary information about phenotypic recessivity in humans comes from pedigree studies, which are costly and suffer from ascertainment bias. Beyond phenotypes, patterns of recessive natural selection in humans must be inferred from highly non-equilibrium natural population data, and are thus fundamentally harder to obtain. Notably, existing population genetic and conservation statistics are largely insensitive to recessive selection, due to a reliance on heterozygosity and fixation rates that are similar in neutral and recessive variation. This leads to an unknown number of functionally important, yet uncharacterized genes under strong selection. To identify this "missing" component of biologically and medically relevant genes under strong recessive selection, we developed a statistic specifically tuned to distinguish between recessive and non-recessive variation under strong selection, and to further distinguish recessivity from weaker selection and neutrality. Using data from 34500 European individuals from the ExAC study, we classified "recessive genes" for which protein damaging variation is severely deleterious only in homozygote form. We find that a substantial fraction of human genes are under recessive strong selection, suggesting a significant impact on both the global distribution of selective effects and a wide range of human genetic applications. To assess the relevance of a large class of recessive genes to analogs of human genetics in other species, we estimate the fraction of recessive genes in orthologs in several model organisms. Relative to all genes under strong selection in humans, recessive genes are preferentially lost in orthologs, with highly significant depletions in distant species beyond vertebrata. This impacts studies of human disease in model organisms that rely on the identification of an ortholog. Genes used in fly models of human disease exhibit a stronger depletion than in all fly orthologs. This suggests a generic bias against human recessivity in studies of both Mendelian and complex human disease in distant model organisms, mirroring the large fraction of genes under strong recessive selection missing from human population genetic inferences.

**Rapid detection of identity-by-descent from whole genome sequence data.** *J.E. Hicks<sup>1,2</sup>, M.A. Province<sup>1</sup>.* 1) Division of Biostatistics, Washington University School of Medicine, Saint Louis, MO; 2) Division of Statistical Genomics, Washington University School of Medicine, Saint Louis, MO.

Detection of shared genome regions identical-by-descent (IBD) from a common ancestor has broad applications in population genetics and genetic epidemiology. Most existing methods for detecting IBD from genotypes were developed for the common variants found on SNP arrays. Because they only examine common variants, these methods require many markers to declare IBD and cannot reliably detect the more distant coancestry that results in IBD segments shorter than 2 megabases. Explosive population growth in recent human history has resulted in an excess of rare variants across the genome. Since they tend to have arisen recently, the presence of a rare variant in two individuals suggests recent coancestry at that locus. By focusing on rare variants, small IBD segments can be more reliably detected. Whole-genome sequencing (WGS) provides access to both rare and common SNPs throughout the genome. However, analyzing WGS data comes with two major obstacles: the large number of variants identified and the presence of error in them. We present a new algorithm for detecting IBD, **Adaptive Detection of IBD Over Sequences (ADIOS)**. In two individuals, only a small subset of sites are informative of the underlying IBD state: rare variants found in both individuals (suggests IBD), and sites where both individuals are homozygous but for different alleles (excludes IBD). These sites differ for each pair of individuals. ADIOS determines pairwise IBD states by including only these variants in a Hidden Markov Model that adjusts for genotyping error and does not require phase information. By restricting to a subset of markers, determining IBD with ADIOS is both CPU and memory efficient. We simulated IBD in pairs of individuals ( $n=5000$ ) from the chromosome 10 data in the 1000 Genomes Project's European samples. For each segment size tested, a region of specified size from a randomly selected individual was copied onto two individuals and tested. ADIOS had high power to detect IBD (46.5% of IBD bases detected for 500 kb segments, 76.1% for 1 Mb segments, 91.4% for 2 Mb, 94.7% for 3 Mb). To test false positive rate, a dataset ( $n=100$ ) of null data was generated by joining 10kb segments from the 1000 Genomes data. ADIOS had a low false positive rate, with 5.5% of examined bases incorrectly shown as IBD. ADIOS shows great potential to facilitate rapid and accurate identification of IBD for rare causative alleles which has become the new genomic focus for complex traits in the WGS era.

**Mutation rate estimation from population data.** X. Tian<sup>1</sup>, B.L. Browning<sup>1,2</sup>, S.R. Browning<sup>1</sup>. 1) Department of Biostatistics, University of Washington, SEATTLE, WA; 2) Department of Medicine, University of Washington, SEATTLE, WA.

We present a new method for mutation rate estimation based on segments of identity by descent (IBD) shared among multiple individuals. The sharing of IBD segments among multiple individuals makes it possible to distinguish true mutations from genotype errors. Our method is applicable to sequence data with or without close relatives. We first assess the performance of our method on simulated data with known phasing information. We simulated genome-wide data having a mutation rate of  $1.25 \times 10^{-8}$  per base pair per generation, a constant population size of 10,000 and a sample size of 400 diploid individuals. The analysis of simulated data indicated that our method is unbiased and has high precision. With true IBD segments, actual effective population size, and no genotype error, our method's mutation rate estimate has a standard error of  $0.01 \times 10^{-8}$ . With inferred IBD segments, inferred effective population size, and 0.01% genotype error added to the simulated data, our method's mutation rate estimate has a standard error of  $0.02 \times 10^{-8}$ . We next applied our method to Framingham Heart Study data from the NHLBI TOPMed project. In this dataset, approximately 4,100 individuals of European ancestry across 3 generations are whole genome sequenced. We identified 701 complete parent-offspring trios. Parental information determines the haplotype phase in the 701 trio offspring at most positions. From the analysis on the 701 phased trio offspring, we estimated the genome average mutation rate to be  $1.10 \times 10^{-8}$  per base pair per generation with a 95% confidence interval of  $[0.91, 1.24] \times 10^{-8}$  per base pair per generation.

**Extremely rare variants reveal patterns of germline mutation rate heterogeneity in humans.** S. Zöllner<sup>1,4</sup>, J. Carlson<sup>2</sup>, J. Li<sup>2,3</sup>, the BRIDGES Consortium. 1) Dept Biostatistics, Univ Michigan, Ann Arbor, MI; 2) Dept Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI; 3) Dept Human Genetics, University of Michigan, Ann Arbor, MI; 4) Dept Psychiatry, University of Michigan, Ann Arbor, MI.

Precise estimates of the single-nucleotide mutation rate and its variability are essential to the study of human genome evolution and genetic diseases. However, estimates using common variants are biased by selection and biased gene conversion while analyzing *de novo* variants provides insufficient observations to consider sequence context. Here we use ~36 million singleton variants observed in 3,716 whole-genome sequences to characterize the heterogeneity of germline mutation rates across the genome. These singletons arose very recently in the population, and are thus largely unaffected by confounding evolutionary factors. We show that nucleotide context is the strongest predictor of mutability, with mutation rates varying by >650-fold depending on the identity of three bases upstream or downstream of the mutated site. We estimate up to 60-fold difference between non-CpG motifs within a single mutation category. Histone modifications, replication timing, recombination rate, and other local genomic features further modify mutability. We see clear evidence of interaction between nucleotide context and genomic features: Presence of a genomic feature can increase or decrease the mutation rate, dependent on the sequence context. Based on our model, we generate a genome-wide distribution of mutation rates that spans over 4 orders of magnitude. We evaluate the estimated models in an independent dataset of ~46,000 *de novo* mutations and show that singleton-based estimates provide a more accurate prediction of the mutation patterns than estimates based on common variants used in previous approaches. Incorporating the effects of genomic features further improves the prediction; combined, sequence motives and genomic features account for ~88% of the explainable variance. Finally, we examine the distribution of mutation rates among known pathogenic mutations and demonstrate how precise mutation rate estimates can further our understanding of heritable diseases. The effects of sequence contexts, genomic features, and their interactions we present capture the most refined portrait to date of the germline mutation patterns in humans.

**Detecting long-term balancing selection using allele frequency correlation.** *K. Siewert<sup>1</sup>, B. Voight<sup>2,3</sup>*. 1) Genomics and Computational Biology Graduate Group, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 2) Department of Systems Pharmacology and Translational Therapeutics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Department of Genetics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Balancing selection occurs when it is beneficial for multiple alleles to be present in a population, which can result in the preservation of variants over long evolutionary time periods. A characteristic signature of this long-term balancing selection is an excess number of intermediate frequency polymorphisms near the balanced variant. However, the expected distribution of allele frequencies at these loci has not been extensively detailed, and therefore existing summary statistic methods do not explicitly take it into account. Using simulations, we show that new mutations which arise in close proximity to a site targeted by balancing selection accumulate at frequencies nearly identical to that of the balanced allele. In order to detect balancing selection, we propose a new summary statistic, Beta, which detects these clusters of alleles at similar frequencies. Our statistic has improved power to detect balancing selection over existing summary statistics under a wide range of simulated models and parameters. We compute Beta on 1000 Genomes Project data to identify loci potentially subjected to long-term balancing selection in humans. We report two balanced haplotypes. The first, located in the *CADM2* gene, is tightly linked to a GWAS SNP for cognitive functions and has been shown to have experienced positive selection in canine. The second, located in the *WFS1* gene, is in high linkage disequilibrium with a GWAS variant for Type II Diabetes. Both haplotypes are in tight linkage with eQTLs for these genes and fall in regions of high regulatory potential, indicating these haplotypes could be affecting regulation of their respective genes. These results suggest that balancing selection maintains variants which influence a wide variety of complex traits.

**2356W**

**Recurrent adaptation of different haplotypes in *FADS* genes to plant-based and animal-based diets in a diverse worldwide set of extant and extinct human populations.** *K. Ye<sup>1</sup>, D. Wang<sup>1</sup>, F. Gao<sup>1</sup>, O. Bar-Yosef<sup>2</sup>, A. Keinan<sup>1,3,4</sup>*. 1) Department of Biological Statistics and Computational Biology, Cornell University, Ithaca, NY; 2) Department of Anthropology, Harvard University, Cambridge, MA; 3) Cornell Center for Comparative and Population Genomics, Cornell University, Ithaca, NY; 4) Center for Vertebrate Genomics, Cornell University, Ithaca, NY.

The fatty acid desaturase (*FADS*) genes encode key enzymes for biosynthesizing omega -6 and -3 long-chain polyunsaturated fatty acids (LCPUFAs). While LCPUFAs can be absorbed from animal-based diets, biosynthesis is essential to compensate for their absence in plant-based diets. Adaptive signals have been reported for some *FADS* variants in Africans, South Asians, some East Asians, Greenlandic Inuit and Native Americans. Recently, we reported two haplotypes (called M2 and D), comprising of opposite alleles of the same *FADS* variants, were respectively adaptive to the animal-based diets of pre-Neolithic European hunter-gatherers by diminishing LCPUFAs biosynthesis and to the plant-based diets of European farmers after the Neolithic Revolution by enhancing biosynthesis. It seems that opposite alleles of the same causal variants were respectively adaptive to the two diets. However, another recent study evaluated linkage disequilibrium among genetic variants and suggested that selection has targeted different variants in Europeans, South Asians and Inuit. Here, we systematically investigated the genetic variants and haplotypes under selection in global present-day populations (e.g. 1000GP, HGDP, SGDP, UK10K) and in historical populations with ancient DNA (aDNA, compiled from over 25 studies). We recalled genotype for critical structural variants with high-depth sequencing data and with imputation we obtained a uniform set of variants across all data sets. We applied three types of selection tests: 1) solely based on present-day DNA (e.g. Tajima's D, Fay and Wu's H, iHS, nSL, and SDS), 2) compared frequency change between ancient and present-day DNA, and 3) inferred selection coefficient from allele frequency time series. We found the same *FADS* haplotypes under selection in multiple populations. Haplotype D carries adaptive signals in most traditional farming populations, ranging from South Asians (current frequency 82%), Europeans (63%), to Africans (40%) and some East Asians (43%). Two closely related haplotypes (M1 and M2) were adaptive in Eskimos (M1:73%), Native Americans (M1:39%; M2:54%), southeastern Asians (M2:53%) and in historical European hunter-gatherers (M2 increased from 29% to 50% from 30 to 7.5kya). We further applied simulation of selection with observed ancient and present-day DNA to prioritize multiple candidate variants. These complex patterns of recurrent dietary adaptation of different *FADS* haplotypes are unique in human evolution.

**Genetic origins of Easter Island and remote Oceania.** *A. Ioannidis<sup>1</sup>, J. Blanco<sup>2</sup>, C. Quinto<sup>2</sup>, K. Sandoval<sup>2</sup>, E. Hagelberg<sup>3</sup>, M. Moraga<sup>4</sup>, J. Miquel-Poblete<sup>4</sup>, T. Parks<sup>5</sup>, M. Ávila-Arcos<sup>6</sup>, E. Burchard<sup>7</sup>, C. Eng<sup>7</sup>, A. Adams<sup>8</sup>, A. Mentzer<sup>8</sup>, C. Bustamante<sup>8</sup>, A. Moreno-Estrada<sup>2</sup>.* 1) Computational and Mathematical Engineering, Stanford University, Palo Alto, CA; 2) Human Population Genomics Lab, Laboratorio Nacional de Genómica para la Biodiversidad, Irapuato, Mexico; 3) Department of Biology, University of Oxford, Blindern, Norway; 4) Facultad de Medicina, Universidad de Chile, Santiago de Chile, Chile; 5) Wellcome Trust Centre for Human Genetics, University of Oxford, Oxford, United Kingdom; 6) International Laboratory for Human Genome Research, Universidad Nacional Autónoma de México, Querétaro, Mexico; 7) University of California San Francisco, San Francisco, United States; 8) Department of Genetics, Stanford University, Palo Alto.

Reaching its easternmost extent in Easter Island less than one thousand years ago, the settlement of Polynesia represents a final chapter in the dispersal of humans across the globe. Though it occurred relatively recently, much remains unknown about this unique oceanic process in historical population genetics, including the sequences of islands settled, the timing of settlements, and the origins of the settlers. Using dense genome-wide SNP array data of 445 modern samples from seventeen key islands (or island clusters) spanning remote Oceania, we infer settlement patterns stretching across the Pacific to Easter Island, and we address the long lingering suggestion that Native Americans could have played a role in the ancient population history of Easter Island. We confirm this theory, but we show that the ancient contact with Native Americans took place in Polynesian "up stream" of Easter Island, that is, before its settlement, and that this component was then carried to Easter Island by its admixed founders. We use three different timing analyses, as well as evidence of differential origins within the Americas of distinct Native American genetic signatures that we find present in Polynesia, to support our conclusions. The isolated Polynesian islands, separated by vast Pacific distances, have provided us with a uniquely structured canvas on which to implement novel variants of ancestry deconvolution and migration analysis techniques; we will describe these techniques, which could be useful for analyzing similarly isolated populations from other understudied regions of the world. Our results demonstrate the important role that both recent and ancient admixture events have played in creating the rich diversity patterns that define modern Polynesian populations.

**A web-based initiative to accelerate research on African ancestry in the Americas.** *M.E. Moreno, K. Bryc, P.K. Penton, R. Rubenstein, L. Vermillion, J.L. Mountain, the 23andMe Research Team.* 23andMe, Inc., Mountain View, CA.

The lack of genetic research on people of African ancestry has greatly limited our understanding of their genetic diversity. Since little is known about the ancestors of African descendants living in the Americas, it is difficult to determine from which ethnic groups or geographical areas slaves were taken. A lack of written records has resulted in ambiguity for many African Americans regarding their ancestors' origins. In 2016, 23andMe launched the African Genetics Project, a web-based genetic research study of individuals with recent African ancestry. The goals were to improve 23andMe's ability to provide more detailed ancestry results for customers with some African origins and to contribute to the global understanding of how people historically migrated throughout Africa and from Africa to the rest of the world. The study was open to any adult in the United States whose four grandparents were born in a single high priority country (Angola, Benin, Burkina Faso, Cameroon, Gabon, Ghana, Guinea Bissau, Guinea, Côte d'Ivoire, Liberia, Republic of Congo, Senegal, Sudan, Togo) or were affiliated with a single ethnic or tribal group in those countries. Consenting participants were asked to provide a saliva sample for genetic analysis and complete a survey about their family's birthplaces. Over a period of seven months, over 1,100 eligible individuals enrolled in the study. To date, 70% of these participants have provided a saliva sample and 60% have completed all study steps. The countries with the largest enrollment rates were Ethiopia, Somalia, and Sudan. The countries with the smallest enrollment rates were Benin, Burkina Faso, Congo (Brazzaville), Gabon, Guinea-Bissau, and Togo. Recruitment efforts included posts on 23andMe's social media channels, including targeted Facebook advertisements, a 23andMe blog post, presentations at university-based African Studies centers, and an article in the online African-American culture magazine, *The Root*. Participants also drove recruitment by posting about the study on blogs, forums, and YouTube. The success of this study puts 23andMe in a position to study African populations that are underrepresented in genetic research and serves as a pilot for recruitment of other underrepresented populations. An important next step will be to compare the genetic data collected from the African Genetics Project with the data of consenting 23andMe research participants from across the Americas.

**2359W**

**Origin and affinities of Lakshadweep Islanders.** *M.S. Mustak<sup>1</sup>, N. Rai<sup>2</sup>, M. Naveen<sup>1</sup>, S. Prakash<sup>2</sup>, N. Pasupuleti<sup>1</sup>, G. Chaubey<sup>2</sup>, K. Thangaraj<sup>2</sup>.* 1) Applied Zoology, Mangalore University, Mangalore, Karnataka, India; 2) CSIR-Centre for Cellular and Molecular Biology, Hyderabad, Telangana-500007, India; 3) Department of Evolutionary Biology, Estonian Biocentre, Riia23b, Tartu, Estonia.

Archipelago Lakshadweep resides in a south-west part of India in the Arabian Sea. In addition to its geographical isolation, the gene pool of these islands encompasses the signatures of ancient human dispersal across the South Asian (SA) corridor. In order to reconstruct the population history of Lakshadweep population, we have analysed uniparental (mtDNA and Y chromosome) and biparental (750K autosomal loci) markers among 1359 individuals belonging to several ethnic groups of Lakshadweep Islands. We observed the overwhelming presence of mitochondrial haplogroup R30, whereas the Y chromosome major haplogroups were P267-R2a (16%), Y495-R1a2b (12%). Both mtDNA and Y chromosome signals showed a close genetic link between Lakshadweep populations with the mainland Indian populations. The allele frequency and haplotype-based autosomal analyses suggested their closest affinity with the Southern Indian state Kerala.

**The genetic substructure of the Japanese population: Results from the Japan Multi-Institutional Collaborative Cohort Study.** *M. Nakatochi<sup>1</sup>, T. Nishiyama<sup>2</sup>, A. Hishida<sup>3</sup>, M. Naito<sup>3</sup>, M. Kubo<sup>4</sup>, K. Wakai<sup>5</sup>,* the Japan Multi-Institutional Collaborative Cohort Study. 1) Statistical Analysis Section, Center for Advanced Medicine and Clinical Research, Nagoya University Hospital, Nagoya, Japan; 2) Department of Public Health, Aichi Medical University School of Medicine, Nagakute, Japan; 3) Department of Preventive Medicine, Nagoya University Graduate School of Medicine, Nagoya, Japan; 4) Laboratory for Genotyping Development, Center of Genomic Medicine, RIKEN, Yokohama, Japan.

*Aims* the Japanese population has been known to be grouped into super-clusters, which are Mainland and Ryukyu clusters, in the population genetics. Investigation of the super-clusters in the detail was very important to perform genetic disease association studies and reveal demographic history in the Japanese population. We examined the Japanese population substructure using genome wide genotyping data from the Japan Multi-Institutional Collaborative Cohort Study (J-MICC), including south west islands of Japan. *Methods* A total of 14,539 study subjects from the 12 areas of the J-MICC study including the Ishigaki and Amami Islands were genotyped at RIKEN Center for Integrative Medicine using a HumanOmniExpressExome-8 v1.2 BeadChip array. Subjects with discordant sex information and close relationship pairs were removed. First, Principal component analysis (PCA) with J-MICC subjects, 1000 genomes East Asian (EAS), and Pan-Asian SNP (PASNP) consortium genotype data were performed to examine the population substructure of east Asian including J-MICC subjects. We also performed ADMIXTURE analysis for J-MICC subjects. *Results* PCA with J-MICC subjects, 1000 genomes EAS, and Pan-Asian EAS showed three clusters (Mainland, Ryukyu, and Korean clusters) from J-MICC subjects. Of the J-MICC subjects, 0.3% were assigned to the Korean cluster. PCA with only J-MICC subjects further indicated the Amami cluster. The Amami cluster existed closest to Ryukyu cluster, but didn't exist closest to Korean and Taiwan populations. The result of ADMIXTURE analysis revealed that the minimum value of the cross-validation (CV) error was observed when the assumed number of ancestral populations (K) was 8. *Conclusion* We examined the population substructure of J-MICC study, and identified four sub-clusters (Mainland, Ryukyu, Amami, and Korean clusters). ADMIXTURE analysis indicated that the K=8 was minimum value of the CV error. Thus, the result suggests the possibility that more genetic clusters exist in Japanese population. These results are expected to be important information to do genetic disease association studies with the use of the Japanese population data.

**IBD detection at biobank-scale.** A. Naseri<sup>1</sup>, X. Liu<sup>2</sup>, S. Zhang<sup>1</sup>, D. Zhi<sup>3</sup>. 1) Department of Computer Science, University of Central Florida, Orlando, Florida; 2) Department of Epidemiology, Human Genetics & Environmental Science, University of Texas Health Science Center at Houston, Houston, Texas; 3) School of Biomedical Informatics, University of Texas Health Science Center at Houston, Houston, Texas.

Recently, very large genotyped cohorts (VLGCs) with rich phenotypes, such as UK Biobank, are becoming available. Unlike traditional cohorts, these cohorts contain samples about 0.1%-1% of the entire population. At this scale, genetic relatedness among these samples are ubiquitous and cannot be simply ignored as unrelated. Identical-by-Descent (IBD) segments, as direct evidence of common ancestry among individuals, are a reliable source for genetic relatedness. Therefore, having direct IBD information will enable a wide range of applications from association studies to population genetics. However, current IBD detection tools are too slow to be applied to biobank-scale data sets. We have developed a new method, RaPID, that is more than 100 times faster than GERMLINE, the fastest IBD detection tool for the past 8 years. The efficiency of RaPID is achieved by an innovative randomization strategy around Richard Durbin's Positional Burrow-Wheeler Transformation (PBWT), which enables PBWT to work with genomic sequences with errors and mutations. Thanks to PBWT's linear time complexity with the sample size, RaPID is the first computationally feasible method that can infer IBD segments among individuals in a biobank-scale cohort. We compared RaPID and GERMLINE by simulations using macs with a demographic history model of the Europeans. We not only verified the speed of RaPID, but also showed that for IBD segments with length >5cM, RaPID can detect more IBD segments (99%) than GERMLINE (85%) with a comparably higher accuracy (99% for both methods). Moreover, at >1.5cM, RaPID reported both more IBD segments (97% vs 65%), and a higher accuracy (92% vs 63%). Interestingly, RaPID also reported sharper segment boundaries (RMSE 0.4cM) than GERMLINE (RMSE 1.5cM) at >5cM. A similar trend is seen at 1.5cM: RaPID (0.5cM) vs GERMLINE (0.7cM). We applied RaPID to the data from 1000 Genomes project, and identified both sub-continental and inter-continental IBDs. Most notably, we identified a genetic relationship at 1.5cM among Finns and Asians, suggesting possible historical migration event. Overall, our results showed that RaPID is not only fast, but also accurate in terms of IBD detection and it may be an essential tool to uncover the rich genetic relatedness information in large genotyped biobank data.

**Exploring the demographic and admixture history of Central Mexico.**

A.W. Reynolds<sup>1,2</sup>, J. Mata-Miguez<sup>2</sup>, D.A. Bolnick<sup>2,3</sup>. 1) Department of Integrative Biology, University of Texas at Austin, Austin, TX; 2) Department of Anthropology, University of Texas at Austin, Austin, TX; 3) Population Research Center, University of Texas at Austin, Austin, TX.

The Spanish colonization of Mexico led to the creation of new communities containing individuals who had been born in three different continents (North America, Europe, and Africa) and who came from diverse cultural and linguistic backgrounds. Major population collapses also occurred in indigenous communities following colonization of this region. While previous research has explored these events in Mexico City and other urban areas, their impact on rural populations remains unclear. In Xaltocan, a small town in central Mexico, historical documents suggest that the Spanish rarely visited the town. To better understand the demographic history of this region and the genetic effects of Spanish colonial history, we collected samples from 47 present-day residents from Xaltocan. The samples were genotyped for >600,000 genome-wide single nucleotide polymorphisms (SNPs) using the Affymetrix Axiom® Human Origins Array. Individual ancestry estimates were calculated using ADMIXTURE and RFMix. Estimates of the number and timing of admixture events at Xaltocan were calculated using TreeMix and Tracts. Past changes in population size were modeled using dadi. We find a much lower average proportion of European ancestry at Xaltocan compared to previously sampled populations in the Americas. We also find evidence that a single admixture event between European and Native American source populations affected our study population at Xaltocan.

**2363T****Signatures of multiple-mergers coalescence in genomic diversity data.**

*D.P. Rice<sup>1</sup>, J. Novembre<sup>1</sup>, M.M. Desai<sup>2</sup>*. 1) Human Genetics, University of Chicago, Chicago, IL; 2) Organismic and Evolutionary Biology, Harvard University, Cambridge, MA.

The genetic diversity of a population reflects its demographic and evolutionary history. Methods for inferring this history typically assume that the ancestry of a sample can be modeled by the Kingman coalescent process. A defining feature of the Kingman coalescent is that it generates genealogies that are binary trees: no more than two ancestral lineages may coalesce at the same time. However, this assumption breaks down under several scenarios. For example, pervasive natural selection, rapid spatial range expansion, and extreme variation in offspring number can all generate genealogies with "multiple-merger" events in which more than two lineages coalesce instantaneously. Therefore, detecting multiple mergers is important both for understanding which forces have shaped the diversity of a population and for avoiding fitting misspecified models to data. Current methods to detect multiple mergers rely on the average site frequency spectrum (SFS). However, many of the signatures of multiple mergers in the average SFS are also consistent with a Kingman coalescent process with a time-varying population size. Here, we present a new method for detecting multiple mergers based on correlations in the SFS across the genome. Unlike the average SFS, these correlations depend mostly on the topologies of genealogies rather than their branch lengths and are therefore robust to most demographic effects. We apply this method to genomic diversity data from a variety of species, including humans and *D. melanogaster*.

**2364F****Studying global variation of gene flow using geo-referenced genetic data.**

*S. Song<sup>1</sup>, N.D. Berkowitz<sup>1</sup>, Y. Wang<sup>1</sup>, D.A. Turissini<sup>1</sup>, H. Guturu<sup>1</sup>, J. Byrnes<sup>1</sup>, E. Hong<sup>1</sup>, C. Ball<sup>1</sup>, K. Chahine<sup>2</sup>*. 1) AncestryDNA, San Francisco, CA; 2) AncestryDNA, Lehi, UT.

Geographic distances often cause genetic similarities to decay. Heterogeneity in the rate of decay is caused by various factors affecting gene flow. Understanding gene flow barriers or corridors is crucial to identify fine scale population structure and can yield insights on evolutionary processes that shape present day genetic diversity. A newly published method EEMS (Estimated Effective Migration Surfaces) models the relationship between genetics and geography and produces a visual representation of population structure highlighting potential regions of historic gene flow (Petkova Nature 2016). Using a research-consented subset for our database of over 4 million samples, we inferred the 'putative geographic origin' from which the individual's recent ancestry is derived based on pedigree information. We then applied EEMS using genome-wide SNP data and estimated effective migration rates among human populations in Europe and North America. We identified several known geographic barriers and regions showing high connectivity. We further investigated observed barriers/corridors and compared these with migration patterns found using pedigree data.

**Genetic structure in Brittany highlights physical and cultural limits.** *J. Giermasz<sup>1</sup>, M. Karakachoff<sup>1</sup>, E. Charpentier<sup>1</sup>, K. Rouault<sup>1</sup>, A. Saint-Pierre<sup>2</sup>, F. Simonet<sup>1</sup>, S. Lecointe<sup>1</sup>, P. Lindenbaum<sup>1</sup>, C. Férec<sup>2</sup>, H. Le Marec<sup>1</sup>, S. Chatel<sup>1</sup>, J.J. Schott<sup>1</sup>, E. Génin<sup>2</sup>, R. Redon<sup>1</sup>, C. Dina<sup>1</sup>.* 1) L'institut du thorax, INSERM, CNRS, UNIV Nantes, CHU Nantes, Nantes, France, Nantes, Pays de la Loire, France; 2) INSERM UMR 1078, CHRU Brest, UNIV Brest, Brest, France.

**Background** The genetic structure of human populations varies throughout the world, being influenced by migration, admixture, natural selection and genetic drift. Characterising such genetic variation can provide insight into demographical history and informs research on disease association studies, especially on rare recent variants. In this study, we examine the fine-scale genetic structure of Brittany and surrounding regions of France. Brittany is a region in the north-west of France, historically and culturally distinctive. Genetic proximity between Bretons and Irish has been shown in [1]. Currently, administrative Brittany covers only 80% of historical Brittany. Southern limits of historical Brittany extend further than the Loire River, the biggest physical barrier in the region. Eastern limits do not coincide with any significant geographical feature, potential genetic barrier could be thus a result of cultural and historical differences. **Methods and Results** We genotyped 1005 individuals from North-Western France, with at least three of their grandparents born within a 15 kilometres distance using Axiom™ Precision Medicine Research Array. Principal Components analysis revealed a high correlation between geographical position and components ( $p$ -value  $< 2e-16$ ). Visualisation of PC1 (0.16 % of variance) on the map points to three subpopulations: one in the south of Loire River and two in the north, one of which overlaps with historical Brittany. Partial Mantel tests confirm that genetic differentiation is not uniform. We also approximate eastern border of "genetic Brittany" based on ADMIXTURE results and test the strength of the barriers with  $F_{st}$  statistic. Southern border, corresponding to Loire River, is more pronounced. **Conclusion** We here report both evidence for isolation by distance within at a very fine level and existence of two genetic barriers, the Loire River and the historical boundary of Brittany Duchy. Subsequently, we will verify and extend our findings with fineSTRUCTURE software and with analysis based on Identity By Descent. This fine-scale population structure may have consequence in association analyses, especially for rare variants which tend to be geographically clustered. These results support the need for a genetically matched panel of controls in gene mapping analyses in French population. 1. Karakachoff, M. et al. Fine-scale human genetic structure in Western France. *Eur J Hum Genet* 23, 831–836 (2015).

**The Irish DNA Atlas: Revealing fine scale population structure and history within Ireland.** *E.H. Gilbert<sup>1</sup>, S. O'Reilly<sup>2</sup>, M. Merrigan<sup>2</sup>, D. McGettigan<sup>2</sup>, A.M. Molloy<sup>3</sup>, L.C. Brody<sup>4</sup>, W. Bodmer<sup>5</sup>, K. Hutnik<sup>6</sup>, S. Ennis<sup>6</sup>, D.J. Lawson<sup>7</sup>, J.F. Wilson<sup>8,9</sup>, G.L. Cavalleri<sup>1</sup>.* 1) Molecular and Cellular Therapeutics, Royal College of Surgeons in Ireland, Dublin, Leinster, Ireland; 2) Genealogical Society of Ireland, Dún Laoghaire, County Dublin, Ireland; 3) School of Medicine, Trinity College, Dublin 2, Ireland; 4) Genome Technology Branch, National Human Genome Research Institute, National Institutes of Health, Bethesda, MD 20892; 5) Weatherall Institute of Molecular Medicine and Department of Oncology, University of Oxford, Oxford OX3 7DQ, UK; 6) School of Medicine and Medical Science, University College Dublin, Dublin, Ireland; 7) University of Bristol, Department of Mathematics, University Walk, Bristol BS8 1TW, UK; 8) Centre for Global Health Research, Usher Institute for Population Health Sciences and Informatics, University of Edinburgh, Teviot Place, Edinburgh, Scotland; 9) MRC Human Genetics Unit, Institute of Genetics and Molecular Medicine, University of Edinburgh, Western General Hospital, Crewe Road, Edinburgh, Scotland.

Demographically, Ireland has remained relatively isolated from mainland Europe, notwithstanding notable historical migrations including the Norse Vikings, Anglo-Normans, and the British Plantations. A considerable number of individuals outside Ireland share Irish ancestry including an estimated 33 million individuals in the United States. Although previous studies have shown the Irish population within Ireland to be situated at the end of a number of genetic clines within Europe, the extent of fine-scale population structure within Ireland is largely unknown and it is unclear to what degree historical migrations have impacted the modern Irish genome. Here we illustrate fine scale genetic structure across Ireland that follows sociological boundaries within Ireland and we present evidence of admixture events into Ireland from both the neighbouring British Isles and continental Europe. Utilising the 'Irish DNA Atlas', a DNA cohort ( $n = 194$ ) of genealogically described Irish individuals with four generations of ancestry linked to specific regions in Ireland, we analysed the Atlas in combination with 2,039 individuals of regional British ancestry (the PoBI dataset) and show that the Irish population can be divided in 10 distinct geographically stratified genetic clusters; three are of shared British and Irish ancestry, and seven of predominantly 'Gaelic' Irish ancestry. This structure is remarkably homogenous, and is associated with few gene flow barriers within Ireland. Using a reference of 6,760 European individuals and two ancient Irish genomes, we quantified the ancestry of these Irish clusters in the context of neighbouring Europe as well as ancient Ireland. We show high levels of North West French-like and Norwegian-like ancestry within Ireland. We also show that our 'Gaelic' Irish clusters present homogenous levels of ancient Irish ancestries. Finally we detect admixture events into Ireland that coincide with the Plantations of Ulster, as well as provide evidence of Norse Viking gene flow into Ireland. Our work informs both on Irish history, as well as the study of Mendelian and complex disease genetics involving populations of Irish ancestry.

**Characterizing heterogeneity within fine-scale population structure.** A. Hippen Anderson<sup>1</sup>, A.R. Girshick<sup>2</sup>, A. Boroomand<sup>2</sup>, R.E. Curtis<sup>1</sup>, B. Wilson<sup>2</sup>, K. Noto<sup>2</sup>, E.L. Hong<sup>2</sup>, C.A. Ball<sup>2</sup>, K.G. Chahine<sup>2</sup>. 1) AncestryDNA, Lehi, UT; 2) AncestryDNA, San Francisco, CA.

We have recently demonstrated the ability to leverage network analysis methods to discover genetic communities within a large identity-by-descent (IBD) network. Members of each community share more IBD with one another than with those outside of their community. We interpreted these genetic communities using pedigree annotations. Using this approach, we discovered, named, and localized over 300 genetic communities. Here we provide a richer understanding of these genetic communities as a group of people within a temporal and geographic context. Using machine learning techniques, we identified common features within 63 different genetic communities including genetic ethnicity patterns and other related meta-data. We found that some communities are more homogenous in this feature space than others. For instance, some genetic communities tend to have a dominant ethnicity while others are highly admixed. The more heterogeneous the genetic community, the more likely we were to find an identifiable sub-group within it. We were also interested in understanding the temporal structure of genetic communities. Communities differed in the distribution of birth years among members, possibly indicating compositional differences on extremely short time scales. We also analyzed these birth year distributions with respect to geographic location. These results provide a novel way to understand IBD network-based genetic communities in their temporal, spatial, and ethnicity contexts.

**The genomic health of ancient hominins.** J. Lachance, T. Cooper, A. Berens. School of Biology, Georgia Institute of Technology, Atlanta, GA.

The genomes of ancient humans, Neandertals, and Denisovans contain many alleles that influence disease risks. Using genotypes at 3180 disease-associated loci, we estimated the disease burden of 147 ancient genomes. After correcting for missing data, genetic risk scores were generated for nine disease categories and the set of all combined diseases. These genetic risk scores were used to examine the effects of different types of subsistence, geography, and sample age on the number of risk alleles in each ancient genome. On a broad scale, hereditary disease risks are similar for ancient hominins and modern-day humans, and the GRS percentiles of ancient individuals span the full range of what is observed in present day individuals. In addition, there is evidence that ancient pastoralists may have had healthier genomes than hunter-gatherers and agriculturalists. We also observed a temporal trend whereby genomes from the recent past are more likely to be healthier than genomes from the deep past. This calls into question the idea that modern lifestyles have caused genetic load to increase over time. Focusing on individual genomes, we find that the overall genomic health of the Altai Neandertal is worse than 97% of present day humans and that Ötzi the Tyrolean Iceman had a genetic predisposition to gastrointestinal and cardiovascular diseases. As demonstrated by this work, ancient genomes afford us new opportunities to diagnose past human health, which has previously been limited by the quality and completeness of remains.

**2369T**

**FastNGSadmix: Admixture proportions and principal component analysis of a single low-depth sequencing sample.** *E. Jørsboe<sup>1</sup>, K. Hanghøj<sup>2,3</sup>, A. Albrechtsen<sup>1</sup>.* 1) The Bioinformatics Centre, Department of Biology, University of Copenhagen, 2200 Copenhagen N, Denmark; 2) Center for GeoGenetics, Natural History Museum of Denmark, University of Copenhagen, 1350 Copenhagen K, Denmark; 3) Université de Toulouse, University Paul Sabatier (UPS), Laboratoire AMIS, CNRS UMR 5288, Toulouse, France.

We present fastNGSadmix, a method for fast and easy estimation of admixture proportions and principal component analysis (PCA), for a single low-depth next generations sequencing (NGS) sample using a panel of reference populations, with population specific allele frequencies. We show that fastNGSadmix has increased accuracy compared to established methods for estimating admixture from reference panels, such as iAdmix and ADMIXTURE. fastNGSadmix corrects for the bias, introduced by having a limited size reference panel, which is a substantial problem with other methods. Reference panels where populations are represented by fewer than 20 individuals has a large impact on the accuracy, if no correction for small reference panels is done. fastNGSadmix works for samples with very low sequencing depth, we show through downsampling that fastNGSadmix is able to estimate the correct admixture proportions for a sample with depth of coverage of less than 0.005X, equivalent of there on average being less than one read per 200 sites. This is because the method works with genotype likelihoods, this enables us to take the uncertainty of the genotypes into account in the proposed admixture model. A bootstrapping approach has been implemented for the admixture estimation, meaning the uncertainty on the admixture estimates can easily be obtained, making it easier to infer if the admixture proportions with regards to different populations differ significantly. We use the estimated admixture proportions to perform PCA incorporating both population structure and genotype uncertainty. Existing PCA methods based on NGS data do not model population structure and simply assume that genotypes between individual are independent. This method does not make this assumption and instead works by modeling the impact of population structure via the estimated admixture proportions from fastNGSadmix. It also works with genotype likelihoods modelling the genotype uncertainty. It is therefore well suited for doing PCA for admixed NGS samples. This method has for example been applied to ancient DNA samples, where it is easy to apply this method to the individual samples. Ancient DNA is usually characterized by high uncertainty on the data, why it is crucial to take genotype uncertainty into account. In addition the samples are modelled independently, which allows for analysing related samples.

**Assessment of BAP1 germline and somatic alterations in uveal melanoma.** *M.H. Abdel-Rahman*<sup>1,2,3</sup>, *G. Boru*<sup>1</sup>, *T. Grose*<sup>1</sup>, *R. Pilarski*<sup>2,3</sup>, *J.B. Massengill*<sup>1</sup>, *F.H. Davidorf*<sup>1</sup>, *C.M. Cebulla*<sup>2,3</sup>. 1) Department of Ophthalmology, The Ohio State University, Columbus, OH; 2) Division of Human Genetics, Department of Internal Medicine, The Ohio State University, Columbus, OH; 3) The Ohio State University Comprehensive Cancer Center, Columbus, OH.

**Objective:** BAP1 (BRCA1-associated protein 1) is a deubiquitinating hydrolase with tumor suppressor function through involvement of various biologic processes including chromatin remodeling, DNA damage response, cell cycle regulation, and cell growth. Germline mutation in BAP1 is associated with Tumor Predisposition Syndrome (BAP1-TPDS, OMIM #614327) with at least four main cancers: uveal melanoma (UM), cutaneous melanoma (CM), mesothelioma (MMe) and renal cell carcinoma (RCC). Somatic mutations in BAP1 are observed in many different cancers with UM the most common. The aim of this project is to assess the frequency and type of germline and somatic alterations in BAP1 in UM patients. **Methods:** Germline mutations in BAP1 were assessed in 160 UM patients with moderate to high risk for hereditary cancer predisposition. Somatic mutations were assessed in an additional 47 UM tumors. Mutations were assessed by direct (Sanger) sequencing. In a subset of patients somatic and germline large deletions and epigenetic inactivation were assessed by MLPA and pyrosequencing respectively. The expression of BAP1 was assessed in tumors and non-tumor choroids by qRT-PCR, immunohistochemistry and/or Western blot. **Results:** We identified a total of 22 patients with one or more germline variants. Six (3.8%) of these patients had truncating mutations. The other 14 patients had benign/likely benign variants or variants of uncertain significance. In patients with familial UM the frequency of truncating mutation was 6/32 (18.8%). Somatic variants were detected in 29/47 (61.7%) of the tumors including 5 (10.7%) with large deletions (>20bp). No germline deletion/duplication in BAP1 was detected in 98 patients. No significant evidence of somatic or constitutional promotor hypermethylation was detected in the samples tested. Two out of the 17 non-tumor choroid tissues showed significant decrease in BAP1 RNA expression compared to normal controls. No detectable germline genomic alteration or aberrant promotor methylation was identified suggesting other mechanisms for epigenetic BAP1 inactivation. **Conclusions:** BAP1 is an important candidate for hereditary predisposition to UM but additional candidate genes exist. Large deletion is not a major mechanism for germline inactivation of BAP1. Epigenetic mechanisms, other than promotor methylation, are possible for both germline and somatic inactivation of BAP1.

**2371W**

**Paperwork matters! The importance of clinical phenotype information in variant interpretation.** *M. Anderson*, *C. Pardo*, *H.C. Kang*, *J. Thusberg*, *R. Quintana*, *K. Erhard*, *S-H. Wang*, *J. Holle*, *D. Iacoboni*, *I. Wilson*, *K. Ouyang*. Invitae, San Francisco, CA.

The validity and utility of genetic testing require that variant classifications be evidence based, objective, and systematic. As genetic testing becomes available to a larger percentage of the population, detailed clinical information about patients and their family members becomes increasingly relevant for variant classification. Although sufficient clinical information is often provided in well-described case reports in the published literature, most classified variants are observed only in the clinical testing laboratory setting. Therefore, the ordering clinician becomes the sole source of phenotypic data, as provided on the test requisition form. To objectively incorporate this clinical data into our laboratory's pre-existing evidence-based variant classification framework called Sherlock, we defined point-based criteria and usage rules allowing us to evaluate the following: 1. clinical phenotype 2. variant segregation in families 3. variant de novo status As part of this process, we developed a set of predefined clinical criteria for approximately 130 oncology genes. For genes such as NF2, FH, and VHL, our interpretation criteria are nearly identical to the consensus clinical diagnostic criteria. For genes that lack a formal consensus, such as SDHB and SDHD, we took a rigorous, conservative approach in establishing internal criteria that consider age of onset, phenotypic specificity, penetrance, prevalence, and the existence of phenocopies. The application of our method is illustrated in cases of STK11 and PTCH1 variants, in which detailed phenotypic information provided by the clinician impacted classification. We also present MEN1 and CASR cases in which clinical information did not meet our threshold criteria for use in the variant classification process. These results highlight the need for ordering providers to share detailed clinical patient information, as it may influence variant classification and ultimately clinical care.

**Mutational spectrum in BRCA1 and BRCA2 genes in Colombia.** *I. Briceño<sup>1</sup>, A. Gomez<sup>2</sup>, N. Diaz<sup>1</sup>, M. Noguera<sup>2</sup>, D. Diaz<sup>2</sup>, M. Casas<sup>3</sup>.* 1) Bioscience, Universidad de La Sabana, Chia, Colombia; 2) Pontificia universidad Javeriana; 3) Instituto de referencia andino.

**Introduction:** The risk of developing breast and ovarian cancer is higher in families that carry one or more mutations in BRCA1 or BRCA2 genes. Detection of mutations in families and patients allows timely decisions in the field of preventive medicine. **Objective:** To identify the presence of mutations in the Colombian population and evaluate two testing strategies. **Methodology:** Tests referred for BRCA1 and BRCA2 analyzed by complete direct sequencing of both genes and partial sequencing based on founder mutations in a test designed by Instituto de Referencia Andino in Bogotá ("Profile Colombia"). **Results:** We found 110 patients carrying deleterious mutations in this group of 900 Colombian patients 65% where found in BRCA1, and 35% in BRCA2. **Conclusions:** The spectrum of 50 different mutations in Colombia as detected in our study is broader than the one previously reported for this country. "Profile Colombia" is a useful screening test to establish both founder and new mutations with a detection rate of 12% in cases with family history of breast cancer. Complete sequencing shows a detection rate of 14%, and should complement the study of a genetic basis for this disease. **Key words:** Breast cancer, BRCA1, BRCA2, sequencing, Profile Colombia.

**2373F**

**Retrospective analysis of 36 fusion genes in 6170 patients of *de novo* acute leukemia and myeloid neoplasms.** *X. Chen<sup>1</sup>, F. Wang<sup>1</sup>, Y. Zhang<sup>1</sup>, M. Wang<sup>2</sup>, W. Teng<sup>1</sup>, X. Ma<sup>1</sup>, L. Guo<sup>1</sup>, J. Fang<sup>1</sup>, Y. Zhang<sup>2</sup>, P. Zhu<sup>2</sup>, H. Liu<sup>1</sup>.* 1) Hebei Yanda Lu Daopei Hospital, Langfang, Hebei, China; 2) Peking University First Hospital, Xicheng District, Beijing, China.

To gain a better understanding of the gene-fusion landscape in different types of hematologic malignancies and different age groups, 36 fusion genes were assessed by multiplex-nested RT-PCR in 6170 *de novo* acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), mixed phenotype acute leukemia (MPAL) or myeloproliferative neoplasms (MPN) patients. 34 distinct fusion genes were detected in 39.06% patients. Fusion genes were detected in 41.21% AML, 28.72% ALL, 22.39% MPAL and 79.96% MPN, respectively. The incidence of fusion genes was higher in pediatric AML than in adult AML. With the exception of infant AML, the incidence of fusion genes decreased with the growth of age. RUNX1-RUNX1T1, KMT2A-MLLT3, KMT2A-MLLT10, KMT2A-MLLT11 and FUS-ERG were more common in pediatric AML while KMT2A-PTD was more frequent in adult AML. The frequency of fusion genes in ALL was lower than in AML. Except for infant ALL, patients of 30-59 years had the highest frequency of fusion genes. BCR-ABL1 and SET-NUP214 were more common in adult ALL while TCF3-PBX1 and ETV6-RUNX1 were more common in pediatric ALL. The occurrence of fusion genes was more frequent in B-ALL than in T-ALL. BCR-ABL1, TCF3-PBX1, KMT2A-AFF1 and ETV6-RUNX1 were more common in B-ALL while KMT2A-MLLT4, SET-NUP214 and STIL-TAL1 were more common in T-ALL. This is a systemic analysis of fusion genes in the largest cohort of leukemia and MPN to date. The identification of gene-fusion spectrums will help to better evaluate the diagnostic and prognostic significance of fusion genes in hematologic malignancies.

**Paternal inheritance of *BRCA* mutations in Algerian hereditary breast/ovarian cancer families.** F. Cherbal<sup>1</sup>, H. Gaceb<sup>1</sup>, C. Mehemmai<sup>1</sup>, K. Yatta<sup>1</sup>, R. Bakour<sup>1</sup>, K. Boualga<sup>2</sup>. 1) Unit of Genetics, LMCB, Faculty of Biological Sciences, University of Sciences and Technology Houari Boumediene Algiers, Algeria; 2) Radiation Therapy Services, Anti Cancer Center, Blida, Algeria.

**Background** Breast cancer is the leading cause of cancer morbidity and mortality among Algerian women. To date, *BRCA* mutations can be transmitted from fathers to their daughters. To the best of our knowledge, there is no study on paternal transmission of *BRCA* mutations in Algerian population. From 2008 to 2016, 150 breast/ovarian cancer families were screened for complete *BRCA1* and *BRCA2* germline mutations (70 families) and for specific mutations detected in *BRCA1* and *BRCA2* genes in Algerian patients (80 families), respectively. **Methods** The patients and their families were referred from public hospitals and private medical clinics which provide oncology services throughout Algeria. Patients were selected on family history of breast and/or ovarian cancer, and male relatives for prostate cancer along three generations at any age. Complete screening of germline mutations in *BRCA* genes has been conducted by HRM-direct sequencing in 70 families and their relatives (86 individuals). 80 families and their relatives (94 individuals) have been screened by PCR-direct sequencing for 4 common mutations, detected in Algerian population (exons 3,5 and 11) in *BRCA1* gene: c.83\_84delITG, c.181T>G, c.798\_799delTT and c.2125\_2156inA, and 2 common mutations in *BRCA2* gene (exons 10 and 14): c.1310\_1313delAAGA and c.7235\_7236insG, respectively. **Results** We noticed that paternal inheritance of *BRCA* mutations resulted in an earlier age of breast cancer in daughters (mean age 38.6 years). In 7 families with *BRCA* mutations, the parent of the origin of the mutation was the father. Four distinct pathogenic mutations in *BRCA1* gene have been detected in 6 families. The *BRCA2* mutation c.1310\_1313delAAGA has been detected in one family. Eleven (11) individuals (9 daughters and 2 sons) inherited pathogenic *BRCA* mutation from fathers (9 affected with cancer). Two ovarian cancers have been identified in two families. Interestingly, in five families with *BRCA1* mutations, male relatives had family history of prostate cancer. Three fathers among seven have developed prostate cancer. **Conclusions** Daughters with paternally inherited *BRCA* gene pathogenic mutation have breast cancer diagnosed at earlier ages. Families with paternal inheritance of *BRCA1* mutation have male relatives with history of prostate cancer. Individuals belonging to families with paternal inheritance of *BRCA* mutations should be tested at earlier age. Further studies in larger cohort are needed to reaffirm our findings.

**Novel acute myeloid leukemia amplicon panel for uniform detection of all target genes, including *CEBPA*.** C. Clear<sup>1</sup>, R. Hrdlickova<sup>1</sup>, J. Nehyba<sup>1</sup>, D. Fox<sup>1</sup>, D. Obermoeller<sup>1</sup>, M. Toloue<sup>2</sup>. 1) Bioo Scientific, Austin, TX; 2) Perkin-Elmer, Boston, MA.

Acute myeloid leukemia (AML) accounts for the largest group among adult acute leukemia patients, with an incidence of over 20,000 cases per year in the United States alone. AML is thought to occur from acquired somatic lesions in regulatory genes, which accumulate in hematopoietic progenitors throughout life. These mutations give rise to malignant clones, which outcompete or suppress normal hematopoiesis. NGS allows rapid and sensitive detection of mutations facilitating deep read coverage of all target regions. However, AML regions of interests include several complex and difficult regions not often covered in amplicon panels, such as GC-rich *CEBPA*. Even though this gene is extremely difficult to amplify, information about the sequence is needed for proper evaluation of AML genotypic status, as biallelic mutations in *CEBPA* have been revealed to be significant in the progression of AML. Therefore, we developed a panel that uniformly covers all regions of interest, with a simplified protocol. Whereas many panels fail to produce any coverage of the *CEBPA* gene, this panel has full mutation calling capabilities. *CEBPA* is composed of roughly 80% guanine and cytosine nucleotides which create numerous secondary structures, preventing amplification. An innovative combination of primer design and PCR conditions has been developed to overcome these difficulties, maintaining the high performance of all amplicons, even when the diversity of nucleotides in some regions is low. The developed panel covers 42 kb, comprising 105 coding exons and limited flanking intron regions of 28 genes. Libraries have 100% uniformity at a 10% of average read threshold, 95% on-target reads, and virtually no dimer contamination. Input is as little as 40 ng DNA from fresh and frozen tissue. High uniformity and high on-target reads allow maximal multiplexing, which is particularly important when identifying somatic mutations due to the necessity for deep coverage. Libraries generated are compatible with both Ion Torrent™ and Illumina® sequencing platforms. Performance of this panel has been validated by positive identification of described mutations in five key genes relevant to the genesis of the disorder. Samples containing mutations in the following genes, *CEBPA*, *NPM1*, *TET2*, *RUNX1*, and *DNMT3*, were analyzed on a MiSeq®, 600 cycle v3 kit.

**Comparison of variant classification algorithms incorporating clinical and family history for breast and ovarian cancer.** J. Clifford, M.H. Black, A. Elliott, H.M. Lu, S. Li. Bioinformatics and Computational Biology, Ambray Genetics, Aliso Viejo, CA.

Pathogenic mutations are more likely to occur in high-risk individuals while benign variants are unrelated to personal and family history. A proband's clinical and family history may be used to form a likelihood ratio (LR) of the probability that the individual is a mutation carrier vs. non-carrier. A variant LR is computed by estimating the joint probability of carrier status across all probands, which may be derived either from odds obtained from a logistic regression model (LRM) or observed proportions in a clinical population (history weighting algorithm (HWA)). While both methods are useful for variant classification, the relative merits of each under a variety of scenarios have not been directly compared. To demonstrate differences in performance and clinical utility of these approaches, we applied both methods to estimate the LRs of classified variants in *BRCA1* and *BRCA2*, using detailed clinical and family history data from 61,851 patients who underwent genetic testing at a single diagnostic laboratory in 2012-2015. To evaluate the performance of each approach under increasing numbers of independent variables, we tested gene-specific models with 6 and 20 binary variables, respectively. Discriminatory power for correctly classifying variants was then assessed using AUCs with 2-fold cross-validation. We also simulated synthetic variant LR distributions for a fixed number of mutation carriers/non-carriers; the number of carriers was incrementally increased to determine the minimum number of probands such that  $\leq 5\%$  of the variant LR distribution for mutation carriers overlapped with the distribution for non-carriers. We observed similar performance, as measured by AUC, for both methods with 6 variables for *BRCA1* (LRM: 0.71, HWA: 0.70) and *BRCA2* (LRM: 0.61, HWA: 0.61). When the number of independent variables increased, LRM had higher AUC (*BRCA1*: 0.83, *BRCA2*: 0.70) than HWA (*BRCA1*: 0.74, *BRCA2*: 0.64). For the 20 variable LRM, our simulations indicated that 40 probands for *BRCA2* and 12 for *BRCA1* were the minimum number necessary to separate 95% of the carrier and non-carrier LR distributions. Variant LR log(e) thresholds were found to predict synthetic variants as benign (*BRCA1*/2:-4.8) and pathogenic (*BRCA1*:5.7, *BRCA2*:5.5) with 95% accuracy. These data show that when the number of variables is large, the LRM may outperform HWA, which may have important implications for variant assessment given the increasing availability of clinical and family history data.

**A t(18;22)(q21;q11) involving *IGL/BCL2*, a rare event in in chronic lymphocytic leukemia.** A. Dowiak<sup>1,2</sup>, J. Ewing<sup>3</sup>, D. Zhao<sup>1,2</sup>, E. Salazar<sup>1,2</sup>, L. Thompson<sup>3</sup>, B. Wyatt<sup>3</sup>, K. Peterson<sup>3</sup>, L. Batholomaeus<sup>3</sup>, A. Nguyen<sup>1,2</sup>, R. Crippen<sup>1,2</sup>, D. Serk<sup>3</sup>, J. Reinartz<sup>3,4</sup>, C.A. Tirado<sup>2,3,4,5</sup>. 1) University of California, Los Angeles, CA; 2) The International Circle of Genetics Studies, Los Angeles, CA; 3) Allina Health, Minneapolis, MN; 4) HPA, Minneapolis, MN; 5) University of Minnesota School of Medicine, Department of Laboratory Medicine and Pathology, Minneapolis, MN.

We report a 63 y.o. male who presented with splenogaly, pallor, mucocutaneous bleeding. Peripheral blood showed more than 5000 monoclonal B Lymphocytes/ $\mu$ l. Blood smears showed small, mature appearing lymphocytes with a narrow border of cytoplasm and a dense nucleus lacking discernable nucleoli, having partially aggregated chromatin. Larger atypical lymphocytes or prolymphocytes were present in 43% of the cells. Flow Cytometry confirmed the presence of CD19, CD20 and CD23 consistent with CLL. Chromosome analysis of the bone marrow showed an abnormal karyotype described as 46,XY,t(18;22)(q21;q11.2)[19]/46,XY[1]. FISH analysis on interphase nuclei revealed an abnormal clone with loss of D13S319 (13q14.3) in 68.0% of the cells examined. Deletion of chromosome 13 is the most common cytogenetic abnormality identified in CLL (approximately 50% of CLL). Recent studies suggest that deletion of chromosome 13q14 in 65% or more nuclei by FISH is associated with an intermediate to unfavorable prognosis in CLL. The t(18;22)(q21;q11.2) present in this case as well as the t(2;18)(p12;q21) is a variant of the t(14;18)(q32;q21) a rare abnormality in CLL. These abnormalities are found in less than 4% of CLL cases. They are usually present within the context of a complex karyotype in a subset of CLL, but can also be observed in cases of benign lymphocytosis. Herein, we report a t(18;22)(q21;q11.2) in a CLL patient as a sole cytogenetic abnormality.

**2378T**

**Differential expression of kallikreins as prognostic markers in recurrent prostate cancer.** E. Guzel<sup>1</sup>, F.B. Buyukozer<sup>2</sup>, O.F. Karatas<sup>3</sup>, N.D. Dibek<sup>2</sup>, S. Simsek<sup>2</sup>, M.E. Ozgurses<sup>2</sup>, E.S. Aslan<sup>2</sup>, M. Ittmann<sup>4</sup>. 1) Istanbul University, Istanbul Faculty of Medicine, Istanbul, Turkey; 2) Biruni University, Department of Molecular Biology and Genetics, Istanbul, Turkey; 3) Molecular Biology and Genetics Department, Erzurum Technical University, Erzurum, Turkey; 4) Department of Pathology and Immunology, Baylor College of Medicine, Houston, 77030, TX, USA.

In the western countries, prostate cancer (PCa) is currently one of the leading causes of cancer death among men over the age of 50 years. Clinical recurrence with increased serum prostate-specific antigen (PSA, also known as Kallikrein 3 or KLK3) level is observed in almost 30% of men within 5 years following a successful radical prostatectomy. Therefore, it is necessary to find out molecular contributors of PCa progression to develop novel diagnostic/therapeutic tools. In this study, it is aimed to evaluate the expression profiles of Kallikrein family proteins in recurrent and non-recurrent prostate tumor specimens as well as in adjacent normal prostate tissues to propose novel prognostic markers in PCa. A total of 69 (35 recurrent, 34 non-recurrent) radical prostatectomy material and 19 normal prostate tissue samples were obtained from Baylor College of Medicine Prostate Cancer program and included into the study. Expressions of Kallikrein protein family members were evaluated using quantitative real-time PCR (qRT-PCR). For statistical analysis, Pearson's correlation test, receiver operating characteristics (ROC) analysis and Kaplan-Meier test were used. QRT-PCR results demonstrated differential expression of Kallikreins both in tumor vs. normal and recurrent vs. non-recurrent comparisons. In addition, Pearson's correlation, ROC and Kaplan-Meier analysis showed the power of Kallikreins for predicting PCa prognosis. Here, we report the deregulated expression of Kallikreins in tumor samples and recurrent PCa specimens, which suggest Kallikreins as valuable predictors of PCa progression.

**2379F**

**A 34-gene, NGS assay for common hereditary cancers reveals a high percentage of variants of unknown significance in the *POLD1* and *POLE* genes.** D. Hodko, R. Nakles, R. Chen, C. Nery, I. Karbassi, F. Lacbawan. Quest Diagnostics, Inc., 33608 Ortega Hwy, San Juan Capistrano, CA 92675-2042.

Multigene panels have become an important tool for risk assessment in hereditary cancers. While such panels provide the benefit of revealing pathogenic variants associated with a broad range of phenotypes, they also tend to reveal more variants of unknown significance (VUS). In genes other than *BRCA1* or *BRCA2*, *CHEK2* and *ATM* variants are typically found in the highest frequencies in previously published multigene panel studies. Often not included in these panels are the DNA polymerase genes, *POLD1* and *POLE*, known to be associated with a moderate risk for colorectal cancers. Here, we present a panel for the simultaneous sequencing of 34 cancer-susceptibility genes (including *POLD1* and *POLE*) and assess the frequency of variants identified among individuals with a personal or family history of cancers including breast, ovarian, colon, and skin. This panel combines next-generation DNA sequencing and confirmatory microarray analysis for comprehensive detection of both sequencing variants and genomic rearrangements. From initial panel screening results, we analyzed the first 350 consecutive individuals referred for hereditary cancer screening. 195 (55.7%) individuals carried a variant in one of the 34 genes analyzed. Pathogenic or likely pathogenic variants were discovered in 35 (10.0%) individuals. Among all pathogenic or likely pathogenic variants detected in the cohort, the greatest number occurred in *BRCA2* (25.7%), *BRCA1* (20.0%), and *CHEK2* (11.4%). Out of 228 unique variants of unknown significance (VUS) detected, 2.2% occurred in *BRCA1* and 3.5% occurred in *BRCA2*. However, the data reveal a higher percentage of unique VUS occurring within *ATM* (11.8%), *POLE* (8.8%), *APC* (7.9%), and *POLD1* (7.5%). The greater percentage of unique VUS occurring in DNA polymerase genes, *POLD1* and *POLE*, may be attributable to analyzing the full coding sequences of each gene. Our analysis finds that only 1.8% of all observed VUS are missense variants located within the exonuclease (proofreading) domains (*POLD1* codons 311-541 and *POLE* codons 269-485), where the only known pathogenic variants in *POLD1* and *POLE* occur. In highlighting the *POLD1* and *POLE* genes, we show that the rate of novel variants and VUS among high-risk cancer families is greater in non-*BRCA1/2* genes within the panel. In agreement with other studies, our data support the view that multiplex hereditary cancer panels alter the focus of genetic counseling, with increased attention to variants of uncertain significance. .

**2380W**

**Hereditary cancer panel results identify gaps in knowledge of cancer risks and limitations in current guidelines.** *H. LaDuca<sup>1</sup>, C. Espenschied<sup>1</sup>, J.S. Dolinsky<sup>1</sup>, L. Panos Smith<sup>2</sup>, K. Fulk<sup>3</sup>, M. Pronold<sup>3</sup>, C. Horton<sup>3</sup>, F.J. Couch<sup>4,5</sup>, B. Tippin Davis<sup>1</sup>.* 1) Department of Research and Development, Ambry Genetics, Aliso Viejo, CA; 2) Department of Genetic Specialists, Ambry Genetics, Aliso Viejo, CA; 3) Department of Clinical Diagnostics, Ambry Genetics, Aliso Viejo, CA; 4) Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN; 5) Department of Health Sciences Research, Mayo Clinic, Rochester, MN.

With increased utilization of hereditary cancer multigene panel tests (MGPT), independent efforts have been made to explore yield and utility for various testing indications. However, few systematic approaches have utilized this data to further our understanding of cancer risk associations and support modifications to current genetic testing and management guidelines. To identify where gaps may exist, we explored mutation frequency by cancer type in a large cohort of patients referred for hereditary cancer MGPT. Patients with a history of a single primary breast, colorectal (CRC, non-polyposis), ovarian, endometrial, pancreatic, or prostate cancer were selected from a larger cohort of approximately 200,000 cases referred for hereditary cancer MGPT at a single commercial laboratory. Pathogenic/likely pathogenic variant (PV) frequencies were calculated for 34 genes known to predispose to at least one of these six cancers. In general, results showed that the more commonly mutated genes for each cancer type have established risk estimates and associated management recommendations for the respective cancers, such as *CHEK2*, *BRCA1/2*, *ATM*, and *PALB2* in breast cancer and mismatch repair genes in CRC and endometrial cancer. Exceptions were most apparent for pancreatic and prostate cancers, suggesting that cancer-specific testing guidelines should be developed to encompass more commonly mutated genes beyond *BRCA1/2* such as *ATM*, *CDKN2A* and *PALB2* in pancreatic cancer (2.7%, 1.3% and 1.2%, respectively), and *HOXB13* and *ATM* in prostate cancer (3.2% and 2.1%, respectively). Other interesting findings were noted for *CHEK2*, *BRCA2* and *ATM*, where mutations were also frequent among cancer types not currently associated with these genes. For example, *BRCA2* PVs were detected in 1.0% of CRC and 0.7% of endometrial cancer patients, and *ATM* PVs were detected in 0.9% of CRC and ovarian cancer patients, even though these genes have not been associated with these cancers. *CHEK2* was among the top five most frequently mutated genes across all cancer types (includes p.I157T); however, risks for ovarian, endometrial and pancreatic cancers have not been well-defined for this gene, and *CHEK2* management recommendations are limited to breast and CRC surveillance. Research efforts aimed at generating precise cancer risk estimates and expanded testing and management recommendations for more commonly mutated genes will have the largest immediate impact for counseling patients and their families.

**TaqMan dPCR liquid biopsy assays targeting the TERT promoter region.** *M. Laig, K. Varma, V. Venkatesh.* Thermo Fisher Scientific, 180 Oyster Point Blvd., South San Francisco, CA 94080.

The enzyme Telomerase maintains telomeres at the ends of chromosomes. The Telomerase Reverse Transcriptase (TERT) gene codes for the enzyme's catalytic domain and is not expressed in normal somatic cells. As a consequence, normal cells acquire senescence by shortening of their telomeres during cell division and eventually undergo apoptosis. In contrast to normal somatic cells, expression of TERT is reinstated in cancer cells causing escape from senescence and apoptosis by maintaining the telomeres. It has recently been shown that mutations in the TERT promoter region play a key role in regulating and reinstating TERT expression. Up to 90% of cancers carry a mutation in the TERT promoter region. Mutations like C228T and C250T create new binding sites for the E26 transformation-specific (ETS) transcription factor that regulates TERT expression. Experimental evidence showed that the ETS factor GA-binding protein, alpha subunit (GABPA) binds to the de novo ETS motif and activates TERT transcription in cancer cells. We undertook a project designing TaqMan® dPCR Liquid Biopsy Assays addressing mutations in the TERT promoter. These assays are TaqMan SNP Genotyping assays that are optimized for use in digital PCR with the Applied Biosystems QuantStudio 3D. In digital PCR, partitioning the sample into many individual reaction wells facilitates detection and quantification of rare mutant alleles. TaqMan SNP Genotyping Assays reliably discriminate mutant and wild-type allele. This will enable easy and sensitive detection of TERT promoter mutations in cancer research samples. These assays are suitable for detection in liquid biopsy applications with cell free DNA (cfDNA). Assay design proved to be challenging due to high GC content and repetitive elements in this region of the TERT gene and required varying both the assay design and experimental cycling conditions. Template for wet-lab testing was synthetic plasmid carrying the mutation spiked into wild-type genomic DNA and wild-type genomic DNA control. The result was two TaqMan dPCR Liquid Biopsy Assays detecting the C228T and C250T mutations in the TERT promoter region. We showed that designing TaqMan dPCR Liquid Biopsy Assays for digital PCR is feasible for the challenging TERT promoter region.

**2382F**

**Clearance of plasma *EGFR* mutations as a predictor of outcome following osimertinib treatment.** A. Markovets<sup>1</sup>, C. Barrett<sup>1</sup>, S. Vowler<sup>2</sup>, G. Oxnard<sup>2</sup>, J. Dry<sup>1</sup>, K. Thress<sup>1</sup>. 1) Oncology, AstraZeneca, Waltham, MA; 2) Global Medicines Development, AstraZeneca, Cambridge, UK; 3) Dana-Farber Cancer Institute, Boston, MA.

Osimertinib is an *EGFR* tyrosine kinase inhibitor (TKI) designed to target activated *EGFR* harboring the T790M resistance mutation. While osimertinib provides high and durable response rates in non-small-cell lung cancer patients with T790M, prediction of response duration can be critical for disease monitoring and to guide subsequent treatment decisions. In this study, we investigated whether changes in the levels of *EGFR* mutations detectable in plasma using digital PCR (dPCR) (BEAMing by Sysmex/Inostics) are associated with clinical outcome on osimertinib. We performed computational analysis to assess fluctuation in *EGFR* mutation concentration levels in the circulating tumor DNA from longitudinal plasma samples of 143 pts from the AURA Phase I clinical trial. We demonstrated that clearance of plasma *EGFR* mutations after 6 weeks of osimertinib therapy associates with improved overall response rate and progression-free survival. We validated this finding in AURA Phase II and III study populations using a different dPCR platform Genestrat (BioDex). For patients that lack such a "plasma response" further in-depth profiling is ongoing to identify causes of more rapid disease progression and potential resistance mechanisms. In summary, monitoring of plasma *EGFR* mutations after initiation of osimertinib therapy can predict clinical outcome, and may rapidly identify patients where deep tumor profiling could be used to characterize drug resistance and, potentially, inform future therapeutic combinations. .

**Digital spatial profiling platform allows for spatially-resolved, multiplexed measurement of solid tumor protein distribution and abundance in FFPE tissue sections.** C. Merritt, G. Ong, K. Barker, J. Jung, I. Sprague, Y. Liang, S. Warren, P. Webster, D. Dunaway, J. Beechem. Nanostring Technologies, Seattle, WA.

Characterization of the spatial distribution and abundance of proteins within tissues enables a better understanding of biological systems in many research areas, including immunology and oncology. However, it has proven difficult to perform such studies in a highly multiplexed manner. To address this unmet need, we have developed a novel optical-barcode based microscope and tissue-sampling platform designed to simultaneously analyze hundreds of proteins on a single FFPE section (Digital Spatial Profiling, DSP). DSP probes are not multiplex-limited by spectral resolution. Instead, "colors" are determined using barcode indexing oligos that are conjugated to antibodies. These indexing oligos are conjugated via UV-cleavable linkers and, following UV light exposure, are released and siphoned off the tissue surface via a microcapillary tip. This UV-cleavage is precisely controlled by a digital micromirror device that can illuminate discrete regions ranging from entire tissue microenvironments to single-cells. For quantification of signal, the photocleaved oligos are hybridized to NanoString barcodes, providing digital counts of the protein in each region-of-interest using NanoString nCounter instruments. Using this novel approach, we spatially resolve over 30 solid tumor targets, simultaneously, on Her2+ breast cancer samples and Diffuse Large B-Cell Lymphoma samples. Solid tumor targets were probed with antibodies that recognize phosphorylated or total protein content (e.g. Her2, Ki67, P-AKT, P-ERK). We demonstrate multiplexed detection from discrete regions within a tumor and the adjacent normal tissue, enabling systematic interrogation of immune activity in FFPE samples. We also show the ability to profile either whole tissue sections or tissue microarrays. Finally, we validate that indexing oligo conjugation and high multiplexing of antibodies do not interfere with specificity. The simplicity of the DSP platform allows high-resolution, high-multiplexed, spatially-resolved protein characterization in any lab capable of performing immunohistochemistry procedures, providing a potential method that can bridge the gap between translational research discovery and clinical applications. Continued work on the platform will expand the library of protein targets accessible for profiling and future assay development will demonstrate multiplexing up to 800 targets.

**2384T**

**Clinical and molecular findings correlation in patients with hereditary cancer syndromes: Experience of a Colombian reference laboratory.** T. Pineda, S. Maradei, A. Zarante, Y. Gomez. Genetics Institute, BIOTECGEN S.A., Bogotá, DC, Bogotá, Colombia.

**Introduction:** Hereditary cancer presents in individuals with a germline pathogenic variant in genes related to cell cycle. In average, they span about 5 to 15% of all human cancers. Gene panels have arisen as an interesting option to identify mutations in families with hereditary cancer syndromes, optimizing diagnosis, treatment and following up algorithms on individuals at risk, with strategies towards decreasing morbidity and mortality rates and proposing new targeted therapies. **Aim:** To describe the experience of a Reference Center in Colombia for the diagnosis of Hereditary Cancer and to provide new data about our population mutational profile. **Methods:** 200 patients with personal and/or family history of breast, ovarian or colon cancer were referred to our laboratory for genetic testing from 2015 through March 2017, all of whom received pre and post-test counseling by a medical geneticist. Genes to be tested on each case were determined by the referring physician. Genomic DNA obtained from each patient's sample was sequenced using Illumina technology. All clinically significant observations were confirmed and then interpreted for their potential pathogenicity. Overall, we tested 170 patients (85%) with personal history of breast, ovarian or colon cancer, with or without family history of cancer. Also 30 patients (15%) with no personal history of cancer but with a positive family history of any tumor suggesting a hereditary cancer syndrome were tested. **Results:** We identified pathogenic variants in at least one of the high risk related genes in 13,53% of individuals with personal history of breast, ovarian or colon cancer with or without family history. Variants of unknown significance (VOUS) were reported in 25,88% of these patients. In 16,67% of individuals with only family history of breast, ovarian or colon cancer, mutations were detected in at least one of the high risk related genes. Variants of unknown significance (VOUS) were reported in 10% of these patients. **Conclusion:** This study highlights the relevance of an adequate use of gene panels on hereditary cancer syndromes as an attractive, efficient and cost-effective tool to identify disease causing mutations in patients and families with a suspected hereditary cancer syndrome, and also, sets a new record on the definition of our population mutational profile.

**2385F**

**Polymorphic SNPs in breast cancer using molecular studies in Indian population.** M. Rao<sup>1,4</sup>, N. Shah<sup>1,2</sup>, P. Shah<sup>1,3</sup>, Y. Panchal<sup>1</sup>, K. Katudia<sup>1</sup>, H. Ray<sup>1</sup>, N. Khatri<sup>1</sup>, U. Bhatia<sup>1</sup>, S. Shah<sup>1</sup>, B. Shah<sup>1</sup>. 1) Supratech Micropath Laboratory and Research Institute, Ahmedabad, Gujarat, India; 2) Department of Pediatrics, Nassau University Medical Center, New York City, NY, USA; 3) Department of Medicine, Lahey Hospital and Medical Center, Boston, MA, USA; 4) Department of Zoology, School of Sciences, Gujarat University, Ahmedabad, Gujarat, India.

A large number of distinct mutations in the BRCA 1 and BRCA 2 genes have been detected. But the role of polymorphic SNPs and except other mutations among Indian women for Breast cancer is scarcely reported. In this cohort, 79 referral breast cancer (B.C) women during 2015-16 were screened for BRCA1 and BRCA2 and BRCA1/2 gene mutations using extracted DNA by Sanger DNA sequencing and Next Generation Sequencing (NGS). The sequence data were analyzed using standard Ion Torrent Suite™ software. Only 35 women were found for breast cancer positive (35/79; 50.72%). In these cases, BRCA1 gene mutation was positive for 9 (26%) cases, followed by 15 (43%) for BRCA2 and 11 (31%) cases for BRCA1/2. The germline mutations for BRCA1 were 39/82 (47%) and BRCA2, 43/82 (53%) from total of 82. The types of mutations were of 72 missense 72/82 (88%), frameshift 5/82 (6%), nonsense 4/82 (5%) and inframe types 1/82 (1%). The novel mutations detected were 5 (p.Pro163fs, p.Asn997fs, p.Ser1481fs and two splice site missense SNPs) in our cohort affecting protein truncation and malfunction in these both homo- and heterozygotic cases. Several missense polymorphic SNPs detected here (72) were in exons 10, 11, 14, 16, 9, 2 and 3 of the two genes which probably were negative for B.C, but support for susceptibility to breast cancer markers. The age groups of <40 years had 11 patients with 21% and 41-60 years possessed 18 cases with 55% followed by >61 years old (6) with 24% mutations in BRCA1 and BRCA2 genes. The age group of 41-60 years old had high incidence of mutation types and were related to pathologic conditions. Thus these data implicate that early age of 20-60 years old is probably susceptible for germline mutations in our study. However, the role of high incidence of polymorphic SNPs in relation to the causation of breast cancer needs to be evaluated in our Indian population.

**2386W**

**Frequency of pathogenic and rare variants of uncertain significance in cancer patients and control cohort.** *K.M. Rocha, M. Lazar, S.A.M. Ezquina, G.L. Yamamoto, M.C. Varela, V.N. Takahashi, M. Aguena, M. Zatz, M.R. Passos-Bueno.* Gen e Biol Evolutiva, Inst Biocien Univ Sao Paulo, São Paulo, SP, Brazil.

From the past five years, our lab has been offering molecular diagnosis using targeted massively parallel sequencing of a panel containing genes associated with several diseases such as neuromuscular, skeletal dysplasias and neurodevelopmental disorders. This panel also contains a few cancer associated genes and, more recently, we started offering molecular diagnosis for cancer as well. Since our cancer cohort is much smaller than for the other diseases (107 x 1593 cases), in our experience, the interpretation of variants that have not been reported in ClinVar or disease-specific databases is much more complex for cancer. This is also challenging given that our population is admixed and not very well represented in public population variants databases. In order to generate a more consistent filter for reporting variants of uncertain significance (VUS) we sought to evaluate the frequency of variants found in cancer and control cohorts in 14 cancer associated genes. Variants classified as pathogenic or likely pathogenic in ClinVar were detected in 9.3% of cancer cases and in 1.2% of the control cohort. Considering not previously reported frameshift and stopgain rare variants (frequency less than 0.5%) that we might consider potentially pathogenic, we detected around 4.7% and 2.6% for cancer and control cohorts respectively. Assuming that the frequency ratio of known pathogenic variants in cancer and control cohorts should be maintained when analysing potentially pathogenic rare variants, our results indicate that it is necessary to increase the stringency of analysis parameters in order to avoid reporting potentially false positives. Supported by: FAPESP-CEPID, CNPq and FUSP. .

**2387T**

**Hereditary cancer risk testing within a Colombian cohort reveals high incidence of Lynch syndrome.** *J.A. Rugeles<sup>1</sup>, A.Y. Zhou<sup>2</sup>, A. Zimmer<sup>2</sup>, J. van den Akker<sup>2</sup>, A. Leon<sup>2</sup>, S.E Aruachan<sup>1</sup>, M.E Gonzalez<sup>1</sup>.* 1) Cancer genetics, IMAT Oncomedica S.A, Monteria, Cordoba, Colombia; 2) Color Genomics, 1801 Murchison Dr #128, Burlingame, CA 94010.

**Background:** To date, hereditary cancer genetics has been most well-studied within the Caucasian and European populations. However, little is known about the incidence of hereditary cancer mutations in other populations. Here, we describe the demographics and characteristics of 145 Colombian high risk breast cancer and colon cancer index cases and referred for a 30-gene panel for hereditary cancer risk (the Color Test). Of the 20 index cases who received a positive result, cascade family testing was pursued in 13 families. **Methods:** All patients were seen at IMAT Oncomedica (Monteria, Colombia) and given pre-test counseling by an in-house genetics specialist. Patients with a significant personal and/or family history of breast or colon cancer were referred for the Color Test. **Results:** In this cohort of 145 high risk breast or colon cancer cases, 20 pathogenic or likely pathogenic mutations were identified and reported. The mutation carrier rate in this cohort was 13.8% (20/145). Among the 96 patients who reported a personal history of breast cancer, the mutation carrier rate was 9.4% (9/96). Among the 19 patients who reported a personal history of colon cancer, the mutation carrier rate was 47.4% (9/19). Of the 9 mutations reported in the breast cancer cohort, 3 mutations were identified in *BRCA1* and *PALB2* respectively, 2 in *BRCA2*, and one in *CHEK2*. Surprisingly, in the colon cancer cohort, all 9 of the patients who received a positive result were found to have a mutation in a Lynch syndrome gene (5 *MSH2* carriers, 3 *MLH1* carriers, 1 *MLH1+MUTYH* concurrent pathogenic mutation carrier). **Conclusion:** These data indicate that there is a significant need for genetic testing within Colombia. Current evidence from the United States suggests that Lynch syndrome accounts for ~5% of all colorectal cancer cases. Thus, our finding that 47.4% of the colon cancer patients in our cohort were found to carry a Lynch syndrome mutation is an indication that Lynch syndrome may be significantly more prevalent in the Colombian population than the United States. Our finding that 9.4% of breast cancer patients carry a mutation is very similar to the rates reported in the United States, where ~10-15% of breast cancer patients are thought to carry a mutation. The number of patients collected for this study is still quite small and further recruitment and analysis is warranted to fully understand the true prevalence of hereditary cancer within the Colombian population.

**Use of functionally classified 207 BRCA2 missense variants to calibrate sequence-based computational prediction models.** *H. Shimelis, S. Hart, T. Hoskin, R. Moore, A. Thomas, V. Suman, F. Couch.* Mayo Clinic, Rochester, Rochester, MN.

Genetic testing of individuals with a family history of breast and/or ovarian cancer has led to the identification of many unique *BRCA2* and *BRCA1* missense variants of uncertain significance (VUS). While breast cancer risk conferred by truncating loss of function variants is known, risks conferred by many germline missense variants have not been established. Classification of missense variants using quantitative models such as the established *BRCA1* and *BRCA2* multifactorial Likelihood Model has proved challenging due to limited availability of family data for each VUS. In contrast, functional analysis of VUS using validated assays and *in silico* prediction models may be useful for classifying VUS in the absence of case-control or family data. We have used a homology directed repair (HDR) cell-based assay to characterize missense variants in the DNA binding domain (DBD) of *BRCA2*. The method has been validated using known pathogenic and known non-pathogenic *BRCA2* missense variants and has 100% sensitivity (95% confidence interval (CI): 75.3%–100%) and 100% specificity (95% CI: 81.5%–100%) for pathogenic *BRCA2* variants. A classifier of variant pathogenicity was also developed based on the mean and variances of the distributions of the HDR results of the known pathogenic and neutral variants (1). We subsequently conducted a comprehensive assessment of 207 *BRCA2* missense variants using the HDR assay and identified 71 deleterious variants with >99% probability of pathogenicity, 116 neutral variants with >99% probability of neutrality, and 20 with intermediate function. Functional assay results were compared to 40 *in silico* prediction algorithms, using default and functional data optimized thresholds. An ensemble prediction model of *in silico* prediction algorithms trained on *BRCA2* functional data was developed using random forest modelling (RF) and a naïve voting method (NVM). Both RF and NVM models yielded high area under the receiver operating characteristic curve (AUC) of 0.90, 95%CI: 0.84-0.95 and 0.89, 95%CI: 0.83-0.96, respectively. Taken together our results show that both validated functional assays alone or *in silico* prediction models trained on functional data provide a robust tool for clinical annotation of *BRCA2* VUS.

**2389W**

**Concurrent multiple molecular alterations involving *ALK*, *RET*, *ROS1* and *MET* in non-small cell lung cancer.** *Z. Tang, J. Zhang, H. Chen, W. Wang, L.J. Medeiros, G. Tang.* MD Anderson Cancer Center, Houston, TX.

Targetable activating alterations in cancer genes, such as *EGFR*, *KRAS*, *ALK*, *RET*, *ROS1* and *MET*, are usually considered as mutually exclusive in non-small cell lung cancer (NSCLC). Rare NSCLC cases with coexistent alterations of *EGFR/ALK*, *EGFR/RET* and *EGFR/ROS1* have been reported. In this study, the database of the Clinical Cytogenetics Laboratory at The University of Texas MD Anderson Cancer Center for NSCLC cases assessed by fluorescence *in situ* hybridization (FISH) for abnormalities of *ALK*, *RET*, *ROS1* or *MET*. Fifteen cases (3 men and 12 women; 14 Caucasians and 1 African American) with ages ranging from 43 to 81 years (median 60 years) with positive results of more than one of these genes were identified. The combination of alterations included *ALK/ROS1* (n=4), *ALK/MET* (n=3), *ALK/RET* (n=1), *RET/MET* (n=4), *RET/ROS1* (n=2), and *ROS1/MET* (n=1). The frequencies of involvement were similar for all 4 genes, 53% for both *ALK* and *MET* (n=8), 47% for both *RET* and *ROS1* (n=7). Activating gene mutations were also detected by next-generation sequencing for *TP53* (n=6), *EGFR* (n=5), *KRAS* (n=3) and *STK11* (n=2). Nine patients reported a smoking history (8 heavy and 1 light) and 6 patients were non-smokers. These findings suggest the need for assessing a panel of genes in NSCLC. Since targetable agents are available for each of these activating alterations, treatment with more than one targeted agent may be beneficial for this rare group of patients.

**2390T**

**Towards prediction of platinum treatment response in ovarian cancer using machine learning approaches.** A. Vladimirova, R. Goold, T. Klingler. Station X, San Francisco, CA.

Ovarian cancer is the eighth most prevalent cancer in women in the US and the fifth most common cause of death. The standard of care for ovarian cancer consists of a combination of surgery and chemotherapy, typically platinum-taxane treatment. However, many patients develop platinum resistance, defined as a relapse within 6 months of starting platinum chemotherapy. Predictive methods for early evaluation of the potential for platinum resistance may benefit patients by identifying those that might be better served with alternative second-line therapies or by enrollment in relevant clinical trials. In this study we generate and evaluate predictive models of resistance and sensitivity to platinum drugs in ovarian cancer by using the GenePool™ genomics platform and the integrated TCGA (The Cancer Genome Atlas) ovarian cancer RNA-seq and clinical data, including manually-curated platinum status information for each patient, and complement these analyses with a battery of machine learning approaches. We utilize GenePool best practices RNA-seq workflows on ovarian primary tumors to derive and prioritize genes most strongly associated with platinum response. First, using clinical information, we define two ovarian cancer cohorts, one platinum-sensitive and the other platinum-resistant. We then compare the expression levels of all genes in these cohorts and identify those that are most differentially expressed. The gene expression results are analyzed using a variety of classifier approaches such as logistic regression, support vector machines and deep learning techniques to create, optimize and evaluate predictive models of platinum sensitivity status. Our workflows leverage cross-validation, dimensionality reduction, a variety of performance metrics to evaluate our models, as well as visualization of results to facilitate interpretation. We demonstrate a combination of approaches to derive and validate predictive models of platinum response in ovarian cancer and illustrate the potential of similar approaches to benefit cancer patient care. .

**Functional analysis of BRCAness in female cancers.** M.P.G. Vreeswijk<sup>1</sup>, L.M. van Wijk<sup>1</sup>, M. de Jonge<sup>2</sup>, K.A.T. Naipal<sup>3</sup>, T.G. Meijer<sup>4</sup>, M. Meijers<sup>1</sup>, N.T. ter Haar<sup>2</sup>, N.S. Verkaik<sup>5</sup>, R.A.E.M. Tollenaar<sup>6</sup>, W.E. Mesker<sup>4</sup>, A. Jager<sup>7</sup>, C.D. de Kroon<sup>2</sup>, J.R. Kroep<sup>2</sup>, K.N. Gaarenstroom<sup>2</sup>, D.C. van Gent<sup>6</sup>, T. Bosse<sup>2</sup>, H. Vrieling<sup>1</sup>. 1) Human Genetics, Leiden University Medical Center, Leiden, Netherlands; 2) Pathology, Leiden University Medical Center, Leiden, Netherlands; 3) Medical Oncology, Leiden University Medical Center, Leiden, Netherlands; 4) Surgery, Leiden University Medical Center, Leiden, Netherlands; 5) Gynaecology, Leiden University Medical Center, Leiden, Netherlands; 6) Genetics, Erasmus University Medical Center, Rotterdam, the Netherlands; 7) Medical Oncology, Erasmus University Medical Center, Rotterdam, the Netherlands.

**Background.** *BRCA1*- and *BRCA2*-related breast and ovarian tumors respond very well to treatment with Poly (ADP-ribose) polymerase (PARP) inhibitors (PARPi) because of their deficiency in homologous recombination (HR). However, tumors may contain a deficiency in HR that is unrelated to germline mutations in *BRCA1* or *BRCA2* (i.e. BRCAness). Assessment of the HR efficacy of tumors might therefore allow identification of an additional group of cancer patients that could benefit from PARPi treatment. **Experimental procedure.** Fresh tumor samples were collected from patients undergoing surgery or ascites/pleural fluid drainage. Samples were *ex vivo* irradiated with ionizing radiation, fixed after 2 hours incubation at 37°C and embedded in paraffin. The ability of replicating tumor cells to accumulate RAD51 protein at DNA double strand breaks (RAD51 foci) was used as functional read out for HR proficiency. **Results.** To date, HR-status has been determined in breast (n= 56), ovarian (n= 59) and endometrial (n=28) tumor samples. Impairment of HR was observed in 20% of breast and in 40% of both ovarian and endometrial tumor samples. Apart from patients with a germline BRCA mutation, also a subset of tumors from non-BRCA mutation carriers showed a HR deficient phenotype. Apparently, germline BRCA testing is not sufficient to identify all HR deficient tumors. Genetic and epigenetic analysis of tumor DNA are ongoing. **Conclusion.** The functional analysis BRCAness in fresh tumor tissue is a promising new tool to identify HR deficient tumors. A significant proportion of breast, ovarian and endometrial tumors are defective for homologous recombination. Functional analysis of HR in fresh tumor samples may therefore allow the identification of a much broader patient population that could benefit from treatments targeting deficiencies in HR.

**Detection and quantitation of M-BCR and m-BCR fusion transcripts by pico-liter digital PCR.** J. Woolworth-Hirschhorn, T. Baker, Y. Wang, C.A. Schandl. Pathology and Laboratory Medicine, Medical University of South Carolina, Charleston, SC.

The BCR-ABL1 fusion gene results from a reciprocal translocation involving the long arms of chromosomes 9 and 22. The major breakpoint (M-BCR) fusion is seen in 99% of CML cases while the minor breakpoint (m-BCR) is rarely identified. In adult Ph+ B-ALL patients, M-BCR is identified in about 40% of cases with m-BCR found in 60%. The clinical significance of minimal residual disease is known, but that of transcript type in CML and in Ph+ ALL is unclear. However, studies suggest prognostic differences and distinguishing between them may become clinically relevant. Thirty CML and three Ph+ ALL cases with previously analyzed BCR-ABL1 transcript quantification by an alternate method were identified for analysis including five cases with no transcript detected. Pico-liter digital droplet PCR (pddPCR) was used for absolute quantitation of BCR-ABL1 transcripts using one-step reverse-transcription and real-time PCR. The presence of the M-BCR (b2a2, b3a2) and m-BCR (e1a2) fusion transcripts were quantified separately in each patient sample in a single assay by consequent droplet fluorophore detection. Results were compared to those obtained by a real-time PCR assay unable to distinguish between the M-BCR and m-BCR fusion transcripts and, when available, a qualitative assay distinguishing M-BCR from m-BCR transcripts. Sixteen of thirty CML cases demonstrated the M-BCR transcript by pddPCR (11/16 with concurrent reference laboratory qualitative agreement), nine were dual-positive for M-BCR and m-BCR (3 of 9 identified as dual-positive by reference laboratory, 3 demonstrating only M-BCR; and 3 not tested), four were not detected, and one demonstrated m-BCR (in conflict with M-BCR reported). Two of three cases of Ph+ B-ALL were dual-positive by pddPCR (one in agreement and one not detected by reference method) while no transcripts were detected in the third at the collection time-point (in agreement with reference result). Two dual-positive cases were identified significantly earlier by pddPCR than reference methodology: a Ph+ ALL 4 months earlier and a CML 8 months earlier. This study suggests that pddPCR may be more sensitive and identify recurrence earlier in a patient's course. As additional outcome data are evaluated for patients with variable transcripts, it is likely that prognostic implications may emerge. Thus, consideration of an ultrasensitive assay able to differentiate between M-BCR and m-BCR such as pddPCR may become clinically imperative.

**2393T**

**Frequent detection of chromothripsis in acute myeloid leukemia with complex karyotype and marker chromosomes.** J. Lee<sup>1</sup>, C. Seo<sup>1,2</sup>, J. Lee<sup>3</sup>, E. Seo<sup>1,2</sup>. 1) Medical Genetics & Genomics Center, University of Ulsan College of Medicine and Asan Medical Center, Seoul, South Korea; 2) Department of Laboratory Medicine, University of Ulsan College of Medicine and Asan Medical Center, Seoul, South Korea; 3) Asan Institute for Life Sciences, University of Ulsan College of Medicine and Asan Medical Center, Seoul, South Korea.

**Background** Genomic rearrangements can drive the development of cancer through different mechanisms including chromothripsis, a catastrophic genomic event, seen in 2-3% of all cancers. Recent studies have revealed that chromothripsis could also be relevant for hematologic malignancies and was detected in 1.2% of myelodysplastic syndromes. We investigated the frequency and characteristics of the chromothripsis in acute myeloid leukemia (AML) patients with complex karyotype and marker chromosomes using array comparative genomic hybridization (aCGH) and fluorescence in situ hybridization (FISH) analysis. **Methods** A total of eight patients diagnosed as AML with complex chromosomal abnormalities and marker chromosomes were studied. Genome-wide copy number alterations (CNAs) and chromothripsis were analyzed in BM samples using SurePrint G3 Human CGH 180K microarray (Agilent Technologies, USA). FISH was performed using BAC clones located within amplified regions. **Results** The analysis of copy number profiles derived from aCGH data identified chromothripsis showing multiple non-contiguous CNAs in three patients who were young males with less than 50 years. These patients had chromothripsis events involving different chromosomes: 5q, 9p, 14q and 21q. Complex karyotype of 3 patients showed a median number of 11.7 chromosomal abnormalities with 1 to 3 marker chromosomes. Important genomic changes found by aCGH but not detected by conventional metaphase cytogenetics were validated by interphase fluorescence *in situ* hybridization (FISH), in the case of large recurrent deletions and gains. Array CGH analysis revealed the origin of marker chromosomes: amplified oncogenes such as DAXX on 6p21.32 and ERG on 21q22.2. **Conclusion** Chromothripsis is a genetic abnormality in which tens to hundreds of clustered genomic rearrangements in a one-step catastrophic event. Our results identified that marker chromosomes reflect heavily rearranged chromosomes following chromothripsis. This study showed three AML patients with gene amplifications had the multiple rearrangements of chromosomal segments, chromothripsis at 5q, 9p, 14q and 21q. Amplified oncogenes and chromothripsis may contribute to the tumorigenesis and progression of AML. Molecular karyotyping such as array CGH and FISH is useful to investigate the origin of marker chromosomes and complex chromosomal rearrangements. .

**Tetraploidy and near tetraploidy in acute myelocytic leukemia and myelodysplastic syndrome: A report of seven new cases.** J. Liu<sup>1</sup>, D. Fortuna<sup>2</sup>, U. Uppal<sup>3</sup>, S. Nedumakel<sup>4</sup>, J. Gong<sup>4</sup>, Z. Wang<sup>4</sup>, S. Peiper<sup>2</sup>. 1) Clinical Cytogenomics Laboratory, Department of Pathology, Anatomy, and Cell Biology Thomas Jefferson University, 1025 Walnut Street, Philadelphia, PA 19107; 2) Department of Pathology, Anatomy, and Cell Biology, Thomas Jefferson University, 1020 Locust Street, Philadelphia, PA 19107; 3) Section of Hematopathology, Hematology and Flow Cytometry, Department of Pathology, Anatomy, and Cell Biology, Sidney Kimmel Medical College, Thomas Jefferson University, 125 South 11th Street, Philadelphia, PA 19107; 4) Molecular & Genomic Pathology Laboratory, Department of Surgery, Pathology, Anatomy, and Cell Biology, Thomas Jefferson University, 1025 Walnut Street, Philadelphia, PA 19107.

Tetraploidy and near tetraploidy (T/NT) (81–103 chromosomes) karyogram with or without numerical and structural abnormalities is rare in acute myeloid leukemia (AML) and myelodysplastic syndrome (MDS). Only single case or small case series have been reported to date. The clinical significance is not well understood mainly due to the rarity of the entity. Here we report the clinical, morphological, cytogenetics, molecular genetics and prognostic features in seven cases of T/NT-AML/MDS. The seven cases were identified by the searching the database of the Clinical Cytogenetics Laboratory at The Thomas Jefferson University Hospital between 2009–2016. Available clinical, hematopathological and laboratory data were all reviewed. A total of seven patients (6 with AML and 1 with MDS) with a T/NT karyogram were identified, comprising ~0.47% of all AML and MDS patients during this seven-year interval at The Thomas Jefferson University Hospital. Four patients were male and three were female. Age ranged from 54–81 years (median, 72 years). T/NT karyogram was detected at initial diagnosis of AML/MDS in five patients, and acquired during the course of disease in two patients. Three patients had a non-complex and four had a complex T/NT karyogram. Other than chromosomal gains, del 7q/7 was the most common structural abnormality in our series (n = 4) followed by del 5q/5 (n=2) and del 17p (n=2). Recurrent translocations seen in AML/MDS which were also present in our series were i(17)(q10) and t(1;7). All patients exhibited medium to large sized blasts, frequently with irregular nuclear contours and prominent nucleoli as well as various levels of cytoplasmic vacuoles and/or inclusions. Auer rods were not common. Mutation tests for *FLT3* internal tandem duplication (ITD) and *IDH1* codon 132 on two patients were negative. Next generation sequencing (NGS) technology based hematological malignancy gene panel test was performed on one case and revealed a pathogenic mutation in the gene *SRSF2*. In summary, T/NT karyogram is an infrequent abnormality in AML and MDS with distinctive morphologic features for blasts. Seven new cases were reported. The prognostic significance and possible mechanism of a T/NT karyogram are discussed. This is also believed to be the first time that NGS panel test was utilized to characterize this unique entity.

**A t(3;8)(q26.2;q24) involving the *EV11 (MECOM)* gene on 3q26 in a case of acute myeloid leukemia preceded by polycythemia vera.** K. Liu<sup>1,5</sup>, C. Makar<sup>1,5</sup>, A. Bond<sup>1,5</sup>, K. Stieglbauer<sup>2,3</sup>, S. Wheaton<sup>2,3</sup>, J. Reinartz<sup>2,3</sup>, K. Cunni<sup>2</sup>, K. Peterson<sup>2</sup>, L. Bartholomaeus<sup>2</sup>, D. Serk<sup>2</sup>, B. Wyatt<sup>2</sup>, S. Khan<sup>1,5</sup>, C.A. Tirado<sup>1,2,3,4</sup>. 1) The International Circle of Genetic Studies, Los Angeles, CA; 2) Allina Health, Minneapolis, MN; 3) HPHA, Minneapolis, MN; 4) The University of Minnesota School of Medicine, Department of Laboratory Medicine and Pathology, Minneapolis, MN; 5) The University of California, Los Angeles, CA.

We report a 68 year old male with a history of polycythemia vera diagnosed in 2000. He was initially treated with phlebotomy and did well for many years until he developed symptomatic splenomegaly and pruritus. The patient was treated with ruxolitinib in 2012 and his splenomegaly improved. In late 2015 and early 2016 the patient developed cytopenias, increasing hepatomegaly, and increased poikilocytosis with dacrocytes in peripheral blood samples, suggesting myelofibrosis. A bone marrow biopsy in June 2016 confirmed the presence of myelofibrosis and revealed a hypercellular bone marrow (80%) with increased reticulin fibrosis (MF2-3), 5% blasts, and normal 46,XY karyotype. The patient was not a candidate for bone marrow transplant at this time, and ruxolitinib was discontinued to determine if blood counts would improve. Unfortunately, cytopenias progressed, and follow-up bone marrow biopsy in November 2016 documented acute myeloid leukemia (post-polycythemic myelofibrosis with acute leukemic transformation) with 20-30% blasts in the bone marrow, dense reticulin fibrosis, focal collagen fibrosis (MF3), and pancytopenia with 14% blasts in the blood. Chromosome analysis revealed an abnormal male karyotype with a t(3;8)(q26.2;q23) in 13 of the 21 metaphase cells examined. The remaining 8 cells were cytogenetically normal. Molecular cytogenetic studies confirmed a rearrangement of *MECOM (EV11)*; however, no *PVT1* rearrangement was detected. We are aware of a case report in the literature previously describing a t(3;8)(q26.2;q24) involving *MECOM (EV11)* and *PVT1*; however, to the best of our knowledge the t(3;8)(q26.2;q23) has not been reported in acute myeloid leukemia (AML), de novo or therapy related-myelodysplastic syndrome (MDS), or MDS or myeloproliferative disorder progressing to AML. Rearrangements of chromosome 3 involving the *MECOM (EV11)* gene on 3q26.2 are recurrent abnormalities in myeloid disorders and are usually associated with disease progression and a poor prognosis.

**Identification of cancer-associated copy number variations through integrated genomic analysis.** M. Luo<sup>1,2</sup>, B. Luo<sup>1,3</sup>, J. Tang<sup>1</sup>, A.G. Gleason<sup>1</sup>, G.T. Akgumus<sup>1</sup>, L.K. Conlin<sup>1,2</sup>, M.M. Li<sup>1,2</sup>. 1) Division of Genomic Diagnostics, Department of Pathology and Laboratory Medicine, The Children's Hospital of Philadelphia, Philadelphia, PA; 2) Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA; 3) Fox Chase Cancer Center, Philadelphia, PA.

Copy number variations (CNV) and loss of heterozygosity (LOH) are common genomic alterations in cancer. These genomic alterations may be critical in cancer diagnosis, prognosis and treatment. CNVs can be detected through different technologies, including traditional cytogenetics, fluorescence in situ hybridization (FISH), chromosomal microarray analysis (CMA), and recently, next generation sequencing (NGS). In 2013, American College of Medical Genetics and Genomics (ACMG) published technical standards and guidelines for CMA including CNV detection and interpretation in neoplastic disorders. However, efficient analysis and accurate interpretation for CNVs still remains to be a challenge for clinical laboratories given the complexity and dynamics of the changes in tumor genomes. In our laboratory, different in-house tools have been created to integrate genotyping data, log R ratio, and gene content. These developments significantly increased our efficiency and sensitivity in the detection of disease-associated changes. They allow us to identify mosaic CNVs at approximately 5-10% allele frequencies and different levels of bone marrow engraftment after transplantation. These tools also assist discerning ploidy changes which are often important in tumor risk stratification. An algorithm to consolidate data from different technologies, including both traditional cytogenetics and sequencing analysis, as well as data from multiple specimens of the same patient, has also been implemented to improve the accuracy of data interpretation and diagnostic yield. The algorithm facilitates the detection of reverse mutations, novel structural abnormalities, relevant germline changes, and other complex genomic alterations. Since 2008, we have studied more than 2,400 pediatric oncologic samples including both solid tumors and hematological malignancies. Clinically significant CNVs were identified in about 80% of the cases which provided solid genomic evidence for precision cancer care.

**Characterization of interstitial deletions of 9q in ten AML cases.** Z. Qi<sup>1</sup>, K.W. Wen<sup>1</sup>, A. Ki<sup>2</sup>, L. Lv<sup>2</sup>, S. Prakash<sup>1</sup>, S. Kogan<sup>1</sup>, J. Yu<sup>1</sup>. 1) Department of Laboratory Medicine, UCSF, San Francisco, CA; 2) Clinical Cytogenetics Laboratory, UCSF Medical Center, San Francisco, CA; 3) Department of Oncology and Hematology, The Second Hospital of Jilin University, Changchun, Jilin, China.

Interstitial deletions of the long arm of chromosome 9 [del(9q)] are seen in 2-5% of acute myeloid leukemia (AML). However, precise breakpoints of del(9q) in AML remain mostly unknown, making it difficult to identify candidate pathogenic genes in the deleted regions and to further understand the pathogenic effect of the deletions. We present here molecular breakpoints of del(9q) in 10 AML cases, detected by single nucleotide polymorphism array. Our study revealed a cluster of proximal breakpoints within 9q13q21, a region enriched with segmental duplication and a "hotspot" for genomic rearrangements. But the distal breakpoints of the del(9q) varied greatly. The deleted 9q regions can be further divided into an approximately 14.4 Mb proximal region (chr9:70950015-85397699, GRCh37) and an approximately 24.0 Mb distal region (chr9:85397700-109427261). The former seems to be not neoplasm-related, since deletions of this region are also reported in individuals without hematological or other neoplasms; whereas deletions of the latter have been reported mostly in hematological neoplasms. It is noteworthy that a 7.3 Mb deletion within the distal region appears to occur in all cases with survival time less than 22 months in this study. Loss of function or reduced expression of the *GADD45G*, *MIRLET7A1*, *MIRLET7D*, *MIRLET7F1*, and *FANCC* genes in this 7.3 Mb region has been associated with neoplasms. The 10 del(9q) cases can be divided into four groups based on additional genetic changes and their response to the treatment, including three cases with t(8;21) or t(15;17) and good response to chemotherapy, two cases with biallelic *CEBPA* mutations that achieved and have remained in complete remission after bone marrow transplant, three cases with *FLT3*-internal tandem duplication and short survival time (<15 months), and two cases with other changes of unknown significance and short survival time (13 and 22 months). Taken together, our findings suggest that only the distal del(9q) appears to associate with AML. Del(9q) may not change the prognosis in cases with favorable AML mutations. The deletions, in particular the deletion of the 7.3 Mb region, may affect the survival time in other AML cases. Further investigation of the pathogenic effects of the del(9q) is warranted.

**2398W**

**Cytogenetic characterization of Richter transformation in chronic lymphocytic leukemia.** G. Tang, Z. Tang. Hematopathology, UT MD Anderson Cancer Center, Houston, TX.

Background: Richter's transformation (RT) is a rare disorder that occurs in < 10% of patients with chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL). The transformation refers to the development of either diffuse large B-cell lymphoma (DLBCL, most commonly) or classical Hodgkin lymphoma (rare) during the disease course. Little information regarding karyotypic or fluorescence in situ hybridization (FISH) findings in RT is available in the literature. Methods: The cytogenetic findings from conventional karyotyping and/or FISH analysis for CLL panel (*ATM*, *CEP12*, *D13S319*, *LAMP1*, and *TP53*) in 32 CLL/SLL patients with transformation to DLBCL were investigated. In 16 of these patients, the results of karyotyping or FISH analysis in a pre RT sample were also available. A comparison between the cytogenetic findings of the pre RT and the RT samples was performed. Results: 28 (88%) RT samples showed complex karyotype (>3 abnormalities), while 4 (12%) had either a normal diploid or non-complex karyotype. Abnormalities involving chromosome 17 (-17 or del(17p)) which resulting in *TP53* deletion were identified in 16 (57%) samples with complex abnormalities; 9 (32%) samples had either triploid or tetraploid clones; 2 (7%) samples had t(8;14)(q24.1;q32)/*IGH-MYC* rearrangement. 25 samples also underwent FISH analysis, 12 (48%) had *TP53* deletion; 5 (20%) had *ATM* deletion and 1 (4%) had both *TP53* and *ATM* deletion, 7 (28%) were negative for either deletion. 16 cases had karyotyping in a pre RT sample, 9 had a normal and 5 had an abnormal karyotype. In comparison with the subsequent RT samples, 7 developed new clones, 5 showed clonal evolution and 2 had no change in the karyotype. 13 samples had FISH testing on pre RT sample, 6 had a *TP53* deletion and 2 had *ATM* gene deletion. In the subsequent RT samples, 12 had FISH testing, 6 had a *TP53* deletion and 3 had *ATM* deletion; all cases with pre RT *TP53* or *ATM* gene deletion had the deletion in the RT sample, 2 pre RT samples that were negative for either deletion acquired a *TP53* or *ATM* deletion in the RT sample, while 3 remained negative. Conclusions: RT has a high frequency of complex karyotype, including -17 or del(17p), which are not commonly seen in CLL/SLL. Clonal evolution and/or the acquisition of new clones are frequent in RT, occurring in 12 of 16 (75%) tumors. *TP53* and *ATM* deletions were present in the pre RT and RT sample, supporting *TP53* or *ATM* deletion as a risk factor for the development of RT.

**A plasma cell myeloma case with an abnormal clone showing a t(8;22)(q24.1;q11.2) within the context of a hyperdiploid complex karyotype.**

C.A. Tirado<sup>1,2,3</sup>, K. Liu<sup>3</sup>, A.V. Dowiak<sup>1</sup>, W. Wyat<sup>1</sup>, S. Wheaton<sup>2</sup>, K. Peterson<sup>1</sup>, D. Serk<sup>1</sup>, K. Cunnien<sup>1</sup>, J.J. Reinartz<sup>2</sup>. 1) Pathology, Allina Health, Minneapolis, MN; 2) Hospital Pathology Associates (HPA), Minneapolis, MN; 3) The International Circle of Genetic Studies, Los Angeles, CA.

We report here a 74-year-old male who was seen for recurrent respiratory infections, fatigue, and weight loss in Nov 2016. A CBC revealed anemia, and a serum protein electrophoresis revealed a large IgG lambda monoclonal gammopathy (total IgG level of 6430) and depressed IgA and IgM levels. His urine immunofixation study showed trace IgG lambda protein with free kappa light chains. A PET/CT scan was negative for lytic lesions; calcium and creatinine were normal. Bone marrow biopsy showed 90% involvement by plasma cell myeloma (PCM) [90% plasma cells, 40% cellular bone marrow]. Cytogenetic analysis of the bone marrow showed complex karyotype as described as: 53,Y,add(X)(p22.1),del(1)(p13p22),+3,add(3)(p13),add(4)(p12),+6,del(6)(q13q25),t(8;22)(q24.1;q11.2),+9,+11,+15,+15,+21[7]/46,XY[13]. This particular pattern with deletion 1p and 6q, and a t(8;22)(q24;q11.2) within the context of a complex karyotype is seen in PCM. Fluorescence in situ hybridization analysis on CDC138 sample was positive for additional copies of CEP7 (centromere 7), CEP9 (centromere 9), CEP11 (centromere 11), and CEP15 (centromere 15) suggesting polysomy. FISH using the *MYC* Vysis break apart probe showed evidence of *MYC* rearrangement similar to the breakpoint site seen in Burkitt lymphoma with t(8;22)(q24;q11). FISH using the *IGL* break apart probe (Cytocell) showed evidence of 22q11.2 rearrangement. The signal pattern showed a residual green signal (BCR), a green signal on the derivative 8 and a red signal on the derivative 22 suggesting that the breakpoint at 22q11.2 in this patient was located downstream of the BCR region of the *IGL* gene. Variant Burkitt-type translocation, t(8;22)(q24;q11), is a very rare abnormality in PCM in this case is one of the few reported up to date. In these patients, *MYC* abnormalities appear late in the course of the disease and have an immature phenotype. A review of several cases in the literature suggest that this translocation leads the *MYC* gene under direct regulation of the enhancer of the partner gene, in our case, the *IGL* or a nearby gene, thereby causing high level transcription of *MYC*. This abnormality is usually present within a complex karyotype and is considered to be associated with tumor progression and poor prognosis.

**2400F**

**A pediatric B-ALL with doubled near-haploidy by chromosomal microarray and negative MRD at day 29 of induction: Case report.** J. Xu<sup>1</sup>, S. Kuerbitz<sup>2</sup>, L.B. Baughn<sup>3</sup>, K. Eickholt<sup>4</sup>, J. Chen<sup>5</sup>, S.C. Reshmi<sup>5</sup>, R.W. Novak<sup>1</sup>, J. Hord<sup>5</sup>. 1) Pathology, Akron Children's Hospital, Akron, OH, USA; 2) Hematology/Oncology, Akron Children's Hospital, Akron, OH, USA; 3) Mayo Clinic, Rochester, MN, USA; 4) Pathology, The University of New Mexico, NM, USA; 5) Institute for Genomic Medicine, Pathology, Nationwide Children's Hospital, OH, USA.

Hypodiploidy (HD) and doubled HD occur in 1-2% and ~0.7% cases, respectively, of pediatric B-ALL. Cytogenomic variation, prognosis and optimal therapies for these cases are yet to be fully appreciated. We present a 13-year-old girl diagnosed with B-ALL, 94% blasts in bone marrow (BM) and negative central nervous system. FISH of 24h BM culture was negative for rearrangements of *BCR/ABL1*, *ETV6/RUNX1*, *MLL* and CEN 4 and 10. G-banding of direct and 24h cultures showed a hyperdiploidy with 49~52,XX,+X,+X,+14,+14,del16q,+21,+21[cp9]/46,XX[16]. Chromosomal microarray (CMA) study indicated a pseudo-hyperdiploid clone from doubling of an original near-haploid (NH) clone with loss of all chromosomes except X, 14 and 21. There were several deletions, including deletions 5q34, 6p22.2 (involving several histone genes), and 16p13.3p13.2 (involving *CREBBP* gene) consisting with previous reports in NH ALL (Nat Genet. 2013; 45:242-252). There were mosaic and heterozygous deletions 16q13q23.2 and 16q23.3q24.3, likely subsequent to the doubling and suggesting clonal evolution. The patient was tested negative for *CRLF2* rearrangements, *JAK* fusions, multiplex RT-PCRs for known actionable fusions, and targeted *JAK/IL7R* sequencing alterations. Treatment included standard 5 drug induction chemotherapy with oral prednisone, intrathecal methotrexate, and intravenous vincristine, daunorubicin and pegasparginase, which was tolerated without significant side-effects. Minimal residual disease (MRD) was negative at day 29 of induction. This is one of few reported B-ALL cases with doubled NH characterized by CMA and raises two interesting points. 1) The G-banding/FISH of this case showed a hyperdiploidy with no evidence of HD, mix of HD/hyperdiploidy, or two copies of the same structurally rearranged chromosome, which would have triggered CMA testing for a pseudo-hyperdiploid. 2) HD was reportedly associated with a very poor prognosis in pediatric ALL. Although our patient is currently undergoing treatment and the outcome is unclear, this case report emphasizes the need for considering CMA for in B-ALL with non-classical hyperdiploidy for accurate risk stratification/treatment.

**2401W**

**A novel XPA gene mutation (c.773delG, p.R258Lfs\*11) in two siblings with Xeroderma Pigmentosum.** B. Balta<sup>1</sup>, M. Erdogan<sup>1</sup>, H. Gumus<sup>2</sup>, A. Kiraz<sup>1</sup>, R. Ertas<sup>3</sup>. 1) Department of Medical Genetics, Kayseri Training and Research Hospital, Kayseri, Turkey; 2) Department of Child Neurology, Erciyes University, Medical Faculty, Kayseri, Turkey; 3) Department of Dermatology, Kayseri Training and Research Hospital, Kayseri, Turkey.

Xeroderma pigmentosum (XP) is a heterogeneous autosomal recessive disorder characterized by increased sunlight sensitivity with the development of carcinomas such as basal cell carcinoma, squamous cell carcinoma, melanoma at an early age. Some patients have neurologic manifestation including acquired microcephaly, absent deep tendon reflexes and progressive sensorineural hearing loss. The diagnosis of XP is based on clinical findings, family history and identification of pathogenic variants in *ERCC1*, *ERCC2*, *ERCC3*, *ERCC4*, *ERCC5*, *POLH*, *DDB2*, *XPA*, or *XPC*. Two brothers at the age of 5 and 4 were admitted our department with photosensitivity, persistent erythema, mild intellectual disability and microcephaly. Parents have not consanguinity but are from same village. Cranial MRI shows mild ventricular dilatation in both lateral ventricles and 3.ventricle. By whole exome sequencing we detected a novel homozygous mutation in XPA gene, c.773delG, p.R258Lfs\*11. The aforementioned mutation has not been previously reported.

### Implementation of a multi-gene panel in selected Greek breast and ovarian cancer patients reveals loss-of-function mutations in multiple genes.

F. Fostira, I. Konstantopoulou, M.S. Papamentzelopoulou, D. Kalfakakou, P. Apostolou, I. Konstanta, A. Vagena, I.S. Vlachos, D. Yannoukakos. Molecular Diagnostics Laboratory, NCSR Demokritos, Athens, Attika, Greece.

**Introduction:** NGS technologies, especially in the form of gene panels, have surely entered the clinical practice for cancer patient management.

Among high-risk breast and/or ovarian cancer patients of Greek descent, although five *BRCA1* alleles with founder effect dominate the mutation spectra, additional susceptibility alleles in a number of genes are definitely present.

**Materials and Methods:** In total, 853 breast and 408 ovarian cancer patients fulfilling NCCN genetic testing criteria have been analyzed by Trusight Cancer panel targeting 94 genes associated with cancer predisposition, in order to identify loss-of-function (LoF) mutations. **Results:** LoF mutations have been identified in 22% and 26% of the breast and ovarian cancer group respectively, in 29 genes involved in DNA repair. Of these, 87% and 89% lie in genes with known or suspected associations with breast and/or ovarian cancer predisposition, predominantly *BRCA1* and *BRCA2* (62%; 74%). Mutations in *CHEK2*, *PALB2* and *ATM* were more frequent in the breast cancer series and *RAD51C* in the ovarian cancer series. Of note is the remaining 12% of LoF alleles in non-associated genes to date, which can be either regarded as incidental findings, while putative causality for breast/ovarian cancer cannot be excluded.

**Conclusions:** Among a high-risk group of breast and ovarian cancer patients of Greek descent, where there are strong founder effects, the mutational spectrum is highly heterogeneous with respect to both loci and alleles. This approach can shed light on associations with the post-BRCA genes and will provide connections of phenotypes with mutations in additional DNA repair genes.

## 2403F

### Screening for rearrangements in *RB1* gene/ 13q14 through real-time

PCR. R.M. Freitas<sup>1</sup>, P. Pereira Sena<sup>2</sup>, M. Campos Junior<sup>3</sup>, F. Regla Vargas<sup>1,4</sup>. 1) Instituto Oswaldo Cruz, Rio de Janeiro, Brazil; 2) Institut für Medizinische Genetik und Angewandte Genomik, Universitätsklinikum Tübingen, Alemanha; 3) Human Genetics Laboratory, Instituto Oswaldo Cruz, Fundação Oswaldo Cruz, Rio de Janeiro, Brazil; 4) Genetics and Molecular Department, Universidade Federal do Estado do Rio de Janeiro, Rio de Janeiro, Brazil.

Patients with deletion of chromosomal region 13q that includes the *RB1* gene show retinoblastoma (RB) and variable clinical features. About 5-15% of the patients with RB are heterozygous for a gross deletion that includes the whole or substantial parts of *RB1* gene. Deletions had been identified by analysis of short tandem repeat (STR) *loci* within *RB1*, quantitative multiplex PCR (QM-PCR), multiplex ligation-dependent probe amplification (MLPA) and classical cytogenetic analysis. We have designed a method based in real-time PCR for search of deletions / duplications of *RB1* gene. The method was tested in control DNA and validated in a set of RB patients with partial or total *RB1* deletions. Additionally, the method was validated in one patient with trisomy 13 (Patau syndrome), who has three copies of *RB1* gene. The specificity, sensitivity and clinical utility of the assay were demonstrated in detecting allele-specific copy number variation, and can be useful for analysis relative copy number. We have selected, in addition to the *RB1* gene, two other genes (*SUCLA2* and *MED4*) that are adjacently located to *RB1* in chromosomal region 13q14.2. Genomic DNA was isolated from peripheral blood samples using standard salting out method. The amplified segments were analyzed by relative quantification, relative copy number method ( $2^{-\Delta\Delta Ct}$ ) (Livak et al., 2001). Each plate contained an internal control (*ALB* gene) and a trisomic sample was also used to observe the duplication of the region, all in triplicate. The CT's (cycle threshold) values obtained were used to calculate the relative copy number of each sample. All reactions were performed with Sybr Green (Invitrogen®). The mean of CT's triplicates were calculated, and the  $\Delta\Delta Ct$  and  $2^{-\Delta\Delta Ct}$  of each sample, having as reference CT normal individual with the primer *ALB* control and the CT trisomic sample, were also estimated. Seven samples of retinoblastoma patients with partial or total *RB1* deletion detected by MLPA were used for validation. All samples were validated by real-time quantitative PCR. Seven retinoblastoma patients carried complete deletion of *RB1* gene were identified by the MLPA technique, among 66 retinoblastoma patients tested (Sena, 2013). These deletions comprise about 10.61% of the mutations identified in retinoblastoma (Price et al., 2014). Thus, the relative quantification real-time PCR technique to investigate deletions in the *RB1* gene becomes advantageous, since it is a fast, sensitive and low-cost technique.

**2404W****Molecular insights into the missing heritability of familial ovarian cancer.**

J. Stafford<sup>1</sup>, G. Dyson<sup>1</sup>, N. Levin<sup>1,2</sup>, S. Chaudhry<sup>1</sup>, C. Wernetter<sup>1</sup>, N. Petrucelli<sup>1,2</sup>, J. Simon<sup>1,2</sup>, M. Tainsky<sup>1,2</sup>. 1) Wayne State University, Detroit, MI; 2) Karmanos Cancer Institute, Detroit, MI.

While up to 25% of ovarian cancer (OVCA) cases are thought to be due to inherited factors, the majority of genetic risk remains unexplained. We sought to identify previously undescribed OVCA risk variants through the whole exome sequencing (WES) and candidate gene analysis of 48 European American women with ovarian cancer selected for high risk for genetic inheritance, yet negative for any known pathogenic variants in either *BRCA1* or *BRCA2*. Whole exome sequencing followed by candidate gene analysis and in silico SNP assessment was employed to identify suspect variants followed by validation using Sanger DNA sequencing. A SNP was considered suspicious if it was rare (MAF < .001 CEU), missense or frameshift, and predicted to be damaging (SIFT/PolyPhen) to a gene associated with hereditary cancer risk or involved in DNA repair or cell cycle control. Five pathogenic variants were detected including two frameshift mutations in *ATM*, two truncating variants in *RAD51D* and another pathogenic nonsense mutation in *FANCM* which predisposes to breast cancer but not featured on current testing panels. Numerous rare and predicted to be damaging variants of unknown significance (VUS) were detected in genes on current commercial testing panels, most prominently in *ATM* (n=6) and *PALB2* (n=5). The *BRCA2* variant p.K3326\*, resulting in a 93 amino acid truncation yet considered benign, was overrepresented in our sample (odds ratio = 4.95, p = 0.01). This variant is has recently been shown to be associated with susceptibility to various cancers and coexisted in the germline with other pathogenic variants, suggesting a possible role as a modifier of genetic penetrance. Furthermore, we detected loss of function variants in non-panel genes involved in OVCA relevant pathways; DNA repair and cell cycle control, including *CHEK1*, *TP53I3*, *REC8*, *HMMR*, *RAD52*, *RAD1*, *POLK*, *POLQ*, and *MCM4*. Functional analysis upon knockdown of some of these genes led to significantly reduced levels of homology directed repair. Our findings suggest that the likely sources of the unexplained genetic etiology in OVCA are due to rare VUSs in panel genes, risk loci occurring in non-panel genes involved in DNA repair or cell cycle control, and polygenic risk inheritance. Definitive functional tests are necessary to discriminate variants of decreased function from benign polymorphisms and ideally, could reveal the impact of multiple low effect mutations as a means of personalized genetic risk evaluation.

Clinical testing for *BRCA1* and *BRCA2* mutations became available more than 20 years ago. Since then, the number of individuals undergoing testing and laboratories offering testing for hereditary breast and ovarian cancer (HBOC) have increased dramatically. With the expiration and overturning of the *BRCA1* and *BRCA2* patents, limitations on which laboratories could offer commercial testing, both nationally and internationally, were lifted. These legal changes occurred approximately the same time as the widespread adoption of massively parallel sequencing (MPS) technologies. Although the combination of advances has significantly changed laboratory practice, little is known about how the new technologies are currently being used in HBOC testing. We sought to obtain a snapshot of current laboratory genetic testing practices for *BRCA1* and *BRCA2* across the world. We employed an online survey of 65 questions covering four areas: laboratory characteristics, technological details on methods used for testing, variant classifications, and customer-service information. Over 78 non-US based laboratories began the questionnaire with 48 laboratories from 6 continents fully completing the survey. The majority of participating laboratories were in Europe. A slightly modified questionnaire was developed for laboratories located in the United States (US). Eight of 27 US-labs invited to participate completed the survey. Survey results were tallied for US and non-US labs. Most non-US based laboratories (92%, 72/78) use MPS-based platforms for *BRCA* analysis with Sanger sequencing for validation of variants, and the remaining 7.6% use Sanger sequencing as their only platform. All eight US laboratories utilize MPS for identification of in/dels and single nucleotide variants. Multiplex ligation-dependent probe amplification is the most common method for identifying and/or confirming large rearrangements. Laboratories differed widely on: 1) criteria for minimum read depths; 2) amount of sequence from intronic and regulatory regions; 3) variant classification criteria and approaches; 4) number of genetic counselors on staff; and 5) deposition of identified variants into public databases. A wide range of approaches and standards were used to determine pathogenicity of *BRCA1/2* variants. Data from this study may be useful for national and international agencies to set recommendations for minimal quality standards for *BRCA1/2* clinical testing.

**Hyb & Seq™: The next generation of simultaneous RNA and DNA detection in liquid biopsy without the library and sample preparation bottlenecks.** *J. Beechem, M. Hoang, M. Walsh, M. McElwain, E. Piazza, M. Rhodes, D. Kim.* Nanostring Technologies, Inc., Seattle, WA.

Nucleic acid (NA) sequencing of circulating cell-free (cf) DNA and RNA or cfNA from blood is an exciting, noninvasive tool for personalized medicine research. However, clinical implementation is hindered by the need for complex sequencing library preparations that amplify the low levels of cfNA but also introduce sampling errors and artifacts. Hyb & Seq technology is a library-free, amplification-free, single molecule sequencing technique that uses cyclic nucleic acid hybridization of fluorescent molecular barcodes to sequence native single molecule targets. Here we demonstrate Hyb & Seq's simple workflow on plasma, simultaneously capturing and directly sequencing both DNA and RNA. Target-specific capture probes were mixed directly into plasma to hybridize with circulating cfNA molecules. Following a short incubation, excess probes were removed, and captured cfNA molecules were immobilized onto a flowcell, and each cfNA molecule directly sequenced using Hyb & Seq. Total processing time from plasma sample to start of sequencing was under 60 minutes, with hands-on time of less than 15 minutes. Experimental results showed that all 100 targets were captured onto the flow-cell using 5 mL – 10 mL of plasma without PCR amplification. Using a reference plasma sample with known mutations and allele frequencies, accurate detection was achieved down to ~1% mutation allele frequency. Finally, 100 targets were simultaneously sequenced and digitally quantified for relative cfDNA and cfRNA levels, and presence of the single nucleotide variant. The Hyb & Seq system demonstrates the unique ability to simultaneously capture and directly sequence cfNA using a rapid sample-to-answer sequencing process without amplification or enzymology, thus opening up the possibility of assessing complex biomarker signatures from liquid biopsy.

**Optimizations in target enrichment and bioinformatics enable sensitive detection of copy number variations in targeted NGS.** *J. van den Akker, G. Mishne, R. O'Connor, Z. Mahkovec, T. Sittler.* Color Genomics, Burlingame, CA.

While copy number variants (CNVs) account for a significant proportion of mutations, their detection in targeted next generation sequencing (NGS) assays has been historically challenging. However, we have developed sophisticated methods for the detection of CNVs (deletions and duplications) in our 30-gene NGS-based test for hereditary cancer risk (the Color Test). This has been accomplished by optimizations at multiple levels to boost detection sensitivity. First, in the enrichment step, we target not only coding sequences, but also extended flanking regions of small exons as well as the breakpoints of published structural variants. Next, CNVs are detected with multiple algorithms targeting different variant properties. Read depths are subject to custom bias correction and segmented by multiple methods by CNVkit (CBS & fused LAS-SO). Segments are annotated and processed by a multi-parameter algorithm trained on past data to call CNVs. In addition, CNVs are detected by an in-house developed split-read algorithm. In regions where reads are not consistently clipped, signals from paired-end reads with large insert sizes are used to assess CNV breakpoints. All variants classified as VUS, likely pathogenic, or pathogenic are confirmed by either aCGH, MLPA, or Sanger sequencing of a PCR fragment covering the breakpoints. Color has identified CNVs in over 220 samples to date, representing approximately 150 distinct variations. They were detected in 22 genes, with almost one-third occurring in *BRCA1*. Detailed breakpoint analysis revealed at least 44 distinct CNVs in *BRCA1* and 7 CNVs in *BRCA2*. Out of the 15 duplications detected in *BRCA1* and *BRCA2*, 12 were confirmed to be in tandem. This knowledge is required to predict the RNA sequence, which guides variant classification. While the clinical relevance of CNV detection in *BRCA1*, *BRCA2*, and the Lynch syndrome genes has been well established, data on other genes associated with hereditary cancer is scarce. Here, we highlight the CNVs we identified in *CHEK2* (n=27, 10 distinct CNVs), *ATM* (n=21, 11 distinct), and *RAD51C* (n=15, 11 distinct). Importantly, our assay can detect CNVs of all sizes, and more than 30% impacted only a single exon. Moreover, our split-read detection algorithm has detected 15 variants between 25-250 base pairs, a size range known to be difficult in most NGS assays. In conclusion, by combining multiple complementary approaches, CNVs of variable sizes can be detected across a multi-gene NGS panel.

**Hereditary cancer risk testing of 11,570 individuals with a multi-gene panel.** J. Ji, A. Zhou, A. Zimmer, W. McFadden, J. Akker, R. O'Connor, K. Kim, D. Keen-Kim, A. Leon. Color Genomics, Burlingame, CA.

Here, we describe the demographics and characteristics of 11,570 individuals who received the Color Test, a 30-gene next generation sequencing (NGS) based panel for hereditary cancer risk. The overall proportion of individuals who carried a pathogenic or likely pathogenic variant in this cohort, or mutation carrier rate, was 11.9% (1,377/11,570). We identified and reported 1,434 pathogenic or likely pathogenic variants in this cohort. A total of 49 (3.6%) individuals were found to carry two concurrent pathogenic variants in different genes, and one individual carried three concurrent pathogenic variants in different genes, indicating the importance of broader multi-gene panel testing. Additionally, 6 individuals carried two different pathogenic variants in the same gene. Many individuals in the cohort were referred to testing for a personal or family history of breast or ovarian cancer. Therefore, it was not surprising that *BRCA1* and *BRCA2* account for 31.5% (452/1,434) of all pathogenic variants identified. Among the 1,377 individuals who received a positive result, 201 (14.6%) carried a single pathogenic variant in *MUTYH*, while 4 individuals carried two different pathogenic variants in *MUTYH*. Additionally, 69 (5.0%) individuals carried the *CHEK2* c.470T>C (I157T) variant and 146 (10.6%) individuals the *APC* c.3920T>A (I1307K) variant, both of which are known to have lower penetrance and specific screening recommendations. The mutation carrier rate amongst individuals who reported no personal or family history of cancer was 8.3% (92/1,108). The majority of the cohort self-reported as ethnically Caucasian (51.9%, 6,001/11,570) or Ashkenazi (10.9%, 1,256/11,570), reinforcing a well-known need to increase genetic testing awareness and uptake within other underrepresented ethnic populations. Only 18.5% (2,140/11,570) of the cohort was male, even though the genes on the panel are relevant to both males and females, indicating a potential underlying bias for women to seek out genetic testing more prevalently than men. Finally, only 28.0% (386/1,377) of individuals who received positive results were under the age of 40, indicating the importance of increasing awareness and uptake of genetic testing within the younger population, at an age for which preventative care is more relevant. Taken together, these data reinforce the continued need to increase awareness and broaden access to genetic testing within the general population.

**What's in a VUS rate? Simulated VUS calculations for hereditary cancer genes in a general population using population frequency data and ClinVar submissions.** K.E. Kaseniit, M. Judkins, R. Mar-Heyming, H.P. Kang, E.A. Evans, K. Ready, D. Muzzey. Counsyl, Inc., South San Francisco, CA.

A common metric by which inherited-cancer tests are compared is the likelihood of a patient receiving a variant of uncertain significance ("VUS"). This "reported-VUS likelihood" or "VUS rate" metric has questionable value, however, because multiple factors influence it: the number of genes tested, the particular assayed regions (e.g., exons, introns), the laboratory variant classification criteria, and the patient ethnicity. By permuting these various determinants for panels of hereditary cancer genes that have specific medical management guidelines, we demonstrate that the reported-VUS likelihood value can vary greatly. We simulated the reported-VUS likelihood for a hypothetical laboratory running a test with three parameters under our control. The first parameter was the stringency in variant interpretation: we used weighted ClinVar classifications and applied different frequency cutoffs for benign (0.3-1%). Second, to represent the impact of an assay's particular region-of-interest, we varied the number of bases sequenced into intronic regions. Finally, to evaluate the impact of ethnicity, we considered a US-population weighted patient cohort, as well as cohorts comprised of each ethnicity individually. All simulations modeled patients' variants using the ethnic-specific gnomAD allele frequencies. For a 27-gene panel, the simulated reported-VUS likelihood values differed by up to 7 percentage points based on the other panel parameters. Decreasing the panel size tended to restrict the range: a 6% spread for a hereditary breast cancer panel with nine genes, and a 3% spread for *BRCA1* and *BRCA2* only. With a non-stringent benign allele frequency cutoff of >0.3%, the VUS rate could differ by up to 2 percentage points for a 27-gene panel depending on whether the 20 intronic bases flanking exons were part of the assay. When stratified by ethnicity, the VUS rate for an African/African-American cohort in one scenario was 12 percentage points higher than the US-population-weighted rate. Our simulations do not reflect any true diagnostic laboratory, yet they show that there is a wide range of reported-VUS likelihoods based on the type of test being ordered, the classification criteria being used, the assay design, and the ethnic mix of the patient cohort. Our results indicate that the VUS rate in isolation is not a reliable measurement of quality, suggesting that multiple criteria should be considered when evaluating which genetic tests to offer patients.

**2410W**

**Integration of calibrated functional assay data into *BRCA1* VUS evaluation.** *B.A. Thompson<sup>1,2</sup>, R. Bell<sup>1</sup>, A. Thomas<sup>3</sup>, B.E. Wehm<sup>4</sup>, J. Burn<sup>5</sup>, S.V. Tavtigian<sup>1</sup>.* 1) Department of Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT; 2) Centre for Epidemiology and Biostatistics, School of Population and Global Health, University of Melbourne, Melbourne, Australia; 3) Department of Internal Medicine, Division of Genetic Epidemiology, University of Utah School of Medicine, Salt Lake City, Utah; 4) Department of Surgery, Huntsman Cancer Institute, University of Utah School of Medicine, Salt Lake City, Utah; 5) Institute of Genetic Medicine, International Centre for Life, Newcastle University, Newcastle upon Tyne, United Kingdom.

Driven by massively parallel sequencing and allied technologies, the scale of genetic predisposition testing is on a dramatic uptrend. While many patients are found to carry clinically actionable pathogenic sequence variants, testing also reveals enormous numbers of Unclassified Variants (UV), or Variants of Uncertain Significance (VUS), most of which are rare missense substitutions. Following International Agency for Research on Cancer (IARC) variant classification guidelines, quantitative methods have been developed to integrate multiple data types for clinical UV evaluation in *BRCA1/2*; results from these analyses are recorded in the BRCA gene Ex-UV database ([hci-exlovd.hci.utah.edu](http://hci-exlovd.hci.utah.edu)). In variant classification, the rate-limiting step is often accumulation of patient observational data. Recently, functional assays evaluating *BRCA1* RING domain (n=10) and C-terminal substitutions (n=242) have been calibrated, in principle enabling variant classification through a combination of sequence analysis-based predictions with functional assay results. This two-component classification was embedded in a decision tree with safeguards to avoid misclassification. For 38 previously classified variants (likely pathogenic, n=1; pathogenic, n=15; likely not pathogenic, n=2; not pathogenic, n=20) the two-component analysis resulted in sensitivity of 87.5% (95% CI: 62-98%), specificity of 100% (85-100%), and an error rate (classification of known neutral variants as pathogenic or vice versa) of 0.0%. Classification of a UV as likely pathogenic or likely neutral does not require certainty; the probabilistic definitions of the categories imply a tolerable error rate. Combining sequence analysis with functional assay data in two-component analysis lead to the classification of 141 *BRCA1* variants as likely pathogenic (n=39) or likely neutral (n=102). Moreover, once higher throughput functional assays achieve acceptable accuracy and have been calibrated, two-component analysis has the potential to dramatically accelerate UV classification.

**2411T**

**Mate-pair sequencing provides advanced molecular characterization of genomic rearrangements in B-Chronic Lymphocytic Leukemia (CLL) and non-Hodgkins lymphoma.** *S.S. Smoley<sup>1</sup>, H.K. Kearney<sup>1</sup>, R.B. Jenkins<sup>1</sup>, N.E. Kay<sup>2</sup>, K.K. Reichard<sup>1</sup>, D.L. Van Dyke<sup>1</sup>.* 1) Laboratory Medicine & Pathology, Mayo Clinic, Rochester, MN; 2) Internal Medicine, Mayo Clinic, Rochester, MN.

Mate pair sequencing (MPseq) is a powerful new approach for the detection and molecular characterization of novel and recurrent chromosome rearrangements in neoplasia. We have explored MPseq on a series of 15 CLL and eight lymphoma cases that were not completely informative using other methods, e.g., FISH, conventional cytogenetics (karyotype), or chromosomal microarray (CMA). DNA was processed using the Illumina Nextera Mate Pair library preparation kit, multiplexed at 2 samples per lane and sequenced on the Illumina HiSeq. Data was aligned to the reference genome using BIMA v3 and abnormalities were identified using SVAtools, both of which are in-house developed bioinformatics tools. Of the 23 CLL and lymphoma cases evaluated, 76 abnormalities were detected by karyotype, FISH or CMA. Mate-pair identified 72 of these 76 abnormalities, identified IGH, IGL, RB1, and CDKN2A rearrangements and copy number changes not detected by the other methods, clarified the extent of 13q deletions in three cases, and in four cases recognized deletions and duplications associated with apparently balanced translocations that had been identified by chromosome analysis. The four abnormalities that MPseq did not detect were all low level clones below the resolution of MPseq testing (the sensitivity of MPseq is 10-25% depending on the abnormality). Two illustrative examples: in a bone marrow aspirate from a CLL patient (case 18) with deletion 11q and 13q and IGH break-apart by FISH, karyotype analysis using CpG stimulation revealed an abnormal 2p and 14q, and an apparently independent clone with 11q deletion. MPseq confirmed loss of ATM and the 13q miRNAs MIR15A/MIR16-1 and identified a BCL11A/IGH translocation, which is an uncommon but recurrent immunoglobulin rearrangement in CLL. In a bone marrow aspirate from a patient (case 24) with a reason for referral of "suspected lymphoma" FISH identified 13q deletion, karyotype analysis identified 13q deletion and a t(18;22), and microarray identified heterozygous RB1 deletion, homozygous miRNA loss, and loss of IGL. Mate pair confirmed these abnormalities and also identified a juxtaposition of IGL 5' of BCL2 with resulting upregulation of the oncogene. These results illustrate the significant power of mate pair sequencing in comparison to FISH, karyotype, or CMA to identify clinically relevant gene fusions, as well as gains and losses of chromosomal segments in hematologic malignancies.

**Loss-of-function *POLE* and *POLD1* variants may not be associated with early-onset colon cancer/polyposis.** E.K. Flynn, M.E. Roberts, L.R. Susswein, K. Retterer, J. Juusola, Z. Xu, R.T. Klein, K.S. Hruska. GeneDx, Gaithersburg, MD.

**Statement of Purpose:** The *POLE* and *POLD1* genes have been associated with Polymerase Proofreading-Associated Polyposis (PPAP), a highly penetrant autosomal dominant condition that increases the risk for early-onset colorectal cancer (CRC) and adenomatous colon polyps. It has been suggested that only missense variants within the exonuclease domain, and not any loss-of-function (LOF) variants, would be pathogenic for PPAP. Our aim was to assess whether *POLE* and *POLD1* LOF variants might be associated with an increased risk of early-onset colon cancer/polyposis as is seen in PPAP.

**Methods:** We retrospectively reviewed the personal and family histories for 73 individuals from 52 families with a LOF *POLE* or *POLD1* variant identified by Exome Sequencing (WES), an unbiased population since testing was not ordered based on a cancer indication, and 14 individuals tested by a 32-gene hereditary cancer panel. "Loss-of-function" variant was defined as any variant predicted to cause protein truncation or nonsense-mediated decay (NMD), including nonsense and frameshift variants as well as canonical splice variants predicted to cause a large out of frame deletion. **Results:** Among our 52 WES families and 14 inherited cancer panel probands, 48 unique LOF variants were identified (*POLE* = 33; *POLD1* = 15). On WES, 73 individuals from 52 families were found to carry a *POLE* (n = 54) or *POLD1* (n = 19) variant. Two families total (3.8%, 2/52) reported personal or family history of CRC. Of the inherited cancer referrals, 14 individuals were found to carry a *POLE* (n=7) or *POLD1* (n=7) variant. None of those <50 years of age (n=9) reported a personal history of colorectal cancer while 1/5 of those ≥50 years of age had a personal history. Additionally, none of the 14 individuals identified via our inherited cancer panel reported a personal history of colon polyps, and five (36%, 5/14) reported a family history of CRC. **Conclusions:** In the WES cohort, only 3.8% (2/52) of families with a LOF *POLE* or *POLD1* variant reported a personal or family history of CRC. While our inherited cancer cohort is subject to ascertainment bias, as we expect referrals to have strong personal or family histories, this group lacks young-onset colon cancers and there are no reports of colon polyps. Based on these preliminary data, it appears that LOF *POLE* and *POLD1* variants may not predispose to early-onset colon cancer/polyposis.

**2413W**

**Library-free, targeted sequencing of native genomic DNA and RNA from FFPE samples using Hyb & Seq™ technology – the Hybridization-based Single Molecule Sequencing System.** D. Kim, L. Manrao, R. Khafizov, M. Walsh, M. Korukonda, M. Gregory, M. Hoang, S. Woo, T. Rane, Y. Deng, M. Rhodes, J. Beechem. Research and Development, NanoString Technologies, Seattle, WA.

DNA sequencing is an enabling tool for personalized medicine research, but widespread implementation is hindered by complexities in sample preparation and sequence analysis. Hyb & Seq™ technology is a library-free, amplification-free, single-molecule sequencing technique that uses cyclic nucleic acid hybridization of fluorescent molecular barcodes onto native targets. Hybridization-based sequencing enables the simplest sample-to-answer workflow; both DNA and RNA are directly sequenced with almost no manipulation of the input material. The advantages of single molecule sequencing include simple error correction and digital counting to elucidate DNA copy numbers and RNA levels. Here we describe an end-to-end Hyb & Seq sequencing process that consists of: i) Sample preparation including rapid gene capture directly from formalin-fixed paraffin embedded (FFPE) tissue. ii) Library-free targeted sequencing of oncogenic mutations. iii) Data analysis using a Hyb & Seq assembly algorithm (ShortStack™) for variant calling. Targeted sequencing of oncogenic mutations was performed on NanoString's prototype Hyb & Seq system. **Highlights of Key Results:** • Total time from FFPE curls to start of sequencing was under 60 minutes, with total hands-on time of less than 15 minutes • Simultaneous capture of 100 DNA gene targets and 20 mRNA from one to three FFPE curls (10 microns thickness) was sufficient for sequencing with no PCR amplification and cDNA conversion • Dual strand capture and simultaneous sequencing of both strands of DNA, increased accuracy of variant detection by identifying single-stranded damage artifacts common in FFPE templates • Automated sequencing carried out on a microfluidic cartridge with runs exceeding 400 Hyb & Seq cycles • Sequencing accuracy reached 99.99% (QV40) when a base from a single molecule was read ≥ 5 times • All targeted variants including variant as low as 1% were detected Hyb & Seq's simplicity, flexibility, and accuracy offers an ideal sample-to-answer solution for the translational sequencing research lab.

**2414T**

**The prevalence of mosaicism in common cancer susceptibility genes from 232,328 individuals undergoing sequential testing.** T. Slavin<sup>1</sup>, B. Coffee<sup>2</sup>, H. Cox<sup>2</sup>, R. Bernhisel<sup>2</sup>, K. Brown<sup>2</sup>, J. Weitzel<sup>1</sup>, S. Neuhausen<sup>1</sup>, D. Mancini-Dinardo<sup>2</sup>. 1) Clinical Cancer Genomics, City of Hope, Duarte, CA; 2) Myriad Genetic Laboratories, Salt Lake City, UT.

**Background:** Previous studies have suggested that age and personal cancer history are associated with an increased risk of mosaic next generation sequencing (NGS) findings. This has been attributed to aberrant mutations in hematologic cell lines termed clonal hematopoiesis. Here, we evaluated mosaic NGS findings from a large hereditary cancer clinical cohort to explore contributing factors. **Methods:** We assessed individuals who had multi-gene pan-cancer panel testing through a large genetic laboratory (Myriad Genetic Laboratories) and were found to carry mosaic variants (NGS read frequency of 10-30%) classified as either pathogenic, likely pathogenic, or uncertain. Logistic regression analysis was used to determine the risk of carrying a mosaic variant after adjusting for 1) personal cancer history (affected vs unaffected), 2) age (<50 vs ≥50 years), 3) germline mutation status, and 4) clinical indication for testing. Odds ratios (OR) and 95% confidence intervals (CI) are reported. **Results:** Overall, 348/232,328 (0.15%) individuals were identified as carrying a mosaic variant, most commonly in either *CHEK2* (29%), *TP53* (23%), or *ATM* (22%). Logistic regression analysis showed that age group (≥50 years) was associated with the greatest risk for carrying a mosaic variant (OR=3.8, 95%CI 2.8, 5.2; p<0.001). Individuals with personal history of cancer (OR=2.4, 95% CI 1.8, 3.2; p<0.001), or a germline pathogenic variant (OR=1.4, 95% CI 1.0, 2.0; p=0.045), also had a significantly higher risk of carrying a mosaic variant. **Conclusions:** Overall, we show that prior history of cancer, age, and germline mutation status were associated with increased risk of carrying a mosaic variant. As the mosaic variants were associated with advanced age, likely chemotherapy exposure, and in genes known to be associated with clonal hematopoiesis, we believe clonal hematopoiesis as the most likely cause of the majority of the mosaicism. It is likely that more cases would have been identified with inclusion of genes frequently associated with clonal hematopoiesis, such as *DNMT3A* or *TET2*. These findings suggest that individuals with germline DNA repair mutations have increased mosaicism; possibly related to underlying genomic instability. As clonal hematopoiesis has been associated with leukemia predisposition, these results may explain previous literature identifying an enrichment of germline DNA repair mutation carriers in therapy related leukemia cohorts.

**2415F**

**Somatic driver mutations enhance survival prediction in familial chronic lymphoid leukemia.** W. Zhou<sup>1,2</sup>, L. Goldin<sup>2</sup>, M. Wang<sup>1,2</sup>, M. McMaster<sup>2</sup>, K. Jones<sup>1,2</sup>, L. Burdette<sup>1,2</sup>, S. Chanock<sup>2</sup>, M. Yeager<sup>1,2</sup>, M. Dean<sup>2</sup>, N. Caporaso<sup>2</sup>. 1) Cancer Genomics Research Laboratory, Leidos Biomedical Research/ NCI, Bethesda, MD 20892; 2) Division of Cancer Epidemiology and Genetics (DCEG), NCI, 9609 Medical Center Drive MSC 9776 Bethesda, MD 20892.

Chronic lymphoid leukemia (CLL) is the most common type of leukemia in adults. Traditionally, four common chromosomal aberrations (deletion of 11q, 13q14, 17p, duplication of 12) as well as the mutational status of the immunoglobulin heavy chain variable (IGHV) gene have been shown to stratify CLL patients into distinct prognostic groups. In the last few years, several tumor sequencing studies have revealed a number of recurrent mutations, some of which also contribute to prognosis. In this study, we performed SNP microarray data on 95 CLL subjects from 40 CLL families. Log R ratio and B allele frequency were used to assess copy number alterations as well as to calculate the proportion of cancer cells. Overall, 142 detectable somatic copy number alterations (SCNAs) from 54 subjects were detected (57%), including the four most common CLL-associated cytogenetic aberrations: losses of chromosome 13q14 (28.9%), 11q (5.6%), and 17p (2.1%); gain of chromosome 12 (4.2%). We found many chromosomal alterations were observed only in a portion of the cells (mosaicism). We performed whole exome-sequencing of whole blood samples from 98 CLL patients (including all 95 subjects with SNP array data). We used a somatic pipeline caller to detect somatic mutations and used other filtering methods to eliminate likely germline mutations. We focused on a panel of 52 genes that have been reported as having recurrent putative driver alterations in mature B-cell non-Hodgkin lymphomas. Overall, 69 somatic mutations (all nonsynonymous except 2 in an intron of the *NOTCH1* gene) within 29 genes were detected among 45 subjects (46%). The most frequently mutated genes were *TP53* (8.2%) and *NOTCH1* (8.2%). We found that patients having both a point mutation in a CLL driver gene and SCNA have worse survival (HR=3.17, 95%CI=0.97-10.35; P=0.056) than patients having either a point mutation (HR = 1.34, 95%CI=0.66-2.71; P = 0.42), as SCNAs (HR = 2.65, 95%CI=0.77-9.13; P = 0.12). *TP53* mutations were associated with poorest overall survival (HR=4.39, 95%CI=1.28-15.04; P=0.018). Our study demonstrates that combining SCNA and mutational data can add to predicting the pathway from an initial diagnosis to outcome in CLL.

**2416W****Combined mutation and CNV detection by targeted next-generation sequencing in uveal melanoma.**

*A. de Klein<sup>1</sup>, K. Smit<sup>1,2</sup>, N. van Poppel<sup>1,2</sup>, J. Vaarwater<sup>2</sup>, H. Dubbink<sup>3</sup>, R. Verdijk<sup>3</sup>, E. Kilic<sup>3</sup>.* 1) Clinical Genetics, Erasmus MC, Rotterdam, Netherlands; 2) Ophthalmology, Erasmus MC, Rotterdam, Netherlands; 3) Pathology, Erasmus MC, Rotterdam, Netherlands.

Uveal melanoma (UM) is a highly aggressive cancer in the eye. It is the most common type of primary eye cancer in adults and nearly 50% of UM patients die from liver metastasis. Chromosome and mutation status have been shown to correlate with the disease free survival. Loss of chromosome 3 and inactivating mutations in *BAP1*, which is located on chromosome 3, are strongly associated with high risk tumors that metastasize early. Other genes often involved in UM are *SF3B1* and *EIF1AX*, which are found to be mutated in intermediate- and low risk tumors, respectively. We developed a targeted sequencing method that can detect mutations in genes involved in UM and chromosomal anomalies of chromosome 1, 3 and 8. Whereas current UM-diagnostics involves several techniques for detection of copy number variations and somatic mutations, our targeted UM panel can detect losses and gains of chromosome 1, 3 and 8 and somatic mutations in the aforementioned genes in a single assay. By sequencing formalin-fixed paraffin-embedded and fresh UM-specimens, we showed that mutations and chromosome-status can reliably be obtained using targeted next generation sequencing (NGS).

**2417T****Applying synthetic long reads to a custom Lynch Syndrome NGS**

**panel to overcome pseudogene interference in *PMS2*, detect structural variations, and enable allelic phasing.** *C. Kao<sup>1</sup>, F. Mafra<sup>1</sup>, M. Gonzalez<sup>1</sup>, R. Pellegrino<sup>1</sup>, S. Wenzel<sup>2</sup>, K. Wimmer<sup>2</sup>, F. Armelao<sup>3</sup>, T. Ripperger<sup>4</sup>, L. Fang<sup>5</sup>, K. Wang<sup>6</sup>, D. Kvitek<sup>6</sup>, S. Garcia<sup>7</sup>, A. Fehr<sup>8</sup>, H. Hakonarson<sup>8</sup>.* 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Dept. for Medical Genetics, Molecular and Clinical Pharmacology Medical University, Innsbruck, Innsbruck, Austria; 3) Department of Gastroenterology, Ospedale Santa Chiara, APSS, Trento, Italy; 4) Institute of Human Genetics, Hannover Medical School, Hannover, Germany; 5) Department of Biomedical Informatics, Columbia University, NY; 6) Invitae, Inc., San Francisco, CA; 7) 10x Genomics, Inc., Pleasanton, CA; 8) Department of Pediatrics, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA.

Massively parallel sequencing technologies have transformed clinical diagnostic screening to make the process more accessible and mainstream for a variety of genetic disorders, including hereditary conditions such as Lynch syndrome (hereditary nonpolyposis colorectal cancer). However, these current methods use short reads (up to 200-400 nt) aligned back to a reference genome, which suffers from some inherent limitations. For example: 1) short reads alone are unable to phase variants to establish compound heterozygosity; 2) detection of structural variants, especially single allele (heterozygous) or copy neutral alterations (e.g. inversions, translocations) remain challenging; and 3) clinically relevant genes with highly similar paralogs are difficult to map/resolve with traditional short read NGS; this includes *PMS2*, one of the Lynch syndrome genes. A pseudogene, *PMS2CL*, located ~0.7Mb away is highly homologous to exons 9, 11-15 in *PMS2*. Pseudogene interference is especially problematic due to frequent *PMS2/PMS2CL* recombination events. Customized, non-NGS based assays have been developed to clinically screen for *PMS2* mutations, however these can be cumbersome and difficult to implement. We used a gel-bead-in-emulsion method with the Chromium instrument (10x Genomics, Inc.) to impart long-range information into traditional short read libraries. DNA from samples (extracted using standard bead/column-based techniques) were segregated into ~1M gel-beads-in-emulsions (GEMs), where mini-libraries are created and tagged with a unique, GEM-specific 16-mer barcode. All mini-libraries are then pooled and finished with Illumina-compatible adaptors and go directly to whole-genome sequencing or undergo target enrichment prior to whole-exome or panel-based sequencing. "Synthetic" long reads are assembled by grouping together short reads sharing the same barcode. Previously, we used linked whole exome sequencing to detect *PMS2* variants (point mutations and structural rearrangements) within the *PMS2CL* paralogous region in clinical "truth" samples. We present here a custom, linked-read panel targeting all Lynch syndrome genes (*MLH1*, *MSH2*, *MHS6*, and *PMS2*) using Agilent SureSelect baits implemented within a fully automated, high-throughput workflow and demonstrate its utility in phasing alleles, overcoming pseudogene interference, and detecting structural variants. Improvements in the informatics pipeline for phasing, variant calling, and visualization are also presented.

**Tumor characteristics provide evidence for mismatch repair (MMR) variant pathogenicity.** S. Li, J. Clifford, D. Qian, Y. Tian, A. Elliott, H.M. Lu, M.H. Black. Ambry Genetics, 15 Argonaut, CA.

Pathogenic mutations in mismatch repair (MMR) genes (*MLH1*, *MSH2*, *MSH6*, and *PMS2*) increase risk for Lynch syndrome and other cancers. MMR deficiency may result in microsatellite instability (MSI); tumor MSI testing and protein immunohistochemical (IHC) analysis for MMR protein expression are often used alone or together to evaluate risk for Lynch syndrome in clinical screening. It has been suggested that these quantifiable tumor characteristics may be useful in assessing germline MMR variant pathogenicity. We obtained research consent and clinical information for 77,071 patients who underwent germline multigene panel testing including MMR genes in 2012-2016. Among the 3,627 patients with available MSI or IHC information, we excluded 69 with conflicting MSI/IHC status and 238 carriers of non-MMR pathogenic variants. Variant pathogenicity was assessed according to ACMG guidelines. Among the remaining 3,320 individuals with MSI ( $n=1,055$ ) or IHC ( $n=2,954$ ) status ( $n=689$  with both), we tested association between MMR carrier status and the combined MSI/IHC phenotype using Fisher's exact test, followed by estimation of MSI/IHC likelihood ratios ( $LR = \frac{\% \text{pathogenic variant carriers}}{\% \text{non-carriers}}$ ). For each variant, we computed the tumor characteristic LR (TCLR) based on the estimated MSI/IHC LRs. While typically  $TCLR > 1$  for pathogenic and  $TCLR < 1$  for benign variants, we used the  $TCLR > 10$  or  $< 0.1$  as thresholds suggestive of pathogenic or benign classification, respectively. Carriers of MMR mutations were more likely to have abnormal MSI/IHC ( $OR = 27.3$ , 95%CI: 16.2-49.0). Estimated LRs for MSI/IHC unstable/abnormal and stable/normal were 3.136 and 0.115, respectively. Overall, we identified 141 pathogenic/likely pathogenic, 217 benign/likely benign, and 223 VUS/unclassified MMR variants. Among pathogenic variants, 73.0% have  $TCLR > 1$  and none have  $TCLR < 0.1$ ; 89.9% of benign variants have  $TCLR < 1$  and none have  $TCLR > 10$ . Moreover, 15% of VUS/unclassified variants have  $TCLR > 1$  and 66%  $TCLR < 1$ , suggesting that many of these may be potentially classified. While no VUS/unclassified variants have  $TCLR > 10$ , 17 (8%) have  $TCLR < 0.1$ , providing stronger evidence for classification as benign/likely benign. These data show that MSI/IHC-based TCLRs provide evidence for or against pathogenicity of variants in MMR genes. Used independently or in conjunction with other evidence, the TCLR may inform variant classification, and thus have important implications for genetic testing and clinical management.

**2419W**

**A case report of a rare germline SVA transposition event in *TP53*.** W. Cheng<sup>1</sup>, R. Torene<sup>1</sup>, J. Mester<sup>1</sup>, Z. Zhang<sup>1</sup>, P. McAndrew<sup>1</sup>, P. Murphy<sup>1</sup>, S. Solomon<sup>1</sup>, C. Cina<sup>2</sup>, R. Klein<sup>1</sup>, K. Hruska<sup>1</sup>. 1) GeneDx, Gaithersburg, MD; 2) Kaiser Permanente Southern California, San Diego, CA.

Germline mobile element insertions (MEIs) disrupting normal coding sequences have been reported in association with hereditary conditions. Although apparently rare, these variants may be under-reported to date. Here we present the first known germline SINE-VNTR-Alu (SVA) insertion in the coding region of *TP53*. A 48yo female presented for cancer genetics evaluation with a personal history of bilateral breast cancer, diagnosed at ages 24 and 26, and multiple non-melanoma skin cancers. Family history was notable for a sister with synovial sarcoma, diagnosed at 50, and maternal grandmother with breast cancer, diagnosed in her late 50s. To explore the possibility of a hereditary cancer syndrome, the patient was tested on a 23-gene hereditary cancer panel, including next generation sequencing (NGS) and concurrent deletion/duplication analysis. The NGS analysis pipeline detected a possible *TP53* variant in the coding region of exon 8. Three groups of sequencing reads were observed: reverse reads containing CCCTCT repeats, forward reads containing a poly-A tract, and reference sequences. Reads containing mismatched soft-clipped sequences flanked a 16-bp duplication; this finding suggested an MEI. NGS data then were analyzed with the 'Mobster' algorithm, which identified an SVA element with 56 supporting reads and confirmed the presence of a target site duplication (TSD). Unmapped paired reads in the region were used for assembly of the MEI sequence for characterization. This SVA element was found to be full length and belonged to the SVA-E subfamily based on the percent identity to the SINE-R derived region. Using patient-specific primers for PCR followed by Sanger sequencing, we were able to confirm the 5' breakpoint of the event. However, due to the large size and the GC-rich VNTR domain, we were unable to obtain a full-length Sanger sequence across the insertion. Considering the presence of the TSD, poly-A tail, and its high identity to a young SVA subfamily, the mechanism of insertion was most likely target-primed reverse transcription. This MEI was reported as a likely pathogenic variant based on ACMG/AMP variant interpretation guidelines. This insertion is predicted to cause loss of normal *TP53* function, consistent with the patient's clinical presentation and family history suggestive of Li-Fraumeni syndrome. Given that germline MEIs disrupting coding sequences are likely disease-causing, it is important to incorporate their detection into analysis pipelines.

**Diagnostic yield and mutation spectrum of multigene panel testing for hypertrophic cardiomyopathy.** L. Qin, J. Wang, L. Hoang, T. Johnston, J. Dolinsky, T. Pesaran, C. Antolik. Ambry Genetics, Aliso Viejo, CA.

Hypertrophic cardiomyopathy (HCM) is the most common inherited cardiovascular disease with a worldwide prevalence of 1:500, and is the leading cause of sudden cardiac death in young people. Genetic etiology is suspected in up to 50% of HCM patients, and genetic testing is highly recommended for HCM patients and family members following the identification of a causative mutation in the proband. To gain insight into the diagnostic yield and mutation spectrum of HCM, a retrospective review was performed for 408 consecutive cases with a clinical suspicion of HCM who underwent multigene panel testing at our laboratory. A pathogenic mutation was identified in 27% (n=112) of these individuals. Eighty two pathogenic mutations in 15 genes were identified. The most frequently mutated genes were *MYBPC3* (48%), *MYH7* (21%), *TNNT2* (9%) and *MYL3* (5%). Further variant-specific analysis identified 38 individuals from 31 families who were positive for the mutation previously identified in their respective probands. The median age for mutation-positive individuals reported to have cardiomyopathy was 38 years (n=5) vs 14 years (n=21) for unaffected mutation-positive individuals, consistent with the age-related penetrance of HCM. This underscores the great utility of genetic testing in identifying pre-symptomatic at-risk individuals. In our study, the diagnostic yield is lower than the value reported in the literature, which may be explained by i) the presence of variable phenotypes in individuals who underwent testing on larger panels designed to detect multiple types of cardiomyopathy, ii) testing of unaffected individuals referred solely due to their family history, iii) differences in testing criteria for research studies compared to that for clinical testing, iv) the lack of clear phenotype information in some cases, or v) the strict variant interpretation guidelines used in a clinical diagnostic laboratory, which results in more frequent reporting of variants of uncertain significance (VUS). In the current cohort, VUS were detected in 46% of the individuals (n=189), including 34 probands who had pathogenic mutations. About one third of the VUS were in *TTN*, followed by *MYH6*, *MYH7*, and *MYBPC3*. VUS interpretation is challenging and will benefit from continually emerging data, including population frequency estimates in larger and more ethnically diverse populations, familial co-segregation studies, and functional studies.

**2421F**

**Prevalence of RASopathy gene mutations in patients who have had multi-gene panel testing for cardiomyopathy.** W. Zhang<sup>1</sup>, S. Chadwell<sup>2</sup>, M. Nicole<sup>1</sup>, C. Prada<sup>2</sup>. 1) Heart Institute, Cincinnati Children's Hospital Medical Center, Cincinnati, OH; 2) Human Genetics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Wenying Zhang, Sarah Chadwell, Nicole Moore, Carlos Prada The RASopathies are a group of developmental disorders caused by pathogenic genetic variations in the RAS-MAPK gene pathway, including Cardiofaciocutaneous syndrome (CFC), Costello syndrome, Neurofibromatosis 1, and the Noonan syndromes (Noonan syndrome, Legius syndrome, Noonan syndrome with Multiple Lentigines/LEOPARD syndrome, and Noonan syndrome-like disorder with loose anagen hair). Cardiomyopathy, specifically hypertrophic cardiomyopathy (HCM), is an established feature of CFC, Costello, Noonan syndrome, and Noonan syndrome with multiple lentigines/LEOPARD syndrome. There may be individuals with milder forms of these RASopathies who have HCM as the only known manifestation of disease. Knowing these individuals have an underlying genetic cause for their symptoms could have implications for their health and/or the health of their offspring. We conducted a retrospective study of all individuals who have had a cardiomyopathy gene panel ordered through Cincinnati Children's Hospital's Heart Institute Diagnostic Laboratory to determine the prevalence of pathogenic or likely pathogenic genetic changes in RAS pathway genes in individuals with cardiomyopathy. We evaluated variants in the following genes: *BRAF*, *CBL*, *HRAS*, *KRAS*, *MAP2K1*, *MAP2K2*, *NF1*, *NRAS*, *PTPN11*, *RAF1*, *SHOC2*, and *SOS1*. We reviewed 74 cases with cardiomyopathy, including 32 with HCM, 24 with dilated cardiomyopathy (DCM), 9 with both Left Ventricular Non-Compaction (LVNC) and DCM, 4 with LVNC only, 2 with Arrhythmogenic Right Ventricular Cardiomyopathy (ARVC) and 3 with unspecified cardiomyopathy. We identified four patients (5.41%) with pathogenic or likely pathogenic variants in *HRAS*, *PTPN11*, and *RAF1* (2 individuals). Indication for testing for all 4 individuals was HCM; three of them were younger than 2 years old when first diagnosed with HCM. The remaining individual was 7 years old at the time of diagnosis. The prevalence of pathogenic or likely pathogenic RASopathy gene mutations in our HCM patient cohort is 12.5% (4/32). Based on these data, we conclude that the RASopathy genes should be included on multi-gene panels for cardiomyopathy to increase diagnostic yield for individuals with HCM.

Arrhythmia is a problem associated with the rate or rhythm of heartbeat. Cardiac arrhythmias are one of the most common causes of sudden death in the world. Sudden death remains an important public health concern. The genetic background of these diseases is complex and heterogeneous with overlapping clinical symptoms that may not always be penetrant. Despite several genes have been reported in ion channel diseases, a large proportion of clinically diagnosed families remain without a recognized genetic cause of disease. In our study, we aimed to screen a targeted NGS panel comprising 68 genes known to be potentially related to cardiac arrhythmias including 104 LQTS, 2 JLNS, 8 SQTS, 9 Brugada syndrome, 10 catecholaminergic polymorphic ventricular tachycardia (CPVT), 5 Ventricular tachycardia, 4 Progressive familial heart block and 9 unexplained arrhythmia with complete coverage of the entire coding region of all the genes analyzed. The genetic study was performed by massive parallel sequencing (IonTorrent PGM) following Sanger sequencing for all suspicious variants and their segregations within the family. In 148 patients tested we identified 319 variants of which 45 (14,11%) were pathogenic, 4 (%1,25) were potentially pathogenic, 249 (61,44%) were variant of unknown significance (53 of them-16,62% were novel) and 21 (6,58%) were probably benign. We identified pathogenic/potentially pathogenic variants in 30% (45) of probands and novel variants in 32% (47) of probands tested. In LQT patients, pathogenic/potentially pathogenic mutations were also observed in *RYR2*, *GPD1L*, *CASQ2*, *JUP*, *LMNA*, *MYBPC3* and *PRKAG* as well as in the reported OMIM genes. SQT patients had pathogenic mutations in *SCN5A*, *RYR2*, *DSP* and *ANK2* genes. Also, one of the CPVT patient had a *GPD1L* mutation. We identified 4 de-novo mutations in *KCNQ1*, *RYR2*, *CACNA1C* and *CALM2* responsible for LQT syndrome and 1 novel de-novo mutation in *SCN5A* related to Brugada Syndrome. Any suspicious variant has not been detected in the remaining 7% (10) of the patients. For future directions functional analysis of found variations are under estimated. This data suggests that our targeted cardiac panel is a gold standard approach to investigate the novel genetic risks and open new opportunities for prevention and therapy of lethal arrhythmias in the common pathologies. **Acknowledgements:** Inherited arrhythmia panel project is supported by grant from SANTEZ (0253. STZ.2013-2), Turkey.

## 2423T

**Involvement of mtDNA variants in patients with cardiac manifestation.** H. Cui, J. Chonis, A. Balog, J. Semotok, K. Haude, D. Dorsainville, R.K. Bai, S. Suchy, G. Richard, D. Macaya. GeneDx, Inc., Gaithersburg, MD.

Among hundreds of mitochondrial DNA (mtDNA) variants reported, many are associated with cardiac disease, with the prevalence of mtDNA-related cardiomyopathy estimated to be at least 1 in 10000-15000 in the general population. Cardiac involvement has important impact on morbidity and mortality in patients with mtDNA disease. A total of 14 mtDNA genes encoding either mitochondrial tRNAs or structural subunits of the respiratory chain complexes were analyzed by our laboratory together with up to 77 nuclear genes in 3 different cardiomyopathy next-generation sequencing panels. In this retrospective study, we report on the molecular findings of 578 patients referred for cardiomyopathy testing to evaluate the involvement of mtDNA variants in their etiology. In this cohort, 53 (9%) patients had pathogenic or likely pathogenic variants (PV/LPV) in mtDNA, 115 (20%) patients had PV/LPV in nuclear genes, and 7 (1.2%) patients had PV/LPV in both mitochondrial and nuclear genes. Half of the patients with positive findings in mtDNA were referred with a clinical diagnosis or suspected diagnosis of hypertrophic cardiomyopathy (HCM) or dilated cardiomyopathy (DCM). Among the 54 PV/LPV identified in mtDNA, 39 were located in mt-tRNA genes. Of those patients, 16 (41%) had HCM and 8 (23%) had DCM, suggesting mt-tRNA as a hotspot for variants associated with cardiomyopathy in the mitochondrial genome. Twelve patients had PV/LPV in the MT-TL1 gene encoding tRNA Leu (UUR), including the recurrent PV m.3243 A>G (tRNA Leu) in 8 patients, which is known to cause mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome, making this the most common reported mtDNA variant. Another factor related to the clinical features of mtDNA-associated disorders is the tissue-specific mutation load (heteroplasmy). PV/LPV in 28 patients (52.8%) were found to be heteroplasmic in the submitted specimen type (predominantly blood), including all patients with m.3243 A>G, ranging from 15% to 87%. For low level heteroplasmic variants (less than 25%), further testing in affected tissues (such as heart or skeletal muscle) was recommended to determine conclusively their clinical significance. In summary, mtDNA testing revealed positive results in at least 10% of patients with cardiomyopathy. Our data underscore that dual analyses of both mitochondrial and nuclear genes maximize the diagnostic yield for patients with these disorders.

**2424F****A genetic background in Czech patients with inherited cardiomyopathies.**

P. Cibulková<sup>1</sup>, M. Dvoraková<sup>1</sup>, P. Vanicková<sup>1</sup>, H. Slaviková<sup>1</sup>, A. Boday<sup>1</sup>, N. Havranová<sup>1</sup>, A. Taborská<sup>2</sup>, K. Veselá<sup>3</sup>, J. Januska<sup>4</sup>. 1) Laboratories AGEL, Nový Jicin, Czech Republic; 2) Ambulance of clinical genetic, Hospital and Comprehensive Cancer Centre Nový Jicin, Nový Jicin, Czech Republic; 3) Institute of Biology and Medical Genetics, 1st Faculty of Medicine, Charles University in Prague and General University Hospital, Praha, Czech Republic; 4) Department of Cardiology, Hospital Podlesí, Trinec, Czech Republic.

**Objectives:** Inherited cardiomyopathies - hypertrophic (HCM), dilated (DCM), arrhythmogenic right ventricular (ARVC), restrictive and left ventricular non-compaction are common, genetically heterogeneous, predominantly autosomal dominant disorders with variable penetrance and age of onset. In our study we focused on the association between cardiomyopathy phenotype and genetic variants in 78 genes encoding cardiac sarcomeric and non-sarcomeric proteins. A cohort of 255 Czech unrelated patients was investigated. **Methods:** Genomic DNA was isolated from peripheral blood leucocytes. The coding regions and splice junctions of the 78 genes were enriched by a custom designed probe library (targeted capture system Nimblegen) and sequenced by massive parallel sequencing on an Illumina platform. Capillary Sanger sequencing was used for a variants confirmation. All variants with possible splice effect were checked with RNA analysis. All detected missense variants were tested by five *in silico* prediction softwares for its effect on the protein function. Nonsense and frameshift variants were considered as pathogenic due to their influence on the protein function. **Results:** A disease causing pathogenic variant or likely pathogenic variant were identified in 106 cases out of 255 cohort (42%). One or more variants with unknown clinical significance (VUS) were identified in 19 cases (7%). Five patients with HCM are digenic and one is trigenic which correlates with their more severe form of inherited HCM. The majority of pathogenic variants were found in sarcomeric genes (98 pathogenic/likely pathogenic variants). Fourty five HCM phenotypes were caused by the pathogenic variant in *MyBPC3* gene, and the others by mutations in *MYH7*, *MYH6*, *CSRP3* and *TRIM63* genes. In the case of DCM patients pathogenic variants were found in *LMNA*, *DSP*, *MyBPC3*, *MYH7* and *TTN* genes. One ARVC case was caused by mutation in *RYR2* gene, two likely pathogenic variants were found in *DSP* gene. **Conclusion:** Germline pathogenic variants are the main cause of inherited cardiomyopathies. The massive parallel sequencing is a great tool for molecular diagnostic testing, cost- and time-effective, but it sometimes makes a clinical genetics counselling more complicated due to indentifying rare sequence variants with unknown clinical significance. In some cases segregation analysis are necessary, classification of variants and their pathogenic role should be interpreted very carefully (e.g. *TTN* gene missense variants).

**2425W****Post-mortem cytogenomic study of Brazilian patients reveals the CNVs connection to complex congenital heart defects.**

F.A.R. Madia<sup>1</sup>, A.T. Dias<sup>1</sup>, E.A. Zanardo<sup>1</sup>, J.G. Damasceno<sup>1</sup>, M. Rocha<sup>2</sup>, A.M. Nascimento<sup>1</sup>, T.V.M.M. Costa<sup>1</sup>, S.N. Chehimi<sup>1</sup>, G.M. Novo-Filho<sup>1</sup>, M.M. Montenegro<sup>1</sup>, Y.G. Oliveira<sup>1</sup>, R. Schultz<sup>2</sup>, F.T. Gonçalves<sup>3</sup>, C. Fridman<sup>4</sup>, C.A. Kim<sup>5</sup>, L.D. Kulikowski<sup>1,5</sup>. 1) Laboratório de Citogenômica LIM 03, Departamento de Patologia, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 2) Centro de Reprodução e Genética – Departamento de Saúde Coletiva – Faculdade de Medicina do ABC – Santo André-SP, Brazil; 3) Serviço de Anatomia Patológica, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 4) Departamento de Medicina Legal, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil; 5) Unidade de Genética do Instituto da Criança, Faculdade de Medicina da Universidade de São Paulo, São Paulo-SP, Brazil.

Heart development is a complex process and the molecular mechanisms remains to be clarified. About ~8% of congenital heart defects (CHD) are caused by chromosomal and single gene mutation disorders. Recent the involvement of copy number variations (CNVs) in the development of CHD was proposed. In this sense, we investigate the contribution of CNVs to the pathogenesis of complex CHD using molecular methods in 29 cases of stillbirth and new-born from Serviço de Verificação de Óbitos, HC-FMUSP. DNA samples from skin and heart tissues were evaluated using AmpFtSTR® MiniFiler™ PCR Amplification Kit (Life Technologies™, California, USA) and Multiplex Ligation-dependent Probe Amplification (MLPA) with kits P036, P064, P070, P095 and P311 (MCR-Holland, Amsterdam, the Netherlands). A total of 10 cases showed genomic alterations: duplications (80%), deletions (10%), and mosaicism (10%). When comparing the most frequent abnormality, we observed that greatest of the cases were compatible with trisomy 18 syndrome (5 cases). Our results displayed duplication of *LPIN2*, *SS18\_ex4* and *SS18\_ex6* probes, associated with alterations the septal and valve defects, in 4 cases with trisomy 18 hypothesis. Also duplications of *SIM2*, *NCAM2*, *USP25*, *HSPA13*, *TIAM1*, *APP\_18* and *TFF1\_1* probes and *D21S11* marker, associated with heart dysplasia, were found in two cases with trisomy 21 hypothesis. The first *Post-mortem* cytogenomic study of Brazilian patients with complex congenital heart defects showed efficiency for identifying pathogenic CNVs associated with complex CHD and also allowed the adequate genetic counseling. **Grants:** FAPESP: 09/53105-9 and FINEP-CT INFRA 0160/12 SP8.

**Molecular review of Polish patients with Smith-Lemli-Opitz syndrome.** P. Halat, E. Ciara, D. Wicher, D. Jurkiewicz, D. Piekutowska-Abramczuk, M. Pelc, D. Siestrzykowska, B. Chałupczyńska, P. Kowalski, M. Krajewska-Walasek. Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland.

Smith-Lemli-Opitz syndrome (SLOS [MIM 270400]) is a rare metabolic disorder in which a defect in cholesterol biosynthesis results in multiple congenital anomalies and intellectual disabilities. The symptoms vary widely from mild to severe among affected SLOS individuals. This autosomal recessive disease is caused by pathogenic variants in the *DHCR7* gene [MIM 602858]. Sequence analysis of *DHCR7* gene detects approximately 96% of pathogenic variants. In approximately 4% of SLOS patients the second mutation remains unidentified. Worldwide the incidence of SLOS has been reported between 1:10,000 - 1:70,000 depending on the population being studied. SLOS appears to be the most frequent (1:10,000 - 1:30,000) among populations of Central Europe, especially in Polish population (1:2,300 - 1:3,937). In our study we examined a group of 112 Polish patients with SLOS by Sanger sequencing. Biallelic changes in *DHCR7* gene were revealed in 108 patients. Twenty five different pathogenic variants, of which five were frequent [c.452G>A, p.(W151\*); c.470T>C, p.(L157P); c.964-1G>C, p.?; c.976G>T, p.(V326L); c.1054C>T, p.(R352W)] were identified in this group. They constitute 85% of all mutated alleles in Polish patients. The most common variants, c.452G>A and c.976G>T, constitute 68%. In our group 4 unrelated patients with a strong suspicion of SLOS had only one mutated allele [c.452G>A (n=3) or c.946-1G>C (n=1)]. In 3 families the child died before complete molecular diagnosis, therefore Sanger sequencing in their parents was performed. Analysis revealed that only one parent from each family was a heterozygous carrier of the molecular variant. We supplemented our molecular analysis with a dosage gene test to identify a disease-causing mutation on the second allele of *DHCR7* in undiagnosed probands. Performed MLPA analysis revealed lack of gross *DHCR7* deletions. Diagnosis of SLOS was confirmed at the molecular level with 96.4% compliance. Our report revealed lack of gross *DHCR7* deletions in examined Polish population. The absence of second mutation in the coding region of the *DHCR7* gene suggests that it may be located in the promoter or deep intron region. To help patients it is still necessary to continue research on SLOS. Grant reference: M21/16.

The BabySeq Project is a randomized clinical trial assessing the impact of genomic sequencing (GS) on sick and healthy infants and their families. Newborns are recruited from ICUs at Boston Children's Hospital and Brigham and Women's Hospital (BWH) and the well baby nursery at BWH. All infants receive state-mandated newborn screening and family history, and half are randomized to receive GS. All babies in the sequencing group receive risk and carrier status for highly penetrant diseases that have onset or management during childhood as well as pharmacogenomic variants relevant to the pediatric population. Here, we describe GS in a newborn with compound heterozygous *BTD* gene variants. Pathogenic defects in the *BTD* gene lead to biotinidase deficiency (BTD) which may present with neurologic and cutaneous abnormalities. BTD is diagnosed based on clinical presentation and biotinidase enzyme activity. Those with partial BTD may develop symptoms upon exposure to metabolic stressors. The two identified variants included a well-established pathogenic variant (c.1612C>T, p.Arg538Cys), causing profound BTD in homozygosity. In addition, a novel splice variant (c.44+1G>A, p.?) was identified in the invariant splice donor region of intron 1, potentially predictive of loss of function. However, due to evidence of exon 1 being alternatively spliced in different tissues, this variant was initially classified as uncertain significance. Sanger sequencing of parental samples demonstrated biallelic inheritance and upon medical record review, it was determined that the infant failed NBS for BTD, though passed on a rescreen. These data led to reconsideration of the pathogenicity of the variant as likely pathogenic. Diagnostic enzyme testing, prompted by the return of the GS results, confirmed partial BTD (1.5 nmol/min/ml serum, reference range: >3.5, 1.47 +/- 0.41 partial deficiency) and the baby was started on biotin supplementation. This outcome highlights the complexity of interpreting novel truncating variants in genes where loss of function is associated with disease, but for which alternative splicing of multiple transcripts confounds variant interpretation, and is an example of complexities involved in interpreting and managing cases without significant medical precedent. In conclusion, this BabySeq case demonstrates the utility of combining genotype and phenotype to more effectively guide the interpretation of both GS and NBS and inform the treatment of a newborn.

**One novel 2.43Kb deletion and one single nucleotide mutation of INSR gene in a Chinese neonate with Rabson-Mendenhall syndrome.** *L. Yang, X. Chen, W. Zhou.* Children's Hospital of Fudan University, Shanghai, China.

**Background:** Insulin receptor gene (*INSR*) is responsible for Donohue syndrome (DS) and Rabson-Mendenhall syndrome (RMS). These two diseases are all characterized as insulin resistance. **Methods:** A Chinese neonate suffering from glucose homeostasis, hyperinsulinemia, dry skin, heavy hair, elevated testosterone and growth retardation was recruited. 2742 inherited disease-gene panel sequencing was performed to search for candidate point mutations, small insertions or deletions and copy number variants. **Results:** One pathogenic mutation (c.3355C>T, p.Arg1119Trp) and a novel 2.43Kb deletion (chr19:7150507-7152938) in *INSR* were found in this patient by Next Generation Sequencing test using ClearSeq. The patient is diagnosed as RMS. Follow-up Sanger sequencing and real-time quantitative PCR confirm the variants. We, therefore, supposed these variants were candidate mutations of this family. **Conclusions:** We report a novel 2.43Kb deletion in *INSR* gene and provide further proof to the power of Next Generation Sequencing in rare disease diagnosis. **Keywords:** Insulin receptor gene (*INSR*); Rabson-Mendenhall syndrome (RMS); Neonate; Mutation; Next generation sequencing.

**Concurrent determination of ABO RhD blood types and the HIV-1 resistance marker CCR5 deletion via rapid multiplex PCR and capillary electrophoresis-based genotyping.** *E. Schreiber<sup>1</sup>, S. Higdon<sup>1</sup>, K. Varma<sup>1</sup>, S. Jackson<sup>1</sup>, T. Nong<sup>2</sup>, J. Lee<sup>2</sup>.* 1) Genetic Sciences Division, Thermo Fisher Scientific, South San Francisco, CA; 2) One Lambda TDX Division, Thermo Fisher Scientific, Canoga Park, CA.

For optimal outcomes when matching bone marrow donors with their recipients, it is preferable to use bone marrow of identical or compatible blood types. Bone marrow registries thus require high resolution HLA genotyping data to match donor specimens with their recipients. We developed a research assay to aid in these investigations, which utilizes buccal swab DNA from potential donors to determine the ABO and Rh-antigen genotypes. In addition, the assay detects a 32 bp deletion in the *CCR5* gene. Homozygous carriers of this deletion are resistant to HIV-1 infection, and thus could be valuable stem cell donors for HIV-infected recipients. This research assay consists of a multiplex-PCR reaction with 5 fluorescently-labeled and 12 allele-specific primers followed by capillary electrophoresis on the new Applied Biosystems SeqStudio™ Genetic Analyzer. Four targeted SNPs of the human ABO gene allow the determination of the A, A2, B, O1,2 and O3 alleles. Rh-antigen genotyping is determined by targeting a small deletion that differs between the *RhD* and *RhCE* genes. The peak pattern is analyzed with GeneMapper™ software, and the resulting peak/genotype table is translated into a genotype/phenotype report using a standard spreadsheet. We verified this research assay by analyzing a panel of DNA samples with known blood group antigens and *CCR5* gene types. The results of this verification were found to be 100% accurate. This easy to use, rapid research assay may prove useful for future development of bone marrow donor identification assays, and other areas of public health studies. For Research Use Only. Not for use in diagnostic procedures.

**Chromosome microarray analysis as a first-tier test for cytogenetic abnormalities in patients with myelofibrosis.** J. Mazzeu<sup>1</sup>, M.R. Paula-Júnior<sup>1</sup>, J. Minuncio<sup>2</sup>, R.S. Bonadio<sup>1</sup>, A. Pic-Taylor<sup>1</sup>, S.F. Oliveira<sup>1</sup>, A. Nonino<sup>2</sup>, C.C. Mascarenhas<sup>3</sup>. 1) Universidade de Brasília, Brasília, Brazil; 2) Secretaria de Estado de Saúde, Brasília, Brazil; 3) Universidade Católica de Brasília, Brasília, Brazil.

Primary Myelofibrosis (PMF), the most infrequent and severe of Philadelphia-negative classical myeloproliferative neoplasms, is characterized by bone marrow fibrosis, extramedullary hematopoiesis and abnormal cytokine expression, with consequent hepatosplenomegaly and cytopenias. Myelofibrosis may also result from late progression of Polycythemia Vera (PV) or Essential Thrombocythemia (ET), being then termed as post-PV myelofibrosis or post-ET myelofibrosis. Cardinal features of myelofibrosis include extramedullary hematopoiesis, hepatosplenomegaly and cytopenias. More than 85 percent of PMF patients have a mutually exclusive mutation in one of the following three genes: *JAK2* (60-65%), *MPL* (5%), or *CALR* (20-25%). All of these, which are referred to as "driver" mutations, activate JAK-STAT pathway. Cytogenetic abnormalities detected by karyotype abnormalities can be found in 32 to 48% of patients and have a high correlation with the prognosis. Though several large chromosome abnormalities have been described in patients with myelofibrosis, most were detected by conventional karyotyping and the influence of minor cytogenetic abnormalities and loss of heterozygosity (LOH) on the course of the disease has not been explored. We studied 15 patients using CytoScan platform (750k or HD- Affymetrix). This platform allows the identification of copy number variations as well as segments of loss of heterozygosity. Chromosome microarray analysis showed abnormalities in 12/15 patients (80%). A total of 35 copy-neutral LOH segments were identified in 10/15 patients, while 10 deletions and 3 duplications were found in 5/15 and 1/15 respectively. Only three imbalances were large enough to be detected by conventional karyotyping and microarray analysis revealed that the rearrangement was more complex. Most aberrations identified were private in our sample with recurrence only of LOH 9p (3/15) and 13q deletion (2/15). Copy-neutral LOH segments are attributed to mitotic recombination in somatic cells and are increasingly being recognized in a variety of neoplasms. Based on the high prevalence of LOH segments identified in our cohort we propose chromosome microarray analysis as a first-tier test for cytogenetic abnormalities in patients with myelofibrosis. Grant support: FAPDF.

**Mutation profiling of 16 candidate genes in de novo acute myeloid leukemia patients.** H.X. Liu, Y. Zhang, F. Wang, X. Chen, W. Teng, J.C. Fang, W.J. Liu, M.Y. Wang, P.X. Cao. Pathology & Laboratory Medicine Division, Hebei Yanda Lu Daopei Hospital, Beijing, China.

**Object:** Acute myeloid leukemia (AML) is a group of heterogeneous diseases. Along with the progress of molecular biology of hematological malignancies and the use of next generation sequencing technology, more and more molecular genetic markers were identified. Hematological malignancies gene mutation profiling is no longer confined to the detection of only a few molecular targets, the current study and application of leukemia has entered the "mutaome" profile era. The initiation and progression of tumors are the result of mutational synergism of many different functional genes. Currently there are some studies that have found certain rules on the occurrence and mutation pattern of gene mutation. In this study, we analyzed 16 common mutated genes in 259 de novo AML patients and investigated the rules of mutation spectrum, offering an approach to further explore the molecular biological mechanism of tumorigenesis and find new therapeutic targets. **Methods:** 259 patients who were diagnosed as de novo AML were enrolled in. Mutations profiling of 16 candidate genes were performed in bone marrow samples by Sanger sequencing, which include *ASXL1*, *CEBPA*, *DNMT3A*, *ETV6*, *FLT3*(ITD and TKD), *IDH1*, *IDH2*, *KIT*, *KRAS*, *NRAS*, *NPM1*, *PTPN11*, *PHF6*, *RUNX1*, *TET2* and *TP53*. **Results:** 76.83% (199/259) cases had at least one mutation, 31.66% (82/259) cases carried more than one. *FLT3*-ITD was the most common mutated gene (16.22%, 42/259), followed by *CEBPA* (15.06%, 39/259), *NRAS* (14.67%, 38/259) and *NPM1* (13.52%, 35/259). 97.14% of *NPM1* and 29.63% of double-mutated *CEBPA* were found to co-occur with other mutations. Distinct patterns of co-occurrence were observed for different hotspot mutations within *IDH2* gene: R140 mutations was associated with *NPM1* and/or *FLT3*-ITD mutations, whereas R172 mutations co-occurred with *DNMT3A* mutations only. The concurrence of 86.57% of epigenetic regulation genes was observed, most of which co-occurred with *NPM1* mutations. **Conclusions:** The results showed that there were certain rules in the mutation profiling and concurrence of AML patients, which was related to the function classification of genes. Defining the mutation spectrum and mutation pattern of AML will contribute to comprehensive assessment of patients and identification of new therapeutic targets.

**2432T**

**Xq22.1 contiguous deletion syndrome as a diagnostic challenge: Detection of a 17 kb deletion ends 30-year diagnostic odyssey.** G. Raca<sup>1,3</sup>, C. Fong<sup>1</sup>, J. Ji<sup>1,3</sup>, B. Liu<sup>1</sup>, D. Estrine<sup>1</sup>, C. Hinh<sup>1</sup>, F. Clarito<sup>1</sup>, S. Saitta<sup>1,3</sup>, J.A. Church<sup>2,3</sup>.

1) Dept. of Pathology and Laboratory Medicine, Children's Hospital Los Angeles; 2) Division of Clinical Immunology and Allergy, Children's Hospital Los Angeles; 3) Keck USC School of Medicine, Los Angeles.

X-linked agammaglobulinemia (XLA) is caused by loss-of-function mutations in the *BTK* (Bruton's tyrosine kinase) gene in Xq22, and manifests in affected males with recurrent bacterial infections in the first two years of life. Mohr-Tranebjærg syndrome (MTS), an unrelated X-linked disorder, is caused by mutations in *TIMM8A* (Translocase of Inner Mitochondrial Membrane 8 Homolog A) and shows early childhood hearing loss, progressive dystonia in adolescence, vision impairment in young adulthood and dementia in the fourth decade. *BTK* and *TIMM8A* are 770 bp apart in Xq22.1 and a rare condition with features of both disorders is caused by Xq22.1 deletions encompassing both genes. We report a 39-year old male with clinical XLA diagnosed in infancy, and sensorineural hearing loss seen at age 2 and attributed to viral encephalitis. His XLA was managed with immunoglobulin replacement therapy and he was never hospitalized for serious infections. A new onset of frequent falls, unstable gait and loss of fine motor skills prompted neurological evaluation with no etiology identified. Genetic investigation for MTS was then pursued, with phenotype-driven analysis of a whole-genome chromosomal microarray (CMA) revealing a small deletion in Xq22.1. Although the deletion was only 17kb in size, it included the 3' end of *BTK* and all of *TIMM8A*. A custom PCR assay showed that the deletion included exons 15-19 of *BTK* and both exons of *TIMM8A*. To our knowledge this is the smallest deletion found for the Xq22.1 contiguous deletion syndrome. The *BTK* and *TIMM8A* gene regions are enriched in interspersed *Alu* elements and prone to small deletions from mispairing and rearrangements between *Alu* repeats (Arai et al., 2017). Genetic evaluation for XLA usually includes both sequencing and deletion/duplication assays, but focuses on the *BTK* gene. XLA patients with additional neurologic phenotypes may be referred for CMA analysis but most platforms lack sufficient resolution to identify small Xq22.1 contiguous deletions. Timely diagnosis of XLA and MTS allows appropriate clinical management of patients, anticipatory guidance for families and an opportunity to test maternal carrier status, enabling recurrence risk counseling. This case underscores that the diagnosis of an Xq22.1 contiguous deletion can be challenging; in addition to a high level of clinical suspicion, it requires close collaboration between the clinician and the diagnostic laboratory to identify an appropriate testing strategy.

**HLA typing using capture based next generation sequencing.** S.K. Lai<sup>1</sup>, P.L. Chen<sup>1,2,3,4</sup>. 1) Graduate Institute of Molecular Medicine, National Taiwan University College of Medicine, Taipei, Taiwan; 2) Department of Medical Genetics, National Taiwan University Hospital, Taipei, Taiwan; 3) Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan; 4) Research Center for Developmental Biology and Regenerative Medicine, National Taiwan University, Taipei, Taiwan.

Human leucocyte antigen (HLA) genes are important in organ transplantation and immuno-related diseases. Current HLA typing methods, either by sequence-based typing (SBT) or sequence-specific oligonucleotide (SSO), may suffer from ambiguous typing results. The problem is caused by the phasing problem or the polymorphic sites lying outside the sequencing region. Using probe capture-based next generation sequencing (NGS) may resolve the phasing problem, and be able to sequence larger regions of genes including introns. Comparing to the traditional methods, NGS provides higher throughput, lower costs and possibility to cover more loci on demand. In this study, we established the probe capture-based NGS method for HLA typing. Probe sets for Class-I HLA gene (HLA-A, B, C) in exon 2-4 and Class-II HLA gene (DRB1, DPA1, DPB1, DQA1, DQB1, DRB3,4,5) in exon 2-3 were designed. Ten samples which were previously known to carry the most common HLA types in Taiwanese were used to validate this method. The results were 100% concordant to SBT method. Furthermore, our data showed that this method could resolve ambiguous HLA types. .

## 2434W

**A patient with hereditary pyropoikilocytosis caused by a combination of a novel in-frame deletion and a common functional but non-pathogenic allele,  $\alpha^{LELY}$ , in *SPTA1*.** T. Goto<sup>1</sup>, T. Togawa<sup>2</sup>, T. Ito<sup>1</sup>, M. Kouwaki<sup>1</sup>, H. Ogura<sup>3</sup>, H. Kanno<sup>3</sup>, S. Saitoh<sup>3</sup>, N. Koyama<sup>1</sup>. 1) Department of Pediatrics, Toyohashi Municipal Hospital, Toyohashi, Japan; 2) Department of Pediatrics and Neonatology, Nagoya City University Graduate School of Medical Sciences, Nagoya, Japan; 3) Department of Transfusion Medicine and Cell Processing, Tokyo Women's Medical University, Tokyo, Japan.

Hereditary pyropoikilocytosis (HPP) and hereditary elliptocytosis (HE) represent genetically and phenotypically heterogeneous hemolytic anemia caused by mutations in *SPTA1*, *SPTB*, and *EPB41* encoding the red blood cell (RBC) cytoskeleton proteins  $\alpha$ -spectrin,  $\beta$ -spectrin, and protein 4.1R, respectively. HPP/HE caused by mutations in *SPTA1* or *SPTB* leads to qualitative defects of  $\alpha$ - or  $\beta$ -spectrin. Here we describe a patient with HPP diagnosed by targeted next-generation sequencing (NGS). The proband was a Japanese male neonate born from nonconsanguineous parents. He presented indirect hyperbilirubinemia with hemolysis from 23 hours after birth. He underwent phototherapy intermittently for 9 days and he required RBC transfusion for hemolytic anemia on 58 days after birth. We analyzed his blood smear and revealed abnormal RBC morphology, poikilocytosis, including elliptocytes, spherocytes, and fragmented erythrocytes. We analyzed his parents' blood smear and only his father's smear showed elliptocytosis. His father had needed phototherapy for his neonatal jaundice, but no RBC transfusion was performed. We performed targeted NGS to the proband, using Agilent HaloPlex custom kit and Illumina Miseq. The custom gene panel included 67 candidate genes, such as *SPTA1*, *SPTB*, and *G6PD*. Consequently, we identified 3 variants in *SPTA1* (NM\_003126.2): c.800\_802del in exon 6 (novel in-frame deletion), c.5572C>G in exon 40, and c.6531-12C>T in intron 45 in heterozygous state each. Sanger sequence using samples of his family members showed that his father and sister had only c.800\_802del in heterozygous state while his mother had c.5572C>G and c.6531-12C>T in heterozygous state each. The doubly mutated allele carrying c.5572C>G and c.6531-12C>T is named  $\alpha^{LELY}$ . Although  $\alpha^{LELY}$  is found 20-30% of the population in Western country, the polymorphism results in partial skipping of exon 46 and a decrease in the amount of spectrin. Monoallelic and biallelic  $\alpha^{LELY}$  are silent, while compound heterozygous for HE-causing *SPTA1* allele and  $\alpha^{LELY}$  in trans cause a severe phenotype, HPP. Most of HE causing pathogenic variants were missense mutations. Only one in-frame deletion (c.1406\_1408del) was reported in patients with HE and we considered that the c.800\_802del was a novel pathogenic variant. This family represents a unique genotype-phenotype correlation; a pathogenic mutation in combination with a common functional but non-pathogenic allele in *SPTA1* could cause much severe phenotype.

## 2435T

**Analysis of germ line predisposition in Chinese children with bone marrow failure.** N. Dai-jing, L. Hong-xing, C. Xue, W. Fang, Z. Hui-zheng, T. Wen. Pathology & Laboratory Medicine Division, Hebei Yanda Lu Daopei Hospital, Langfang, China.

**Purpose:** The role of germ line predisposition plays in the pathogenesis of Bone Marrow Failure (BMF) has not been explored as yet, the aim of the study is to detect it in Chinese children with BMF. **Methods:** Bone marrow or peripheral blood samples of 110 children with BMF were collected. All coding exons and flanking sequences of BRCA2, FANCA, FANCC, FANCD2, FANCG, CTC1, DKC1, NHP2, NOP10, RTEL1, TERC, TERT, TIN2 and WRAP53 were amplified and sequenced by Next Generation Sequencing (NGS) technology. Clinical significance of mutations were predicted by SIFT and PolyPhen-2 simultaneously. **Results:** The median age was 10(1-13) years with male/female ratio of 1.56:1. All patients were confirmed Bone marrow hyperplasia or severe hyperplasia by Bone marrow aspiration smears. 96 patients were diagnosed as Aplastic anemia, 2 as low proliferative MDS, 10 as Fanconi anemia (FA) and 2 as Dyskeratosis congenita (DC). Mutations were observed in 58(52.73%) of them. The number of patients harboring mutations of each gene were 11, 15, 7, 6, 10, 4, 0, 2, 0, 10, 0, 4, 4 and 1 respectively. In the patients those with FANCA mutations, 3 were homozygous and 1 was compound heterozygous, those with FANCC mutations, 1 was homozygous, those with RTEL1 mutations, 1 was compound heterozygous, those with TERT mutations, 2 were compound heterozygous, and all the rest were heterozygous. All mutations were confirmed to be germ line derived. Compared with 71 healthy Chinese people we tested and 208 healthy Chinese people in 1000 genomes database, the total mutation rate and pathogenic mutation rate of the case group were statistically high (52.73% vs. 37.63%,  $p=0.007$ ); (30.00% vs. 19.71%,  $p=0.029$ ). **Conclusion:** A boy who carried FANCA c.1074\_1075del/p.Y359PfsX49 monoallelic mutation manifested BMF at the age of 7 with positive chromosome breakage test, suggesting nonclassical Mendelian inheritance patterns in FA. Mutation rate and pathogenic mutation rate were significantly high in case group, suggesting an important role hereditary susceptibilities have played in the pathogenesis of BMF, haploinsufficiency may be the explanation to some extent. New genes related to Inherited bone marrow failure syndromes have been identified continuously. Tested genes here were very limited, we speculate expanding the spectrum may find more patients with hereditary predisposition, which may be useful to predict clinical outcome and optimize the diagnosis and treatment of these patients.

**2436F**

**The study of the applicability of three statistical methods in IGH immune repertoire analysis.** *F. Wang, J.C. Fang, Y.L. Xu, M.M. Wang, T.T. Li, C.Y. Cao, Y. Zhang, H.X. Liu.* Molecular Medicine Lab., Hebei Yanda Ludaopei Hospital, Beijing, China.

**Objective** To explore the applicability of rarefaction, Shannon-Wiener Index and Simpson Index in immunoglobulin heavy chain (IGH) immune repertoire analysis. **Methods** We selected 15 B cell tumor patients at diagnosis and 9 healthy individuals who were tested IGH clonal rearrangement using capillary electrophoresis (CE). Then extracted DNA from bone marrow or peripheral blood sampled from them. We amplified IGH V region segments using LymphoTrack® IGH Assay-PGM kit, and performed next generation sequence on Ion Torrent PGM. The FASTQ data sets were performed quality control and comparison analysis using MiXCR software, and were analyzed rarefaction, calculated Shannon-Wiener Index and Simpson Index, and drew rarefaction curve using VDJtools software. Then analyzed the differences of Shannon-Wiener Index and Simpson Index between groups using Mann-Whitney U test. **Results** We grouped these samples into 2 groups (B cell tumor patients and healthy individuals) based on the positive and negative CE results. Rarefaction curve visualized the diversity of IGH V region segments in 2 groups. Compared to negative samples, the curve of positive samples faster reached the platform period when the sample sizes were same, and the diversity did not increase following the growing of the sample size. The median value of diversity in the positive samples was 45(15-100), which was lower than the negative samples that was 370(219-580); ( $P=0.000$ ), indicating that the IGH V region segments diversity in positive samples was reduced compared to negative samples. Shannon-Wiener Index and Simpson Index could quantify the diversity, and the median values were 1.639(1.091-3.980); vs 236.069(142.975-488.816);, 0.127(0.023-0.614); vs 0.995(0.991-0.998); between positive and negative samples respectively. The two index there were both statistically difference; ( $P=0.00$ ). **Conclusion** In this study, we could visualize and quantify the IGH immune repertoire diversity using rarefaction, Shannon-Wiener Index and Simpson Index.

**47,XY,+21/46, XX chimera identified in an infant with ambiguous genitalia without Down syndrome features.** *C. Charalsawadi, S. Jaruratanasirikul, P. Limprasert.* Department of Pathology, Faculty of Medicine, Prince of Songkla University, Hat Yai, Songkhla, Thailand.

Chimerism resulting from a fusion of two different zygotes is a very rare genetic finding in humans and is mostly identified by the coexistence of XX and XY chromosomal complements in an individual. Most reported cases exhibit a chi 46,XX/46,XY karyotype and ambiguous genitalia while only a few cases exhibited an abnormal lineage coexisting with a normal one. To the best of our knowledge, only three, non-twin cases carrying both trisomy 21 and a normal karyotype have been reported. These include two cases with a chi 47,XY,+21/46,XX karyotype and a single case with a chi 47,XX,+21/46,XY karyotype. A DNA polymorphism study to identify the mechanism underlying chimerism was performed in two cases. Herein, we report an additional case of a chi 47,XY,+21/46,XX karyotype. Physical examination at 1 month of age revealed a small phallus, an opening of the urogenital slit, labioscrotal swellings without rugae formation, and a palpable gonad in the right inguinal area. Besides ambiguous genitalia, the infant had no features of Down syndrome. Growth and developmental milestones were within normal ranges. Cytogenetic analyses found approximately 17% of a 47,XY,+21 lineage for both G-banding karyotype analysis of 100 metaphase cells and FISH analysis of 1000 interphase cells obtained from uncultured peripheral blood. Short tandem repeat analysis using AmpFLSTR™ Identifiler™ Plus PCR Amplification Kit and ABI3130 Genetic Analyzer revealed 3 alleles at 7 different loci, in which 5 loci indicated a double paternal contribution and 2 loci indicated a double maternal contribution to the patient. This finding suggests the chimerism in our patient arose from either early fusion of dizygotic twins from double fertilization, or double fertilization of an ovum and a polar body by two different sperm with subsequent fusion of the zygotes.

**Novel approach using NGS assay for detection of mutations of the CYP21A2 gene.** G. Bennett<sup>1</sup>, C. Clear<sup>2</sup>, R. Hrdlickova<sup>2</sup>, J. Nehyba<sup>2</sup>, D. Fox<sup>2</sup>, D. Obermoeller<sup>2</sup>, M. Toloue<sup>1</sup>. 1) PerkinElmer, Boston, MA; 2) Bioo Scientific, Austin, TX.

Congenital Adrenal Hyperplasia (CAH) is a disease associated with mutations in the cytochrome p450 (CYP) 21A2 (*CYP21A2*) gene, leading to impaired function and reduced levels of the enzyme 21-hydroxylase (21OHD). CAH is the most common autosomal recessive disorder, with frequencies of carriers ranging between 4-10% in the population. The *CYP21A2* gene has a nonfunctional pseudogene, *CYP21A1P*, located 30 kb upstream of *CYP21A2*. *CYP21A2* and *CYP21A1P* are located in the HLA class III region on chromosome 6p21.3. The nucleotide homology between these two genes in their exonic regions is 98%. Two genetic events create non-functional chimaeras between *CYP21A2* and *CYP21A1P* – gene conversion and rearrangement. Gene conversion replaces specific sequences in *CYP21A2* with homologous sequences from *CYP21A1P*. Genomic rearrangement forms chimaeras between both genes by a 30 kb deletion of the neighboring sequence and bringing the two loci together. Both events generate a different set of products which will impact the phenotype. Unfortunately, it is impossible to detect these chimaeras by classical next generation sequencing (NGS) approaches. Congenital Adrenal Hyperplasia Amplicon Panel allows the rapid detection of these mutations using a novel, simplified protocol. The workflow starts with a long range PCR which will amplify the target gene, as well as rearranged chimaera if present, by using as little as 20 ng DNA from fresh and frozen tissue. A portion of this enriched template is taken and placed in a second PCR to generate amplicons that cover all coding exons, exon-intron boundaries, and a portion of the promoter. Further, tags are bound to each amplicon to differentiate between product resulting from gene conversion and the product from gene rearrangement during analysis. The final panel has 100% uniformity at 20% average amplicon read threshold, 92% on-target reads, and <1% dimer formation. Using the NEXTflex® barcode system, 384 samples can be multiplexed in a single Illumina® MiSeq® run. Additionally, the panel is compatible with both Ion Torrent™ and Illumina® sequencing platforms. The entire *CYP21A2* gene and its chimaera with *CYP21A1P* are each amplified in 3.2 kb comprising 10 exons and a partial promoter region. This approach is unique in the way that it will detect complex genetic changes in the *CYP21A2* and *CYP21A1P* loci by taking advantage of precise and economical NGS technology.

**NEBNext Direct CFTR enrichment panel: Interrogation of genetic variants by Illumina sequencing.** S. Adams<sup>1</sup>, K. Patel<sup>1</sup>, A. Emerman<sup>1</sup>, S. Bowman<sup>1</sup>, C. Effe<sup>1</sup>, T. Davis<sup>2</sup>, S. Russello<sup>2</sup>, A. Barry<sup>2</sup>, C. Hendrickson<sup>1</sup>. 1) Directed Genomics, Ipswich, MA; 2) New England BioLabs, Ipswich, MA.

Prompt and accurate diagnosis of cystic fibrosis (CF) is vital for achieving optimal therapies and outcomes. The screening and detection of variants in the cystic fibrosis transmembrane conductance regulator (CFTR) are critical for the effective management of this disease. More than 2000 CFTR mutations have been reported worldwide and refined sequencing technologies may provide improved genotype–phenotype correlations and better-informed genetic counseling. Here, we introduce the NEBNext Direct CFTR target enrichment panel for the interrogation of genetic variants in CFTR. The NEBNext Direct® technology uses a novel approach to selectively enrich nucleic acid targets ranging from a single gene to several hundred genes without sacrificing specificity. The approach rapidly hybridizes both strands of genomic DNA with biotinylated baits, captures the targets on streptavidin beads, enzymatically removes off-target sequence, and directly converts captured molecules into Illumina-compatible sequencing libraries in a single day protocol. Unlike alternative hybridization methods, NEBNext Direct does not require upfront library preparation. Instead, target molecules acquire an 8 base pair sample ID and a 12 base pair Unique Molecular Identifier (UMI) as part of the targeting protocol. The UMI tags each individual molecule prior to the final PCR amplification and enables identification of PCR duplicates. The CFTR panel consists of a single pool of baits targeting both strands of DNA across 23 exons and 7 intronic sites, for a total covered territory of 6.7 kb. The panel provides uniform coverage of the CFTR region and allows for germline variant detection with 10 ng of input DNA.

**2440W**

**Novel pathogenic variants are routinely detected even in extensively-sequenced genes, such as CFTR.** *N. Faulkner, C. Perreault-Micale, M. Zhu, K. Robinson.* Good Start Genetics, Cambridge, MA.

Cystic fibrosis (CF), caused by pathogenic variants in the *CFTR* gene, is one of the most common autosomal recessive disorders. Carrier screening for CF is recommended for all couples considering a pregnancy, regardless of ethnicity. However, many carrier screening laboratories only offer testing for limited panels of the most prevalent pathogenic variants, resulting in CF screening tests with lower detection rates in non-Caucasian populations. Using a clinical NGS-based assay, we sequenced the coding region and intron-exon boundaries of *CFTR* in a large pan-ethnic population of individuals referred for carrier screening. Sequencing results were filtered for known pathogenic variants, as well as previously unreported ("novel") variants predicted to be pathogenic based on their truncating effect (nonsense, frameshift, and canonical splice site variants). Despite the fact that *CFTR* has been extensively studied with >2000 variants identified to date, we detected 34 different novel truncating *CFTR* variants in our patients. One novel variant was found in two individuals; all others were detected only once. Self-reported ethnicities of the 35 carriers included 11 Asian, 8 African American, 4 Caucasian, 2 Hispanic, 1 South East Asian, and 9 individuals who did not provide their ethnicity, indicating that the majority of novel variant carriers were not Caucasian. Five of the variants (c.51delC, c.3743C>G (p.Ser1248X), c.874\_875delGA, c.1943delA, and c.1807delG) have been subsequently reported in CF patients, further affirming their pathogenic status. Of note, we did not detect any mutational hot spots as novel variants were distributed throughout the gene. It is remarkable that, in a well-studied gene like *CFTR*, we identified 35 carriers of pathogenic variants that had not been previously reported in the literature. Even the most comprehensive targeted panel of known pathogenic variants would have missed these carriers. Novel truncating variants were preferentially detected in non-Caucasian individuals, highlighting both the need for better characterization of the variant spectrum in these populations and the importance of offering them a truly pan-ethnic carrier screening test. Additionally, screening for large (exon-level) deletions and duplications across the *CFTR* gene can further enhance detection rates by identifying carriers of both rare and novel changes. We recently added del/dup analysis to our CF carrier screening test and will share our experience.

**2441T**

**Mutations in the *DHX37* gene identified by whole-exome sequencing (WES) are a novel cause of the embryonic testicular regression syndrome (ETRS).** *T.E. da Silva<sup>1</sup>, A.M. Lerário<sup>1</sup>, C.E. Keegan<sup>2</sup>, M.Y. Nishi<sup>1</sup>, F.M. Ferreira<sup>3</sup>, B.M. Yashar<sup>2</sup>, E.M.F Costa<sup>1</sup>, B.B. Mendonca<sup>1</sup>, S. Domenice<sup>1</sup>.*  
 1) Disciplina de Endocrinologia e Metabologia, Laboratório de Hormônios e Genética Molecular/ LIM42, Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brazil; 2) Department of Pediatrics and Human Genetics, University of Michigan Medical School, Ann Arbor, Michigan, USA; 3) Laboratório de Imunologia, Instituto do Coração, Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brasil.

WES have been an efficient tool in the genetic investigation of disorders of sex development (DSD). Affected and non-affected members of two unrelated Brazilian families with familial ETRS (Family 1 (F1)-2 affected brothers and the unaffected parents; Family 2 (F2) - affected maternal uncle and his nephew) and one Chinese-American family with sporadic ETRS were studied by WES using a HiSeq 2500 platform. A novel single heterozygous variant, p.Arg308Gln in the *DHX37* was identified in the affected members of the two families and in the Chinese-American child. This variant was confirmed by Sanger in all affected members and in the F1 father and the F2 mother. p.Arg308Gln variant was considered damaging in six predictor sites (Mutation Taster, Mutation Assessor, SIFT, Polyphen-2, CADD, GERP++) and was absent in EXAC, 1000GENOME, ESP6500, dbSNP population databases. Thirty-five additional patients with sporadic 46,XY DSD due to abnormalities of gonadal development (5 with ETRS and 30 with gonadal dysgenesis) were screened for this variant by Sanger methods. One out of 15 sporadic ETRS patients had the same heterozygous variant. *DHX37* (12q24.31) encodes a RNA helicase protein that belongs to the DEAH (Asp-Glu-Ala-His) family. Male patients with 12q24.31 deletions and genital abnormalities have been described in the literature, reinforcing the hypothesis that the *DHX37* could be involved in the 46,XY DSD etiology. Absence of the p.Arg308Gln *DHX37* variant founder effect between the two Brazilian families was confirmed by haplotypes analyses. Epigenetic analysis performed by Infinium Methylation EPIC 850K BeadChip demonstrated hypomethylated promoter regions of *DHX37*, *FGF9*, *DMRT1* in the F1 father when compared with sons. The identification of deleterious variant in *DHX37* in 6 patients with embryonic testicular regression syndrome provides strong genetic evidence that this gene is a novel candidate gene for 46,XY DSD due to abnormalities of gonadal development.

**2442F****Diagnostic utility of whole-exome sequencing for chronic kidney**

**disease.** *E. Groopman<sup>1</sup>, S. Cameron-Christie<sup>2</sup>, J. Fleckner<sup>2</sup>, R. March<sup>2</sup>, D. Goldstein<sup>3</sup>, A. Gharavi<sup>1</sup>.* 1) Department of Medicine, Columbia University, New York, NY; 2) Centre for Genomics Research, AstraZeneca UK LTD; 3) Institute for Genomic Medicine, Columbia University, New York, NY.

**Background:** Whole-exome sequencing (WES) has recently been introduced into clinical diagnostics, but its value for adult constitutional disorders requires further evaluation. We are assessing the diagnostic yield of WES in a large cohort of adults with all-cause Chronic Kidney Disease (CKD) or End-Stage Renal Disease (ESRD) recruited at Columbia University (N=1920) or enrolled in the AURORA study (N=1141). **Methods:** To date, the exomes of 765 patients have been analyzed using the American College of Medical Genetics (ACMG) guidelines for clinical sequence interpretation. **Results:** 97.4% of 765 patients were adults and 51.0% were non-Caucasian; 54% had a glomerulopathy, 7% had congenital defects, and 17.5% had CKD of unknown etiology. In total, 82 (10.7%) patients had a diagnostic variant for a genetic form of nephropathy. Among these diagnosed cases, 19.5% had presented with "CKD of unknown origin" and 41.5% noted no family history of nephropathy. In 47.6% of diagnosed cases, the molecular diagnosis confirmed the clinical diagnosis (e.g., Alport syndrome); in 52.4% it clarified the diagnosis (e.g., *UMOD* mutation in a patient with tubulointerstitial nephropathy) or provided an alternative diagnosis (e.g., Dent disease in a case of suspected glomerulopathy). Diagnostic variants were mainly found in genes for glomerulopathies (65.9%), followed by those for cystic disease (11.0%), tubulointerstitial disease (9.8%), other nephropathies (9.8%), and congenital anomalies (3.7%). In addition, 6 patients (0.8%) had a secondary, pathogenic variant in one of the 59 ACMG actionable genes. In the majority of cases, the results impacted clinical decision-making, including elements such as initiation of targeted surveillance, family counseling, selection of transplant donors, and modification of pharmacotherapy. **Conclusions:** In a large all-cause CKD cohort, WES gave a molecular diagnosis for 1 in 10 patients, and in 52.4% of positive cases, pinpointed an etiology not detected using traditional diagnostics, impacting clinical care. The completion of this study will provide comprehensive information about the clinical utility and the impact of genetic testing for nephropathy across broad demographic subgroups and etiologic subtypes.

**2443W****De novo unbalanced insertional translocation, der(X)ins(X;5)**

**(q?13;q12.3q13.1) in an adult female patient with developmental delay and ovarian insufficiency identified by DNA MicroarrayCGH and FISH.** *M. Pitch<sup>1</sup>, M. Guo<sup>2</sup>, M. Shaver<sup>2</sup>, A. Schroeder<sup>3</sup>, M. Anwar Iqbal<sup>3</sup>.* 1) University of Rochester School of Medicine & Dentistry, Rochester, NY; 2) Department of Pathology and Laboratory Medicine, University of Rochester, Rochester NY; 3) Division of Genetics, University of Rochester, Rochester, NY.

Insertional translocations (IT's) involving the X chromosome are a relatively rare entity. Insertional rearrangements on the X chromosome may cause disruption of genes responsible for sexual maturity or by chromosome effect such as inhibition of meiotic pairing or skewed X inactivation (Prueitt 2002). We report a 21 year old patient with a history of intellectual disability, developmental delay who presented to clinic with amenorrhea. Previous karyotype testing at age 18 were reported as normal. The patient was referred for array comparative genomic hybridization (aCGH) and whole exome sequencing (WES). The WES findings did not report any pathogenic variants. Interestingly, a 3.3Mb duplication of 5q12.3q13.1 segment was revealed by aCGH. Fluorescence in-situ hybridization (FISH) with probe RP11-841D3 (5q12.3) identified the duplication 5q12.3q13.1 segment inserted within the long arm of chromosome X near the vicinity of XIST region (Xq13.2). Parental studies did not identify a carrier translocation by FISH. Follow up X chromosome inactivation studies in the patient lymphocytes reported highly skewed non-random X inactivation (97.3%). Our results demonstrate that the clinical symptoms in the patient are potentially due to the disruption of the XIST gene leading to skewed X-inactivation.

**2444T**

**Pathogenic variants and variants of uncertain significance in autosomal dominant polycystic kidney disease (ADPKD) causative genes are commonly found in early-onset PKD patients: 2.5-year experience in a CAP/CLIA diagnostic laboratory.** *W. Chen, D. Allingham-Hawkins, C. Iwaszchenko.* Clinical DNA Testing, PreventionGenetics, Marshfield, WI.

Autosomal dominant polycystic kidney disease (ADPKD) is one of the most common human Mendelian disorders with a prevalence of 1:400 to 1:1000. ADPKD is typically a late-onset disorder with nearly complete penetrance. An individual who carries a germline pathogenic variant in one of the three known ADPKD causative genes (*PKD1*, *PKD2* and *GANAB*) is expected to develop renal cysts detectable by ultrasound by age 30 or later. It has been well documented in literature that biallelic *PKD1* variants (including hypomorphic alleles) or multiple alleles from different PKD causative genes can manifest as a much more severe early-onset condition prenatally or in newborns. Here we present the genetic findings of autosomal dominant PKD genes in early-onset PKD patients tested in our CAP/CLIA diagnostic laboratory in the past 2.5 years. Of 97 unrelated patients no older than two years at age (including seven prenatal cases) referred for our PKD panel testing (including *PKD1*, *PKD2* and *GANAB*, as well as *HNF1B* and *PKHD1*), 40 cases (41%) were found to have at least one pathogenic variant or variant of uncertain significance in at least one of the autosomal dominant genes (*PKD1*, *PKD2*, *HNF1B* and *GANAB*). Notably, early-onset PKD in 18 patients (18.5% of total cases) can be possibly explained by biallelic *PKD1* variants while five cases (5.1% of total cases) had notable variants from different PKD causative genes including the autosomal recessive PKD (ARPKD) gene *PKHD1*. In 13 patients (13.7% of total cases), we found only one pathogenic variant or variant of uncertain significance (i.e. no other notable variants were found). Interestingly, we found a heterozygous pathogenic or highly suspected pathogenic *HNF1B* variant in remaining four patients (4.1% of total cases). In summary, our experience with diagnostic testing of very young children (including prenatal testing) with symptoms of PKD supports the hypothesis that biallelic *PKD1* variants and multiple alleles from different PKD causative genes can result in exceptionally early-onset PKD. Our data supports the clinical utility of testing autosomal dominant PKD genes in patients with early-onset PKD.

Segmentation defect of the vertebrae (SDV) are commonly found while exploring malformative syndromes. Multiple SDV (M-SDV) are defined by the association of fused and/or abnormally formed vertebra and represent a rare clinical entity. The molecular bases of M-SDV are not fully elucidated due to the wide range of phenotypes and classification issues. The genes involved are in the Notch signaling pathway which is a key system in somitogenesis. Here we report on the genetic screening in a diagnostic cohort of patients with M-SDV and further delineate the genotype-phenotype correlations in order to establish a decision tree. The clinical and molecular data of 73 patients were included. A targeted sequencing of the 5 known spondylocostal dysostosis (SCD) causing genes (*DLL3*, *MESP2*, *LFNG*, *HES7* and *TBX6*) was performed in the 48 first patients and a whole exome sequencing (WES) in 28 patients. A targeted sequencing approach diagnosed 10 patients with autosomal recessive variants in the 5 known genes: 4 patients with *TBX6* variations, 2 with *LFNG* variations, 2 with *DLL3* variations, one with *MESP2* and one with *HES7* variations. Among the 4 patients presenting with biallelic *TBX6* variation, two had M-SDV and a 16p11.2 deletions encompassing *TBX6* associated with a published common haplotype. WES diagnosed two patients and allowed differential diagnosis of Spondylo-carpo-tarsal fusion syndrome (FLNB) and Klippel-Feil syndrome (MEOX1). The diagnostic rate of the gene panel including the 5 genes of SCD was 10/73 (13.7%) in the global cohort, and 8/10 (80%) in the subgroup fulfilling the SCD criteria. We also established genotype phenotype correlation in patients presenting with biallelic *TBX6* variations, ranging from regional M-SDV to SCD. The molecular bases of SDV are complex and a complex genetic architecture should be investigated. The diagnostic work-up of a M-SDV should be guided by the clinical description. Because of their genetic complexity, we would suggest a targeted sequencing of the five disease causing genes for SCD. In the subgroup of patients presenting with asymmetric thoracic SDV, no variation was identified and those patients should be included in research project considering non mendelian inheritance.

**Small 17p13.3 duplication including *BHLHA9* in a Brazilian family with incomplete penetrance of split-hand/foot malformation.** W.A.R. Barateia<sup>1</sup>, H. Hijazi<sup>2</sup>, C.M.B. Carvalho<sup>3</sup>, G.L. Yamamoto<sup>1,3</sup>, S.S. Costa<sup>3</sup>, C. Rosenberg<sup>3</sup>, C.A. Kim<sup>1</sup>, D.R. Bertola<sup>1,3</sup>, J.R. Lupski<sup>2,4,5</sup>. 1) Unidade de Genética, Instituto da Criança - Hospital das Clínicas - Universidade de São Paulo, São Paulo, São Paulo, Brazil; 2) Department of Molecular and Human Genetics, BCM, Houston, TX; 3) Centro de Pesquisas sobre o Genoma Humano e Células-Tronco, Instituto Biociências - Universidade de São Paulo, SP, Brazil; 4) Department of Pediatrics, BCM, Houston, TX; 5) Texas Children's Hospital, Houston, TX.

Split-hand/foot malformation (SHFM) with long bone deficiency (SHFLD) is a rare limb developmental abnormality typically involving the central rays of the autopod associated with long bone deficiencies, especially the tibia or the femur. Recurrence in familial cases is compatible with an autosomal dominant inheritance, with incomplete penetrance. Genomic imbalances, especially microduplications (254 to 527 kb) in 17p13.3, but also the presence of triplications and quadruplications, encompassing *BHLHA9*, a gene that encodes a basic helix-loop-helix transcription factor, have been found in several families. Although these copy-number gains are present in the majority of the reported cases, suggesting a gene dosage effect, the penetrance is approximately 50%, indicating that other genetic and/or epigenetic factors are required for phenotypic expression. We report a familial case with three individuals (the proband, his father and his paternal uncle) presenting SHFM with absent tibia, therefore SHFLD. High-density aCGH was performed in these individuals, as well as in three non-affected family members. A microduplication of ~ 62 Kb in 17p13.3 has been identified in all affected individuals, as well as in the proband's paternal grandmother and his paternal cousin. Exome sequencing performed in the proband's father failed to show any rare pathogenic variant in *BHLHA9* or other gene associated with SHFM. In the present family, all affected individuals were males, giving further support to previous descriptions involving male sex bias. In an attempt to identify a possible second genetic factor that could contribute to the high variable phenotypic expression and incomplete penetrance, exome sequencing was performed in one affected individual, but no other good candidate was found. Thus, further studies are required to understand the complete genetic mechanism responsible for SHFLD. FAPESP (2013/08028-1; 2015/21783-9), CNPq (302605/2013-4).

**Novel pathogenic variants in craniosynostosis genes identified by NGS.**

E. König<sup>1</sup>, K. Platzer<sup>2</sup>, I. Spier<sup>2</sup>, S. Spranger<sup>1</sup>, A. Tzschach<sup>5</sup>, B. Zirn<sup>6</sup>, T. Schweitzer<sup>7</sup>, W. Kress<sup>1</sup>, E. Klopocki<sup>1</sup>. 1) Institute of Human Genetics, University of Würzburg, Würzburg, Germany; 2) Institute of Human Genetics, University of Leipzig, Leipzig, Germany; 3) Institute of Human Genetics, University of Bonn, Bonn, Germany; 4) Praxis fuer Humangenetik, Bremen, Germany; 5) Institute of Clinical Genetics, Technische Universität Dresden, Dresden, Germany; 6) Genetikum, Stuttgart, Germany; 7) Department of Pediatric Neurosurgery, University of Würzburg, Würzburg, Germany.

Craniosynostosis, the premature fusion of one or more cranial sutures, is a frequent craniofacial malformation affecting 1 in 2500 newborns. Premature ossification of the cranial sutures can occur either as isolated malformation or as part of a syndrome. So far genetic causes have been identified mainly for syndromic craniosynostoses, i.e. mutations in *FGFR2*, *FGFR3*, *TWIST1*, and *EFNB1*. High phenotypic variability and clinical overlap of the different syndromes often hamper straight forward genetic diagnostics, thus, necessitating conventional sequencing of more than one gene. Furthermore, in more than 50% of cases the underlying genetic cause remains unknown. We compiled a next generation sequencing (NGS) gene panel comprising 68 genes including known and candidate craniosynostosis genes of the syndromic and isolated type as well as genes associated with bone development. Target enrichment was performed by the Nextera Rapid Capture (Illumina) as well as by SureSelect<sup>QXT</sup> (Agilent). Sequencing was done on the Illumina MiSeq platform. Sequencing data were analyzed with the GensearchNGS software (PhenoSystems). Performance of the NGS gene panel was validated by sequencing five control patients with known mutations. All of these mutations were detected correctly. Subsequently, we sequenced genomic DNA of 54 patients with syndromic as well as isolated craniosynostosis. Hot spot sequencing of *FGFR1-3* and *TWIST1* was performed previously for most of the cases. Until now sequencing of craniosynostosis patients with our NGS gene panel enabled the detection of likely pathogenic variants in 32% of the cases. We identified 8 already known mutations in *FGFR1*, *FGFR2*, *FGFR3*, and *TWIST1*. In addition, we detected 9 novel, potentially disease causing variants in the genes *ERF*, *MEGF8*, *MSX2*, and *TCF12*. We want to highlight a novel, likely pathogenic variant in *MEGF8*, the Carpenter syndrome 2 gene: a homozygous variant (c.828G>A) predicted to affect the splice site in two children of consanguineous parents. Our patients show an overlapping phenotype with Carpenter syndrome 2 (MIM #616294). An *in-vitro* minigene assay showed that the c.828G>A variant leads to skipping of exon 5 which is predicted to result in a frameshift and subsequently in a premature stop codon. In summary, our NGS panel approach provides a useful tool in determining the underlying genetic cause of craniosynostosis in a time and cost efficient manner especially in patients with an unclear clinical diagnosis.

Whole exome sequencing (WES) emerged as a powerful tool for deciphering the molecular basis of developmental disorder, either single nucleotides variants (SNVs), indels, or recently copy number variants (CNVs). In mosaic development disorders, it has allowed detection of post-zygotic point mutations (mosaic SNVs) in various genes, mainly in the RAS-MAPK and PI3K-MTOR pathways. However, detection of mosaic CNVs still relies on conventional cytogenetic studies, such as array-CGH and array-SNP. We sought to develop an all-in-one strategy for patients with mosaic disorders, using trio-WES on lesional skin from patient and blood from his parents. We combined a conventional SNV detection pipeline with a CNV detection approach, based on both a read depth approach (using XHMM) and a custom SNP-based approach on inherited variants. In a cohort of 57 patients with various mosaic disorders involving the skin, pathogenic SNVs were detected in 22 patients (38.5%) in already known or previously uninvolved genes. In a subgroup of 19 patients with hypomelanosis of Ito (linear mosaic depigmentation), we were able to detect 6 mosaic CNVs (10,5%): 3 complete mosaic trisomy (for chromosomes 7, 12 and 15) and 3 mosaic CNVs of smaller size (3q26.1-q29 and 6p22.3-p25.3 gains, 13q12.11-q13.3 loss) increasing our diagnostic rate to just under 50%. Blood and skin karyotypes and array-CGH were previously negative, due either to the absence of mosaic cells in blood or to their elimination from cultured fibroblasts. All variants were confirmed using array-CGH, array-SNP and FISH on skin DNA. Among the 3 complete mosaic trisomies, the data on single nucleotides polymorphism inheritance and b-allele frequency provided information on the parental origin of extra chromosomes and clues to understand the underlying mechanism, such as meiotic non-disjunction. Hence, we have confirmed that chromosomal mosaicism is frequently associated with mosaic pigmentation disorders (6/19, 32% in our cohort). The use of an appropriate fresh tissue sample is essential, as CNVs were not detected in blood or cultured fibroblasts. Our combined approach showed a good efficiency to provide information both on SNVs and CNVs in a single one-step assay, offering new perspectives in the study of mosaic developmental disorder.

**Diagnosing connective tissue disorders by clinical exome sequencing.** H. Cheng<sup>1</sup>, X. Wang<sup>1,2</sup>, M. Leduc<sup>1,2</sup>, M. Walkiewicz<sup>1,2</sup>, W. Bi<sup>1,2</sup>, P. Liu<sup>1,2</sup>, R. Xiao<sup>1,2</sup>, L. Meng<sup>1,2</sup>, F. Xia<sup>1,2</sup>, Y. Yang<sup>1,2</sup>, Z. Chen<sup>1,2</sup>. 1) Baylor Genetics, Houston, TX 77021; 2) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030.

Connective tissue disorders (CTDs) mainly manifest in skin, eye, musculoskeletal, cardiovascular and neuron systems. Diagnosis by targeted gene approaches can be challenging due to late disease onset, variable phenotype expressivity, clinical and genetic heterogeneity and overlapping phenotypic features. This study retrospectively evaluated CTDs diagnosed by clinical exome sequencing in our lab including Ehlers-Danlos (EDS) syndrome related (including Cutis laxa), Osteogenesis Imperfecta (OI) related (including Hypophosphatasia, Cole-Carpenter syndrome), Marfan syndrome (MS) related (including Loeys-Dietz syndrome, Familial thoracic aortic aneurysms), and a newly described genetic disorder related to defects in the *ABL1* gene. Of the ~3000 positive clinical exome cases identified in our laboratory, 97 individuals were diagnosed with CTDs mentioned above. Of the CTD positive cases, 26 individuals were diagnosed with EDS related disorders. The genes most frequently identified were *COL5A1* (11.5%) and *PLOD1* (11.5%). Causative variant in *TNXB* was identified in one individual affected with hypermobility type EDS. Two individuals affected with vascular type EDS had mutations in *COL3A1*. Out of the 19 cases affected with OI related disorders, the genes frequently identified were *COL1A1* (26.3%) and *COL1A2* (15.8%). Causative variant in *COL1A2* was identified in one case with EDS features instead of OI. Out of the 46 individuals affected with MS related disorders, the genes frequently mutated were *FBN1* (21.7%) and *MED12* (13.0%). *De novo* variants in *SKI* were identified in two individuals with Shprintzen-Goldberg syndrome. All the *MED12* (X linked Lujan syndrome) variants were *de novo*; the variant identified in a female patient was reported in manifesting female carriers. In one family, two molecular diagnoses of Loeys-Dietz (*TGFβ3*) and Stickler (*COL2A1*) syndromes were established, in which multiple family members were affected with either one or both diseases. Intriguingly, 8 individuals in 5 unrelated families were first reported in our laboratory to be affected by a new AD genetic disorder caused by gain of function variants in *ABL1*. The phenotypic features of the *ABL1*-related disorder resemble those in patients with Marfan syndrome. In summary, clinical exome sequencing in our laboratory identified a wide spectrum of genotypes in individuals with connective tissue disorders; in addition, it also enabled the discovery of a new disease gene related to CTDs.

Heritable forms of ichthyoses, also referred to as generalized Mendelian disorders of cornification, are clinically diagnosed as dry and scaly skin, and histopathology reveals thickening of stratum corneum at the outer layer of the epidermis. In this study, we have developed a gene-targeted next generation sequencing (NGS) array consisting of 38 genes reported in association with ichthyosis phenotypes and sequenced total of 189 Iranian patients with clinical diagnosis of non-syndromic (autosomal recessive congenital) ichthyosis (ARCI), and syndromic forms of ichthyosis. The designed library contained 38 genes (*ABCA12*, *ABHD5*, *AGPS*, *ALDH3A2*, *ALOX12B*, *ALOXE3*, *AP1S1*, *ARSE*, *CERS3*, *CLDN1*, *CYP4F22*, *EBP*, *ELOVL4*, *GJB2*, *GJB3*, *GJB4*, *GJB6*, *KRT1*, *KRT10*, *KRT2*, *KRT9*, *LIPN*, *LOR*, *NIPAL4*, *PEX7*, *PHYH*, *PNPLA1*, *PNPLA2*, *POMP*, *SLC27A4*, *SNAP29*, *SPINK5*, *ST14*, *STS*, *TGM1*, *TGM5*, *VPS33B*, *ZMPSTE24*) divided into 351 targets covered by 558 amplicon probes with an estimated coverage of 99%. NGS panel detected pathogenic and likely pathogenic variants in 155 out 189 families (82% detection rate). In 110 families, mutations were found in 8 associated ARCI genes: (*ABCA12*: 12.5%; *ALOX12B*: 9%, *ALOXE3*: 3%, *CERS3*: 8%, *CYP4F22*: 6.5%, *NIPAL4*: 4.5%, *PNPLA1*: 18%, and *TGM1*: 37%). Most common mutated gene in ARCI was *TGM1* (37%). Surprisingly, about 26% of all ARCI mutations were found in *PNPLA1* and *CERS3*; the reported variants in these genes are extremely rare. In 45 families, mutations were found in 18 genes associated with different syndromes in which ichthyosis is one of their clinical manifestations. We also characterized a new type of entity of ichthyosis follicularis with profound bilateral deafness and leukonychia totalis which segregate in 4 patients in a large multiplex family. All patients had compound heterozygous mutations (a missense and a deletion) in *GJB2*, and the parents of the proband were heterozygous. In *Xenopus* oocytes expressing the missense variant, membrane currents were elevated ~7 fold higher than wild-type *GJB2* expressing cells denoting increased hemichannel activity in mutant cells in comparison to control cells. Co-expression of both missense and wild-type *GJB2* reduced the magnitude of the current to about half between expressions of either protein separately, similar to of other *GJB2* associated skin disorders. Collectively, identification of specific mutations in a large cohort of ichthyosis patients allowed us to examine phenotype/genotype correlations.

**Purpose:** Epidermolysis bullosa (EB), the prototype of heritable blistering diseases, is caused by mutations in genes expressed in cutaneous basement membrane zone. We have now evaluated the molecular basis of EB in 91 families, many of them of unknown subtype. **Methods:** A next generation sequencing panel (NGS) covering 21 distinct genes, including 18 EB-associated genes, was developed, and mutation profiles, together with clinical features, were used to classify the patients into distinct clinical subcategories. **Results:** A total of 72 pathogenic/likely pathogenic variants in 68 families were identified in 11 candidate genes, most of them (75%) being homozygous consistent with considerable consanguinity in the cohort. Half of the mutations (48.6%) were previously unreported. Refined analysis of the types of mutations with addition of variants of unknown significance suspected of causing EB allowed subclassification of patients into different subcategories of EB in 76 of 91 families, with prognostic implications. A genetically challenging case with homozygous loss-of-function pathogenic mutations in two different EB-associated genes resulting in different subtypes was identified. **Conclusion:** Utilization of next generation sequencing panel of EB-associated genes allowed diagnostic subclassification in the neonates particularly in families of unknown subtype, with prognostication of the overall long-term outcome of the disease.

**Exome sequencing in 170 patients with diverse ataxia-related phenotypes identifies the genetic basis of disease in over 50%. A. Knight Johnson<sup>1</sup>, M. Sun<sup>2</sup>, V. Nelakuditi<sup>3</sup>, D. Fischer<sup>4</sup>, K. Arndt<sup>5</sup>, L. Ma<sup>1</sup>, D. del Gaudio<sup>1</sup>, M. Burmeister<sup>6</sup>, V. Shakkottai<sup>6</sup>, K. Boycott<sup>6</sup>, J. Warman Chardon<sup>6</sup>, D. Waggoner<sup>6</sup>, C. Gomez<sup>2</sup>, S. Das<sup>1</sup>.** 1) Human Genetics, University of Chicago Genetic Services, Chicago, IL; 2) Department of Neurology, The University of Chicago, Chicago, IL; 3) Department of Human Genetics, University of Michigan, Ann Arbor, MI; 4) Neurology Department, University of Michigan Health System, Ann Arbor, MI; 5) Department of Genetics, Children's Hospital of Eastern Ontario, Ottawa, ON; 6) Neurogenetics, Children's Hospital of Eastern Ontario, Ottawa, ON.

Ataxias are a group of neurological disorders that demonstrate significant clinical and genetic heterogeneity, and as such, exome sequencing provides an effective approach for the genetic diagnosis of this condition. We examined the utility of an exome sequencing-based approach for the molecular diagnosis of patients with a wide range of ataxia-related phenotypes. We studied 170 patients with ataxia of unknown genetic etiology referred from 63 different genetics or neurology clinics primarily within the United States and Canada, in whom prior trinucleotide repeat expansions had either been excluded or not implicated. Patients ranged in age from 2 years to 88 years. Exome-based target capture was performed using Agilent SureSelect technology and samples were sequenced on a NextSeq Illumina instrument, with an average coverage of 96% of all coding exons at minimum 30X read depth. Our analysis was focused on variants within 441 curated genes associated with ataxia and ataxia-like phenotypes as either an isolated finding, or as part of a more complex syndromic presentation. Combined, pathogenic variants and suspected diagnostic variants were identified in 88 of the 170 patients, providing a positive molecular diagnostic rate of 52%. Pathogenic and suspected diagnostic variants were observed in 57% of patients  $\leq 30$  years old (45/79), and 47% of patients  $> 30$  years old (43/91). Overall, forty-six different genes were implicated in the ataxia phenotype in our cohort. Pathogenic or suspected diagnostic variants in *SPG7*, *SYNE1*, *ADCK3*, *CACNA1A*, *ATP1A3* and *SPTBN2* together accounted for 41% of the positive cases. 33% of patients in whom a molecular diagnosis was made had a positive family history. Our strategy of analyzing a large set of ataxia-related genes in all referred patients provided a high diagnostic yield, and was particularly useful for making a molecular diagnosis in patients who had an atypical presentation for a particular disorder. In several cases the results from our cohort broadened the known clinical spectrum of genetic ataxia-related disorders. Our cohort represents the general population of patients with ataxia seen in neurology and genetics clinics, regardless of age or the presence or absence of additional clinical features. Our finding of pathogenic or suspected diagnostic variants in 52% of our cohort therefore represents the likely diagnostic yield of exome sequencing for unselected patients with ataxia referred for clinical exome sequencing.

**2453T**

**Incidentaloma in neurogenetics: Pathogenic variant in NSD1 in a patient with spinocerebellar ataxia. H.M. Velasco, D.A. Ramirez.** Genetic Institute, National University, Bogota Cundinamarca, Colombia.

**Background:** Genetic studies of late-onset sporadic ataxias ( $> 40$  years) are not routinely indicated. In patients for whom the most common acquired causes are ruled out, diagnostic algorithms such as triplet expansions in genes related to spinocerebellar ataxia (SCA) can be used, and in the unresolved cases, next-generation sequencing (NGS), such as Whole Exome Sequencing (WES), are available for definitive diagnosis. **Case report:** Female patient with usual facial phenotype and anthropometry, who developed ataxia at 45 years of age, with no relevant family history, and initial clinical approach that ruled out common etiologies. Genetic assessment was performed at age 47 yielding negative studies for SCAs through triplet expansion (SCA 1,2,3,6). WES was performed, reporting a heterozygous pathogenic variant c.248delA (p.N83MfsX4) in the NSD1 gene (related to Sotos Syndrome), which was not associated with ataxia and is not related to the patient's phenotype. The variant was confirmed by complete sequencing of NSD1 in two different laboratories through Sanger sequencing. **Conclusion:** Findings obtained through NGS generally offer valuable results which serve to make medical decisions. However, finding incidental results that lead to define new clinical and bioethical actions is also possible. Is necessary confirm and establish the biological importance of this type genetic incidentaloma. This particular finding in NSD1 could demonstrate that there are clinically silent pathogenic variants or that these variants could be related to genopatogenic phenomena in ataxia.

**Intracellular FmRppolyG-HSP70 complex: Possible use as biochemical marker of FXTAS.** *G. Bonapace<sup>1</sup>, R. Gullace<sup>1</sup>, D. Concolino<sup>1</sup>, G. Arabia<sup>2</sup>, A. Quattrone<sup>2,3</sup>, R. Procopio<sup>3</sup>, G. Iannello<sup>2,3</sup>, M. Gagliardi<sup>3</sup>, G. Annesi<sup>3</sup>.* 1) Pediatrics, University Magna Graecia, Catanzaro, Italy; 2) Institute of Neurology, Department of Medical Sciences, University "Magna Graecia" of Catanzaro; 3) Institute of Molecular Bioimaging and Physiology, National Research Council, Section of Germaneto, Catanzaro, Italy.

Fragile X-associated tremor/ataxia syndrome (FXTAS) is a late-onset neurodegenerative disorder that affects about 25% of carriers of small, non-coding CGG-repeat expansions (55–200 repeats) in the premutation range within the fragile X gene (*FMR1*). Main clinical features of FXTAS include intention tremor, cerebellar ataxia, and Parkinsonism. The pathogenesis of FXTAS has been demonstrated to involve different overlapping molecular and biochemical mechanisms, with a common feature due to an increased expression of *FMR1* gene. Recently, great emphasis on toxic aggregates, produced by a RAN translation process on the 5' expanded CGG region of the gene, has been given. These aggregates contain a fragile mental retardation protein with a polyglycin stretch on the aminoterminal ends, (FmRp-polyG) and so far, have been isolated and characterized only in drosophila models, mouse model and post mortem FXTAS patients brain, but never in FXTAS living patients. Unfortunately, the role of these aggregates in the pathogenesis of FXTAS is still not well understood. Furthermore, the syndrome is frequently misdiagnosed because of the early diagnosis in adult carriers remains difficult due to the lack of specific biochemical markers. The same situation hampers the possibility to predict the clinical outcome in children carriers of premutation on the *FMR1* gene, negative for the Fraxa syndrome, but at risk for developing FXTAS. Here we demonstrate, for the first time, using immunohistochemistry (IHC) and Western Blot procedure (WB), the presence *in vivo*, of toxic aggregates produced by the expanded polyG FMRP protein in fibroblasts from a carrier of a premutated *FMR1* allele associated to clinical signs of FXTAS. This finding is very promising and offer the possibility to use the interaction between polyG-FMRP and HSP70 as novel early diagnostic biomarker of FXTAS in living patients. Even though the validation of this procedure needs larger research to study its predictive value for the clinical outcome of *FMR1* premutation carriers without signs of FXTAS, we recommend considering its use for patients showing neurological signs of FXTAS associated to a well defined CGG premutated allele. .

**The AAGAAAG duplication at nucleotides 2023-2029 of SCN8A gene of EIEE13 (early infantile epileptic encephalopathy-13) presenting with no epilepsy, but variable expression of intellectual disability, ADD/ADHD and autism in the same family.** *M. Hajianpour<sup>1</sup>, D. Lewis<sup>2</sup>.* 1) Pediatrics/Medical Genetics, East Tennessee State University, Quillen College of Medicine, Johnson City, TN; 2) Pediatrics, Holston Medical Groups, Kingsport, TN.

Proband is a 15-year-old male with a history of developmental delay, speech and language deficit, intellectual disability (ID) with FSIQ of 40, and ADHD. He was born full-term, by vaginal delivery to a 24-year-old, G1, P0 mother. No prenatal exposure to teratogens. BW; 8 lbs 1 oz, and BL; 21". He had mild motor delay. He did not talk in sentences until 3 years of age. He is in 9th grade special education but functions well below this level. He has autistic behavior and ADHD. The EEG and MRI for an episode of shivering were normal. He has had hypermetropia since age 5 years. Molecular studies for ID (a panel of 140 genes by AmbryGenetics) showed a pathogenic mutation of **SCN8A Gene on Chromosome 12q13 (paternally inherited): c.2023\_2029dupAAGAAAG**. The test also showed two variants of uncertain significance (VUSs) of **VPS13B Gene: p.T1271S, p.S2596F (maternally inherited)**. Family history is remarkable for LD in father (currently, has his own business), and 2 out of 4 brothers, one of whom has also ADD. Another brother has ADD only, and youngest brother (4 yo) is apparently normal. Testing for SCN8A mutation and VUSs on brothers are in progress. Alterations in SCN8A gene are typically inherited in an autosomal dominant fashion in association with early infantile epileptic encephalopathy-13 (EIEE13); characterized by frequent tonic seizures or spasms beginning in infancy with specific EEG findings. Additional features may include mild cerebral atrophy, progressive microcephaly, interrupted myelination on brain imaging (which are not present in proband and his father), regression of speech and language skills, developmental delay, intellectual disability, hypotonia, difficulties with coordination and balance, and autistic behaviors. Out of all these features, only DD/ID, motor coordination problems and autistic behavior are present in proband, and only history of LD in his father (who is a carrier of the same SCN8A alteration). Mother (with 2 VUSs) had LD requiring special education. She may also have a coagulation disorder with tendency to bleeding (as well as one of her sons). Contribution of maternally inherited 2 VUSs to the phenotype in proband is possible. Trudeau et al. (2006) identified heterozygosity for a 2-bp deletion in SCN8A gene, in 4 members of a family; 3 had cognitive and behavioral deficits/ ADHD, while 1 had cerebellar atrophy, ataxia, and mental retardation, indication variable expression of the phenotype in members of the same family.

**2456T****Further investigation of variants discovered in an early onset dementia cohort: Additional family member sequencing.**

S.A. Bucks<sup>1</sup>, C.J. Hale<sup>2,3</sup>, D.S. Hanna<sup>2,3</sup>, M.B. Dauer<sup>2,3</sup>, L. Mathew<sup>2,3</sup>, D. Sarroza<sup>2,3</sup>, S. LaDuke<sup>2,3</sup>, M.A. Weaver<sup>2,3</sup>, T. Tran<sup>2,3</sup>, M. Rumbaugh<sup>1</sup>, D. Tsuang<sup>1,4</sup>, S. Jayadevi<sup>1</sup>, T.D. Bird<sup>1,4,5</sup>, M.O. Dorschner<sup>2,3,5</sup>. 1) Neurology, University of Washington, Seattle, WA; 2) Pathology, University of Washington, Seattle, WA; 3) UW Medicine Center for Precision Diagnostics, University of Washington, Seattle, WA; 4) Department of Medicine (Medical Genetics), University of Washington, Seattle, WA; 5) Department of Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA; 6) Geriatric Research, Education, and Clinical Center, VA Puget Sound Health Care System, Seattle, Washington.

Dementia affects an estimated 47 million people worldwide. It is caused by, or associated with, several neurological disorders, including Alzheimer's disease (AD), Parkinson's disease (PD), and frontotemporal dementia (FTD). Identifying the precise genetic cause of dementia contributes to accurate diagnosis, inclusion into appropriate clinical trials, potential discovery of novel gene targets for therapeutic development, and more informative genetic counseling for family members. To determine the genetic cause of dementia in patients, we previously developed a clinical exome-based panel using an optimized IDT Exome v1.0 capture system for library enrichment followed by Illumina sequencing. The panel included 38 genes associated with dementia phenotypes, including genes in AD, PD, FTD, and amyotrophic lateral sclerosis (ALS). The clinical panel was developed by experts engaged in neurodegeneration research and clinical practice at the University of Washington. We previously identified pathogenic or likely pathogenic genetic variants in 14 out of 145 cases (10%) of early onset and/or familial dementia, including in the genes *MAPT*, *NOTCH3*, *PSEN1*, and *PSEN2*. We also identified 33 variants of uncertain significance (VUS) in 29 cases. To further clarify the pathogenic nature of these VUSs, we then used Sanger sequencing to analyze samples from affected or unaffected family members of probands from the initial cohort. After Sanger sequencing the relatives of 12 probands with dementia, we identified three candidate variants that were also present in several affected individuals: *NPC1*, c.1778delA, p.Asn593Thrfs\*7; *PSEN1*, c.322C>T, p.Arg108Trp; and *PSEN1*, c.122\_128delGACGGAG, p.Arg41Thrfs\*31. Remaining families that showed no clear aggregation of the proband's VUS with the dementia phenotype are undergoing whole exome analysis to identify candidate variants that may contribute to the family's dementia. Exome sequence data for members of a single family will be compared to eliminate private, rare benign polymorphisms and enrich for variants carried by more than one affected individual. Retrospective analysis of our procedure (dementia panel, Sanger sequencing in relatives, and exome analysis) should provide insight into which steps are necessary to determine the genetic cause of dementia in most patients suspected of having single gene drivers of dementing disease.

**2457F****Comparison of the diagnostic yield of multi-gene panels for neuromuscular disorders.**

A. Gruber, K. Williams, J. Schroeder. Prevention Genetics, Marshfield, WI.

Neuromuscular disorders (NMDs) are a clinically, pathologically, and genetically heterogeneous group of diseases that impair muscle function or the peripheral nervous system. With the reduction in NextGeneration Sequencing (NGS) costs, genetic testing has become a cost efficient approach for NMD clinical diagnosis. A patient cohort of 950 patients with a wide range of NMDs was evaluated for pathogenic variants using NGS. Thirteen NMD panels were retrospectively analyzed and ranged from comprehensive (124 genes) to phenotype-specific (6 genes). A positive result was reported in patients with one or more pathogenic or likely pathogenic variants based on ACMG variant interpretation guidelines. The highest performing panel was a custom muscular dystrophy panel (57 genes, 10 patients) in which all patients were thoroughly evaluated with muscle biopsy results from a single provider. For this panel, 60% of patients were positive, 40% were inconclusive, and there were on average 2.3 VUSs/patient. The nemaline myopathy panel (10 genes, 58 patients) had a 47% positive rate, 22% inconclusive rate and 0.7 VUS/patient. Other panels which include limb-girdle muscular dystrophy (24 genes, 236 patients), congenital muscular dystrophy (27 genes, 104 patients), and congenital myasthenic syndrome (15 genes, 265 patients) were positive in 20%-30% of cases and averaged less than one VUS/patient. Two recently released panels, including a comprehensive neuromuscular panel (124 genes, 5 patients) and comprehensive neuropathy panel (71 genes, 7 patients), were positive in 20%-30% of cases but had 2.5-3 VUS/patient. In conclusion, larger multigene panels have become a cost effective tool in clinical diagnosis of NMDs. Smaller phenotype based panels are less likely to result in variants of uncertain significance, which are a burden for providers. Due to the clinical and genetic heterogeneity of NMDs, large multigene panels are now commonly offered as a diagnostic test. However, they do come at the cost of additional VUSs being identified due to the large number of genes being analyzed.

**2458W**

**Identification of a novel *de novo* nonsense mutation of the *NSD1* gene in monozygotic twins discordant for Sotos syndrome.** J. Han, S. Her. Pediatric Neurology, Daejeon St. Mary's Hospital, Daejeon, South Korea.

Sotos syndrome is a congenital overgrowth disorder characterized by facial gestalt, excessively rapid growth, acromegalic features and a non-progressive cerebral disorder with intellectual disability. We used diagnostic exome sequencing (DES) to identify a heterozygous *de novo* mutation of the *NSD1* gene in monozygotic twins with Sotos syndrome. DES revealed a novel nonsense mutation c.2596G>T (*p.Glu866\**) of the *NSD1* gene in the proband, the first of monozygotic twins. Sanger sequencing analysis of the proband and his family members showed that this nonsense mutation was present in the proband and his sibling, but was absent in their parents, indicating that it occurred with *de novo* origin. Interestingly, the identical male twins showed somewhat different clinical, cognitive and behavioural phenotypes. Abnormal clinical manifestations including seizures, scoliosis, enlarged ventricles, and attention-deficit/hyperactivity disorder (ADHD) were found in the proband (first twin), but not in the sibling (second twin). This finding expands the phenotypic spectrum associated with variable expression of the Sotos syndrome caused by *NSD1* mutation, and it adds further support for postconceptual mutation, epigenetic change and/or an environmental factor involved in the cause of the Sotos syndrome. We demonstrate that DES is a valuable approach to identify a genetic cause in sporadic cases of Sotos syndrome due to inherited *de novo* mutations.

**2459T**

**Novel myopathic phenotype due to a newly detected stop-loss mutation in *MYH7* gene.** K. Sumeg<sup>1,2</sup>, Z. Banfai<sup>1,2</sup>, K. Hadzsiev<sup>1,2</sup>, E. Paß, E. Kovcsdi<sup>1,2</sup>, B. Melegh<sup>1,2</sup>. 1) Department of Medical Genetics, University of Pecs, Pecs, Hungary; 2) Szentagotai Research Centre, University of Pecs, Pecs, Hungary; 3) Neurology Clinic, University of Pecs, Pecs, Hungary.

**Purpose:** Defects of the slow myosin heavy chain (MyHC1) encoding *MYH7* gene result predominantly in cardiomyopathies and skeletal myopathies including distal myopathy and skeletal muscle abnormalities caused by thick filament deposition in the sarcomeres. However, according to the reports from recent years, phenotypic characteristics of myopathies arising from *MYH7* gene defects have a rather wide spectrum. Pathogenesis of the C-terminal mutations of *MYH7* gene are less known, only two article deals with the phenotypic impact of the elongated mature protein product due to termination signal loss. Here we present a male patient with an unusual phenotypic variant of early-onset and predominant involvement of neck muscles, with muscle biopsy indicating myopathy and sarcoplasmic storage material. **Methods:** Our investigation consisted of standard clinical examination procedures, including electromyography, electroneuronography, MRI, histopathological (Hematoxylin-Eosin, modified Gomori and NADH staining, electron microscopy) and laboratory examinations. Our molecular genetic investigation included the diagnostic Sanger sequencing of *MYH7* gene. We also used various prediction software (Mutation Taster, Human Splice Finder 3.0, Netgene2) in order to characterize the clinical significance of the detected mutations. We also applied the Parcoil2 software in order to investigate probable structural changes in the rod region of the protein due to the identified mutation. **Results:** Sequencing of *MYH7* revealed three novel point mutations at the 3'-end of the gene, one of them (c.5807A/T) causing the loss of termination signal and elongation of the mature protein. Parcoil2 result showed a probability score approaching 1 for the likelihood of coiled-coil formation of the elongated region. The elongated protein likely disrupts the functions of the sarcomere by multiple functional abnormalities, resulting in severe myopathy of certain axial muscles and leading to the defect of thick filament degradation, causing protein deposition and accumulation in the sarcomeres. **Conclusion:** The number of currently identified mutations causing termination signal loss in *MYH7* are few, their impact on the structure of MyHC1 is unique and do not show a uniform phenotype. Examination of *MYH7* mutations is essential to improve our knowledge about congenital myopathies, classification of clinical patterns and the diagnosis of currently unidentified cases.

**2460F**

**Whole exome sequencing: An effective and comprehensive genetic testing approach for leukodystrophy.** F. Zou, K. Retterer, J. Scuffins, D. McKnight. GeneDX, Gaithersburg, MD.

Leukodystrophies are a group of rare genetic disorders caused by abnormal development or destruction of the white matter of the central nervous system (CNS) with or without peripheral nervous system involvement. The diagnosis of leukodystrophies is challenging due to heterogeneous phenotypes, although early diagnosis is critical for prognosis and family planning and in some cases to take advantage of available treatments to slow disease progression. The objective of this study was to establish the positive diagnostic rate (PDR) for leukodystrophies by whole exome sequencing (WES) and summarize a variety of underlying genetic etiologies. In this retrospective study, we reviewed the results of clinical WES testing of 541 patients with leukodystrophy reported as a clinical feature. A positive test outcome was defined as presence of one or two pathogenic or likely pathogenic variants in a single gene, depending on the mode of inheritance. In 33% (176/541) of cases, WES yielded a positive result, 44% (242/541) of cases were reported as non-diagnostic (inconclusive), and 23% (123/541) of cases were negative. Approximately 51% (90/176) of patients had an autosomal recessive (AR) disorder, 41% (72/176) had an autosomal dominant (AD) disorder, and 8% (14/176) had an X-linked (XL) disorder. WES-trio testing with concurrent sequencing and analysis of probands and both parents revealed that the majority of patients diagnosed with an AD disorder (81%, 58/72) had *de novo* variants. The PDR for WES-trios was 34% (136/399), which was significantly higher than the 23% PDR (20/86,  $p < 0.05$ ) for proband-only WES. Overall, pathogenic or likely pathogenic variants were reported in 133 different genes and most frequently seen in well-known leukodystrophy genes including TUBB4A (3.4%, 6/176), RNASEH2B (2.8%, 5/176), GFAP (2.8%, 5/176) and EIF2B5 (1.7%, 3/176) and POLR3A (1.7%, 3/176). More interestingly, over 8% of these genes were only described in connection with a specific disease within the last two years. In summary, WES is an effective diagnostic tool that can identify the underlying genetic etiology of leukodystrophy in up to 34% of patients. The WES-trio approach which is more efficient than proband-only WES is recommended to enable segregation analysis and aid in variant interpretation. These results, along with the growing number of newly described leukodystrophy genes, emphasize the importance of a comprehensive and flexible genetic testing approach for leukodystrophy.

**2461W**

**Copy number analysis using next-generation sequencing: Comprehensive genetic testing and its application to neuromuscular and epilepsy panels.** A. Entezam, J. Westbrook, C. Tan, S. Yang, R. Truty, N. Patel, P. Taylor, M. Rabideau, H. White, T. Winder, S. Aradhya. Invitae, San Francisco, CA.

**Objective** The diagnosis of Mendelian disorders is routinely performed through gene sequence or chromosomal copy number variant (CNV) analysis. Although exon-level CNVs contribute significantly to disease burden, their testing has traditionally been limited to a few loci. We evaluated a next-generation sequencing (NGS) method that simultaneously evaluates sequence changes and gene-level CNVs in hundreds of genes. **Our data show that a high frequency of gene and exonic CNVs are associated with neurological disorders.** **Methods** We investigated subsets of 300 genes curated for neuromuscular disorders in 2316 unrelated individuals and up to 186 genes curated for epilepsy in 1131 unrelated individuals. Validated coverage-based CNV detection algorithms and custom algorithms designed to flag split-read signals were applied to all samples. **Results** Among individuals with neuromuscular disorders, 247 had pathogenic variants detected with CNV analysis. These variants represented 39% of all neuromuscular diagnostic findings. The majority of pathogenic CNVs were in PMP22 or DMD, but they were also identified in several other genes not traditionally tested for CNVs. Among individuals with epilepsy, 44 had whole-gene or exonic CNVs in 23 genes, representing 14% of the pathogenic variants in epilepsy genes. **Conclusions** Exonic CNVs explain a substantial (~10%) proportion of pathogenic variants across several disorders and occur in a broader variety of genes than previously appreciated. This NGS-based sequence and CNV detection method can be used routinely in germline genetic testing in neurological disorders to identify both common and rare events that together result in a high diagnostic yield. .

**Combining repeat expansion testing with phenotype based NGS panels provides significant diagnostic benefit.** *H.A. Marton, D.P. Kolev, W.A. Langley, P.L. Nagy.* MNG Laboratories, Atlanta, GA., US.

Phenotype-based Next Generation Sequencing (NGS) panels are a powerful tool for clinical diagnostics and have made variant calling cheaper, faster, and more accessible. The availability of NGS panels has increased over the past few years to cover a range of conditions including inherited and rare diseases. A number of diseases assessed by NGS panels are known to have multiple genotypic causes, ranging from single nucleotide polymorphisms (SNPs) and copy number variants (CNVs) to repeat expansions. While NGS panels can precisely identify SNPs and CNVs, due to the current limitations of sequencing technology, NGS cannot accurately detect large repeat expansions. To date, more than 20 diseases have been found to be caused by repeat expansions, including Huntington's, Friedreich's Ataxia (FRDA), myotonic dystrophy, spinocerebellar ataxia (SCA), amyotrophic lateral sclerosis (ALS), frontotemporal dementia (FTD), Fragile X, and others. Research has shown that repeat expansions are responsible for as many as 1 in 3 cases of familial ALS and 1 in 4 cases of familial FTD. For other diseases, such as the rarer SCAs, the prevalence in the general population is currently unknown. By including repeat expansion testing with phenotype-based NGS panels, we can increase the clinical diagnostic sensitivity of the NGS panels. We currently perform repeat expansion testing for FRDA, C9ORF72, HTT, eleven SCAs, and Fragile X. Initial findings suggest that repeat expansion testing in conjunction with our neuromuscular and movement disorder panels increases positive reports by 5-20%.

**Diagnostic yield for neurological and neuromuscular disorder testing via high-depth multi-gene panel analysis with integrated sequence and copy number detection.** *T. Winder, A. Entezam, S.P. Taylor, H. White, M. Rabideau, S. Yang, C. Tan, J. Westbrook, S. Aradhya.* Invitae Corporation, San Francisco, CA.

**Objective** The objective of this study was to evaluate diagnostic yield using systematically curated multi-gene panels and simultaneous sequence and exonic copy number variant (CNV) detection. **Methods** Using high-depth next-generation sequencing (NGS), we investigated subsets of approximately 300 genes curated into ten disease-specific, multi-gene panels in 2,316 unrelated individuals diagnosed with neurological or neuromuscular disorders. Each gene in every panel was evaluated with our validated custom-built algorithms that use depth-of-coverage information and split-read detection to identify CNVs, small and large indels, and single nucleotide changes. **Results** We observed clinically reportable variants in 727 individuals. A definitive molecular diagnosis was reached for 27.9% of the 2,316 patients, and another significant percentage had results that would likely reach clinical significance with additional evidence such as observation of de novo occurrence or compound heterozygosity in trans. Whole-gene or exonic CNVs composed 39% of all diagnostic findings, two-thirds of which were identified in PMP22 or DMD. The highest observed diagnostic yield was obtained in DMD testing (65.6%), in which 66% of the findings were CNVs. The most frequently observed pathogenic variants were PMP22 CNVs. Diagnostic yields for muscular dystrophy, myopathy, neuropathy, and comprehensive neuromuscular disorders were 43.7%, 14.6%, 19.5%, and 19.1%, respectively. **Conclusions** Pre-curated multi-gene panels and our custom NGS-based system enable simultaneous sequence and CNV calling and, owing to high yield, are appropriate for diagnosing neurological conditions before exome sequencing.

**Milder-Dieker syndrome: Clinical, radiological, and molecular characterization.** A. Cortes, N. Laza, A. Latorre, C. Silvera, P. Garavito. Universidad del Norte, Barranquilla, Atlantico, Colombia.

Background: Miller-Dieker syndrome (MDS) (OMIM 247200) is caused by a microdeletion in chromosome band 17p13.3, that involves the genes *PAFAH1B1* (*LIS1*), *YWHAE*, *HIC1*, *PRPF8*, among others. MDS has a prevalence of 1/100.000 live births. These patients present brain anomalies, like convulsions and cognitive decline; also, facial dysmorphisms, like prominence in the frontal and occipital regions, small nose, anteverted nostrils, low set ears, prominent lips, micrognathia, and heart and genitourinary anomalies. The purpose of this case report is to present the clinical manifestations suggestive of a patient with MDS and its molecular studies for confirmation. Case report: 8-month-old female patient referred from Neuropediatrics to the Genetic clinic because of epilepsy, hypotonia, and global developmental delay; she was the first pregnancy full term of parents age-appropriate. On physical examination, she presented generalized hypotonia, fixed gaze, anteverted nostrils, carp-shaped mouth, micrognathia, large ears with mild posterior rotation, long neck, and cutaneous syndactyly between second and third toes. Brain MRI reported loss of cortical gyrus, lissencephaly, cortical thickening, and CT brain scan did not show brain calcification. Chromosomal Microarray Analysis demonstrated a 657kb microdeletion of 17p13.3. This region included 4 OMIM genes (*RFA1*, *R4RL1*, *DPH1*, *HIC1*, and *SMG6*). Discussion: MDS is a low prevalence disease that should be considered in patients with lissencephaly associated with facial dysmorphism and consider in the differential diagnosis the isolated lissencephaly and the microcephalic osteodysplastic primordial dwarfism. Our case did not show the typical brain calcifications described in the literature.

**Clinical application of whole exome sequencing in patients with uncertain neurological disorders.** Y. Lee<sup>1</sup>, J.S. Lee<sup>2,3</sup>, B.C. Lim<sup>2</sup>, Y. Yoo<sup>1</sup>, T.K. Yoo<sup>1</sup>, S. Lee<sup>1</sup>, J. Seo<sup>1</sup>, M. Lee<sup>1</sup>, J.M. Ko<sup>2</sup>, M. Choi<sup>1,2</sup>, J.H. Chae<sup>2</sup>. 1) Department of biomedical sciences, Seoul National University College of Medicine, Seoul, Republic of Korea; 2) Department of Pediatrics, Seoul National University College of Medicine, Seoul National University Children's Hospital, Seoul, Republic of Korea; 3) Department of Pediatrics, Gachon University Gil Medical Center, Incheon, Republic of Korea.

Inherent complexity of brain developmental processes inevitably generates patients with neurological defects of varying clinical outputs that frequently challenge conventional diagnostic criteria. Therefore, accurate diagnosis of the patients with unconventional or complicated pediatric neurological defects demands well-coordinated combination of robust genetic analytic ability and delicate clinical evaluation. Using a trio-based whole exome sequencing approach, we analyzed 310 patients with a broad spectrum of neurological disorders without any pathogenic variants revealed by the conventional methods. Overall, we identified disease-causing variants in 54.5% of the probands and 64.5% of them were previously reported as pathogenic. We also discovered 60 potentially pathogenic variants that require further functional assessments (19.4%). These genes containing novel variants are also enriched with the neuron part gene ontology classes (adjusted  $P = 0.0007$ ), and coexpression network analysis using developing human brain transcriptome data revealed that these genes are more tightly connected to the known disease associated genes than expected by chance (the best  $P = 0.0003$ ), providing support that these novel genes might have roles in human brain development. Furthermore, we introduce a few clinical vignettes that well illustrate potential diagnostic pitfalls that one could have encountered without this approach. Our results highlight the heterogeneity of clinical and genetic profiles of pediatric neurology patients and propose utility of whole exome sequencing for improved patient care and discovery of novel pathophysiology mechanisms.

**2466F**

**Molecular diagnosis of Colombian patients with myopathies through next generation sequencing panel.** R. Garcia-Robles<sup>1</sup>, P.A. Ayala-Ramirez<sup>1</sup>, T. Pineda<sup>2</sup>, M. Garcia-Acero<sup>1</sup>, M. Guerra<sup>1</sup>, F. Suarez-Obando<sup>1</sup>. 1) Instituto de Genetica Humana, Pontificia Universidad Javeriana, Bogota, Colombia; 2) Biotecgen, Bogota, Colombia.

**Introduction:** Myopathies are a group of disorders characterized by muscle weakness, with a high clinical overlap that makes the diagnosis tough to establish among all the phenotypes. Recently, some new tests based on NGS (next generation sequencing) have been used to detect the molecular alteration and allow an adequate diagnosis of patients. Additionally, the molecular characterization of the disease is necessary for genetic counseling, prognosis, and management. **Methodology:** Since January of 2014 to December of 2016 we assessed 50 patients with clinical suspicion of muscular dystrophy using the Invitae Comprehensive Muscular Dystrophy Panel. This panel analyzes sequence changes and exonic deletions/duplications in 55 genes associated with muscular dystrophies. The panel includes: *ANO5, B3GALNT2, B4GAT1, CAPN3, CAV3, CHKB, COL6A1, COL6A2, COL6A3, DAG1, DES, DMD, DNAJB6, DPM1, DPM2, DPM3, DYSF, EMD, FHL1, FKRP, FKTN, GAA, GMPPB, ISPD, ITGA7, LAMA2, LARGE, LMNA, MYOT, PLEC, PNPLA2, POMGNT1, POMGNT2, POMK, POMT1, POMT2, SGCA, SGCB, SGCD, SGCG, SYNE1, TCAP, TMEM43, TMEM5, TNPO3, TOR1AIP1, TRAPPC11, TRIM32, TTN*. **Results:** We analyzed 51 patients clinically diagnosis with myopathy/muscular dystrophy (range of age: 2 to 61 years). In 4 patients the diagnosis was not established. The 3 most frequent diagnoses were: Duchene/Becker muscular dystrophy (58%), Titinopathy (8%) and Bethlem myopathy related to COL6A1 (6%). **Conclusions:** Molecular diagnosis based on NGS panels increase the possibility of precise diagnose of muscular diseases, (myopathies and muscular dystrophies), where the phenotype is highly overlapped. The increased use of NGS, in the diagnostic of specific groups of diseases, allows the improvement of its clinical utility, clarify its indications, and limitations, and gives to the physician, a highly useful tool for the improvement of genetic counseling and treatments based on accurate diagnosis. We used the Invitae Comprehensive Muscular Dystrophy Panel in 50 individuals with clinical suspicion of muscular dystrophy, reaching specific diagnostic rate in 92% of the cases.

**A novel approach distinguishing the SMN1 and SMN2 genes in spinal muscular atrophy (SMA) using a linked-read NGS custom panel.** R. Pellegrino<sup>1</sup>, C. Kao<sup>1</sup>, M. Gonzalez<sup>1</sup>, F. Mafra<sup>1</sup>, J. Garifallou<sup>1</sup>, C. Kaminski<sup>1</sup>, L. Tian<sup>1</sup>, S. Garcia<sup>2</sup>, O. Thomas Mueller<sup>3</sup>. 1) Center for Applied Genomics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) 10XGenomics, Pleasanton, CA; 3) Department of Pathology and Laboratory Medicine Johns Hopkins All Children's Hospital, FL.

SMA types I-IV are caused by loss of both copies of the survival motor neuron 1 (*SMN1*) gene in 5q13. Expression of the SMN protein is essential for motor neuron survival. Most functional SMN protein is produced by *SMN1*, with a small contribution from a paralog, *SMN2*. Resolving *SMN1/SMN2* by sequencing is challenging using short read NGS due the unstable high homology regions containing a variety of pseudogenes and repetitive elements subject to "de novo" rearrangements. Sequencing methods reliant on short reads have difficulty defining large structural variations and repetitive gene sequences. Advances in microfluidics technology and precision reagent delivery allow long-range information (short reads) to be rescued and preserved through the use of the 10x Genomics Chromium platform. Each input DNA fragment (~40-200kb) is partitioned into a gel-bead in emulsion (GEM). This approach can be extremely powerful to define breakpoints, large rearrangements and "dark-matter" regions such as the one involving the SMA genes. **METHODS** We sequenced subjects with clinically diagnosis of SMA, using the Chromium technology (10X Genomics) to generate barcoded reads that identify segments that are immediately contiguous to each other in the genome. High Molecular Weight (HMW) DNA was isolated and QC performed with Genomic TapeStation to verify the size of the DNA (where all samples achieved the mandatory 60Kb). In the microfluidic Genome Chip, a library of Genome Gel Beads is combined with an optimal amount of HMW template gDNA in Master Mix and partitioning oil to create Gel Bead-In-Emulsions (GEMs). The barcoded libraries then underwent a special custom baits design (target enrichment) using an expanded prototype OneSeq bait set (Agilent SureSelect) containing "bridging baits" spaced within intronic and intergenic regions to preserve long-range information following capture and Illumina sequencing **RESULTS** We use linked read technology coupled to whole exome sequencing to differentiate between single nucleotide variants, indels, and larger structural variants residing in the *SMN1* vs *SMN2*. This was done through accurately phasing of the compound mutations in the complex region for all cases.

**Detection rate of chromosomal microarray in individuals with ADD/ADHD.** A.L. Baxter, A. Ortega, C. Bracken, E.R. Harward. Lineagen, Inc., Salt Lake City, UT.

Chromosomal microarray (CMA) is a guideline recommended first-tier genetic test for individuals with autism spectrum disorder (ASD), developmental delay (DD), intellectual disability (ID), or multiple congenital anomalies (MCA). It is often used for assessing the underlying genetic cause in other childhood disorders, although the utility is not as well established. Attention deficit disorder (ADD) and attention deficit hyperactivity disorder (ADHD) affect 11% of children in the United States and are frequently part of the phenotype of individuals tested by CMA. Additionally, over 150 genetic conditions have ADD/ADHD as a documented clinical feature. However, few studies have assessed the utility of genetic testing for individuals with ADD/ADHD. We retrospectively reviewed the ICD codes and medical records submitted for individuals who had high-resolution CMA through our laboratory between July 2012 and April 2017 to identify those with ADD/ADHD. A total of 1,891 individuals with ADD/ADHD were identified and, of those, 8.4% (159) had an abnormal result. There was a subset of 165 individuals with ADD/ADHD who had other clinical features but did not have ASD, DD, ID, or MCA (typical first-tier clinical indications); 7.3% (12) of that group had an abnormal result. Fifteen individuals had only ADD/ADHD listed as the clinical indication for testing and 13.3% (2) of them had an abnormal result. These findings demonstrate that ADD/ADHD has a similar CMA detection rate as typical first-tier indications. Therefore, CMA should be considered in the evaluation of an individual with ADD/ADHD.

**Repeat expansions that cause central nervous system disorders present challenges for long-read sequencing technologies.** M.T.W. Ebbert, S.L. Farrugia, K. Jansen-West, M. Prudencio, M. van Blitterswijk, R. Rademakers, L. Petrucelli, J.D. Fryer. Neuroscience, Mayo Clinic, Jacksonville, FL.

**Background.** Structural variants are the greatest source of variation in the human genome, affecting an estimated 13% of an individual's genome, and long-read sequencing technologies such as PacBio and Oxford Nanopore Technologies (ONT) provide an exciting opportunity to understand how an individual's genome structure affects her health. Many types of structural variants exist, including insertions and deletions (INDELs), and translocations, amongst others, and researchers are discovering how structural mutations cause several diseases, including cancer, autism, and schizophrenia. Structural mutations like INDELs are commonly reported, but repeat expansions are a special class that has received little attention. Repeat expansions are an insertion where a given base nucleotide sequence (e.g., CAG) is expanded to be repeated hundreds to thousands of times, for unknown reasons. Numerous CNS diseases, like Huntington's disease, spinocerebellar ataxias (SCA's), frontotemporal dementia (FTD), and Amyotrophic Lateral Sclerosis (ALS) are caused by repeat expansions, many of which are GC-rich, making them difficult to sequence. We tested whether PacBio and ONT sequencing platforms can accurately sequence repeat expansions for SCA36 (GGCCTG in *NOP56*), Fuch's disease (TGC in *TCF4*), and ALS/FTD (GGGGCC in C9orf72). **Methods.** We cloned specified repeats into 5 plasmids of known size: (1) SCA36 (66 repeats); (2) Fuch's disease (220 repeats); (3) ALS/FTD (423 repeats); (4) ALS/FTD (774 repeats); and (5) a control plasmid with no repeats. All plasmids were digested with a single-cut restriction enzyme and sequenced on both the PacBio RS-II and the ONT's MinION. Plasmids were verified for correct size on a gel. **Results.** All repeat plasmids presented significant challenges to both sequencing technologies, while both platforms performed seamlessly on the control plasmid. Both platforms sequenced the primary plasmid backbones without issue until they reached the given repeat region, where coverage dropped dramatically. Particularly interesting was the number of reads where the sequencers appeared to read "through" the repeat, but were missing significant portions of the repeat sequence. i.e., reads contained sequence on both sides of the repeat region, but the number of repeats present in the final sequence was significantly lower than the true number of repeats. **Conclusion.** While the repeats presented significant challenges, these can be overcome through informatic improvements.

**2470W**

**Attacking a VUS from multiple angles: An integrated and functional approach for reclassifying variants of uncertain significance.** *R.N.T. Lassiter, J. Wang, E.C. Weltmer, J. Tinker, H. Newman, T. Carter, S. Ichikawa, A. Chamberlin, I. Petrik, R. Karam, T. Pesaran.* Clinical Diagnostics, Ambry Genetics, Aliso Viejo, CA.

Neurodevelopmental disorders (NDDs) involve a wide range of symptoms and severity. Individuals may present with multiple indications including epilepsy, autism, intellectual disability, and developmental delay. The nonspecific nature of NDDs can lead to significant diagnostic challenges. Multi-gene panel testing (MGPT) can help to stratify NDDs and identify causative variants. Though large MGPT allows for the molecular diagnosis of many possible rare diseases, they can also result in numerous variants of uncertain significance (VUS). High VUS rates can be confusing and discouraging to both patients and clinicians. Here we describe three effective approaches for reducing VUS rates in neurology MGPT. Combining parental co-segregation studies, protein structural analysis, and RNA functional splicing assays with additional strong lines of evidence, led to a significant decrease in VUS rates. Parental co-segregation studies were performed following initial results of the proband's neurology MGPT. Parental samples were tested for all VUS detected in proband MGPT in autosomal dominant (AD) and X-linked (XL) genes. Of the 200 VUS submitted for parental co-segregation studies, approximately 5% (10/200) were upgraded to variant likely pathogenic (VLP), 35% (70/200) were downgraded to variant likely benign VLB, and 60% (120/200) remained VUS. These data show that testing of parental samples is informative in ~40% of VUS. Protein structural analysis can be leveraged to identify and explain the effects of a variant on protein function. The structure based assessment strategy utilized for classification consists of several complementary tools (Rosetta, FoldX, ELM, etc.) to address the distinct structural impact of a variant. Of the 49 VUS with a structural assessment, 96% contributed to reclassification. Approximately 78% (38/49) were upgraded to likely pathogenic VLP, 18% (9/49) were downgraded to likely benign VLB, and 4% (2/49) remained VUS. RNA functional studies, designed to identify alternative splicing, resulted in reclassification from VUS to likely benign VLB in 100% (3/3) of splicing cases. These data show that a comprehensive approach to variant reclassification is an effective method for reducing VUS rates in neurology MGPT.

**2471T**

**Parental variant study is informative for variant classification in significant number of neurodevelopment genes.** *E.C. Weltmer, R. Lassiter, S. Ichikawa, T. Pesaran, J. Tinker, H. Newman, T. Carter, N. Ghahramani, L. Guidugli, J. Wang.* Ambry Genetics, Aliso Viejo, CA.

Parental variant study (PVS) can provide powerful segregation data for variant classification. However, in genes with reduced penetrance, variable expressivity, or a non-specific associated phenotype, common in neurodevelopmental disorders, PVS may be less powerful. We sought to identify characteristics common to genes for which PVS was informative for variant classification. Retrospective analysis of 100 cases for which PVS was completed July 2016-March 2017 for variants of unknown significance (VUS) found on multi-gene panels for neurodevelopmental disorders. Parental samples were received after the proband report was issued. VUS in autosomal dominant (AD) and X-linked (XL) genes were eligible for PVS. Variants were classified using a 5-tier system based on established algorithms. Genes in which PVS was not informative were compared. 179 unique VUS were found in 84 AD or XL genes. Seven VUS (4%) were upgraded to likely pathogenic (VLP), 68/179 (38%) downgraded to likely benign (VLB), 104 (58%) remained VUS. The 7 upgraded VUS were found in 5 genes: *ATP1A2*, *CHD2*, *CREBBP*, *KCNQ2*, *PCDH19*; all due to *de novo* event in proband. 52/68 (76%) downgraded VUS were due to informative PVS (found in asymptomatic parent); these 52 VUS were found in 33 genes. Of these 33 genes, 5 (15%) had  $\geq 3$  unique VUS downgraded per gene: *CHD8*, *EHMT1*, *FOXP1*, *KCNT1*, *PACS1*; 28 had 1-2 downgraded VUS per gene. PVS was informative for 38/104 (38%) VUS in 29 genes but VUS were not reclassified due to lack of additional supportive evidence (parental inheritance alone insufficient). PVS was not informative for 44/104 (42%) VUS found in 15 genes with multiple inheritance pattern, incomplete penetrance, variable expressivity, or non-specific disease phenotype (e.g., developmental delay, epilepsy). PVS was also not informative for 14/104 (13%) VUS inherited from a symptomatic parent, and 8 (8%) with only one parent tested. PVS was informative for 45% (38/84) of genes with VUS and 19% (38/196) of all genes analyzed. PVS was most likely to be informative for genes associated with a well described syndrome, e.g., CHARGE, Kleefstra, Rubinstein-Taybi syndrome, or severe, early-onset phenotype, e.g., infantile epileptic encephalopathy. Understanding the types of genes for which PVS is likely to be informative may be useful for clinicians coordinating parental testing. Further understanding of the genes themselves may allow for effective variant classification using evidence not limited to PVS.

Hereditary neurological diseases (HNDs) are debilitating and often untreatable disorders caused by mutations in many known genes; however the genetic basis of many others is still not established. In addition, despite its genetic diversity, studies of hereditary neurological disorders in the African population have been limited. We have aimed to characterize families with HND and to identify the underlying genetic defects. Patients have undergone neurological examination, and laboratory evaluation was performed to consolidate our diagnoses or exclude common causes. For genetic analysis, candidate gene analysis was done in some families and exome sequencing coupled with linkage analysis was performed in other cases. To date, 587 participants from 141 families have been enrolled. The mean age was 26.9 years and sex ratio was 1.18 (male:female). Consanguinity was reported by 40% of families, and a recessive inheritance pattern was found in 34%. Major clinical entities included ataxia, muscle disease, hereditary spastic paraplegia (HSP), Charcot-Marie-Tooth disease (CMT), Huntington's disease (HD) and progressive myoclonic epilepsy (PME). Several families displayed unusual features. Genetic diagnosis was established for 37 families. Among them were four novel mutations in three and one families with HSP and CMT, respectively. Interestingly, many of these diseases were not previously described in Africa, especially in sub-Saharan Africa. While the majority were described broadly elsewhere, one disease was identified in only one Chinese family and another in an Arab family in Israel. Exome sequencing and disease gene panel testing have excluded known disease-causing genes in several families; suggesting new variants or entities. Linkage analysis has identified regions of interest in some families and exome sequencing variants in the regions of interest are being investigated. Our study established for the first time the molecular diagnosis of HNDs in sub-Saharan Africa and expanded their genetic epidemiology. Our results open the way for the discovery of new disease-causing genes in this and other populations. **Keywords:** neurogenetics, genetic diversity, novel mutations, Mali.

**Characterization of copy number variations of genomic regions containing long noncoding RNA in children with neurological phenotypes.** S.C. Smith<sup>1</sup>, V. Srivastava<sup>2</sup>, J. Saunders<sup>3</sup>, N. Miller<sup>3</sup>, L.D. Cooley<sup>1,2</sup>, E.A. Repnikova<sup>1,2,3</sup>. 1) Department of Pathology/Genetics, Children's Mercy Hospital, Kansas City, MO; 2) University of Missouri-Kansas City School of Medicine, Kansas City, MO; 3) Center for Pediatric Genomic Medicine, Children's Mercy Hospital, Kansas City, MO.

Children with congenital malformations and neurological disorders comprise 5-10% of the general pediatric population and represent the largest group referred for genetic evaluation. Microarray analysis provides a diagnostic yield of ~10-15% for patients with such conditions. While the diagnostic yield from whole exome and genome sequencing is significantly higher at ~25-34%, a significant proportion of affected children is still undiagnosed. A definitive genetic diagnosis remains elusive for many children because their phenotypic features are not specific and the majority of them do not have identifiable mutations or copy number variations (CNV) of the known clinically significant genes. In recent years, comprehensive analysis using RNA deep sequencing showed that a large number of long non-coding RNAs (lncRNAs) display neuronal-specific expression, suggesting their role in neurological disorders. In this study we screened for CNVs containing lncRNA in children referred for clinical microarray in order to identify new diagnostic and therapeutic targets for further research. In a review of 4647 patients referred to our laboratory for microarray analysis for various clinical indications during 2008-2012, we identified 50 individuals (35 males/15 females) with deletion (33 patients) or duplication (17 patients) of a genomic region containing only lncRNA(s). No genetic diagnosis was established for these patients. The average size of a deletion or duplication was 249.5 kb and 266.3 kb, respectively. Of those 50 patients, 48 (~96%) presented with various neurological disorders (ex. autism, developmental delay, epilepsy) compared with 58% of patients overall who had neurological phenotypic features for the same period of time. We found that 11 CNVs containing lncRNA were recurrent and 22 were unique. Interestingly, 16 CNVs containing lncRNAs in our dataset were not recorded in the benign CNVs per the Database of Genomic Variants (DGV), and 18 are present in the DGV, but at a frequency of 0.06% or lower. The highest frequency of such CNVs was observed for chromosomes 5, 8, 21 and X. Our initial investigation seems to support the hypothesis that lncRNA may be involved in neuronal development in humans. Further studies of CNVs containing lncRNAs, analysis of lncRNA tissue-specific expression and the genes they regulate will help to clarify how lncRNAs may influence disease susceptibility.

**Analysis of total RNA in the cerebrospinal fluid environment.** *S.L. Farrugia, M.T.W. Ebbert, K. Jansen-West, M. Prudencio, R. Rademakers, M. van Blitterswijk, L. Petrucelli, J.D. Fryer.* Neuroscience, Mayo Clinic, Jacksonville, FL.

Cerebrospinal fluid (CSF) shields the brain from physical trauma and pathogens while also aiding in cerebral circulation to supply the brain with blood. CSF has shown great potential as a predictive and diagnostic tool for a wide range of diseases and conditions such as multiple sclerosis, Alzheimer's Disease, and Parkinson's Disease. Metabolites in CSF have been examined for their role in depression and several behavioral disorders. Although metabolites and proteins in CSF have been analyzed extensively with conventional methods, these experiments have not accounted for all of the valuable information present in the RNA. MicroRNAs in CSF have received some research attention due to their potential role as a biomarker in brain diseases, however, the rest of the RNA population has barely been investigated. Analysis of total RNA in CSF can provide a plethora of information vital to understanding CSF function and various illnesses. We are collecting CSF from lumbar punctures of patients with various health diagnoses, including healthy controls. Total RNA is isolated, polyadenylated, and sequenced. The reads are then base called and aligned with the Burrows-Wheeler Aligner (BWA). Reads that are not able to be aligned to the human genome are tested for alignment with microbial species (fungi, bacteria, and virus). The study of total RNA in CSF will provide a more complete picture of the cerebral environment, including the "normal" RNA population in healthy individuals. Additionally, any bacterial RNA discovered can prompt the characterization of the "CSF microbiome." In future studies, CSF of diseased patients can be compared more extensively with control patients using unbiased or targeted RNA analysis to search for meaningful differences between the two groups. The categorization and evaluation of total RNA in CSF is essential to utilizing the full capabilities of CSF as a biomarker.

**Optimized, modular, target-enrichment gene panels for the detection of genetic variants associated with neurological disorders.** *A.B. Emerman<sup>1</sup>, K.M. Patel<sup>1</sup>, S.K. Bowman<sup>1</sup>, S.M. Adams<sup>1</sup>, C.D. Elfe<sup>1</sup>, T.B. Davis<sup>2</sup>, S. Russello<sup>2</sup>, A. Barry<sup>2</sup>, C.L. Hendrickson<sup>1</sup>.* 1) Directed Genomics, Ipswich, MA; 2) New England Biolabs, Ipswich, MA.

Next-generation sequencing (NGS) is increasingly being used to better understand the genetic basis of inherited neuropathies and neuromuscular disorders, as well as for diagnostic testing for these conditions. The enrichment of targets of interest prior to NGS reduces sequencing costs while focusing data collection on the desired regions, resulting in greater coverage of relevant regions of the genome relative to whole genome sequencing. The diversity of neurological disorders necessitates customized gene panels for focused diagnostic tests or genomic studies; however, custom gene panels are often costly and time-intensive to develop de novo. To reduce cost and improve turnaround time for custom gene panels for neurological studies and diagnostics, we have predesigned bait sets specific to over one hundred genes associated with these disorders for use with the NEBNext Direct target enrichment kit. These bait sets are a part of a larger collection of predesigned content that has been optimized for specificity and uniform coverage, and subsets of genes from this collection can be selected and pooled into customized panels with a rapid turnaround time. The NEBNext Direct technology converts targets of interest into sequencer-ready libraries in a 1-day protocol while removing off-target sequences and incorporating unique molecular identifiers (UMIs) and sample indexes. Here we demonstrate that high-performing custom panels can be rapidly generated to target diverse neurological disorders using the predesigned bait sets. Subsets of genes from the predesigned neurological gene content were combined into custom panels to target specific neurological disorders. Each unique panel maintained high specificity and uniformity of coverage of the selected targets regardless of panel size or content. Additionally, we demonstrate that genetic variants within the selected targets were confidently detected with 10 ng of input DNA.

**Autism spectrum disorder: A study of series of cases with genetic alterations.** J.L. Mussolini, A.M. Freitas, D. Brunoni. Universidade Presbiteriana Mackenzie, São Paulo, Brazil.

The Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder with communication and social interaction impairments, also repetitive and restricted behaviors. Affecting about 1% of the population, ASD has a heterogeneous clinical picture, besides several syndromes and psychopathies in comorbidity. Between the causal factors, it's known that the genetic causes represent up to 20% being that the copy number variations (CNVs) in microdeletions and microduplications forms are the principal ones. These cytogenomic alterations involve dozens of genes. The objective of this present work is to describe a convenience sample found in 6 ASD patients. The patients were investigated in the Clínicas TEA of Universidade Presbiteriana Mackenzie and the tests were performed in commercial laboratories. Five patients were diagnosed by microarray and one by exome sequencing. The genomic coordinate interpretation was performed with usual bioinformatics tools, like Genome Browser. The chromosomal regions involved were: 3p26.3; 6q; 7q31.3; 7q36.3; 9p21.1; 17q22 and the possible relevant genes in the manifestation of the clinical picture were: *B4GALT1*, *PTPRN2*, *CNTN4*, *CNTN6*, *OXTR*, *GRM7*, *SETD5*, *BZRAP1*, *SYNGAP1* e *IMMP2L*. These results were already been published in other patients with ASD. Hundreds of ASD patient samples are mentioned in the international literature. Individuals who present genetic alterations similar to the studied patients have in common the intellectual disability. Thus, this clinical feature should be the main indication to investigate the genetic cause comorbidity in patients with ASD. Both microarray and exome are of great use and importance in diagnosis due to their high resolution. It is clear that the case study should be expanded using the genetic tests already available clinically. This knowledge will improve the understanding of the changes caused by genetic alterations in individuals with ASD.

**An inherited distal 16p11.2 deletion demonstrates association with rhizomelic shortening, variable expressivity, and incomplete penetrance for psychiatric illness: A case report.** E. Morris<sup>1,2</sup>, B. McGillivray<sup>1</sup>, A. Lehman<sup>1</sup>, J. Austin<sup>1,2</sup>. 1) Department of Medical Genetics, University of British Columbia, Vancouver, BC; 2) Department of Psychiatry, University of British Columbia, Vancouver, BC.

**Background:** The most commonly reported 16p copy number variant (CNV) - 16p11.2 deletion syndrome (16pDS) (~600 kb; 29.5 -30.1 Mb) - is associated with intellectual disabilities (ID)/developmental delays (DD), schizophrenia (SZ), congenital anomalies, dysmorphic features and obesity. Non-overlapping "distal" 16p11.2 deletions (~200 kb; 28.7 -28.9 Mb) are less commonly reported, but have a variable phenotype similar to that of 16pDS. We report here on a parent/child dyad who share a distal 16p11.2 deletion. **Methods:** Patient 1 (index) was assessed (for indications including seizures, DD, and short limbs) at ages 2, 17, and 36, when she had clinical chromosomal microarray (CMA) (Affymetrix Cytoscan HD array, clinical thresholds: 200 kb (deletions), 400 kb (duplications), Chromosome Analysis suite (v2.0.0 195)). Fluorescence *in situ* hybridization (FISH) was used to confirm the deletion and determine origin. **Results:** Patient 1 was born at term to non-consanguineous parents. A 46XX karyotype was confirmed at age 2 and 17 (testing indications: myoclonic seizures, DD, rhizomelic shortening of upper limbs). At age 17, she was also noted to have small hands (<3rd %ile) and feet (-3.5 SD), large posteriorly rotated ears (+3 SD), brachycephaly, high nasal bridge, and low posterior hair-line. She had developed psychosis at 13, and received diagnoses of bipolar disorder type I, ADHD, possible ASD and ID. At 37, she is obese with impaired fasting glucose, and ongoing psychiatric symptoms. CMA revealed a 238Kb deletion at 16p11.2 (28 819 028 – 29 056 973; hg19) confirmed by FISH as being paternally inherited. Patient 2 is the 69 year-old father of Patient 1. He completed high school despite difficulties, and is not obese but has diabetes mellitus type II. He has rhizomelic shortening of both upper limbs but no history of psychiatric illness. **Discussion:** This report supports emerging evidence that this CNV is associated with psychiatric symptoms, including bipolar disorder, and contributes to the generation of a more thorough clinical description of the phenotypic range of distal 16p11.2 deletion, which we suggest, includes rhizomelic limb shortening.

**Diagnostic yield of chromosomal microarray in a community sample of adults with schizophrenia.** C. Lowther<sup>1</sup>, G. Costain<sup>2</sup>, J. Waserman<sup>3</sup>, K. Boyd<sup>4</sup>, A. Noor<sup>5</sup>, M. Speevak<sup>6</sup>, D.J. Stavropoulos<sup>6</sup>, D. Merico<sup>6</sup>, J. Wej<sup>6</sup>, A.C. Lione<sup>6</sup>, C.R. Marshall<sup>6,7</sup>, S.W. Scherer<sup>6,8</sup>, A.S. Bassett<sup>6,10</sup>. 1) University of Toronto, Toronto, Ontario, Canada; 2) Division of Clinical and Metabolic Genetics, The Hospital for Sick Children, Toronto, Ontario, Canada; 3) Humber River Regional Hospital, Toronto, Ontario, Canada; 4) Department of Psychiatry & Behavioural Neurosciences, McMaster University, Hamilton, Ontario, Canada; 5) Laboratory Medicine and Pathobiology, University of Toronto, Toronto, Ontario, Canada; 6) The Centre for Applied Genomics and Program in Genetics and Genome Biology, The Hospital for Sick Children, Toronto, Ontario, Canada; 7) Genome Diagnostics, Department of Paediatric Laboratory Medicine, The Hospital for Sick Children, Toronto, Ontario, Canada; 8) Molecular Genetics and McLaughlin Centre, University of Toronto, Ontario, Canada; 9) Department of Psychiatry, University of Toronto, Toronto, Ontario, Canada; 10) Toronto General Hospital Research Institute, University Health Network, Toronto, Ontario, Canada.

Schizophrenia (SCZ) is a severe psychiatric disorder associated with significant impairments in intellectual functioning. Rare copy number variations (CNVs) have been established to play an important role in the aetiology of SCZ. Additionally, CNVs associated with SCZ have been shown to negatively affect IQ in population-based controls without any major neuropsychiatric disorder. However, very few studies have examined the impact of rare CNVs on IQ in SCZ. The aim of this study was to perform genome-wide microarray testing in a community ascertained cohort of adults with SCZ to determine the diagnostic yield of rare CNVs across a range of IQ levels. We recruited 546 adults of European ancestry with SCZ from six community psychiatric clinics across Central and Eastern Canada. Each individual was assigned to one of three IQ sub-groups (average IQ, borderline intellectual functioning, ID) based on standardized IQ tests and/or educational attainment. We used rigorous methods to detect genome-wide rare CNVs from high resolution SNP microarrays and compared the burden of rare CNVs >100 kb deemed to be clinically relevant by a laboratory cytogeneticist between each of the IQ sub-groups. There were 39/546 (7.1%; 95% CI 5.2-9.7%) SCZ subjects with at least one pathogenic CNV detected. However, the yield of pathogenic CNVs was not uniformly distributed across the SCZ cohort: individuals with SCZ and average IQ had the lowest yield of pathogenic CNVs (n=9/325; 2.8%), followed by borderline intellectual functioning (n=9/130; 6.9%), and ID (n=15/62; 24.2%). In contrast, there was no significant difference in the yield of CNVs classified as variants of unknown significance between any of the IQ sub-groups. Many of the pathogenic CNVs identified in this study have been previously associated with SCZ, including 1q21.1 duplications, 2p16.3 deletions overlapping *NRXN1*, 2q13 deletions/duplications, 15q11.2-q13.1 duplications, 16p11.2 deletion/duplications, and 22q11.2 deletions. We also identified several CNVs that have not been previously associated with SCZ, including a 3q27.1-q27.2 deletion, 6q26-q27 deletion, 13q14.13-q14.3 deletion, Xp11.23-p11.22 duplication, and an Xp22.33-p22.2 deletion. Finally, we identified a novel 280 kb 3p26.1 deletion overlapping two genes, *ITPR1* and *SUMF1*, which has not been previously reported in the literature. The results of this study have important implications for clinical practice and may help inform future rare variant studies of SCZ.

**Clinical utility of exome sequencing in individuals with large homozygous regions.** A. Prasad<sup>1</sup>, M.A Sdano<sup>2</sup>, R.J. Vanzo<sup>1</sup>, M.A. Serrano<sup>1</sup>, C.H. Hensel<sup>1</sup>, E.R. Wassman<sup>1</sup>. 1) Lineagen, Salt Lake City, UT; 2) Department of Biochemistry, University of Utah, Salt Lake City.

Chromosomal microarray analysis (CMA) is recommended as the first-tier clinical diagnostic test for individuals with developmental disabilities. CMA platforms with single nucleotide polymorphism probes can detect large homozygous regions within the genome, which represent potential risk for recessively inherited disorders. Clinical laboratories typically proceed with targeted sequencing by selecting candidate genes within the homozygous regions based on a patient's phenotype. However, heterozygous variants associated with autosomal dominant or X-linked conditions could also explain at least part of the patient's phenotype. The purpose of this study is to evaluate heterozygous variants in a cohort of individuals with large homozygous regions. We performed whole exome sequencing (WES) in 53 patients referred to our clinical laboratory for a variety of phenotypes including autism spectrum disorder (ASD), developmental delay, epilepsy, intellectual disability or microcephaly where homozygosity was detected by CMA. We have previously examined homozygous variants and identified pathogenic or likely pathogenic variants in 6/53 cases (11%). These variants, in *GJB2*, *TPP1*, *SLC25A15*, *TYR*, *PCCB*, and *NDUFV2*, are implicated in a variety of diseases. In this study, we investigated heterozygous likely protein disrupting variants across the whole exome and identified an additional 8/53 (15%) cases with pathogenic or likely pathogenic variants. We found one of the patient to have a homozygous pathogenic variant in *TPP1* as well as a likely pathogenic hemizygous variant in the *OTC* gene. In one of the patients with strabismus, dysmorphic ear shape, language and developmental delays and ASD, we identified a pathogenic missense variant in the *SOS1* gene which is reported to cause Noonan syndrome. In two unrelated patients with muscle weakness, we identified a likely pathogenic hemizygous variant in *PNPLA4* which has been shown to cause mitochondrial respiratory chain complex deficiencies. The other likely pathogenic variants were in the *CADM1*, *HBB*, *SFTPC* and *ASMT* genes. These findings have important medical management implications including screening and treatment options. Our study highlights the clinical utility of WES in individuals whose CMA uncovers homozygosity. Importantly, our results demonstrate that some of the causative mutations do not lie in regions of homozygosity, suggesting that the appropriate follow up test is WES rather than a targeted approach.

Phelan-McDermid syndrome (PMS) is characterized by a variety of clinical symptoms with heterogeneous degrees of severity, including intellectual disability (ID), absent or delayed speech, and autism spectrum disorders (ASD). It results from a deletion of the distal part of chromosome 22q13 that in most cases includes the *SHANK3* gene. *SHANK3* is considered a major gene for PMS, but the factors that modulate the severity of the syndrome remain largely unknown. In this study, we investigated 85 patients with different 22q13 rearrangements (78 deletions and 7 duplications). We first explored the clinical features associated with PMS, and provide evidence for frequent corpus callosum abnormalities in 28% of 35 patients with brain imaging data. We then mapped several candidate genomic regions at the 22q13 region associated with high risk of clinical features, and suggest a second locus at 22q13 associated with absence of speech. Finally, in some cases, we identified additional clinically relevant copy-number variants (CNVs) at loci associated with ASD, such as 16p11.2 and 15q11q13, which could modulate the severity of the syndrome. We also report the first inherited *SHANK3* deletion transmitted to five affected daughters by a mother without ID nor ASD, suggesting that some individuals could compensate for such mutations. In summary, we shed light on the genotype-phenotype relationship of patients with PMS, a step towards the identification of compensatory mechanisms for a better prognosis and possibly treatments of patients with neurodevelopmental disorders.

**Post-zygotic copy number variations in autism spectrum disorder discordant monozygotic twins.** D.L. Nuñez<sup>1</sup>, C. Ospina<sup>2</sup>, F. Paredes<sup>2</sup>, M.C. Lattig<sup>1</sup>. 1) Universidad de Los Andes, Colombia; 2) Liga Colombiana de Autismo.

Copy Number Variations (CNVs) are deletions and duplications which change the number of copies of chromosome regions. CNVs may contribute greatly to genomic variation in human population, and also provide a potential risk to develop a wide kind of disorders such as Autism Spectrum Disorder (ASD). Pathogenic and normal CNVs are formed in germinal and post-zygotic cells. Specifically, meiotic formation of CNVs is mediated by mistakes in homologous recombination while post-zygotic CNVs are formed by mechanism related with DNA replication (Campbell, 2015). A minority of CNVs associated to genetic disorders are inherited, suggesting that most pathological CNVs are developed by germinal or early post-zygotic processes. Indeed, the most critical period for somatic changes is the early embryonic development due to high cell division rate (Iourov, 2010). Current studies with monozygotic (MZ) twins, genetically identical at conception have shown CNVs discordances in elder age (Koldby, 2016). Moreover, although post-zygotic mutations are poorly characterized in neurodevelopmental disorders, recent evidence suggest the role of multi-tissue mosaic mutations in individuals with ASD (Freed D., 2016). We report a Colombian family with both parents and 3 sons: an older healthy brother and a couple of phenotypically discordant MZ twins (one MZ twin has clinical diagnosis of ASD while the other MZ twin does not). The clinical evaluation was completed with the Autism Diagnostic Interview-Revised (ADI-R) and the Autism Diagnostic Observational Schedule (ADOS) tests. DNA from blood samples of MZ twins were evaluated by SNP 6.0 microarray of Affymetrix, and the .CEL files were analyzed by PennCNV software. We found a small 46Kb deletion present only in the ASD twin. The deletion includes the complete exon 2 of the *GPHN* gene (GENE ID 10243). This gene encodes a neuronal assembly protein named Gephyrin that interacts with subunits of GABA<sub>A</sub> receptors regulating its clustering and diffusion in postsynaptic membrane (Dejanovic, 2015). Indeed, exonic deletions in *GPHN* have been implicated in risk for schizophrenia, autism and epilepsy (Balan, 2017). Moreover, the reduction in its expression levels has been related with Alzheimer disease (Puthiyedth, 2016). This result supports previous observations that somatic CNVs could be also responsible of neurodevelopmental disorders such as ASD.

**Chromosomal microarray analysis of pediatric patients with autism spectrum disorders and intellectual disabilities.** A.R. Patel<sup>1</sup>, D.D. Jhala<sup>2</sup>, S.S. Chettiar<sup>1</sup>. 1) Department of Genetics, GeneXplore Diagnostics and Research Center Pvt. Ltd., Ahmedabad, Gujarat, India; 2) Human Genetic Center, Department of Zoology, Gujarat University, Navrangpura, Ahmedabad, Gujarat, India.

Autism spectrum disorder (ASD) and Intellectual disabilities (ID) are complex and phenotypically heterogeneous neurodevelopmental disorders characterized by significant deficit in cognitive and adaptive skills, debuting during the developmental period. Chromosomal microarray (CMA) offers superior sensitivity and high resolution survey of the entire genome for identification of submicroscopic copy number variants (CNV). It also contributes to understand the etiology of disease which makes it the first tier genetic testing for patients with autism spectrum disorder (ASD) and Intellectual disabilities (ID). In the present study, we studied 67 children (43 Males and 24 Females; Age ranges from: 2.0 yrs.-14yrs.) diagnosed with Autism or Autism spectrum disorder or intellectual disabilities. array CGH was performed on oligonucleotide microarray platform. Data of the array was analyzed using cytogenomics software (CytoGenomics v4.0.3, Agilent technologies). Statistical analysis was performed using SPSS. Results of the microarray analysis showed 28 clinically relevant (Likely Pathogenic) chromosomal imbalances in 14 patients leads to an overall diagnostic yield of 20.89%(14/67). 11 clinically significant variations were detected in patients with Autism or Autism spectrum disorders. Among which Microdeletion of 5,741kbp at chr15q11.2-q13.1 was detected in three patients. 17 chromosomal imbalances were detected in the children with Intellectual disabilities. The range of the imbalances in ID patients ranges from 712kbp to 10463 kbp. While, both groups contained more males than females, a significantly higher percentage of males were present in the ASD group. The likelihood of an abnormal microarray result increased with the number of clinical abnormalities. Microarray analysis will likely become the diagnostic genetic test of choice as its potential implication in Autism spectrum disorders and in idiopathic Intellectual disabilities patients.

**Whole genome sequencing of neurodevelopmental disorders in Japanese.** C. Abe-Hatano<sup>1,2</sup>, A. Iida<sup>3</sup>, K. Ishikawa<sup>3</sup>, Y. Momozawa<sup>4</sup>, S. Kosugi<sup>5</sup>, I. Nishino<sup>3</sup>, K. Inoue<sup>1</sup>, Y. Kamatani<sup>5,6</sup>, M. Kubo<sup>4</sup>, Y. Goto<sup>1,3</sup>. 1) Department of Mental Retardation and Birth Defect Research, National Institute of Neuroscience, National Center of Neurology and Psychiatry, Kodaira, Japan; 2) Department of Pediatrics, Nagoya University Graduate School of Medicine, Nagoya, Japan; 3) Medical Genome Center, National Center of Neurology and Psychiatry, Kodaira, Japan; 4) Laboratory for Genotyping Development, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 5) Laboratory for Statistical Analysis, RIKEN Center for Integrative Medical Sciences, Yokohama, Japan; 6) Center for Genomic Medicine, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Neurodevelopmental disorders (NDDs) are clinically and genetically heterozygous diseases characterized by autism spectrum disorder (ASD), intellectual disability/developmental delay (ID/DD), attention-deficit/hyperactivity, motor and tic disorders, and language communication disorders. Severe NDDs and/or major congenital malformations affect 2-5% among global population, but the etiology remains unclear. We employed whole genome sequencing (WGS) to identify the causative genes in Japanese patients with NDDs. Thirty six patients (20 males and 16 females) with NDDs from 36 unrelated families were included in this study. The common clinical features among all patients were included ID/DD. We performed WGS in all patients and their parents and used to identify the causative genes by the candidate gene approach. The candidate variants were evaluated by *in silico* analysis programs. Finally, we confirmed the variants by Sanger sequencing. We found a total of seven single nucleotide variants (SNVs) in seven known NDDs genes, *MID* (1 SNV), *TCF4* (1), *SPAST* (1), *TSPYL2* (1), *SLC6A8* (1), *SATB2* (1), and *SMS* (1). We found two genes with *de novo* single nucleotide variants in two families and one gene with autosomal dominant inheritance. The remaining four was occurred in four families with X-linked recessive NDDs. Six SNVs were considered to be novel variants by comparing our data with the variants deposited in the public databases. The remaining two SNVs were previously reported. One of these SNVs, c.1738C>T (p.R580W) in *TCF4*, was the causative variant in Pitt-Hopkins syndrome, which is characterized by severe developmental delay and breathing anomalies. Another variant, c.1496G>A (p.R499H) in *SPAST* was the same variant mutated in autosomal dominant spastic paraplegia. We also identified a 10-base deletion of *ADNP* in one patient with stereotypic behavior and ventricular septal defect. Now we are investigating the genotype-phenotype correlations of these patients, and the WGS data from the remaining 28 patients. This is the first report of WGS of NDDs in Japan. A total of seven SNVs and one small deletion in eight patients were identified. These data might contribute to a more precise understanding of correlation between genotypes and phenotypes.

## 2484F

**Diagnostic yield of chromosomal microarray analysis in patients with intellectual disability and developmental delay.** A.C. Ceylan<sup>1,2</sup>, S. Citli<sup>1</sup>, H.B. Eerdem<sup>3,4</sup>, I. Sahin<sup>3,4</sup>, E. Acar Arslan<sup>5</sup>. 1) Department of Medical Genetics, Trabzon Kanuni Training And Research Hospital, Trabzon, Turkey; 2) Department of Medical Genetics, Yıldırım Beyazıt University, Ankara Atatürk Training and Research Hospital, Ankara, Turkey; 3) Department of Medical Genetics, Atatürk University, Medical Faculty, Erzurum, Turkey; 4) Department of Medical Genetics, Ankara Dışkapı Training and Research Hospital, Ankara, Turkey; 5) Department of Child Neurology, Karadeniz Technical University, School of Medicine, Trabzon, Turkey.

Intellectual disability (ID) and developmental delay (DD) are clinically heterogeneous neurodevelopmental disorders seen in approximately 1 % of children. Chromosomal microarray (CMA) is a first-tier test in the evaluation of individuals with ID and DD with the diagnostic yield varying based on population examined, ranging from 5-25% in recent literature. In this study, we present the diagnostic rates for copy number variations (CNVs) detected by CMA in a cohort of 125 Turkish patients with ID and DD. Affymetrix CytoScan Optima® chips were used to perform CMA in 125 patients with ID and DD at Trabzon Kanuni Training and Research Hospital. Data analysis was performed using Chromosome Analysis Suite3.1 (ChAS) software. The analysis and interpretation of the obtained results were performed by using public genomic databases, such as UCSC, OMIM, DGV, DECIPHER, CLINGEN. In 24 individuals (from 23 families), CMA analysis revealed likely pathogenic CNVs including 6 microduplications (2p25p24, 22q11.2 [2 cases], 2p25, 14q32, and 15q11.2), 14 microdeletions (1p36.3, 1q21 [2 cases], 2q36, 6p25.1p23, 6q25q27, 14q32, 15q11.2, 16q24 [KBS syndrome], 18p11.3, 18q22, 18q21q23, 19p23, and 22q11.2) and 2 triplications identified in same locus (22q11.2) in two patients. All identified CNVs were interpreted as having a pathogenic significance in concordance with the clinical findings in the patients examined. Interestingly, in 2 out of 24 individuals multiple CNVs have been identified including 2 different deletions (6q13q14 and 8q21.3) in one patient and 1 deletion (6q25) and 2 duplications (6q24.1 and 6q26) in another patient. The diagnostic yield of CMA in our study was 19.2% which is consistent with the results of previous studies (5-25%). The length of 18 CNVs were below 5 Mb and could not be detected with conventional karyotyping. The length of 7 CNVs were also between 5-10 Mb. Interestingly siblings, whose parents were consanguineous and carrying 22q11.2 duplication, were diagnosed with 22q11.2 triplication. 23 of 27 CNVs were revealed de novo. Although 8 out of 23 families had consanguineous marriages, our analyses revealed de novo variations in these families rather than homozygous mutations. CMA is a first-tier test in the evaluation of individuals with ID and DD which provides opportunities to discover new ID-DD associated syndromes and uncover the genetic background of many syndromes by revealing genetic heterogeneity and identifying new loci for novel candidate genes.

**Introduction:** Apparently balanced chromosomal rearrangements (ABCR) associated with abnormal phenotype are rare events, but may be challenging for genetic counseling. Abnormal phenotype may be explained either by cryptic genomic imbalances detectable by array-CGH or by gene disruption or position effect. However, breakpoint cloning using conventional methods is laborious and not performed routinely. Recently, Whole Genome Sequencing (WGS) proved to be a powerful and rapid technique to characterize ABCR breakpoints at the molecular level. **Material and methods:** The ANI project is a French collaborative study that aims at characterizing ABCR in patients presenting with intellectual disability and/or congenital anomalies. We included 55 patients (41 reciprocal translocations, 4 inversions, 2 insertions, 8 complex chromosomal rearrangements). Array-CGH showed no pathogenic imbalance. **Breakpoints were characterized by paired-end WGS** and confirmed by Sanger sequencing. Expression studies of disrupted and neighboring genes were performed on blood cells. **Results:** Breakpoints were characterized for 49/55 patients (89%). The rearrangements showed unexpected complexity, since 211 breakpoints were identified against 119 breakpoints according to karyotype and included 6 cases of chromoanagenesis. 59% (29/49) of rearrangements resulted from non-homologous end-joining (NHEJ) mechanism, 27% (13/49) may involve micro-homology mediated mechanisms and 14% (7/49) may involve a combination of both mechanisms. Ninety-four breakpoints disrupted a gene (44%). In 17/49 patients, WGS allowed a diagnosis, either by gene disruption (12) or by position effect (5), thus a diagnostic rate of 35%. **Conclusion:** These results revealed the diversity and complexity of chromosomal rearrangements at the molecular level. It also shows the diagnostic relevance of WGS approach in ABCR. This work is supported by ANR and DGOS (PRTS 2013 grants).

**Using parental report questionnaires to identify developmental delay in a 22q11.2 deletion specialty clinic.** *K. Coleman*<sup>1,2</sup>, *L. Kobrynski*<sup>3</sup>, *C. Chris Gunt-er*<sup>1,2,3</sup>, *O. Ousley*<sup>1,4</sup>. 1) Marcus Autism Center, Children's Healthcare of Atlanta, 1920 Briarcliff Rd NE, Atlanta, GA 30329; 2) Department of Human Genetics, Emory University School of Medicine, Atlanta, GA 30322; 3) Department of Pediatrics, Emory University School of Medicine, Atlanta, GA 30322; 4) Emory Autism Center, Department of Psychiatry and Behavioral Sciences, Emory University School of Medicine, Atlanta, GA 30322.

22q11.2 deletion syndrome (22q11.2DS) occurs in approximately 1:4000 live births and encompasses significant phenotypic heterogeneity. In addition to providing complex medical care, a multidisciplinary team is responsible for assessing these patients for a variety of developmental delays and making appropriate referrals. In any setting, this team could benefit from establishment of reliability for parental-report questionnaires. We conducted a medical chart review for children seen within the Emory-CHOA (Children's Healthcare of Atlanta) 22q Specialty Clinic. During each medical visit parents completed developmental questionnaires appropriate to their child's age, including 1) Communication and Symbolic Behavior Scales Developmental Profile Infant Toddler Checklist (**CSBS-DP-ITC**) for ages 6 to 24 months (n=87, mean age=15.0 months; SD=5.2); 2) Child Development Inventory Profile (**CDIP**) for 25 to 72 months (n=86, mean age=47.4 months; SD=14.2); or 3) Adaptive Behavior Assessment System, Second edition (**ABAS-II**) for 6 to 21 years (n=101, mean age=12.3 years; SD=4.1). We determined that approximately half of the children showed evidence of developmental delay across communication, social, and conceptual domains for each age group. For the **CSBS-DP-ITC**, referrals for further services were indicated for each composite score: Social (39.1%), Speech (54.0%), Symbolic (51.7%), and Total (52.9%). For the **CDIP**, children scored 2 SD below the mean at the following rates for each domain score: Social (60.5%), Self-help (68.6%), Gross Motor (60.5%), Fine Motor (51.2%), Expressive Language (67.4%), and Language Comprehension (62.8%). For the **ABAS-II**, children and adolescents scored 2 SD below the mean at the following rates for each composite score: Conceptual (44.5%), Social (29.7%), Practical (51.5%), and General Adaptive (51.5%). In addition, for a subset of children who were assessed at multiple time points, we found evidence of sustained developmental delay. We conclude that parental report questionnaires provide quantitative measurements of various developmental skills, allowing medical professionals to initiate referrals for developmental delay and assisting them in determining if a comprehensive speech/language or neuropsychological assessment is warranted in children with 22q11.2DS. Notably, despite the high rates of developmental delay found, many children also obtained age-appropriate scores, highlighting the range of outcomes for children with 22q11.2DS.

**Increased yield of clinically relevant candidates in the UK 100,000 Genomes Project using the Fabric Genomics platform.** *M. Babcock*<sup>1</sup>, *C. Son Rigby*<sup>1</sup>, *M. Falcioni*<sup>1</sup>, *A. Guo*<sup>1</sup>, *E. Kofman*<sup>1</sup>, *A. P. Fejes*<sup>1</sup>, *J. Grigoris*<sup>1</sup>, *E. S. Kiruluta*<sup>1</sup>, *M. Yandell*<sup>2</sup>, *M. G. Reese*<sup>1</sup>. 1) Fabric Genomics, Oakland, CA; 2) Department of Human Genetics, University of Utah, Salt Lake City, UT.

The 100,000 Genomes Project, spearheaded by Genomics England (GeL), is a United Kingdom National Health Service sponsored study aimed at identifying disease-causing genetic variants in patients and families with rare genetic diseases and cancer using a whole genome sequencing (WGS) approach. For this study, clinical history was used to recruit patients into specific disease categories, each of which were associated with gene panels curated in the GeL PanelApp tool. Fabric Genomics™, a clinical interpretation partner for the 100,000 Genomes Project, has analyzed over 600 clinical cases using Opal™ Clinical. The variant filtering and prioritization protocols utilized for case analysis include GeL's variant tiering methodology, ClinVar, and Fabric Genomics' proprietary variant and gene ranking algorithms VAAST (Variant Annotation, Analysis and Selection Tool) and Phevor (Phenotype Driven Variant Ontological Re-ranking Tool). We report results showing that by applying VAAST and Phevor we increase the clinical candidate yield compared to using the GeL tiering system alone. We identified candidate causal genes/variants in 44.7% of the cases. In 19.6% of these cases (8.7% overall) candidates were only obtained by using the VAAST/Phevor top 20 ranked genes/variants.

**Next generation sequencing based on long range PCR: A reliable, expeditious, cost effective genetic testing strategy for lysosomal storage diseases.** *M.C. Vanaja<sup>1</sup>, P. Ranganath<sup>1,2</sup>, A. Bhattacharjee<sup>1</sup>, A. B Dalal<sup>1</sup>.* 1) Diagnostics, Centre for DNA Fingerprinting and Diagnostics, Hyderabad, Telangana, India; 2) Department of Medical Genetics, Nizams Institute of Medical Sciences, Hyderabad.

Lysosomal storage diseases (LSDs) are rare inherited metabolic disorders resulting from defective lysosomal function. There are over 50 different disorders which affect different parts of the body including the skeleton, brain, heart and the central nervous system. Many factors make LSD diagnosis difficult, including phenotype and penetrance variability, shared signs and symptoms, and problems inherent to biochemical diagnosis. Even though enzyme analysis is the most effective method for definitive diagnosis, molecular genetic testing can refine the enzymatic diagnosis. Further accurate prenatal diagnosis can be done using molecular genetic testing. Molecular genetic testing has conventionally been done using the Sanger sequencing technique. While Sanger sequencing is very useful for sequence analysis of small genes, when applied for large genes it becomes time consuming, costly and laborious, requiring multiple PCR reactions for generating amplicons for sequencing. We have designed a strategy based on next generation sequencing (NGS) for the simultaneous testing of different lysosomal genes, using Long Range PCR technique. Primers were designed for each gene to amplify 5-10kb fragments containing the exons and intronic regions. Long PCR was set up for the patients DNA who were diagnosed to be affected with the respective LSDs based on clinical features and enzyme assay for respective genes. Libraries were constructed by mixing the amplified products from gene fragments of **NEU1, SMPD1, IDUA, ARSA, NPC1, NPC2, GBA, GAA, GLB1, GNPT-AB, and GALNS**. The constructed libraries were sequenced on an Illumina MiSeq platform. The Quality analysis of the fastq file generated was done by FASTQC, followed by data alignment by Burrow's Wheeler algorithm, Variant calling by GATK pipeline and Variant Annotation by Annovar. The identified sequence variants were validated by Sanger sequencing. Initial standardization was done using 40 patient samples with known variants in 9 genes and we found 100% concordance in the identified sequence variants by NGS. Later, 40 samples with unknown variants were included and the identified 38 likely pathogenic sequence variants which were validated by Sanger sequencing. We conclude that Long-range PCR combined with next-generation sequencing is a reliable, expeditious, cost effective choice for mutational analysis of lysosomal storage diseases and can be applied as a method of choice in low income countries for cheaper molecular diagnostics. .

**StarSeq, an innovative method based on NGS for accurate detection of punctual mutations and copy number variants in children with intellectual disability and obesity.** *A. Bonnefond<sup>1,2,3</sup>, L. Montagne<sup>1,2,3,4</sup>, M. Derhourhi<sup>1,2,3</sup>, E. Durand<sup>1,2,3</sup>, I. Rabearivelo<sup>1,2,3</sup>, O. Sand<sup>1,2,3</sup>, B. Delobel<sup>4</sup>, P. Froguel<sup>1,2,3,5</sup>.* 1) CNRS UMR8199, Lille, France; 2) Univ. Lille, Lille, France; 3) Institut Pasteur de Lille, Lille, France; 4) Hôpital Saint-Vincent de Paul, Lille, France; 5) Imperial College, London, UK.

Although targeted or exomic next generation sequencing (NGS) is now widely used for the detection of punctual coding mutations, DNA microarrays (e.g. CGH/SNP microarrays) are still the current gold standard methods for the detection of copy number variants (CNVs) in the molecular diagnosis of genetic disorders. Indeed, several studies demonstrated reproducibility issues in CNV calling based on whole-exome sequencing. We have developed a groundbreaking, NGS-based, one-step tool (StarSeq) for an accurate and cost effective detection of both punctual mutations and CNVs. We assessed its usefulness and accuracy for the molecular diagnosis of patients with monofactorial diseases. We used a custom capture (NimbleGen SeqCap EZ Choice XL) which included probes regularly spaced in the entire genome, in combination with a capture targeting the whole exome (NimbleGen SeqCap EZ MedExome Enrichment Kit). The resulting probes covered >80 Mb of the genome. Probes were placed every 10 kb apart in the regions known to be affected by CNVs (based on the literature and public database), and probes were placed every 25 kb in the rest of the genome. We tested this capture in a cohort of 120 obese children with intellectual disability and their parents, whose 50% had already been analyzed by DNA microarrays (CGH Agilent 60k v2) for CNV detection. The sequencing was performed through Illumina HiSeq 4000, using 100 bp paired-end reads, and a mean sequencing depth higher than 85x was achieved for each individual. We detected all the CNVs previously identified by DNA microarrays and we found additional CNVs which were not found by DNA microarrays in our patients, probably due to the better resolution of StarSeq. In parallel, we detected novel punctual mutations with the same accuracy as a standard exome sequencing. We were able to diagnose more than half of the patients, establishing causality to either punctual mutations and/or CNVs. For instance, in a young boy with obesity, macrocephalia and large abdominal lipoma (without intellectual disability), we surprisingly detected a chr16p11.2 deletion along with a heterozygous nonsense mutation (p.R130\*) in *PTEN*. We demonstrated that our custom capture in combination with NGS enables an accurate, inexpensive detection of CNVs and punctual mutations in only one step. StarSeq dramatically improves genetic diagnosis and thus has the potential to replace standard exome sequencing and DNA arrays as this method is cost-effective and fast.

**Genetic causes of intellectual disability in 102 consanguineous families from Jordan.** *T. Froukh<sup>1</sup>, O. Nafie<sup>2</sup>, J. Sommerfeld<sup>3</sup>, S. AlHait<sup>4</sup>, M. Sturm<sup>3</sup>, A. Baraghiti<sup>1</sup>, P. Koch<sup>3</sup>, J. Hanselmann<sup>3</sup>, B. Kootz<sup>3</sup>, J. Gohlke<sup>3</sup>, T. Haack<sup>3</sup>, W. Al-Ameri<sup>5</sup>, R. Abou Jamra<sup>6</sup>, A. Alfrook<sup>4</sup>, M. Hamdallah<sup>7</sup>, A. Riess<sup>3</sup>, P. Bauer<sup>3</sup>, O. Riess<sup>3</sup>, R. Buchert<sup>3</sup>.* 1) Philadelphia University, Amman, Jordan; 2) Mutah University, Amman, Jordan; 3) University of Tübingen, Tübingen, Germany; 4) Private Clinic, Amman, Jordan; 5) Ibn Alhytham Hospital, Amman, Jordan; 6) University Medical Center Leipzig, Leipzig, Germany; 7) Farah Hospital, Amman, Jordan.

Intellectual disability (ID), defined by an intelligence quotient of less than 70, occurs in approximately 1 to 3% of the population and tends to be higher in low-income countries and in inbred communities. Despite high rates of consanguineous marriages and likely enrichment for recessive forms of ID, the genetic bases of ID in Jordan are largely unstudied. In this study, we used whole exome sequencing (WES) to identify the genetic causes of ID in 102 consanguineous families from Jordan with one or more intellectually disabled progeny. While sequencing and variants filtration are progressing, likely pathogenic mutations were identified in 15 families and strong candidates were identified in other 20 families. Variants in six genes not previously implicated with ID were assigned as possible causative to ID in six families, including: APBA1, EGFL6, DENND5A, NEK5, SALL3, and PKP3. In addition, two *de novo* CNV deletions were detected in two families, one with 2.8Mb on 4q21.22-21.23, previously recorded as pathogenic and the other with 1.5Mb on 7q11.23, previously associated with Williams Beuren Syndrome. This study demonstrates the power of examining consanguineous families to identify genes not previously implicated with ID and motivates larger gene discovery endeavors in the Jordan population.

Callier<sup>1,3</sup>.* 1) Equipe GAD, EA4271, UMR 1231, Dijon, France; 2) Centre de Génétique et Centre de Référence Anomalies du Développement et Syndromes Malformatifs de l'Interrégion Est, Centre Hospitalier Universitaire Dijon, 21079 Dijon, France; 3) Laboratoire de Génétique Chromosomique et Moléculaire, Plateau technique de biologie, Centre Hospitalier Universitaire Dijon, 21079 Dijon, France.

Whole-Exome Sequencing (WES) is becoming a standard application for the detection of gene mutations responsible for human disease, especially SNVs and indels. To date, most studies of CNVs were diagnosed by array-CGH or array-SNP with a lower detection limit of about 30kb. The challenge is now to detect both SNVs and CNVs using an exome-wide approach with a single test. Several algorithms have been developed to call CNV from WES data (Exome CNV, CONTRA, ExomeCopy, ExomeDepth, ConiFer, XHMM). The XHMM program is optimized for the identification of rare variants in large exome data sets, in particular exonic CNVs smaller than 30kb. We used XHMM to screen for exome CNVs in data from 350 patients with developmental disorders for whom exome sequencing was performed in a research or diagnostic setting with normal array-CGH 4x180K Agilent design used in our lab. We identified pathogenic CNVs, ranging in size from 685pb to 11kb (all confirmed by qPCR), in five patients (1.4%). Among these, four patients showed clinically relevant deletions in neurodevelopmental disorders (4.5 kb homozygous deletions of *PPT1*; 5kb for *PIGN*; 637pb for *TCF4*; 2.2kb homozygous *CLCN2* deletion), one patient had Cohen syndrome (11kb homozygous *VPS13b* deletions). This study shows that the XHMM program detected five CNVs from whole-exome data. This study underlines the interest of whole-exome sequencing in genetic disorders to identify SNVs and CNVs especially those smaller than 30kb not detected by array-CGH.

**2492T**

**MIDAS Project status report: Trio whole exome sequencing in patients with intellectual disability.** Y. Dinçer<sup>1,2</sup>, J. Schulz<sup>1</sup>, M.Y. Cohen<sup>1</sup>, D. Wahl<sup>1,2</sup>, S. Wilson<sup>1</sup>, S.H. Eck<sup>1</sup>, V. Mall<sup>1</sup>, I. Rost<sup>1</sup>, H.G. Klein<sup>1</sup>. 1) Center for Human Genetics and Laboratory Diagnostics (AHC), Martinsried, Germany; 2) Chair of Social Pediatrics, Technical University of Munich, Munich, Germany; 3) Practice for Genetic Counselling and Psychotherapy, Augsburg, Germany.

**Introduction:** This report presents the first 16 of 50 patients with intellectual disability (ID) enrolled in the Multiple Integration and Data Annotation Study (MIDAS). Due to the extensive clinical and genetic heterogeneity, the causes of ID remain mainly unknown. Whole exome sequencing (WES) was shown to be an effective diagnostic strategy for the detection of causative mutations in patients with rare ID; however, NGS approaches are still limited by time-consuming human interpretation of genomic data. To overcome this bottleneck, MIDAS aims to accelerate NGS data analysis and to enhance the validity of the results by computer-based variant prioritization using clinical data of the patient. For this purpose, a central software system for data integration in a diagnostic laboratory based on genotype-phenotype correlations will be developed within MIDAS. **Methods:** By now, 16 patients (8 males, 8 females) with unexplained ID and their unaffected parents (trios) were analyzed in MIDAS. All patients were evaluated by clinical geneticists and phenotypic features were recorded in a standardized way. Before enrollment, the patients had undergone extensive diagnostic testing, including karyotyping, genome-wide array comparative genomic hybridization (aCGH), and Fragile-X analysis. A subset of the patients was analyzed by targeted gene tests specific for the suspected disorder, but all these tests did not lead to a diagnosis. We sequenced the patients as well as their healthy parents and used the WES data to perform a trio analysis afterwards. Identified variants were evaluated using population (dbSNP, ExAC, gnomAD) and disease databases (HGMD, OMIM, ClinVar). Identified variants were evaluated by molecular geneticists and clinicians in the context of patients' clinical presentation. **Results:** We were able to identify four *de novo* loss-of-function mutations as well as one autosomal recessive inherited mutation in a consanguineous family. So far, the diagnostic yield for patients with ID enrolled in MIDAS and analyzed by Trio WES is 31%. All causative *de novo* mutations were located in genes (*ADNP*, *ARID1B*, *GATAD2B*, *KDM5C*) associated to known ID syndromes. **Discussion:** Whole exome sequencing is an effective diagnostic strategy for the detection of causative mutations in patients with rare diseases. Nevertheless, due to large amount of genetic data by NGS approaches in diagnostics, powerful computational algorithms are necessary to accelerate NGS data interpretation.

**Copy number reanalysis: The hidden contribution of *MED13L* to intellectual disability.** L.K. Conlin<sup>1</sup>, J.R. Murrell<sup>1</sup>, R. Rajagopalan<sup>1</sup>, V. Jayaraman<sup>1</sup>, E.J. Romasko<sup>1</sup>, B. Devkota<sup>1</sup>, P. Vaidiswaran<sup>1</sup>, P. Jayaraman<sup>1</sup>, S. Biswas<sup>1</sup>, M. Sarmady<sup>1</sup>, A. Santani<sup>1</sup>, B.L. Krock<sup>1</sup>, M.C. Dulik<sup>1</sup>, E. Zacka<sup>1</sup>, I.D. Krantz<sup>2</sup>, M. Luo<sup>1</sup>, N.B. Spinner<sup>1</sup>. 1) Division of Genomic Diagnostics, Department of Pathology and Laboratory Medicine, Children's Hospital of Philadelphia, Philadelphia, PA; 2) Division of Human Genetics, Department of Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA.

While exome sequencing (ES) as a clinical diagnostic tool has advanced greatly in recent years, identification of copy number variation (CNV) using ES is not widely used clinically due to low sensitivity and high false-positive rates. In order to optimize CNV detection, we used ES data from 160 probands and compared the results to their clinical chromosomal SNP microarray data. As part of this validation, we identified pathogenic CNVs in haploinsufficient genes *MBD5*, *ANKRD11*, *SYNGAP1*, and *KCNH2*, heterozygous deletions *in trans* with a sequencing variant in *SPATA5* and *TRAPPC9*, and a likely pathogenic duplication of *FGF12*. Surprisingly, deletions in *MED13L* were identified in three probands. For all but two of these findings, the CNVs were also detected by the array, but the CNV had not been reported clinically as the disease-gene association was not known or not well understood at the time of original testing, and the CNVs were below the reporting criteria (20 probes and 200kb) for variants of uncertain significance. In particular, variants in *MED13L* were first described in a small cohort of patients with transposition of the great arteries in 2003; however, in 2013, reports began to emerge linking *MED13L* to both syndromic and non-syndromic intellectual disability (ID). The frequency of *MED13L* CNVs prompted us to re-evaluate array data from over 12,000 patients who received clinical testing since 2008. We identified 5 additional *MED13L* deletions, only one of which had been reported as a variant of uncertain significance at the time of testing. In total, 7 unique deletions in *MED13L* were identified in 9 individuals, including two brothers who inherited the deletion from a mosaic parent. The deletions ranged in size from 10kb to 214kb, with the majority of deletions involving only one or two exons. Overall, exonic deletions of *MED13L* were found in ~0.1% of individuals with array testing who presented with ID or developmental delay, compared to ~2% in the ES cohort. The differences may be due to the poor coverage of this gene in earlier array designs, thus the contribution of deletions of this gene to ID may be underappreciated. While reanalysis of ES data has highlighted the impact of new knowledge regarding gene-disease associations on improved diagnostic yield, our experience also shows the importance of reanalysis of CNV data, both as a supplement to ES sequencing as well as increasing diagnostic yields of chromosomal microarray testing.

Trio Whole Exome Sequencing (WES) has proven to be a valuable strategy to identify molecular basis of syndromic or non-syndromic intellectual disabilities (ID). As part of the *HUGODIMS* project, a trio-based WES analysis was performed in 69 patients affected with moderate to severe ID without familial history of ID and normal array-CGH and fragile X testing. A definitive diagnostic or a strong candidate gene was identified for 69% of the cases (48/69). In patients without diagnosis, Whole Genome Sequencing (WGS) is able to increase coding genes coverage together with detecting structural variations (SVs) and giving an insight into noncoding variants. Up to now, however, WGS implementation for diagnostic or research purposes is still challenging due to computational and analysis issues. As a pilot study, we performed WGS in 7 patients negative after trio WES and their healthy parents on Illumina HiSeqX5 using TruSeq PCR-free. Single nucleotide variants and short indels were jointly called across the 21 samples using GATK HaplotypeCaller. For SVs, we used both read depth and split/paired-reads approaches: i) to detect copy number variants (CNVs), we generated a read count matrix over 500bp non-overlapping intervals covering the entire genome and a read-depth approach using the R algorithm *cn.MOPS* (Klambauer et al. 2012) was applied, calling CNVs from 3 consecutive intervals, ii) split and paired-reads analysis were performed with MANTA (Chen et al. 2016) on the 21 WGS jointly, it allowed the identification of all SVs classes (CNVs, insertions, inversions and translocations). We then developed Python scripts to identify *de novo events* and to annotate SVs with several external databases (RefSeq, OMIM, segmental duplications, DGV gold standard etc). We also extracted rare coding variants in genes covered by a SV to identify compound heterozygous events. As preliminary results, we identified two *de novo* missense variants in the same exon of a strong ID candidate gene not covered in the previous WES analysis, a *de novo* 2Mb inversion disrupting a known ID gene and a *de novo* balanced reciprocal translocation. Confirmation of these results using another technique is underway. We will therefore report the first results of this pilot study and we will discuss actual challenges subsisting with WGS analysis.

As a part of the CSER Consortium, we are actively sequencing the genomes of children with developmental delay/intellectual disability (DD/ID) and of their unaffected parents. To date, we have enrolled 463 families (1308 individuals) and have sequenced exomes from 368 individuals (120 families) and whole genomes from 940 individuals (343 families). Of the 480 DD/ID affected children sequenced and analyzed, 59% did not receive any findings (pathogenic, likely pathogenic or VUS) related to their disease. In an attempt to identify new diagnoses in probands where there was not one previously identified, our team has elected to perform reanalysis of sequence data. With more groups performing routine exome and genome sequencing, more sequence data is available describing the genetic makeup of both healthy controls and affected individuals. The rapid accumulation of data poses both a challenge and an advantage to analysis, as available data on a given gene changes relatively quickly and integration of such data into our analysis pipeline must therefore occur on a routine basis. The increased amount of new information that is now available prompted our reanalysis efforts. To begin the reanalysis process, we annotate additional data pertaining to variants or genes (gnomAD data, ClinVar updates, publication data, and updates to impact predictions such as CADD and RVIS) then re-filter and manually curate variants. Through reanalysis efforts, we have identified 19 diagnostic variants in 22 children, representing 6% of previously undiagnosed cases. These variants were not returned at the time of original analysis due to inadequate support for pathogenicity of the variant (14/19) or the variant was originally scored as a VUS, but new evidence suggests upgrading to likely pathogenic/pathogenic (5/19). Additionally, both our first-line analysis and reanalysis efforts have greatly benefited from collaborations initiated via GeneMatcher. We have submitted 50 genes to date, and approximately 25% have resulted in an active collaboration with the goal of publication. Our findings demonstrate that reanalysis of exome/genome sequence data, as well as data sharing with clinicians and researchers, leads to increased diagnosis for those with DD/ID and contributes greatly to the scientific and medical knowledgebase.

**2496F****The clinical application of chromosomal microarray in in the diagnosis of children with developmental delay/intellectual disability in Korea: A single tertiary center experience.**

*Y. Kim<sup>1</sup>, L. Yoon<sup>1</sup>, Y. Shin<sup>2</sup>, Y. Lee<sup>3</sup>, S. Nam<sup>3</sup>.* 1) Department of Pediatrics, Pusan National University Hospital, Pusan National University School of Medicine and Biochemical Research Institute, Busan, Korea; 2) Department of Rehabilitation, School of Medicine, Pusan National University Hospital, Pusan National University School of Medicine and Biochemical Research Institute, Busan, Korea; 3) Department of Pediatrics, Pusan National University Yangsan Hospital, Pusan National University School of Medicine and Biochemical Research Institute, Yangsan, Korea.

**Background:** Chromosomal microarray (CMA) is the first-tier genetic test for children with developmental delay (DD), intellectual disability (ID), autistic spectrum disorders (ASD), and multiple congenital anomalies in many countries. In this study, we report our experiences with the use of CMA in Korean children with DD/ID. **Methods:** We performed CMA in a cohort of 143 children with DD/ID from Jan 2010 to Apr 2017. We retrospectively reviewed their medical records. The CMA was conducted with CytoScan 750K array (Affymetrix, USA) with an average resolution of 100 kb. **Results:** Eighty-one patients (56.6%) had non-syndromic DD/ID. Among 62 patients (43.3%) with syndromic DD/ID, there were 52 patients (36.4%) with dysmorphisms, 10 patients (7.0%) with epilepsy, and 6 patients (4.2%) with ASD. Among total 103 copy number variations (CNVs) identified in 73 patients (51.0%), 30 CNVs (21.0%) were pathogenic. Genetic loss of CNVs were more common in pathogenic CNVs than benign CNVs and variants of unknown significance ( $P=.045$ ). Pathogenic CNVs showed bigger average size of CNVs ( $P<.001$ ) and more genes between CNVs ( $P<.001$ ) than benign CNVs and variants of unknown significance. The diagnostic yields were 11.1 % in non-syndromic DD/ID and 27.4% in syndromic DD/ID. Microdeletion and duplication syndromes were diagnosed, including Phelan-Mcdermid syndrome, DiGeorge syndrome, steroid sulfatase deficiency, 16p11.2-p12.2 microdeletion syndrome, 15q13.3 microdeletion syndrome, 1q21.1 recurrent microdeletion, 6q25 microdeletion syndrome, Wolf Hirschhorn syndrome, Miller-Dieker syndrome, 7q11.23 duplication syndrome, and 16p13.11 recurrent microduplication. **Conclusion:** This study provides additional evidence of the clinical usefulness of CMA in the diagnostic genetic testing for children with DD/ID in Korea.

**2497W****Case study: Identification of a pathogenic microdeletion using exome**

**data.** *M.N. Luong, W. Scaringe, C.Y. Lee, M. Li, Y. Shen, S.P. Strom, H. Gao.* Fulgent Genetics, Temple City, CA., Select a Country.

Recent advances in bioinformatics have enable the identification of Copy Number Variants (CNV) using targeted next generation sequencing. In this case study, we utilized the CNVexon™ algorithm to detect CNVs using exome data in an individual with developmental delay. A multi-gene deletion was detected, and confirmed to be a microdeletion of 2q12.3-2q13. Evaluation of the identified microdeletion using publicly available CNV databases resulted in a classification of pathogenic, as it has been previously reported in two individuals with developmental delay (ISCA, Kaminsky et al., 2011) and is absent from the general population. This novel large genomic deletion was previously detected by chromosomal microarray analysis, indicating that CNV analysis by exome sequencing is a good alternative to traditional microarray analysis for detecting and evaluating copy number variants.

**2498T****Genetic evaluation of patients with intellectual disability (ID) using chromosomal microarray and next-generation sequencing at the "ID clinic".**

Intellectual disability (ID) results from significant limitations in both intellectual functioning and adaptive behavior and starts before the age of 18. ID is one of the most frequent developmental disorders in children, and its prevalence is 1–3% in the general population. However, more than half of ID was of unknown etiology due to its clinical and genetic heterogeneities. Recently, genome-wide approaches, such as chromosomal microarray (CMA) and next-generation sequencing (NGS) have improved the diagnostic yield of ID. The "ID clinic" was established at the Center for Medical Genetics, Shinshu University Hospital in April 2014. We provide clinical diagnosis, systematic genetic evaluation, and genetic counseling to patients with ID or global developmental delay (GDD). To date, 109 patients have visited the "ID clinic". In the first-tier genetic testing, CMA detected 6 pathogenic copy number variants. In the second-tier genetic testing, targeted NGS using the "ID panel" (49 or 80 ID-related genes) identified 15 pathogenic variants. In the third-tier genetic testing including medical exome sequencing (TruSight One Sequencing Panel, Illumina), whole-exome sequencing or specific genetic testing, genetic causes were identified in 7 patients. The total diagnostic yield was 25.7% (28/109). Genetic evaluation in the "ID clinic" is thought to be useful in providing definitive diagnosis, expected clinical course, and recurrence risk to patients and their family.

**2499F****Targeted next-generation sequencing of 75 genes in Japanese patients with intellectual disability and multiple congenital anomalies of unknown etiology.**

D.T. Uehara<sup>1</sup>, K. Tanimoto<sup>2</sup>, J. Inazawa<sup>1,3</sup>. 1) Department of Molecular Cytogenetics, Tokyo Medical and Dental University, Tokyo, Tokyo, Japan; 2) Genome Laboratory, Medical Research Institute, Tokyo Medical and Dental University, Tokyo, Japan; 3) Bioresource Research Center, Tokyo Medical and Dental University, Tokyo, Japan.

Intellectual disability (ID) is a genetically heterogeneous condition affecting 1–3% of the population, often associated with other clinical findings broadly referred to as multiple congenital anomalies (MCA). The genetic diagnosis of a large subset of cases remains unknown, and identifying their causes is a core step for the consideration of targeted therapies. Aiming at detecting pathogenic single nucleotide variants leading to undiagnosed ID/MCA in Japanese patients, previously negative for genomic rearrangements, we have employed high-throughput sequencing using a custom panel composed of 75 genes. In this panel, 61 genes are the most frequently mutated known genes causing ID/MCA, selected on the basis of published studies in large cohorts. Most of those genes are causative for autosomal dominant forms of ID, consistent with the sporadic nature of ID/MCA. The remaining 14 genes were included as candidate genes that emerged from our previous microarray screenings, and were selected based on the higher probability of exhibiting haploinsufficiency. To date, we have screened 48 patients, in which likely causative variants were found in 25% of the cases. Notably, we detected pathogenic variants in genes recently implicated with ID/MCA, namely *DDX3X*, *PPP2R1A*, *PPP2R5D* and *WDR45*. Among candidate genes, we identified a missense mutation (c.536C>T, p.Ala179Val) in *GAP43*, a gene highly expressed in brain that had been previously pointed as the candidate to explain the phenotype of patients carrying microdeletions at 3q13.31. Due to the great cost-effectiveness, targeted sequencing as a first approach is ideal for the exclusion of mutations in known genes prior to the application of broader strategies such as whole-exome sequencing.

**2500W**

**Diagnostic testing using capture-based NGS reveals a high rate of mosaicism in genes associated with neurodevelopmental disorders.** *D. McKnight, W. Wang, A. Lai, K. Retterer, R. Brandon, G. Richard, A. Lindy.* GeneDx, Gaithersburg, MD.

Historically, mosaicism was challenging to detect using conventional sequencing methods and has likely represented an under-reported cause of genetic disease. Capture-based NGS with high read-depth, mosaic-aware variant calling, and reduced random sequencing error provides a more sensitive and quantitative approach for the identification of mosaicism. We conducted a retrospective study to identify genes with a high rate of mosaicism tested by NGS. The study included only likely pathogenic or pathogenic variants (L/PV) in 188 genes associated with autosomal dominant or X-linked disorders and a high positive rate (>9 reported L/PV). These genes were assigned to phenotypic groups based on the major disease association and rate of mosaicism was calculated by group. Mosaic L/PVs were observed in 9-39% of reads in AD genes, 10-25% of reads in XL genes in females, and 13-88% of reads in XL genes in males. In a two year time period, 1.4% (111/7859) of L/PVs were classified as mosaic. Mosaic variants were identified in 59/188 genes and accounted for 4.8% (111/2314) of all L/PVs in these genes. The highest rate of mosaicism was observed in genes associated with neurodevelopmental disorders (NDD); specifically 8.4% (17/202) of L/PVs were mosaic in brain malformation syndromes (BMF) and 3.2% (57/1778) in epilepsy and intellectual disability disorders (Epi/ID). Notably, some BMF genes with high rates of mosaicism were PFAFH1B1 (15.8%, 3/19), FLNA (13.6%, 3/22), and TUBA1A (12.0%, 3/25), and Epi/ID genes included SCN2A (7.8%, 6/77), PCDH19 (6.3%, 3/48), and MECBP2 (4.3%, 4/93). In contrast, only 1/2378 and 1/658 L/PVs were mosaic in genes associated with cardiomyopathy/arrhythmia and neuromuscular disorders, respectively. Parental mosaicism was observed in 32 cases; mosaic L/PVs were observed in 2-35% of reads including 8 parents who had mosaic L/PVs in <5% of reads. Clinical information was available for 63% (20/32) of parents and 75% were unaffected, whereas 25% were either similarly or more mildly affected than their child. Collectively, these data emphasize that mosaic L/PVs are more common than previously reported in some genes associated with NDD. Diagnostic testing for patients with NDD should include capture-based NGS with high read-depth and mosaic-aware variant calling. Additionally, parental testing by NGS or a comparable quantitative method, should be considered when the child has a L/PV in a gene with a high mosaic rate.

**Recurrent telomere captures as the mechanism producing uniquely complex 1p UPD mosaicism.** *P.L. Pearson<sup>1</sup>, A. Santos<sup>1</sup>, F. Campagnari<sup>2</sup>, A.C.V. Krepisch<sup>1</sup>, A.M. Vianna-Morgante<sup>1</sup>, M.L.R. Câmara<sup>2</sup>, R.C.E.A. Brasil<sup>2</sup>, L. Vieira<sup>1</sup>, C. Rosenberg<sup>1</sup>.* 1) Genetics and Evolutionary Biology, University of São Paulo, Sao Paulo SP, São Paulo, Brazil; 2) Center of Odontological Assistance, Faculty of Odontology, São Paulo State University, Araçatuba, SP, Brazil; 3) Deoxi Biotecnologia, Araçatuba, São Paulo, Brazil.

A complex UPD mosaicism of chromosome 1p was detected by SNP microarray analysis in a patient presenting a 4 Mb 1p36 terminal deletion with associated clinical features. The microarray pattern revealed a progressive distal reduction of heterozygosity frequency from the expected 50% towards the 1p36 terminal deletion, indicating the presence of mosaic uniparental disomy (UPD). UPD involving terminal deletions has been observed as a result of telomere capture, with the reduction of heterozygosity remaining constant along the entire captured segment. In our case, the unique SNP array pattern observed can be explained by overlap of differently sized UPD segments producing a stepped pattern of heterozygosity resulting from recurrent telomere captures from the normal homologue in independent cell lineages. Comparisons between blood and buccal mucosa, the only tissues available from our patient, indicated four independent telomere captures involving blood cells, and an additional fifth capture encompassing the entire 1p in buccal mucosa. The putative timing of these events suggests that the first four segments arose in a common precursor of blood and buccal mucosa, with a further UPD segment arising in buccal mucosa following embryonic differentiation of the two tissues. This latter segment contributed approximately 50% of the total UPD observed in buccal mucosa and facilitated measuring the UPD contribution of the segments with more distal breakpoints. The contribution of individual segments to the total frequency of UPD mosaicism in both tissues was approximately linearly additive. The most likely mechanism for this complex mosaicism is a chain of events initiated by occurrence of a 1pter deletion in either a gamete or a very early embryonic cell division. The deletion was "rescued" by several early, independent telomere captures, involving varying lengths of the normal 1p homologue: this resulted in a pattern of overlapping segments of partial 1p UPD, with the most distal segments exhibiting the most reduction in heterozygosity, and the most proximal, the least. Although this is the first description of multiple independent telomere capture events of a single deletion lesion, other cases probably exist but have remained undetected due to inadequate microarray procedures. High SNP density appears to be one of the most important requirements.

**2502F**

**Genetic spectrum of limb-girdle muscular dystrophy in Taiwan.** Y.L. Lin<sup>1</sup>, C.C. Yang<sup>2</sup>, N.C. Lee<sup>1</sup>, C.H. Huang<sup>3</sup>, Y.H. Chien<sup>1</sup>, T.M. Ko<sup>3</sup>, W.L. Hwu<sup>1</sup>. 1) Medical Genetics and Pediatrics, National Taiwan University Hospital, Taipei, Taiwan; 2) Neurology, National Taiwan University Hospital, Taipei, Taiwan; 3) GenePhile BioScience Laboratory, Ko's Obstetrics and Gynecology, Taipei, Taiwan.

**Background** Limb-girdle muscular dystrophy (LGMD) is a genetically and clinically heterogeneous group of muscular dystrophies. Individuals with LGMD generally show weakness and wasting of the muscles in the arms and legs, and gradually worsen over time. The muscles most affected are usually the proximal muscles. The age of onset, severity, and features vary among different subtypes of LGMD, sometimes even within the same family. The various types of LGMD are caused by mutations in different genes. At least 31 genes have been found to be associated with LGMD which is far too much to screen each gene one-by-one. The NGS approach could save both time and cost, as well as labor. **Materials and methods** We designed a targeted panel for LGMD containing 32 muscular dystrophy related genes, from which exome-captured libraries were built. Our goal is to describe the spectrum of mutations and genes related to LGMD patients in Taiwan using NGS panel we designed, identify factors associated with diagnostic findings, and evaluate the assessments of genetic variants. **Results** Thirteen LGMD patients were enrolled in the study. We were able to identify likely pathogenic (LP) or pathogenic (P) variants in 8 patients (61.5%) according to ACMG guideline. Variants were most commonly observed in *DYSF* gene (25%), then in *TRAPPC11* (12.5%) and *CAPN3* (12.5%), all of which are associated with type 2 LGMD, specifically, 2B, 2S, 2A, respectively. Two variants were found in genes associated with type 1 LGMD, *LMNA* and *HNRNPDL*, particularly 1B and 1G, respectively. The rest of the variants were associated with other myopathies, such as cardiac and distal myopathy, and Duchenne muscular dystrophy (DMD)/Becker muscular dystrophy. **Conclusion** Targeted panel helps us to molecular diagnosis of LGMD. In our cohort, type 2 LGMD is the most common form of LGMD. This benefits the management, clinical care and genetic counseling in these patients.

**2503W**

**A novel intronic mutation in MTM1 detected by RNA analysis in a case of X-linked myotubular myopathy.** A.H. AlHashim<sup>1,2</sup>, H. Gonorazky<sup>2</sup>, K. Am-burgey<sup>2</sup>, S. Das<sup>3</sup>, J. Dowling<sup>2</sup>. 1) pediatric neurology, King Fahad Medical City, Riyadh, Saudi Arabia; 2) Division of Neurology and Program for Genetics and Genome Biology, Hospital for Sick Children, Toronto, ON Canada; 3) Department of Human Genetics, University of Chicago, Chicago, IL USA.

X-linked myotubular myopathy (XLMTM) is a rare neuromuscular condition that presents with neonatal hypotonia and weakness and is associated with severe morbidities (including wheelchair, feeding tube, and ventilator dependence) and early death. It is defined by muscle biopsy features, including central nuclei, abnormal oxidative stain distribution, and type I fiber hypotrophy. Mutations in myotubularin (*MTM1*) account for all genetically solved cases of XLMTM, but have not been discovered in all individuals with characteristic clinical and biopsy features. Of note, there are some forms of autosomal centronuclear myopathy that can resemble XLMTM, such as those associated with mutations in *BIN1*, *DNM2*, *RYR1*, and *SPEG*, though rarely are such cases a completely phenocopy of XLMTM. In this study, we present a case that illustrates the importance of considering non-coding mutations as a cause of XLMTM and illustrate the utility of RNA analysis in individuals with a phenotype suggestive of a particular genetic diagnosis.

**2504T**

**Development of a unified *DMPK* and *CNBP* PCR workflow for determining repeat expansions relevant to myotonic dystrophies.** *J. Wisotsky, J. Kemppainen, G. Latham, B. Hall.* Asuragen, Austin, TX.

Myotonic Dystrophy type 1 and 2 (DM1 and DM2) are the most common adult onset muscular dystrophies. DM1 is caused by a trinucleotide expansion of CTG in the 3' UTR of myotonic dystrophy protein kinase (*DMPK*). Clinical phenotypes manifest in patients who have >50 repeats with classic disease occurring in those with >100 repeats. DM2 is caused by a tetranucleotide expansion of CCTG in intron 1 of the cellular nucleic acid-binding protein (*CNBP*). Pathogenicity is observed in those with >75 repeats. In both cases, expansions often include hundreds to thousands of repeat units. DM1 and DM2 molecular diagnosis relies on a complex combination of PCR and Southern blot analysis. Here, we describe a unified PCR/ capillary electrophoresis (CE) assay that interrogates repeat loci in both *DMPK* and *CNBP* and generates accurate sizing up to 200 (*DMPK*) or 75 (*CNBP*) repeats. AmpliDeX® PCR reagents were optimized for the repeat-primed amplification of both *DMPK* and *CNBP* repeats using distinct dye-tagged primers. Amplicons were sized on a 3500xL Genetic Analyzer (Thermo Fisher). A total of 40 DNA samples were evaluated: 20 previously-characterized genomic DNA samples (Coriell) with *DMPK* or *CNBP* expansions and 20 specimens collected from healthy volunteers. A subset of samples were also amplified by gene-specific PCR and evaluated by Sanger sequencing as an orthogonal comparison to identify interruptions within *CNBP*. The PCR/CE assay achieved accurate repeat sizing for both *DMPK* ( $\leq 200$ ) and *CNBP* ( $\leq 75$ ). Furthermore, samples with >200 CTGs in *DMPK* were identified in agreement with reference results. *CNBP* alleles with <25 repeats contained interruptions identified by both CE and sequencing, whereas in expanded alleles fewer interruptions were observed. Current methods fail to identify expansions in *DMPK* and *CNBP* using a streamlined assay format. We report a novel PCR based workflow that combines optimized reagents and unifies *DMPK* and *CNBP* molecular analyses. This technology can advance clinical research by enabling rapid, simple, and accurate profiling of repeat expansions in individuals with phenotypes consistent with DM1 or DM2.

**2505F**

**Clinical correlations of a streamlined molecular assay based on AmpliDeX® PCR/CE technology that determines repeat size for both normal and expanded alleles in *DMPK* for myotonic dystrophy 1.** *B. Hall<sup>1</sup>, P.J. Snyder<sup>2</sup>, J. Kemppainen<sup>1</sup>, T.W. Prior<sup>2</sup>, G.L. Latham<sup>1</sup>.* 1) Research and Development, Asuragen, Austin, TX; 2) Department of Pathology, Ohio State University, Columbus, OH.

Myotonic dystrophy type 1 (DM1) is an autosomal dominant disease characterized by more than 50 CTG repeats in the 3' UTR of *DMPK*. In clinical labs, DM1 testing requires a combination of PCR and Southern blot (SB) analysis because PCR cannot reliably amplify over 100 repeats. Here, we describe results using a novel PCR technology that permits sizing of normal and expanded alleles in a single tube to identify up to 200 repeats using capillary electrophoresis (CE). The assay can identify longer repeats that can be further sized by SB analysis if desired. Genomic DNA samples were procured from 100 presumed healthy whole blood donors (Asuragen) and 100 DM1 affected patients (Ohio State University) with different repeat sizes (50-2,000) and degrees of mosaicism identified previously by SB. Sample gDNAs were amplified using prototype AmpliDeX® *DMPK* PCR/CE reagents (Asuragen) in laboratories at Asuragen or Ohio State. FAM-labeled amplicons were resolved on 3130 or 3500 xL Genetic Analyzers (Thermo Fisher). CTG-specific and gene-specific priming were optimized with other PCR components in a single reaction to produce complementary data signatures from repeat-primed and full-length amplicons. These signatures confirmed the genotypes of normal and expanded alleles without the need for separate PCR and SB, resulting in a faster and simpler assay and analysis workflow. Prototype PCR reagents could resolve more than 200 CTG repeats from as little as 20 ng gDNA and generated repeatable results. The assay was sensitive to mosaicism down to 2.5% mass fraction. Assay performance and clinical correlations are currently being assessed using samples from patients with mild to severe phenotypes over a range of expansions and different degrees of mosaicism. Current methods fail to amplify moderate-to-large repeat expansions in DM1, and allele drop-outs may be indistinguishable from frequently-encountered homozygous samples. We report the first single-tube, long-read PCR technology that can resolve zygosity, identify expansions to over 200 repeats, and flag larger expansions. This approach may significantly reduce the need for DM1 SB analysis.

**2506W**

**NGS-based diagnostics at Newborn Screening Ontario.** *L. Racacho*<sup>1,2</sup>, *D.E. Bulman*<sup>1,2,3,4</sup>. 1) Newborn Screening Ontario, Ottawa, ON; 2) Children's Hospital of Eastern Ontario, Ottawa, ON; 3) Children's Hospital of Eastern Ontario Research Institute, Ottawa, ON; 4) Department of Pediatrics, Faculty of Medicine, University of Ottawa, Ottawa, ON.

Newborn Screening Ontario (NSO) is a public health program that screens approximately 140000 babies annually in the province of Ontario for 30 treatable disorders. NSO also provides repatriated diagnostic tests with massively parallel sequencing (MPS) to target 76 newborn screening genes and 406 nuclear encoded mitochondrial genes. We have implemented SeqCap EZ (Roche) library preparation for MPS on the MiSeq (Illumina) to deliver this service. In addition, a hybrid cloud informatics solution was adopted to quickly meet our needs without major restructuring of our information systems' ecosystem. Our first year of delivering MPS-based diagnostics has yielded 76 positive, 148 negative and 67 inconclusive findings. Of 291 patients reported thus far, 25 originated from screen positive cases. We discuss the challenges of delivering MPS-based diagnostics at NSO and present the distribution and classification of the sequence variants that we have identified to date.

**2507T**

**Wide range of maternal heteroplasmy for inherited pathogenic mtATP6 variants.** *J. Thompson*<sup>1</sup>, *E. White*<sup>1</sup>, *C. Gault*<sup>1</sup>, *R. Batorsky*<sup>1</sup>, *E. Lopez*<sup>1</sup>, *T. Ross*<sup>1</sup>, *D. Campagna*<sup>2</sup>, *M. Fleming*<sup>2</sup>. 1) Res & Development, Claritas Genomics, Cambridge, MA; 2) Dept of Pathology, Boston Children's Hospital, Boston, MA.

Pathogenic variants in mitochondrial DNA can cause a wide variety of diseases. Understanding the impact of these variants can be difficult because the variants may be heteroplasmic and vary across tissues within an individual and over time. Three individuals with congenital sideroblastic anemia from different families were identified by Sanger sequencing with the identical pathogenic variant in mtATP6 at an allele frequency estimated to be >80%. Sanger sequencing showed evidence of the allele in one of the proband's mothers, but not in the two other mothers or one female sibling. Given that Sanger sequencing is insensitive to low-level heteroplasmy, we employed next generation sequencing technology to determine whether the variants might be present at low levels in other family members. However, when short-read NGS technologies are used to determine low-level heteroplasmy, they are subject to potential contamination by the many mtDNA homologs found throughout the nuclear genome. We used two independent primer sets for long range PCR of mtDNA to eliminate the nuclear DNA issue. Each set of primers yielded two amplification products that covered the whole mtDNA genome. The independent amplifications also served to minimize any potential issues with PCR-induced errors. Use of these primers verified that the pathogenic variant was present in the maternal samples (1.9% to 37.2%) while not present in unaffected family members (<0.2%).

**Development of a strategy for the genetic diagnosis of mitochondrial diseases in paediatric population.** G. Barcia<sup>1</sup>, Z. Assouline<sup>1</sup>, M. Rio<sup>1</sup>, M. Maryse<sup>1</sup>, S. Hanein<sup>2</sup>, C. Fourrage<sup>1</sup>, B. Ruzzenente<sup>2</sup>, M. Metodiev<sup>2</sup>, C. Bole<sup>2</sup>, P. Nitschke<sup>2</sup>, A. Munnich<sup>1,2</sup>, J.P. Bonnefont<sup>1,2</sup>, J. Steffann<sup>1,2</sup>, A. Rotig<sup>2</sup>. 1) Department of genetics, Necker-Enfants Malades Hospital, APHP, Paris Descartes University, Paris, France; 2) INSERM U1163, Imagine Institute, Paris Descartes University, Paris, France.

**Purpose:** Mitochondrial diseases (MD) are a clinically and genetically heterogeneous group of disorders caused by mutations of nuclear DNA (nDNA) or mitochondrial DNA (mtDNA) and resulting in mitochondrial respiratory chain dysfunction. The global incidence of MD is estimated 1/4000 live birth, corresponding to 200 new patients/year in France. Clinically, childhood MD are characterized by a more severe phenotype than adult MD and by a frequent brain involvement. **Methods:** In 2015-2016, we performed whole exome sequencing (WES) or targeted next generation sequencing (TNGS) in 240 consecutive patients with a diagnosis of MD according to 5 criteria, namely clinical, biochemical, metabolic, histological and neuroradiological. We aimed to evaluate 1) in which cases is more appropriate to choose TNGS or WES as a first diagnostic step and 2) which of our inclusion criteria is the best predictor of a molecular diagnosis. **Results:** We identified pathogenic variants in 45% of patients, respectively 32% by TNGS and 47% by WES. In patients with at least 4 inclusion criteria the diagnostic yield of TNGS was 63% compared to 71% of WES. In 8 patients, WES allowed the detection of mutations in genes not involved in mitochondrial function. However, TNGS, allowed the detection of exonic deletions or duplications in 8 patients (3 with a negative WES result). In these series, increased lactic acid, abnormal respiratory chain assembly and altered respiratory chain enzyme activity were the better predictor of a positive results with causal mutations identified respectively in 58%, 62% and 45% of patients. **Conclusions:** We established a molecular diagnosis in 45% of patients in a cohort of 240 patients affected by childhood MD. In the MD diagnostic landscape, TNGS and WES are complementary approaches, but in patients with several criteria evocating a MD, in particular increased lactic acid or abnormal respiratory chain function, it is appropriate to choose TNGS as a first diagnostic step.

**2509W**

**Complexities of mitochondrial gene testing.** C. Kaiwar<sup>1</sup>, E.W. Klee<sup>2</sup>, K.D. Kennelly<sup>2</sup>, P.S. Atwal<sup>4</sup>. 1) Center for Individualized Medicine, Mayo Clinic, Scottsdale, AZ; 2) Center for Individualized Medicine, Mayo Clinic, Rochester, MN; 3) Department of Neurology, Mayo Clinic, Jacksonville, FL; 4) Department of Clinical Genomics, Mayo Clinic, Jacksonville, FL.

Single large deletions in the mitochondrial DNA are associated with progressive external ophthalmoplegia (PEO), Kearns-Sayre syndrome (KSS) and Pearson syndrome. Patients can present with a spectrum of symptoms ranging from early onset KSS with severe muscle involvement or a less severe, later onset, predominantly myopathic PEO. The size of the deletion as well as the level of heteroplasmy is negatively correlated with the phenotypic severity of the disease. We report a 39 year old woman with congenital myopathy (congenitally dislocated hips and scoliosis requiring surgery), who recently developed numbness in extremities and worsening balance. Family history was significant on the maternal side for myopathy and neuropathy of variable presentations in different members. Physical examination revealed a high arched palate, wide-based gait, weakness worse distally, absent reflexes and markedly reduced distal sensation with gait imbalance. EMG revealed bilateral median neuropathies at the wrists and patchy distal neurogenic and more diffuse myopathic changes. MRI of the head without contrast was normal. Laboratory levels for lactate and creatine kinase were normal and free and total carnitine levels were low. Muscle biopsy from two different sites showed severe denervation atrophy with extensive reinnervation. Electron transport chain analyses were reported as normal. Whole exome sequencing on a blood sample did not reveal any variants. Mitochondrial analysis showed a Variant of Uncertain clinical Significance (VUS) in *MT-CYB*, m.14841 A>G, p.Asn32Ser that was homoplasmic in the proband. A mitochondrial genome panel, including nuclear encoded mitochondrial genes, was ordered on skin fibroblasts as well as the biopsied vastus lateralis. A novel deletion m. 5975\_16074del10100 was identified in the skin fibroblasts and confirmed by Southern blot. This deletion was not identified in the muscle specimen, although its presence at levels below detection cannot be excluded. The muscle specimen did have smaller deletions of multiple sizes, present at a low level of heteroplasmy, confirmed by long range PCR. These mitochondrial aberrations, varying between tissues, demonstrate that a high level of suspicion from the clinician and testing of multiple tissues is key to confirming mitochondrial phenotypes that are otherwise undiagnosed or often misdiagnosed.

**Mitochondrial genome sequencing in phenotype-based panels and exome sequencing increases test sensitivity.** M.A. Reott, N.A. Rouse, R.R. Kelly, K. Patterson, K.H. Stovall, W.A. Langley, P.L. Nagy. MNG Laboratories, Atlanta, GA.

Next Generation Sequencing (NGS) allows rapid variant analysis for identifying disease causing variants. Exclusion of mitochondrial sequencing analysis in NGS disease screening panels limits their power by ignoring the potential of pathogenic mitochondrial variants. Initially thought to be rare, mitochondrial genetic diseases represent important and common sources of disorders. Recent genetic epidemiological studies quantifying the most common pathogenic mtDNA variants have shown the incidence of clinical mitochondrial diseases is about 1 in 5000. Additionally, a survey of newborn cord bloods revealed that 1 in 200 infants harbored common pathogenic mtDNA variants. Coupled with variant assessment and curation database software, the addition of mtDNA sequencing to phenotype-based panels and exomes increases the ability to discover variants of interest that aid in the determination of patient treatment. Upon including mtDNA sequencing with the panels, we have positively identified pathogenic or potentially pathogenic variants in patient samples having no definitively pathogenic nuclear genome variants. The effect of this inclusion has been particularly beneficial in NGS panels associated with neurological disorders. The increased sensitivity of the NGS panels and the ease of ordering a single test instead of two provides added value for both clinicians and their patients.

The recently published ACMG/AMP variant interpretation guidelines (Richards *et al* 2015), along with the more recent Clinical Genome Resource (ClinGen) framework for assessing the clinical validity of gene-disease associations (Strande *et al* 2017), represent major milestones in genomic interpretation. Applying these frameworks, ClinGen is building an authoritative central resource that defines the clinical relevance of genes and variants for use in precision medicine and research ([www.clinicalgenome.org](http://www.clinicalgenome.org)). The ClinGen Hereditary Hearing Loss Working Group (HL WG) was assembled in June 2016 from a team of experts including over 40 genetic counselors, researchers, geneticists, and clinicians from 12 U.S. and 14 international academic institutions on five continents. The aim of this HL WG is to create a comprehensive, standardized knowledge base of genes and variants relevant to HL which affects 1 in 300 infants, half of whom may have a genetic etiology due to one of over 400 described genes (Abou Tayoun *et al* 2016). This HL WG leveraged the unique clinical and research expertise of its members as well as both published and unpublished data to characterize key attributes of HL genes. Using this information, the HL WG has specified most of the ACMG variant interpretation guidelines relevant to HL including allele frequency cutoffs for benign and likely benign classification, functional assays supporting pathogenicity (or not), criteria for loss-of-function as a disease mechanism, and gene-specific phenotypes. The group continues to specify the remaining ACMG/AMP rules in concert with the ClinGen Sequence Variant Interpretation (SVI) Working Group. Using ClinGen's gene-disease clinical validity classification framework, over 93 gene-disease associations currently under expert review have been curated resulting in 48 strong/definitive, 25 moderate, and 20 limited/conflicting/no evidence classifications, and more are underway. Over 11,108 interpreted variants in 99 hearing loss genes have been submitted to ClinVar (May 2017), of which 653 variants (5%) across 68 genes have significant conflicting classifications. An ongoing goal of the standardization is to apply specific rules established by this HL WG to evaluate those variants, and to reach expert panel (3 star) status in ClinVar in order to resolve discrepancies in variant interpretation and to facilitate patient management and care. Funding: NIH U41 HG006834.

**A comprehensive resource and guideline for the development and validation of exome-based panels for clinical laboratories.** R. Niazji<sup>1</sup>, M. Gonzalez<sup>1</sup>, M. Sarmady<sup>1,2</sup>, A. Abou Tayoun<sup>1,2</sup>. 1) Division of Genomic Diagnostics, Children's Hospital of Philadelphia, Philadelphia, PA; 2) University of Pennsylvania Perelman School of Medicine, Philadelphia, PA.

Exome-based panels (exome slices) are becoming the preferred diagnostic strategy for genetically heterogeneous disorders. The advantages of this approach include 1) Enabling frequent updates to gene lists without the need for re-designing 2) Reflexing to exome analysis bioinformatically without requiring additional sequencing 3) Streamlining lab operation by using established exome kits and protocols. However, exome-slices are subject to the same pitfalls of exome captures including potential lack of adequate coverage for all the relevant genes. Additionally, more bioinformatics analysis is needed during test development and validation to identify gaps in coverage and/or regions of high homology and to design ancillary assays. Currently there is no uniform standard for the development and validation of exome slices in a clinical setting. Here, we present guidelines, resources, and principles to design and validate exome slices in a clinical lab. This includes criteria for gene selection, a resource for gene technical assessment, a guideline for establishing the test's performance characteristics, and a framework for variant filtration based on the disease's relevant genetic attributes. We have categorized the most relevant and useful public resources for each of the above. However, we identified a gap in the online resources and therefore built a web-based application called ExomeSlicer, an algorithm that leverages next generation sequencing (NGS) exon-level quality metrics from 166 clinical exome samples to characterize technically challenging regions such as GC-rich, repeat, and/or high homology regions. ExomeSlicer allows users to visually inspect such regions (and any other) in genes of interest and provides scores, based on coverage and mapping quality metrics, to guide the decision for ancillary assays development. We applied all of the above to develop an epilepsy clinical exome slice. 100 clinically valid genes were selected for which more than 10 problematic regions, requiring ancillary assays, were identified by ExomeSlicer. These included repeat (e.g. *ARX* exon 2), GC-rich (e.g. *SYNGAP1* exon 1) and high homology (e.g. *CHRNA7*) regions. Finally, our overall validation demonstrate >99% sensitivity and specificity for variant detection, and 100% accuracy for filtering clinically significant variants. In summary, we provide a comprehensive resource and guideline for successful development and validation of clinical exome-based panels.

## 2513T

**Exome sequencing leads to the identification of two novel MYO15A mutations in a German family with autosomal recessive non-syndromic hearing loss.** R. Birkenhager, S. Arndt, A. Aschendorff, R. Laszig. Department of Otorhinolaryngology, Head and Neck Surgery, University Medical Center Freiburg, Killianstrasse 5, D-79106 Freiburg, Germany.

Hearing impairment is the most prevalent sensorineural disorder and also the most common birth defect. Approximately one of every 1000 newborns is born profoundly deaf and one of every 300 newborns has a permanent mild-to-profound congenital hearing impairment. More than half of pre-lingual hearing impairment cases occur due to genetic factors. Currently, over 120 genes and over 180 loci have been identified for non-syndromic hearing impairment. Autosomal recessive non-syndromic hearing loss (ARNSHL) is a genetically heterogeneous sensorineural disorder, with prelingual hearing loss and absence of other clinical manifestations. Based on the clinical diagnosis it is not possible to recognize in which gene mutations are present. This is only feasible in exceptional cases (7/180). The aim of this study is to identify the pathogenic gene in a non-consanguineous German family with 13 children, 8 affected with prelingual ARNSHL. Hearing testing BERA/Electrocochleography and radiological a high-resolution CT scan was made. Mutational analysis of two affected family members was performed using direct sequencing of the coding exon and intron transitions of the genes *GJB2* and *GJB6*, including deletion analysis. For investigation of autosomal recessive nonsyndromic hearing loss genes, whole exome sequencing was performed, with the "INVIEW HUMAN EXOME" platform; array Agilent Genomics SureSelectXT All Exon V5. No mutations could be identified in the *DNFB1* gene locus, containing the genes *GJB2* and *GJB6*. A further targeted analysis of other genes was not possible; therefore complete exome sequencing took place. All known genes for hearing impairment were analyzed. Only in the gene *MYO15A* two heterozygous pathogenic variations were detected. A deletion c.3141delC, p.Pro1047fsX1124 and a splice-side mutation c.IVS3+1G>A, the mutations were confirmed by sanger sequencing for all 14 family members. The protein encoded by *MYO15A* (MIM 602666), is critical for the differentiation and elongation of the stereocilia and has important roles in actin organization in hair cells. Myosin *MYO15A* is localized at the tip of the stereocilia of cochlear and vestibular hair cells. Diagnostic testing for this gene is not routinely offered due to its large size. The study demonstrated that exome sequencing is a powerful molecular diagnostic strategy for ARNSHL, an extremely heterogeneous genetic disorder.

**Genome and exome sequencing application in clinical diagnostics for deafness: Not quite there yet.** *H. Azaiez<sup>1</sup>, K.T. Booth<sup>1,2</sup>, G. Yu<sup>3</sup>, F. Bu<sup>1</sup>, D. Walls<sup>1</sup>, E.A. Black-Ziegelbein<sup>1</sup>, R.J. Smith<sup>1,2,3</sup>.* 1) Otolaryngology, University of Iowa, Molecular Otolaryngology & Renal Research Laboratory, Iowa City, IA; 2) Department of Molecular and Cellular Biology, University of Iowa, Iowa City, Iowa; 3) Iowa Institute of Human Genetics, University in Iowa City, Iowa.

The elucidation of the genetic etiology of human disorders has been revolutionized with the advent of targeted genomic enrichment and massively parallel sequencing (TGE+MPS). In diseases which display great genetic heterogeneity, such as deafness, TGE+MPS has been shown to be a proven method both for research applications and in clinical diagnostic settings. Several platforms differing by the genomic regions they cover are available such as whole exome sequencing (WES), whole genome sequencing (WGS) and disease-specific targeted gene panels (TGP). In a comparative study to assess the coverage of known deafness-causing genes and its impact on diagnosis accuracy between the different platforms, we have evaluated the data derived from sequencing 100 samples using a deafness-specific TGP we have developed; OtoSCOPE and WES. Additionally, 10 samples also underwent WGS. Bioinformatic analysis was completed on a custom pipeline and was limited to the regions that cover genes and mutations involved in deafness. The average target depth of coverage for deafness genes on OtoSCOPE was >400 reads, whereas it only reached 70 and 31 reads for WES and WGS respectively. Consequently, coverage at 10, 20 and 30X was consistently higher with OtoSCOPE than WES and WGS with 96.5% of regions of interest covered at 30X in OtoSCOPE versus 53% and 47% with WES and WGS respectively. This drop in coverage correlated with a decline in base and variant quality, an increase in uncertainty of zygosity status and, most notably, a lower detection rate of genomic variants. A comparison of variant lists after filtering for quality and minor allele frequency ( $\leq 2\%$ ) revealed that OtoSCOPE detected variants that were missed in either WES or WGS. Of those variants, some were of clinical significance and were deemed to be the causative variants for the deafness phenotype in patients. Detection of Copy Number Variations (CNVs) also differed between the different platforms with OtoSCOPE showing the most robust and accurate detection rate especially for heterozygote CNVs. In conclusion, several factors need to be considered when choosing and implementing a clinical diagnostic test, chiefs amongst them, are sensitivity, accuracy, turn-around-time and cost. We showed that for deafness, targeted gene panels such as OtoSCOPE offer higher diagnostic yields at lower cost when compared to WES and WGS making them the most sensible choice for comprehensive genetic testing for deafness.

**2515W**

**Targeted exome sequencing as a molecular diagnostic tool for syndromic hearing loss.** *Y.S. Lima<sup>1</sup>, M.A. Chiaba<sup>2</sup>, J. Shen<sup>3</sup>, M.S. Córdoba<sup>4</sup>, B.R. Versiani<sup>5</sup>, R.A. Benício<sup>4</sup>, R. Pogue<sup>2</sup>, A. Pic-Taylor<sup>1</sup>, J.F. Mazzeu<sup>5</sup>, S.F. Oliveira<sup>1</sup>.* 1) Institute of Biology, University of Brasília, Brasília, Brasília, Brazil; 2) Catholic University of Brasília, Brasília, Brazil; 3) Brigham and Women's Hospital, Harvard Medical School, Boston, MA, USA; 4) University Hospital of Brasília, University of Brasília, Brasília, Brazil; 5) Faculty of Medicine, University of Brasília, Brazil.

Target exome sequencing based-panels are being used successfully as a diagnostic tool for genetic diseases. In this work, we propose a panel designed for syndromic hearing loss. It is estimate that approximately 50-60% of the world's hearing loss cases have a genetic etiology and 30% of these are represented by syndromic hearing loss, which includes more than 400 syndromes. The customized Ion Ampliseq panel is composed of exons related to 51 genes associated with syndromic hearing loss, added to *GJB2*, covering 98.95% of the exons. 26 patients with a clinical diagnosis of a syndromic hearing loss with no previous molecular diagnosis were analyzed: 17 with a clinical diagnosis of a syndrome with described genes (included in the panel) and nine with syndromes with undescribed genes (Goldenhar syndrome) or without clinical diagnosis. Potentially causative mutations were found in nine patients with clinical diagnosis of syndromes with described genes and none with undescribed genes, whereas we were able to diagnose six patients, reaching a diagnostic rate of 23% (6/26). From the nine different mutations identified, three are novel mutations, related to Waardenburg, Treacher Collins and CHARGE syndromes. We noticed that all the patients diagnosed by the panel had a previous clinical diagnosis, suggesting that the panel has more effectiveness in diagnosing this group of patients. Considering only this group, the diagnostic rate would increase to 35% (6/17). Regarding patients with syndromes with described genes that we were not able to find any potentially causative mutation, we hypothesize that another gene not included in the panel can be involved or the causative mutation can be in the few regions not covered by the panel. Concerning to patients with Goldenhar syndrome or without clinical diagnosis, we think that the enormous genetic heterogeneity and variety of rare described syndromes not covered by the panel can influence the difficult to find the genetic etiology for these patients. The panel here developed demonstrates a good effectiveness in molecular diagnostic when compared to others in the literature, especially for clinical diagnosed patients with a syndrome with described genes.

**2516T**

**Kagami Ogata Syndrome caused by a 14q32 microdeletion that did not encompass MEG3 DMR.** *W.T. Keng<sup>1</sup>, K.H Teh<sup>2</sup>, F. Mansor<sup>2</sup>, Azli. Ismail<sup>3</sup>, Z. Zakaria<sup>2</sup>.* 1) Genetic Department, Hospital Kuala Lumpur, Kuala Lumpur, Malaysia; 2) Paediatric Dept, Hospital Sultan Abdul Halim, Kedah, Malaysia; 3) Unit Hematologi, CaRC, Institute of Medical Research, Malaysia.

Kagami Ogata Syndrome patients have small thorax and developmental delay. Some have abdominal wall defect or contractures. Radiologically, the ribs have characteristic coat hanger configuration. The pregnancy is often associated with polyhydramnios and large placenta. This syndrome is caused by paternal UPD 14, epimutation or microdeletion on maternal chromosome 14. There are 2 differentially methylated regions [DMR] on 14q32 region, DLK1-MEG3 intergenic differentially methylated region (IG-DMR) and MEG3-DMR. The microdeletions usually involved MEG3-DMR. We describe here a patient who presented with respiratory distress at birth, small thorax and rib cage with coat hanger appearance. Chromosome 14q32methylation analysis showed normal MEG3 DMR methylation. Array CGH detected a 126.8 kb deletion at 14q32 which deleted several imprinted genes including part of MEG3 gene but not the MEG3 DMR region. There have been 5 previous reported cases of Kagami Ogata syndrome caused by microdeletion that did not involve DMR region on chromosome 14q32. Those cases and our case showed that deletion of imprinted genes without involvement of DMR is enough to cause Kagami Ogata Syndrome and methylation study on its own is not enough to rule out this syndrome.

**2517F**

**De novo variant in SOS2 with a concurrent SHOX deletion: Report of a patient with short stature, dysmorphic features and heart defect.** *D. Lyalin<sup>1</sup>, L. Grote<sup>2</sup>, S. Amudhavalli<sup>2</sup>, J. Jenkins<sup>2</sup>, C. Saunders<sup>1</sup>, L. Zhang<sup>1</sup>, E. Repnikova<sup>1</sup>.* 1) Department of Pathology and Laboratory Medicine, Children's Mercy Hospital, University of Missouri-Kansas City School of Medicine, Kansas City, Missouri; 2) Division of Clinical Genetics, Children's Mercy Hospital, University of Missouri-Kansas City School of Medicine, Kansas City, Missouri.

Noonan syndrome (NS) is a common autosomal dominant disorder characterized by short stature, congenital heart disease, and facial dysmorphism with an incidence rate of ~1/2500 live births. NS is one of the RASopathies, a genetically heterogeneous group of multisystemic disorders caused by the dysregulation of the RAS/MAPK pathway. To date, 75-80% of NS can be explained by heterozygous pathogenic sequence variants in the known genes. Patients with SOS2-related NS exhibit a wide range of clinical findings, including typical facial features of NS, cardiac anomalies, learning difficulties, and ectodermal involvement including curly hair, sparse eyebrows, and keratosis pilaris. All the missense variants in SOS2 reported in NS patients are located in the DH domain and could result in gain-of-function mutations, leading to upregulation of the RAS/MAPK pathway. Here we report a heterozygous *de novo* pathogenic variant, c.1127C>G (p.Thr376Ser) in exon 9 of SOS2 identified in a 7 y.o. male with NS features. In addition, this patient has a paternally inherited ~372 kb deletion involving SHOX. This patient's features include short stature with a muscular build, dysmorphic features (sparse eyebrows, anteverted ears with overfolded upper helices, a broad nasal base, high arched palate), pectus carinatum, stretchy/loose skin over abdominal wall, keratosis pilaris, hyperopic astigmatism, pelviectasis, and septal hypertrophy. Analysis of the clinical features of 12 previously reported patients with SOS2 missense variants revealed that all patients had striking ectodermal involvement and facial dysmorphisms typical of NS. In contrast, short stature, which is observed in our patient, was noted in only 2/12 patients. Our patient is the first with this variant to have septal hypertrophy, although it was previously noted in two patients with a different SOS2 variant. This patient was found to have two distinct genetic disorders: NS and SHOX deficiency. His short stature is likely due to the SHOX deletion and the SOS2 variant explains the dysmorphic features and cardiac anomaly. Also, this is the first report of a patient with an SOS2 variant and a concurrent SHOX deletion. Both, microarray and sequencing analyses were important for establishing the diagnosis in this patient as well as appropriate genetic counseling.

**Defects in cohesin components STAG1 and STAG2 expand the locus heterogeneity of “cohesinopathies”.** B. Yuan<sup>1,2</sup>, J. Neira<sup>1,3</sup>, T. Santiago-Sim<sup>1,2</sup>, J. Rosenfeld<sup>1,2</sup>, W. Jin<sup>2</sup>, M.P. Adam<sup>4,5</sup>, J. Dean<sup>6</sup>, C.T. Fong<sup>7</sup>, L. Hudgins<sup>8</sup>, S. Madan-Khetarpa<sup>9</sup>, M. McGuire<sup>1,2</sup>, L. Slattery<sup>8</sup>, L. Martin<sup>7</sup>, L. Ramsdell<sup>4,5</sup>, D.D.D. Study<sup>10</sup>, W. Bi<sup>1,2</sup>, S.W. Cheung<sup>1,2</sup>, A. Breman<sup>1,2</sup>, J. Smith<sup>1,2</sup>, C. Eng<sup>1,2</sup>, Y. Yang<sup>1,2</sup>, R. Xiao<sup>1,2</sup>, P. Liu<sup>1,2</sup>. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX 77030, USA; 2) Baylor Genetics, Houston, TX 77021, USA; 3) Texas Children's Hospital, Houston, TX 77030, USA; 4) Seattle Children's Hospital, Seattle, WA 98105, USA; 5) Department of Pediatrics, University of Washington School of Medicine, Seattle, WA 98105, USA; 6) Clinical Genetics Service, NHS Grampian, Aberdeen, AB25 2ZA, Scotland; 7) Department of Pediatrics, University of Rochester Medical Center, Rochester, NY 14642, USA; 8) Division of Medical Genetics, Stanford University, Stanford, CA 94305, USA; 9) Children's Hospital of Pittsburgh of UPMC, Pittsburgh PA 15224, USA; 10) The Deciphering Developmental Disorders (DDD) Study.

The cohesin complex is critical in various cellular functions, including sister chromatid cohesion, recombination-mediated DNA repair, chromosomal looping and architecture, and gene transcriptional regulation. Cohesin is a multi-subunit protein complex composed of four structural components, including SMC1A, SMC3, RAD21 and STAG1/2, and numerous regulatory factors, such as NIPBL, MAU2, PDS5A/B, WAPL, and HDAC8, which are in charge of the precise progression of the cohesion cycle. Defects of the cohesion pathway have been associated with developmental disorders collectively described as “cohesinopathies”, notably Cornelia de Lange Syndrome (CdLS) that are caused by loss-of-function mutations in the genes encoding SMC1A, SMC3, RAD21, NIPBL and HDAC8. We investigated subjects referred for clinical whole exome sequencing (WES) with various genetic disorders and identified pathogenic or likely pathogenic variants in the known CdLS genes including 5 in *NIPBL*, 14 in *SMC1A*, 4 in *SMC3*, 2 in *RAD21* and 8 in *HDAC8*. Interestingly, by expanding the analysis to genes involved in the cohesion pathway in addition to the well-established CdLS genes, we identified two *de novo* heterozygous likely pathogenic single nucleotide variants (SNVs) in *STAG1* and three *de novo* SNVs in *STAG2*. When we examined regions encompassing these two genes in our copy number variants (CNVs) database of subjects who were referred for chromosome microarray analysis (CMA) due to neurodevelopmental disorders, we identified two *de novo* deletions and one deletion of unknown inheritance for *STAG1* and one deletion of unknown inheritance for *STAG2*. *In silico* analysis suggested haploinsufficiency as the likely mechanism for disease-contribution. Patients identified in this study did not present with the classical distinctive facial features of CdLS, making the diagnostic process more challenging. Clinical profiling suggested overlapping features with CdLS, including developmental delay, short stature, microcephaly, micrognathia, limb abnormalities and male genital hypoplasia among others. This study therefore contributes to genetic and phenotypic expansions of “cohesinopathies”. Moreover, this study demonstrates the efficacy of genome-wide assays, such as WES, in new gene discovery by allowing investigation of genes in the same pathway or with functions related to the known disease-contributing genes.

**Constitutive supernumerary marker chromosomes are the chromothripsis remnant of the supernumerary chromosome present in trisomic embryos.** N. Kurtas<sup>1</sup>, L. Leonardelli<sup>2</sup>, L. Xumerle<sup>2</sup>, M. Delledonne<sup>2</sup>, A. Brusco<sup>3</sup>, K. Chrzaowska<sup>4</sup>, A. Schinzel<sup>5</sup>, S. Guerneri<sup>6</sup>, E. Manolakos<sup>7</sup>, S. Giglio<sup>8</sup>, T. Liehr<sup>9</sup>, O. Zuffardi<sup>1</sup>. 1) Molecular Medicine, University of Pavia, Pavia, Pavia, Italy; 2) Department of Biotechnology, University of Verona, Verona, Italy; 3) Department of Medical Sciences, University of Turin, Torino, Italy; 4) Department of Medical Genetics, The Children's Memorial Health Institute, Warsaw, Poland; 5) Institute of Medical Genetics, University of Zurich, Zurich, Switzerland; 6) Laboratory of Medical Genetics, Fondazione IRCCS Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy; 7) Laboratory of Genetics, Access to genome P.C., Thessaloniki, Greece; 8) Biomedical Experimental and Clinical Sciences "Mario Serio", University of Florence, Firenze, Italy; 9) Institute of Human Genetics, Jena University Hospital, Jena, Germany.

We hypothesize that most *de novo* constitutional non-recurrent supernumerary marker chromosomes (sSMC) are the final outcome, via a chromothripsis event, of the partial trisomy rescue of supernumerary chromosomes present in trisomic embryos. The hypothesis is based on the following facts, fully coincident with the known biological characteristics of human trisomies: (i) sSMCs are associated with maternal age, (ii) most sSMCs are in mosaic with a normal cell line, (iii) in some sSMCs maternal UPD for the chromosome by which the marker derives was reported. Moreover, a few sSMCs appear to be constituted by non-contiguous portions of the original chromosome, a clear indication of a previous chromothripsis event. To investigate this hypothesis, we collected DNA from 20 cases of non-recurrent *de novo* sSMCs, already defined by array-CGH, and from their parents. We performed whole genome paired-end sequencing (WGS) in the first five cases, chosen among those in which the array-CGH had shown their constitution by non-contiguous portions. We also analysed the trios by microsatellites spread along the entire chromosome by which the sSMC originated. As a result, in four cases, sSMC2a, sSMC2b, sSMC7, sSMC17, sSMC18, a disordered assembly of chromosomal segments was highlighted. In two of them, sSMC7 and sSMC2b, we could demonstrate that the marker was even more complex, revealing some regions that were represented at different level of copy number gain (duplicated, triplicated, or even amplified) as if multiple types of sSMC were present in the different blood cells. In the fifth case, sSMC18, the non-contiguous regions remained in the reference order. In each case the novel order of the chromosomal segments was confirmed by breakpoints (bps) PCR amplification and cloning. In all bps the fusion signature showed repair mechanisms such as non-homologous end joining and microhomology mediated processes. Microsatellite and SNPs analysis in the five trios indicated a maternal origin of the sSMC18 and sSMC17 with biparental origin of the related homologous chromosomes, and a paternal one in the remaining sSMC7, sSMC2a, and sSMC2b, with maternal hetero/isodisomy of their related chromosomes. These data demonstrate both a link between numerical and structural anomalies and that early lethal trisomies may leave a dramatic legacy in the postnatal life.

**2520F**

**Association of 22q11.2 duplication with two variants in *FREM2* gene in a patient with an unusual phenotype.** M.I. Melaragno<sup>1</sup>, M.Z. Souza<sup>1</sup>, A.G. Dantas<sup>1</sup>, M.F.F. Soares<sup>2</sup>, E.J. Bhoj<sup>3</sup>, D. Lj<sup>3</sup>, R.P. Silva<sup>2</sup>, V.A. We report on a 6-month-old male patient, the fourth child of a non-consanguineous couple, who presents a unique phenotype with facial asymmetry, ocular hypertelorism, malformed ears, macrostomia, right-hand radial deviation, proximal implantation of a hypoplastic fifth finger in right hand, corporal asymmetry, and complex congenital heart disease. Skeleton X-ray showed cranial asymmetry, accentuation of the dorsal kyphosis and lumbar thoracic scoliosis, butterfly vertebrae anomaly in T11 and T12, subluxation of the right elbow, right radial agenesis, and shortening and bowing of the ulna. 3-D helicoidal tomography showed ribs fusion and hemivertebrae scoliosis. The cardiac evaluation revealed *cor triatriatum sinistrum*, atrial and ventricular septal defects, and pulmonary hypertension, surgically corrected. MLPA with P250 kit revealed a 22q duplication inherited from his father who presents a normal phenotype. Chromosomal microarray showed a 2.8 Mb duplication: arr[hg19] 22q11.21(18640729\_21465659)×3 pat. Exome-sequencing showed two variants in *FREM2* (FRAS1 related extracellular matrix protein 2) gene, each one inherited from a parent: c.1837C>T:p.R613C, and c.2770\_2772del:p.924\_924del (GRCh37). Some clinical features of our patient could be explained by the 22q11.2 duplication such as facial dysmorphisms and congenital heart defects, features not found in his father. As expected, 22q11.2 duplications are frequently inherited and associated with variable phenotypes. A patient recently reported in the literature presents a smaller 22q11.2 duplication associated with a mutation in *SALL4*, a gene responsible for Duane-radial syndrome. This patient had multiple skeletal anomalies, but no Duane anomaly. Our patient presents a worst, but similar skeletal anomalies, and also no ophthalmologic anomaly. Exome sequencing in our patient revealed no rare variants in *SALL4* (Spalt Like Transcription Factor 4) gene. However, two heterozygous variants were found in *FREM2* gene, whose mutations are associated with the Fraser syndrome, an autosomal recessive disease. Our patient is a compound heterozygote for the gene *FREM2*, but his phenotype is not compatible with Fraser syndrome, although we cannot exclude the possibility of a phenotype derived from the association of two genetic alterations. Thus, the unusual phenotype in our patient remains unexplained and the diagnosis, a challenge for geneticists. Financial support: FAPESP, Brazil.

**Case report of an unusual situation in which mother and daughter have two different chromosomal abnormalities.** J. Neri<sup>1,2</sup>, E. Gil<sup>2</sup>. 1) Medicina, Universidade Potiguar, Laureate International Universities, Natal, RN, Brazil; 2) DNA Center, Natal, RN, Brazil.

V.F.O.A., 20 years old, female, young parents at the time of pregnancy and childbirth. She did not cry at birth, stayed one day in incubator with oxygen halo and more six days for phototherapy and observation. She is accompanied by specialists and is in stimulation therapies from the first month of life, but had significant motor retardation, moderate-severe intellectual disability and never developed speech. Physical examination revealed macrocrania, hypertelorism, alternating strabismus, ogival palate, discrete splenomegaly, genu recurvatum, intermittent hypotonia. As a complementary evaluation, she has several nuclear magnetic resonance imaging of brain describing multiple malformations, among them, cerebral atrophy, tapering of corpus callosum and important ventricular dilatation; several altered electroencephalograms; continuous thrombocytopenia. During evolution, she had repeated urinary tract infections and otitis, controlled with continued use of Nitrofurantoin, and due to the development of severe scoliosis, surgery was performed for spinal fixation. Her karyotype describes mosaic of normal cells and cells with additional material on a chromosome 16 [46,XX/46,XX,der(16)add(16)(p13.3)?], which aCGH revealed to be part of short arm of a chromosome 7 (7p22.3-p15.3). The karyotype of the father and the older sister were normal. In the karyotype of the mother, robertsonian translocation involving chromosomes 13 and 14 was observed [45,XX,rob(13;14)(q10;q10)]. The mother does not present any clinical alterations detected so far and negated miscarriages.

**Breakpoint mapping in five Brazilian cases of distal 5p deletion: Influence of copy number variable regions and haploinsufficiency to clinical phenotype.** S.N. Chehimi<sup>i</sup>, E.A. Zanardo<sup>i</sup>, J.R.M. Ceroni<sup>i</sup>, F.A.R. Madia<sup>i</sup>, G.M. Novo-Filho<sup>i</sup>, T.V.M.M. Costa<sup>i</sup>, J.G. Damasceno<sup>i</sup>, M.M. Montenegro<sup>i</sup>, A.M. Nascimento<sup>i</sup>, Y.G. Oliveira<sup>i</sup>, C.A. Kim<sup>ii</sup>, L.D. Kulikowski<sup>i</sup>. 1) Laboratório de Cito-genômica - Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brasil; 2) Unidade de Genética, Instituto da Criança - Hospital das Clínicas da Faculdade de Medicina da Universidade de São Paulo, São Paulo, Brasil.

Recent cytogenomic studies demonstrated the contribution of copy number variations (CNVs) to the phenotype variability among individuals with deletions syndromes. We used Illumina BeadChip array (San Diego, CA, USA) to map the breakpoints in five patients with 5p distal deletion (four females and one male). Four of the patients had a previous diagnosis of 5p- Syndrome by G-banded karyotype and one of them was confirmed after performing array. Array analysis revealed a 5p *de novo* deletions ranging from 17.43 Mb to 25.63 Mb (5p15.33-5p14.1) in four patients and unexpected showed a 5p interstitial deletion for one of the patients. The interstitial deletion present a breakpoint start at 4,788,892 and end at 22,219,836, while the four other deletions present start at 25,328 and with different breakpoints ends (18,022,107; 18,921,988; 22,039,679; 22,219,836; 25,658,882), respectively. Apart from the 5p deletion, we found a total of 33 benign CNVs (ranging from 5 to 13 CNVs in each patient). We observed that the patient with mild to moderate intellectual disability present the larger 5p deletion (25.6 Mb) while the other patients present moderate to severe cognitive impairment. Our analysis also showed haploinsufficiency for several different genes, including *SEMA5A*, *CTNND2*, *MARCH6* and *TERT* that have already been associated with the main clinical phenotype of the 5p deletion syndrome, even though *TERT* gene was not deleted in the patient with the interstitial deletion. This study highlights the importance of mapping the breakpoints in deletions syndromes in order to study the phenotypic consequences for both clinical and research applications. Also, the study of haploinsufficiency in the era of gene therapy and CRISPR-Cas9 technology can provide future alternative treatments and healthcare to patients with the 5p deletion syndrome and other genetic disorders.

**Mosaicism and chimerism: Mechanistic answers for chromosomally distinct cell populations.** R. Rowsey, L. Baughn, H. Kearney, U. Aypar, D. Van Dyke, N. Hoppman, E. Thorland. Department of Laboratory Medicine and Pathology, Mayo Clinic, Rochester, MN.

Constitutional blood specimens that contain an admixture of cell populations are uncommon and can represent either mosaicism or chimerism. The distinction is that mitotic mosaicism derives from a single fertilization, whereas chimerism derives from separate zygotes. Distinguishing between the two requires techniques other than G-banded karyotyping, such as SNP-microarray. With an understanding of SNP patterns, this testing can provide mechanistic answers to the origins of the multiple cell lines. Before the routine use of SNP-based arrays, most recognized cases of chimerism were those in which XX and XY cell lines were present, and therefore were unlikely to be a result of mosaicism. Today, examination of the allele patterns on a SNP-microarray will easily demonstrate two non-identical cell lines, regardless of sex chromosome complement. The allele patterns also reveal if the two cell lines present are related. For example, in a case of twin chimerism, we observed several regions (approximately 25%) across the genome with a normal allele pattern, implying both cell lines have identical alleles in those regions, whereas in a mixture of unrelated cell lines share no identical allelic regions, and therefore a noisy allelic pattern throughout the genome. Perhaps the most challenging mosaic/chimeric cases are those that contain multiple abnormal cell lines, as it becomes difficult to understand the mechanism and to predict the clinical implications. We observed two patients with a novel combination of cell lines that highlights these challenges. They each had, two abnormal cell populations: one XX cell line with an unbalanced Robertsonian translocation (der(13;13) in one patient and der(21;21) in the other), and one cell line with monosomy X and no translocation. Utilizing SNP-microarray on the patient with the der(21;21), several mechanistic factors were inferred. First, we observed a normal allele pattern for most of the genome, consistent with mosaicism. Second, the allele pattern on chromosome 21 confirmed the der(21;21) was an isochromosome, as commonly observed in cases of der(21;21). Finally, the array showed X chromosome heterozygosity, confirming one X was lost to form the 45,X cell line, effectively ruling out the possibility of Y chromosome material being present. These example cases will demonstrate that the academic puzzles leading to a mechanistic understanding of mosaic/chimeric cases can also provide clinically relevant information.
